Stage 6: We must consider the effects of this act on everyone concerned—the doctor, the dying woman, other terminally ill people, and all people everywhere. Basic moral principle dictates that all people have a right to dignity and self-determination as long as others are not harmed by their decisions. Assuming that no one else will be hurt, then, the dying woman has a right to live and die as she chooses. The doctor may be doing right if he respects her integrity as a person and saves her, her family, and all of society from needless suffering.	Stage 6: If we truly adhere to the principle that human life should be valued above all else and all lives should be valued equally, it is morally wrong to “play God” and decide that some lives are worth living and others are not. Before long, we would have a world in which no life has value.

So, Kohlberg maintained that progress from preconventional to conventional to postconventional moral reasoning is most likely to occur if the individual has acquired the necessary cognitive skills (perspective-taking skills and, later, formal-operational thinking) and has growth-inducing social interactions, especially discussions with peers, advanced education, and participation in democratic governance.

Moral Behavior: Social Learning Theory

Social learning theorists such as Albert Bandura (1991, 2002, 2015), whose social cognitive theory was introduced in Chapter 2, have been primarily interested in the behavioral component of morality—in what we actually do when faced with temptation or with an opportunity to behave prosocially. These theorists say that moral behavior is learned in the same way that other social behaviors are

learned: through observational learning and reinforcement and punishment principles. They also emphasize situational influences on moral behavior—for example, how closely a professor watches exam takers, whether jewelry items are on the counter or behind glass in a department store. Due to situational influences, what we do is not always consistent with our moral values and standards.

Applying his social cognitive perspective, Bandura went on to emphasize that moral cognition is linked to moral action through *self-regulatory mechanisms* that involve monitoring and evaluating our own actions (or anticipated actions), disapproving of ourselves when we contemplate doing wrong, and approving of ourselves when we behave responsibly or humanely. By applying consequences to ourselves in this way, we become able to exert self-control, inhibit urges to misbehave, and keep our behavior in line with internalized standards of moral behavior.

Sometimes this system of moral self-regulation can triumph over strong situational influences pushing us to do wrong.

Did you ever cheat on a test in high school? In one survey of high school students across the United States, 64% admitted to cheating in the past year, more than in earlier surveys; yet 93% said that they were satisfied with their “personal ethics and character” (Crary, 2008). Most college students also admit to cheating, sometimes justifying it by saying that “anything goes” in the pursuit of achievement goals (Pulfrey & Butera, 2013). Why do you think cheating is so rampant today? Is it pressure to succeed? Peer influence? Albert Bandura’s concept of moral disengagement?

Yellow Dog Productions/The Image Bank/Getty Images

However, according to Bandura we have also devised mechanisms of **moral disengagement** that allow us to avoid condemning ourselves when we engage in immoral behavior, even though we know the difference between right and wrong (Bandura, 2015). For example, a store clerk who feels underpaid and mistreated by his employer may convince himself that he is justified in pilfering items from the store, or citizens may disengage morally from the use of military force by their country by dehumanizing their foes as “animals” or by calling the civilians who are accidentally killed during bombing raids “collateral damage.” Most of us learn moral standards, but some people hold themselves strictly to those standards while others find ways to disengage morally and slither out from under guilt. Those of us who have perfected techniques of moral disengagement engage in more antisocial and unethical

behavior than other people (Detert, Treviño, & Sweitzer, 2008; Gini, Pozzoli, & Bussey, 2015; Paciello et al., 2008).

Foundations of Morality: Evolutionary Theory

Finally, evolutionary theorists such as Dennis Krebs, Michael Tomasello, and others argue that all three aspects of morality (moral emotion, thought, and behavior) have become part of our human nature because they helped humans adapt to their environments over the course of evolution (see Buss, 2012; Jensen & Silk, 2014; Krebs, 2008, 2011; Tomasello, 2009; Tomasello & Vaish, 2013). Just as having a theory of mind helps humans get along with others and adapt to living in groups, prosocial behaviors such as cooperation and altruism may have evolved because our ancestors were better able to obtain food and protect themselves from harm if they worked together than if they went it alone and pursued their selfish interests (Krebs, 2011). Mechanisms for controlling and inhibiting selfish, antisocial behavior such as rules and laws against theft and assault may also have proved adaptive. To evolutionary theorists, then, morality and prosocial behavior are rooted in human nature. Unfortunately, so are immorality and antisocial behavior (Krebs, 2011).

How could humans have evolved to have altruistic tendencies when altruists, who sacrifice their lives for others, die rather than pass on their genes? Evolutionary theorists have argued that it can be in our genetic self-interest to act altruistically toward kin because they will pass on the family’s genes if we help them survive (Verbeek, 2006). Even helping nonrelatives may be adaptive if we have reason to believe that the help we give will be reciprocated. Similarly, cooperating with other people to obtain resources that the individual could not obtain alone, abiding by society’s rules in order to avoid punishment, and punishing people who *do* violate society’s rules all make good genetic sense (Krebs, 2008). So, whereas Freud emphasized the dark, selfish, and aggressive side of human nature, and social learning theorists have seen us as blank slates who can be molded in a variety of directions, evolutionary theorists argue that humans have an evolved genetic makeup that predisposes them not only to behave antisocially at times but also to behave prosocially and morally in many situations.

Indeed, humans may be a uniquely prosocial species. Michael Tomasello has concluded that what makes us different from chimpanzees and other great apes is our ability to collaborate and cooperate with others (Tomasello, 2009; Tomasello & Herrmann, 2010; Tomasello & Vaish, 2013). Primates are quite good at figuring out others’ goals and intentions but their social cognitive skills likely evolved in competitive situations where they could get food, mates, and other resources by outwitting their rivals. To not only understand others’ intentions but to be able to *share* intentions with others in order to pursue common goals—that’s what Tomasello believes distinguishes the human species.

To highlight differences among the four theoretical perspectives on moral development we have discussed, ● **Table 13.3** compares them and shows how different theorists might try to predict whether a college student (call him Bart) will cheat on his upcoming math test.

We are now ready to trace the development of morality, and aspects of prosocial and antisocial behavior, from infancy to old age, considering moral emotion, cognition, and behavior as we go.

● **Table 13.3** Comparison of Theoretical Perspectives on Moral Development

Perspective/Theorists	Focus	Message	Predicting Behavior (Will Bart cheat on his math test?)
Psychoanalytic theory (Freud)	Moral emotion	Early parenting and emotional conflicts forge the superego and guilt.	Did Bart develop a strong superego (conscience) and sense of guilt in his preschool years?
Cognitive-developmental theory (Piaget, Kohlberg)	Moral reasoning	Cognitive maturation and interaction with peers bring stagelike changes in thinking about moral issues.	At what stage is Bart's reasoning about moral dilemmas?
Social learning theory (Bandura)	Moral behavior	Observational learning, reinforcement, self-regulation processes, moral disengagement, and situational influences affect what we do.	Did Bart's parents model and reinforce moral behavior and punish misbehavior? Do well-developed self-regulatory mechanisms cause Bart to take responsibility for his actions rather than disengage morally? Do situational forces in the class discourage or encourage cheating?
Evolutionary theory (Krebs, Tomasello)	Moral emotion, reasoning, and behavior	Humans have evolved not only to be aggressive on occasion but to have moral and prosocial tendencies that equip them to live cooperatively in groups.	Does cheating, or refraining from cheating, serve adaptive functions for Bart and his social group? Might he cheat in the interest of cooperating with friends? Does the classroom environment encourage or discourage cheating?

● Checking Mastery

1. What are the three major components of morality, and what is one theory of moral development that emphasizes each?
2. What is the main difference between conventional and pre-conventional moral reasoning about why stealing is wrong?
3. How do evolutionary theorists differ from Freud in their view of human nature?

● Making Connections

1. A pre-conventional thinker, a conventional thinker, and a post-conventional thinker all face a moral dilemma the

night before the final exam: A friend has offered them a key to the test. Should they use it? Provide examples of the reasoning you might expect at each of Kohlberg's three main levels of moral development—one argument in favor of cheating and one against it at each level. Are any of these arguments especially easy or difficult to make? Why?

2. Jamal decides to become a kidney donor and live the rest of his life with only one kidney so that his brother Malcolm can live. How do you think Freud, Kohlberg, Bandura, and Krebs would explain his altruistic action?

13.3

The Infant

LEARNING OBJECTIVES

- Summarize evidence that infants are capable of empathy and prosocial behavior.
- Describe antisocial behavior in infancy and how it differs from that of older children.
- Explain how parents can help their infants develop a conscience.

Do infants have a sense of right or wrong? If an infant bashes another child on the head with a sippy cup, would you insist that the infant be put on trial for assault? Of course not. We tend to view infants as **amoral**—lacking any sense of morality. We do not believe that infants are capable of evaluating their behavior in relation to moral standards, and so we do not hold them responsible for wrongs they commit (although we certainly attempt to prevent them from harming others). Nor do we expect them to be “good” when we are not around to

watch them. Yet we learn a lot about human nature from infant behavior. It is now clear that infants are not as amoral as we thought. Nor are they as selfish and in need of proper socialization as Freud and others have claimed. Although infants do indeed have a capacity for selfishness and aggression, they are at the same time predisposed to be empathic, prosocial beings (Bloom, 2013; Hamlin, 2013). They also learn many important moral lessons during their first 2 years of life and develop a conscience.

Empathy, Prosocial Behavior, and Morality

Infants are not as selfish, egocentric, and unconcerned about other people as Freud, Piaget, Kohlberg, and many other theorists have assumed. Rather, some of their behavior supports the view of evolutionary theorists such as Michael Tomasello that empathy and prosocial behavior are part of our evolutionary heritage.

Start at birth: Even newborns display a primitive form of empathy, becoming distressed by the cries of other newborns (Eisenberg, Spinrad, & Knafo-Noam, 2015; Hastings, Zahn-Waxler, & McShane, 2006). It is unclear whether these very young infants are experiencing empathy for another or are simply distressed by crying sounds, however. From age 1 to age 2, according to Martin Hoffman (2000, 2008), infants become capable of a truer form of empathy that motivates helping and other forms of moral behavior. Toddlers begin to understand that someone else's distress is different from their own, and they try to comfort the person in distress. So, for example, a 10-month-old watching a peer cry looked sad and buried her head in her mother's lap, as she often did when she herself was distressed. A 2-year-old, though, brought his own teddy bear to comfort a distressed friend and, when that failed, offered the friend's teddy instead, showing an ability to take the perspective of the friend (Hoffman, 2000). As children get older, according to Hoffman, empathy becomes more sophisticated as cognitive processes, including the child's developing perspective-taking skills, shape empathy into a variety of moral emotions such as guilt, sympathy, and eventually a sense of injustice (see also Eisenberg et al., 2015; Gibbs, 2014).

How prosocial are infants and toddlers? Some years ago, Carolyn Zahn-Waxler and her colleagues (1992) reported that more than half of the 13- to 15-month-old infants they observed engaged in at least one act of prosocial behavior—helping, sharing, expressing concern, comforting, and so on. These behaviors became increasingly common from age 1 to age 2, when all but one child in the study acted prosocially. More recently, Michael Tomasello and other researchers have been documenting just how prosocial and morally sophisticated infants and toddlers are:

- **Helping.** As early as 14 months, infants will spontaneously—without being asked—help an adult who drops a clothes pin on the floor while trying to hang items on a clothesline, who is carrying an armful of papers and cannot open a cabinet door, or who otherwise needs help to achieve a goal (Warneken & Tomasello, 2007). This early spontaneous helping has been observed in cultures as diverse as Canada, India, and Peru (Callaghan et al., 2011).
- **Cooperation.** As early as 14 months, infants can also participate in simple cooperative games and will even try to get their adult partner reengaged if she stops playing, suggesting that they understand that they and their partner had a shared goal while they were cooperating (Warneken & Tomasello, 2007).
- **Altruistic rather than selfish motivations.** Before they are 2, children show greater happiness when they give treats like Goldfish crackers to an appreciative puppet than when they receive them, especially when they altruistically give up their own treats (Aknin, Hamlin, & Dunn, 2012). They find prosocial behavior intrinsically rewarding (Hepach, Vaish, & Tomasello, 2012).

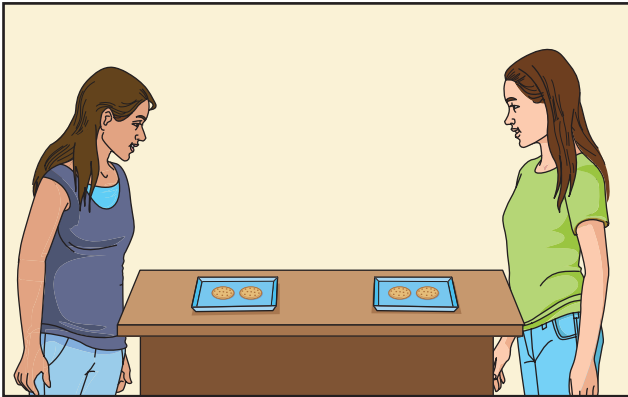

Before they are age 2, toddlers show evidence of a moral sense when they attempt to comfort distressed peers.

altrendo images/Altrendo /Getty Images

- **A sense of fairness.** At 15 months of age, infants are more surprised (look longer) when they see one actor given three crackers and another given one than when the actors get two apiece, suggesting that they recognize fairness and unfairness when they see it (Schmidt & Sommerville, 2011; and see ■ Figure 13.2). Yet despite their preference for dividing rewards equally if two actors both clean up their toys, infants are surprised and look longer when a hard worker and a loafer are rewarded equally than when the hard worker gets more (Sloane, Baillargeon, & Premack, 2012).
- **Moral judgments.** As noted earlier, infants much prefer to interact with a “helper” puppet who aids another puppet in achieving a goal than with a “hinderer” puppet who blocks another puppet from achieving a goal (see Hamlin, 2013). And despite their positive view of helping, they seem to think it is quite appropriate to punish a “hinderer” by taking things away from him (Hamlin et al., 2011). In short, babies distinguish between and have quite different feelings about good guys and bad guys!

Antisocial Behavior

If prosocial tendencies are so evident by a year or two of age, when do antisocial tendencies first show themselves? Physical aggression, behavior that harms another person physically, comes naturally to humans, starting as soon as babies are able to hit, bite, push, or otherwise harm others (Tremblay, 2011). And verbal aggression begins almost as soon as infants utter their first words. Antisocial behavior therefore seems to be as much a part of human nature as empathy and prosocial behavior are. Infants are less likely than older children to intend to cause harm, however.

■ **Figure 13.2** When 15-month-olds are shown two girls asking for crackers and then see a screen lifted to reveal either a fair, equal distribution (two crackers to each) or an unfair distribution (one cracker to one girl, three to the other), which do they look at longer? The unfair distribution surprises them, suggesting that they already have an intuitive sense of fairness.

Source: Adapted from Schmidt, M. F. H., & Sommerville, J. A. (2011). Fairness expectations and altruistic sharing in 15-month-old human infants. *PLoS ONE*, 6, e23223. Figure 1.

Most often their goal is to get a toy they want or to defend a toy they had played with and put down (Hay, Hurst, et al., 2011; Tremblay, 2011). As they develop better self-control, they will become more able to delay gratification and wait for the toy.

As early as 1½ years of age, some toddlers engage in more physical aggression than others, though (Tremblay, 2011). Their high rates of aggressive behavior can be traced to both their genetic

makeup and environmental factors such as harsh, coercive parenting or a depressed, emotionally unavailable parent (Dionne et al., 2003; Hay, Mundy, et al., 2011; Tremblay, 2011). Their peers, meanwhile, are learning to control their aggressive urges better. The frequency of aggression normally rises from infancy to a peak around age 3 and then decreases with age as verbal skills, social skills, and self-control skills improve (Eisner & Malti, 2015; Tremblay, 2011).

Early Moral Training

Part of the reason for increased prosocial and decreased anti-social tendencies as infants become children is moral socialization. Drawing on learning principles, parents and others reinforce toddlers for helpful actions such as putting toys away and chastise or otherwise punish them for wrongdoings. Through such learning experiences, infants and toddlers come to understand and internalize simple moral rules and standards such as “Don’t hit,” “Don’t steal,” and “Share.” They see that their actions have consequences, some good, some bad. Parents can help foster early moral development by discussing their toddlers’ behavior and its good or bad effects on the toddler and other people (Dunn, 2014; Thompson, Meyer, & McGinley, 2006; Thompson, 2012).

Grazyna Kochanska has studied the development of a conscience in toddlerhood and believes it involves mastering: (1) moral emotions—learning to associate negative emotions like guilt with violating rules, and learning to empathize with people who are in distress, and (2) self-control—becoming able to inhibit one’s impulses when tempted to violate internalized rules (Kochanska, 1993, 2002).

By 18–24 months, children are already beginning to show visible signs of distress when they break things, spill their drinks, or otherwise violate standards of behavior (Cole, Barrett, & Zahn-Waxler, 1992; Kagan, 1981). Made to think that they have caused a doll’s head to fall off, some toddlers even show signs of guilt, as opposed to mere distress, making frantic attempts to repair the doll or otherwise make amends (Kochanska, Casey, & Fukumoto, 1995). Self-control also becomes more evident by age 2, as when toddlers comply with a parent’s request not to play with certain toys even after the parent leaves the room (Aksan & Kochanska, 2005). In **Exploration 13.1**, we see just how important **self-control**—the ability to regulate one’s desires, impulses, and behavior—is in many aspects of life-span development.

How can parents help children develop moral emotions, self-control, and thus a strong conscience? Kochanska and her colleagues have found that forming a secure parent–infant attachment is the best way to get moral socialization off to a good start (Kochanska, Barry, Stellem, & O’Bleness, 2009). Then it is important for caregiver and child to establish a **mutually responsive orientation**—a close, emotionally positive, and cooperative relationship in which child and caregiver care about each other and are sensitive to each other’s needs (Kochanska & Aksan, 2006). Parents who are responsive to their infants are likely to raise children who are responsive to them. A mutually responsive orientation makes children trust their caregivers and want to comply with their rules and adopt their

● EXPLORATION 13.1

Marshmallows and the Life-Span Significance of Self-Control

imageBROKER/Alamy Stock Photo

Whether you call it the aspect of temperament called effortful control, the dimension of personality called conscientiousness, self-control, executive control, or even willpower, it is a good thing to have. Nowhere is this better illustrated than in the famous marshmallow study conducted by social learning theorist Walter Mischel in the 1960s (Mischel, Shoda, & Peake, 1988; Mischel, 2014). The experimenter gave 4- to 5-year-olds a choice: Eat the marshmallow I am giving you now, or get a second marshmallow if you wait until I return (in 15–20 minutes). How many children do you think waited?

values and standards. These children then learn moral emotions such as guilt and empathy and develop the self-control needed to resist temptation even when no one is around to catch them.

In sum, moral development builds on a base of empathy and prosocial behavior that strengthens with age as physical aggression

Apparently marshmallows are irresistible to 4-year-olds: Only about 30% of the children passed this **delay of gratification** task and were able to wait for the more desirable two-marshmallow reward later. Most children gave in to their desire to eat the marshmallow in less than 3 minutes. (Search for “marshmallow test” on the Internet and you’ll find entertaining film clips from this famous study.)

But the most fascinating finding of the research was revealed when the children were followed up as adolescents and then as adults. As adolescents, the children who delayed gratification were judged by their parents to be more academically and socially competent, more responsible, and more able to cope with stress; they even scored significantly higher on the SAT exam than their peers who gave in to temptation (Mischel et al., 1988; Shoda, Mischel, & Peake, 1990). As adults, these more self-controlled individuals also had fewer drug problems and lower body mass indexes (Casey et al., 2011; Mischel et al., 2011). Measuring children’s self-control, not with tempting marshmallows but through behavioral observations and parent-, teacher-, and child-reports of behavior, Terri Moffitt and her colleagues (2011) obtained similar results: Childhood self-control predicted becoming an adolescent who stayed in school and avoided delinquent behavior—and later a 30-year-old with good physical health and financial stability who avoided substance dependence and criminal activity. So, whether self-control shows itself in

being able to wait for that second yummy marshmallow, keeping at your studies while your friends party, staying on your diet, saving money, or resisting the temptation to do wrong, it is a very important life skill.

Yet you should not conclude that self-control is a genetically based trait that we either have or do not have for life. Mischel and others have shown that children can be taught strategies of self-control—for example, distracting themselves by singing songs or covering their eyes. And in an interesting demonstration of how environmental influences may affect self-control, Kidd, Palmeri, and Aslin (2013) told 4-year-olds that if they waited, the experimenter would bring them better art supplies than the lousy ones they had been given. The catch was that in the “reliable” condition, she delivered the new supplies, whereas in the “unreliable” condition she confessed that she did not have any better art supplies after all. When they were then given the marshmallow test, the children in the reliable condition waited an average of 12 minutes for two marshmallows, but the children in the unreliable condition waited only 3 minutes. Moreover, Melissa Sturge-Apple and her colleagues (2016) have shown that a physiological indicator of self-control that is associated with longer delay of gratification among high SES children predicts *shorter* delay of gratification among poor children. Perhaps, then, regardless of their temperamental traits, children living in poverty learn through experience an adaptive strategy: Gobble any marshmallows that come your way right away rather than wait for bigger rewards that may or may not come tomorrow.

is brought under better control. By establishing a secure attachment and a mutually responsive orientation and by discussing the emotional consequences of the child’s behavior, parents help infants and toddlers develop a conscience (Emde et al., 1991; Thompson et al., 2006).

● Checking Mastery

1. According to Martin Hoffman, when is empathy first evident in infancy and how does it change thereafter?
2. When one infant pushes another, what is usually the motive?
3. What is Grazyna Kochanska's main message to parents who want their infants to develop a conscience?

● Making Connections

1. Philosopher John Locke and learning theorists like B. F. Skinner have viewed human beings as “blank slates” (tabulae rasae) who have no biologically based predispositions to be either antisocial or prosocial. Thinking about evolutionary theory and research on infant social behavior, what arguments can you give for and against the blank slate position?
2. Given what you have learned about moral socialization in infancy, do you think it is possible to raise a moral child without ever using physical punishment? Why or why not?

13.4

The Child

LEARNING OBJECTIVES

- Discuss key ways in which children are more morally sophisticated than Piaget and Kohlberg believed.
- Summarize an optimal approach to socializing morality in childhood.

Research on moral development during childhood has explored how children of different ages think about moral issues and how parents can raise moral children. This research shows that children's moral thinking is far more sophisticated than Piaget and Kohlberg believed and that parents can have a much bigger impact on their children's moral development than these two theorists believed.

Moral Understandings

The hypothetical moral dilemmas that Lawrence Kohlberg devised to assess stages of moral reasoning (for example, the mercy-killing dilemma presented in Section 13.2) were intended primarily for adolescents and adults; the youngest individuals Kohlberg studied were age 10. As a result, Kohlberg did not have much to say about children except that they are mostly pre-conventional moral reasoners. They take an egocentric perspective on morality and define as right those acts that are rewarded and as wrong those acts that are punished (Colby et al., 1983). At best, older school-age children are beginning to make the transition to conventional moral reasoning by internalizing authorities' rules and displaying a Stage 3 concern with being a good boy or a good girl who takes others' perspectives and is concerned with others' approval. However, both Piaget and Kohlberg seriously underestimated children. Having already seen that infants are well on their way to being moral beings, you will not be surprised to learn that children engage in some very sophisticated thinking about right and wrong.

Weighing Intentions

Both Piaget and Kohlberg believed that young children (indeed, children under 10) were primarily focused on the consequences of acts rather than the intentions behind them. However, it turns out that even 3-year-olds can take both intentions and consequences into account if presented with simple stories portrayed

in drawings (Nelson, 1980). They judge a ball thrower less favorably when he hits his playmate in the head than when the playmate catches the ball, but they also judge a well-intentioned boy who had wanted to play ball more favorably than a boy who intended to hurt his friend—even when the friend caught the ball and was not harmed. Apparently, then, even young children can base their moral judgments on both a person's intentions and the consequences of his act. Sensitivity to good or bad intentions does increase as children get older, however (Lapsley, 2006).

Intentions are mental states, of course, and are therefore part of what children come to understand better as they develop a theory of mind. Indeed, children's moral thinking becomes more sophisticated once they have the basics of a theory of mind down at about age 4 (Killen et al., 2011; Lane et al., 2010). Children who have mastered theory-of-mind skills not only try to evade punishment by crying, “I didn't mean it!” but they are also:

- more forgiving than children lacking theory-of-mind skills of wrongs committed accidentally than of wrongs committed intentionally (Chandler, Sokol, & Wainryb, 2000; Fu et al., 2014; Killen et al., 2011);
- better able to distinguish between lying (deliberately promoting a false belief) and simply having one's facts wrong or exaggerating for the sake of a good story (Peterson & Siegal, 2002); and
- more attuned to other people's feelings and welfare when they think about the morality of snatching a friend's toy or calling a friend a bad name (Dunn, Cutting, & Demetriou, 2000).

In short, mastering the basics of a theory of mind at age 4 and refining theory-of-mind skills later put children in better position to interpret the motives behind and the consequences of people's actions. The development of moral judgment and theory of mind develop hand in hand and influence one another (Smetana, Jambon, et al., 2012).

Distinguishing among Rules

Piaget claimed that 6- to 10-year-old children view *all* rules as sacred prescriptions laid down by authority figures that cannot be questioned or changed. However, Elliot Turiel (1978, 1983, 2006), Judith Smetana (Smetana, Jambon, & Ball, 2014), and others have discovered that children distinguish between different kinds of rules. Most importantly, they distinguish between **moral rules**, or standards that focus on the welfare and basic rights of others, and **social-conventional rules**, standards determined by social consensus that tell us what is appropriate in particular social settings. Moral rules include rules against hitting, stealing, lying, and otherwise harming others or violating their rights. Social-conventional rules are more like rules of social etiquette; they include the rules of games, school rules that forbid eating snacks in class or going to the restroom without permission, and parent rules that require saying “Please” and “Thank you.”

From their preschool years, children understand that moral rules are more compelling and unalterable than social-conventional rules (Smetana, 2006; Turiel, 2006). Judith Smetana (1981; Smetana, Rote, et al., 2012), for example, has discovered that children as young as age 3 regard moral transgressions such as hitting, stealing, or refusing to share as more serious and deserving of punishment than social-conventional violations. Young children also appreciate that hitting is wrong even if the teacher did not see it; even if the rules say hitting is okay; and whether it is done at home, at school, or in a faraway land with different laws. They feel very differently about social-conventional rules; it might be okay for another country to declare that girls should wear pants and boys should wear skirts.

Being Fair

As you have seen already, even infants seem to have a sense of fairness, as shown when they expect goods to be shared equally between two people. Indeed, children’s first concept of fairness is an equality rule: Everyone should get the same—or else “It’s not fair!” It was long believed that children younger than 5 or 6 did not understand or use another important rule of justice: an equity rule that takes merit into account and gives more to whoever did the most to earn the rewards to be distributed (Damon, 1977).

Yet we now know that even 3- and 4-year-olds are able to take merit into account if you can get them past their strong preference to give equal rewards to all. Thus, if children are given three cookies to distribute to two workers, they very often give each worker one cookie and set aside the third cookie. However, if prompted to give the third cookie to someone, they will give it to the more meritorious of the two workers (Baumard, Mascaro, & Chevallier, 2012).

As children progress through elementary school, their ideas of fairness and justice become more elaborated and they show more understanding of which rule is fairest in which situation. Thus, 5-year-olds often use an equality rule regardless of the context, but 9- and 13-year-olds use an equality rule when distributing voting ballots to campers who will vote to select a new game for the camp, an equity rule when rewarding workers according to the number of pots they made for sale by the camp, and a need-based rule in giving more of the funds donated to the camp to a

poor camper than to campers who are not as needy (Sigelman & Waitzman, 1991). Cross-cultural research tells us that children in different societies may develop different ideas of fairness; thus, among the Akhoe Hai of Namibia, African foragers who value equal relationships and share food often, children much prefer to reward workers using an equality rule rather than the merit-based equity rule that Western children prefer in such situations (Schafer, Haun, & Tomasello, 2015).

Children are not above giving themselves more than they give others, of course. However, they clearly have a basic sense of fairness. At first, they favor an equality rule but soon they apply rules of equality, equity or merit, and need appropriately depending on the situation and their cultural context (see also Killen & Smetana, 2015).

Overall, then, both Piaget and Kohlberg seriously underestimated how sensitive even toddlers are to moral issues and how much moral growth takes place during infancy and early childhood. We now know that even young children judge acts as right or wrong according to whether the actor’s intentions were good or bad, using their theories of mind; distinguish between moral rules and social-conventional rules and view only moral rules as absolute, sacred, and unchangeable; and appreciate and apply rules of fairness.

Moral Socialization

How can parents best raise a child who can be counted on to behave morally? You have already seen that a secure attachment and a mutually responsive orientation between parent and child starting in infancy help. Social learning theorists like Bandura would also advise parents to reinforce moral behavior, punish immoral behavior (but mildly and with caution, as discussed in Chapter 2), and serve as models of moral rather than immoral behavior.

The important work of Martin Hoffman (2000) has provided additional insights into how to foster moral development. As you saw earlier, Hoffman (2000) believes that empathy is a key motivator of moral behavior and that a key task in moral socialization, therefore, is to foster empathy. Hoffman (1970) compared the pros and cons of three major approaches to disciplining children:

1. **Love withdrawal.** Withholding attention, affection, or approval after a child misbehaves—in other words, creating anxiety by threatening a loss of reinforcement from parents.
2. **Power assertion.** Using power to threaten, chastise, administer spankings, take away privileges, and so on—in other words, using punishment.
3. **Induction.** Explaining to a child why the behavior is wrong and should be changed by emphasizing how it affects other people.

Suppose that little Angel has just put the beloved family cat through a cycle in the clothes dryer. Using love withdrawal, a parent might say, “How could you do something like that? I can’t stand to look at you!” Using power assertion, a parent might say, “Go to your room this minute; you’re going to get it.” Using induction, a parent might say, “Angel, look how scared Fluffball is. You could have killed her, and you know how sad we’d be if she died.” Induction, then, is a matter of providing rationales or explanations that focus attention on the consequences of wrongdoing for other people (or cats).

Martin Hoffman's formula for raising a moral child involves lots of induction and affection and only occasional power assertion.

Which approach best fosters moral development? Induction wins hands down over love withdrawal and power assertion, and power assertion has proven to be the least effective approach (Brody & Shaffer, 1982). In Hoffman's (2000) view, induction works well because it breeds empathy. Anticipating empathic distress if we contemplate harming someone keeps us from doing harm; empathizing with individuals in distress motivates us to help them.

Although expressing disappointment in a child's behavior can be effective on occasion, making a child worry that their parents' love can be snatched away at any time usually is not effective (Patrick & Gibbs, 2007). Frequent use of power assertion is more often associated with moral immaturity than with moral maturity. Power assertion does not foster empathy, the internalization of moral rules, or the development of self-control, and physical punishment in particular can produce unwanted consequences such as anxiety and aggression (see Chapter 2).

Despite this evidence, Hoffman (2000) concludes that mild power assertion tactics such as a forceful "No," a reprimand, or the taking away of privileges can be useful occasionally if they arouse some but not too much fear and motivate a child to pay close attention to the inductions that follow. Such careful uses of power assertion work best in the context of a loving and mutually responsive parent-child relationship. All in all, Hoffman's work provides a fairly clear roadmap for parents: The winning formula is "a blend of frequent inductions, occasional power assertions, and a lot of affection" (Hoffman, 2000, p. 23).

Let's add that effective parents also use **proactive parenting strategies**, tactics designed to prevent misbehavior and therefore reduce the need for any of Hoffman's types of discipline. Proactive parenting techniques include distracting young children from temptations and explicitly teaching children values such as the importance of telling the truth, sharing, and being kind (Thompson et al., 2006).

Yet parents do not settle on one best approach and use it all the time. Both the moral socialization technique chosen in a situation

and its effectiveness depend on a host of factors such as the particular misdeed, child, parent, situation, and cultural context (Grusec, 2006). For example, a child's temperament is an important influence on how morally trainable she is and what motivates her to comply with parents' rules and requests (Thompson et al., 2006). Grazyna Kochanska and her colleagues have found that children are likely to be easiest to socialize if they are by temperament (1) fearful or inhibited and therefore are likely to experience guilt when they do wrong, become appropriately distressed when they are disciplined, and want to avoid such distress in the future; and (2) capable of self-control and therefore are able to inhibit their urges to engage in wrongdoing (Kochanska, Barry, Jimenez, et al., 2009).

Children with different temperaments may require different socialization approaches. Fearful, inhibited children can be socialized through a gentle approach that capitalizes on their anxiety but does not terrorize them (Fowles & Kochanska, 2000). Children who are fearless or uninhibited do not respond to this gentle approach—but they do not respond to being treated harshly, either. These fearless children are most likely to learn to comply with rules and requests when there is a mutually responsive orientation between parent and child, and the child is therefore motivated to please the parent and maintain a good relationship (Fowles & Kochanska, 2000; and see Kochanska, Aksan, & Joy, 2007). Here, then, is another example of the importance of the goodness of fit between a child's temperament and her social environment. Socialized in a way that suits their temperament, most children will internalize rules of conduct, experience appropriate moral emotions, learn to regulate their behavior, and behave more prosocially than antisocially.

● Checking Mastery

1. How is a moral rule different from a social-conventional rule and at what age can children tell the difference?
2. What are two capacities shown by preschool children that contradict Piaget's and Kohlberg's views that they are limited moral thinkers?
3. Create an example of induction and explain why Martin Hoffman concludes that it is the best approach to discipline.

● Making Connections

1. Teddy, age 6, lies and steals frequently, bullies other children, and rarely complies with rules at home or at school. Using what you have learned about moral socialization and referring to appropriate concepts and research, describe how ineffective parenting might have contributed to the development of this apparently immoral child.
2. What approaches to moral socialization did your parents use with you? Did they make their moral values clear? Did they explain their rules? Did they threaten you with punishment or make you feel you would lose their love if you broke their rules? Finally, do your parents' strategies seem sound in view of research on moral socialization?

13.5

The Adolescent

LEARNING OBJECTIVES

- Describe how moral reasoning changes during adolescence and the significance of developing a moral identity.
- Compare how Kenneth Dodge and Gerald Patterson account for the behavior of aggressive youth.
- Explain the roles of nature and nurture in aggression and what has been learned about preventing and treating it.

As adolescents gain the capacity to think about abstract and hypothetical ideas, and as they begin to chart their future identities, many of them reflect on their values and moral standards and some make morality a central part of their identities. At the other extreme are the adolescents who end up engaging in serious anti-social behavior.

Moral Identity

Some teens come to view being a moral person who is caring, fair, and honest as a central part of who they are—that is, they develop a **moral identity** (Krettenauer & Hertz, 2015). Adolescents who have a sense of moral identity tend to be more capable than other adolescents of advanced moral reasoning (Hart, 2005). Especially if something in the situation reminds them of their moral values, they are also more likely to act morally than adolescents who do not define themselves in moral terms (Aquino & Reed, 2002; Aquino et al., 2009). Thus developing a moral identity may be critical when it comes to translating moral values into moral action (Hardy & Carlo, 2011). If you have a strong moral identity, you cannot live with yourself if you do wrong.

A moral identity starts to take shape as children develop a sense of being a good boy or good girl who tries to follow rules, avoids misbehaving, and cares about other people (Kochanska et al., 2010). The development of a moral identity in adolescence

A moral identity can be built stronger through community service.

KidStock/Blend Images/Getty Images

can be fostered by parents who use induction and on occasion express disappointment in their teen's behavior rather than relying on power assertion and love withdrawal (Patrick & Gibbs, 2012). It can also be fostered through involvement in community service and other prosocial activities (Hardy & Carlo, 2011; Pratt et al., 2003). In adulthood, a strong moral identity is more predictive than a person's stage of moral reasoning of ethical and prosocial behavior in the workplace (Cohen et al., 2014).

Changes in Moral Reasoning

Adolescence is a period of significant growth in moral reasoning. Consider the results of Lawrence Kohlberg's 20-year longitudinal study that involved repeatedly asking the 10-, 13-, and 16-year-old boys he originally studied to respond to moral dilemmas (Colby et al., 1983). **Figure 13.3** shows the percentage of judgments offered at each age that reflected each of Kohlberg's stages.

Figure 13.3 Average percentage of moral reasoning at each of Lawrence Kohlberg's stages for males from age 10 to age 36. You can see the decline of pre-conventional thinking and the rise of conventional thinking with age—and very little post-conventional thinking.

Source: From Colby, A., Kohlberg, L., Gibbs, J., & Lieberman, M. A. (1983). A longitudinal study of moral judgment. *Monographs of the Society for Research in Child Development*, 48 (1–2, Serial No. 200). Copyright © 1983 Blackwell Publishing. Reprinted with permission.

Notice that the preconventional reasoning (Stage 1 and 2 thinking) that dominates among 10-year-olds decreases considerably during the teen years. During adolescence, conventional reasoning (Stages 3 and 4) becomes the dominant mode of moral thinking. So, among 13- to 14-year-olds, most moral judgments reflect either a Stage 2 (instrumental hedonism) approach—“You scratch my back and I’ll scratch yours”—or a Stage 3 (good boy or good girl) concern with being nice and earning approval. More than half the judgments offered by 16- to 18-year-olds embody Stage 3 reasoning, and about a fifth were scored as Stage 4 (authority and social order—maintaining morality) arguments. These older adolescents were beginning to take a broad societal perspective on justice and to ask whether actions would help maintain or undermine the social system.

In short, the main developmental trend in moral reasoning during adolescence is a shift from preconventional to conventional reasoning. During this period, most individuals begin to express a genuine concern with living up to the moral standards that parents and other authorities have taught them and ensuring that laws designed to make human relations just and fair are taken seriously and maintained. Postconventional reasoning does not emerge until adulthood—stay tuned.

Antisocial Behavior

Although most adolescents internalize society’s moral standards and behave morally, a few youths engage in serious antisocial conduct—muggings, rapes, armed robberies, knifings, drive-by shootings. School shootings by adolescent and young adult males—from Columbine to Virginia Tech to Newtown and beyond—have heightened concern about what causes serious antisocial behavior and how to prevent it. Is it weak gun laws, violent video games, mental illness, a violent culture, or what?

The quality of antisocial behavior changes from childhood to adolescence; physical aggression decreases, while non-aggressive rule-breaking behavior such as vandalism and theft increases (Burt, 2015). The consequences of teens’ early misbehavior cumulate, and they engage in **juvenile delinquency**, lawbreaking by a minor. They may then find themselves leaving school early, participating in troubled and sometimes abusive relationships, having difficulty keeping jobs, and engaging in lawbreaking as adults (Huesmann, Dubow, & Boxer, 2009; Maughan & Rutter, 2001). The most seriously disturbed of these individuals may qualify as youth for psychiatric diagnoses such as **conduct disorder**—a persistent pattern of violating the rights of others or age-appropriate societal norms through such behaviors as fighting, bullying, and cruelty; as adults, they may be recognized as “psychopaths” and qualify for a

diagnosis of antisocial personality disorder (see Dodge, Coie, & Lynam, 2006). Some also end up in the 5% or so of the population who are identified as career criminals and account for most of the violent crimes committed in the United States (DeLisi, 2016).

Yet most adolescents who engage in aggressive behavior and other antisocial acts do not grow up to be antisocial adults. There seem to be two subgroups of antisocial youths, then (Moffitt & Caspi, 2001; Monahan, Steinberg, & Cauffman, 2009; Odgers et al., 2008):

1. a small, early onset, seriously disturbed group that is recognizable in childhood and is persistently antisocial across the life span; and
2. a larger, late onset, less seriously antisocial group that begins to behave antisocially during adolescence, partly in response to peer influences, and outgrows this behavior in early adulthood.

The decline of antisocial behavior after adolescence in the second group may reflect increased autonomy and increased ability to resist peer pressures as well as the taking on of adult responsibilities. It may also reflect brain development—the maturation of the prefrontal cortex that continues into the mid-20s and results in better self-control and a greater ability to think through the consequences of behavior (Giedd et al., 2013). Crime rates rise to peak during adolescence and emerging adulthood and then fall in most societies, especially for “hell-raising” crimes such as vandalism (Agnew, 2003; Tremblay, 2010). This developmental trend is reflected in the official statistics on arrests for violent crime in the United States shown in **Figure 13.4**. The graph also shows that males are far more involved in violent crime than females (see Chapter 12 on gender differences in aggression).

What causes some youths to become menaces to society? Might adolescents who engage repeatedly in antisocial acts be

Figure 13.4 Arrests for violent crimes by males and females of different ages in the United States, 2010. Violent crimes include murder, manslaughter, rape, robbery, and aggravated assault.

Source: U.S. Department of Justice, Federal Bureau of Investigation, Crime in the United States 2010. Figures retrieved and calculated from Tables 39 and 40, www.fbi.gov/about-us/cjis/ucr/crime-in-the-u.s./2010/crime-in-the-u.s.-2010/persons-arrested

cases of arrested moral development who have not internalized conventional moral values? Juvenile delinquents are indeed more likely than nondelinquents to rely on preconventional moral reasoning (Spenser, Betts, & Das Gupta, 2015; Stams et al., 2006). They also do more poorly on tests of theory-of-mind skills (Spenser et al., 2015). Yet many delinquents have good social cognitive skills and can engage in conventional moral reasoning but commit illegal acts anyway. So to understand the origins of antisocial conduct, we must consider more than social cognitive skills and stage of moral reasoning (see Gibbs, 2014; Quinsey et al., 2004).

What about moral emotions? The highly aggressive, antisocial adolescents destined to become career criminals are less likely than other adolescents to show empathy and concern for others in distress or to feel guilty after they do wrong (Gibbs, 2014; Lovett & Sheffield, 2007). They are described as having “callous-unemotional traits” (Fontaine et al., 2011; Marsee & Frick, 2010). And indeed, their brain’s amygdala, center of emotional experience, does not respond as much as those of other youths to photographs of painful injuries suffered by other people that should arouse empathy (Marsh et al., 2013). So lack of appropriate moral emotions is important, but as will now become clear, highly antisocial adolescents also process social information differently than other adolescents do and have often grown up in family environments that breed aggression.

Dodge’s Social Information-Processing Model

Kenneth Dodge and his colleagues have advanced our understanding by offering a social information-processing model of aggressive behavior (Crick & Dodge, 1994; Dodge, 1986). Imagine that you are walking down the aisle in a classroom, trip over a classmate’s leg, and end up in a heap on the floor. As you fall, you are not sure what happened. Dodge believes that our reactions to frustration, anger, or provocation depend on the ways in which we process and interpret cues in situations like this. An individual who is provoked (as by being tripped) progresses through the six steps in information processing shown in ● Table 13.4, according to Dodge.

Highly aggressive youths, including adolescents incarcerated for violent crimes, show deficient or biased information processing at every step (Dodge, 1993; Slaby & Guerra, 1988), as illustrated in Table 13.4. Many aggressive youths act impulsively, “without thinking”; they respond automatically based on their past experiences. These youths have often developed a **hostile attribution bias**; they tend to see the world as a hostile place and quickly assume that any harm to them was deliberate rather than accidental. Severely violent youths have often experienced abandonment, neglect, abuse, bullying, and other insults that may have given them some cause to view the world as a hostile place and to feel justified in retaliating against individuals they believe are “out to get them” (Gibbs, 2014; Lansford et al., 2007). Of course the responses that pop to mind when they are provoked are mostly aggressive ones.

Dodge’s social information-processing model is helpful in understanding why certain children and adolescents might behave aggressively when provoked. However, it leaves somewhat unclear the extent to which the underlying problem is *how one thinks* (how skilled the individual is at processing social information), *what one thinks* (for example, whether the individual has a hostile attribution bias), or *whether one thinks* (how impulsively the person acts). Moreover, we have to look elsewhere to understand why only some children develop the social information-processing styles associated with aggressive behavior.

Patterson’s Coercive Family Environments

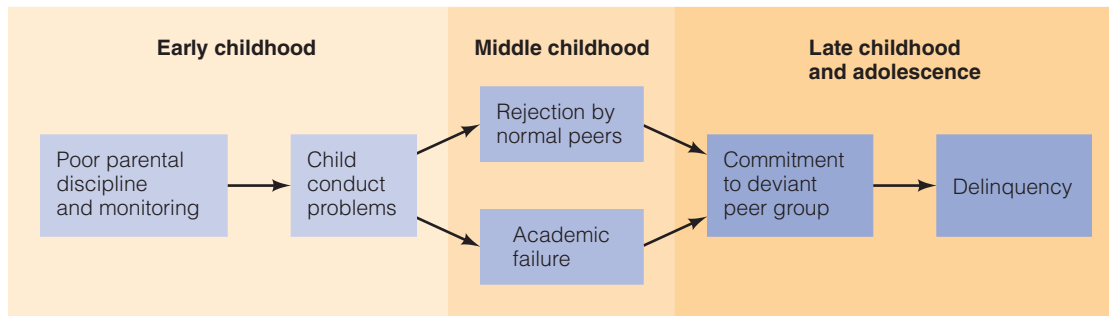

Gerald Patterson and his colleagues have found that highly antisocial children and adolescents often grow up in **coercive family environments** in which family members are locked in power struggles, each trying to control the others through negative, coercive tactics (Patterson, 2008; Patterson, DeBaryshe, & Ramsey, 1989). Parents learn (through B. F. Skinner’s principle of negative reinforcement) that they can stop their children’s misbehavior, temporarily at least, by threatening, yelling, and hitting. Meanwhile, children learn (also through negative reinforcement) that they can get their parents to lay off them by ignoring requests, whining, throwing full-blown temper

● **Table 13.4** The Six Steps in Dodge’s Social Information-Processing Model and Sample Responses of Aggressive Youth

Step	Behavior	Likely Response of Aggressive Youth
1. Encoding of cues	Search for, attend to, and register cues in the situation	Focus on cues suggesting hostile intent; ignore other relevant information
2. Interpretation of cues	Interpret situation; infer other’s motive	Show hostile attribution bias, assuming other person meant to do harm
3. Clarification of goals	Formulate goal in situation	Make goal to retaliate rather than smooth relations
4. Response search	Generate possible responses	Generate few options, most of them aggressive
5. Response decision	Assess likely consequences of responses generated; choose the best	See advantages in responding aggressively rather than nonaggressively (or fail to evaluate consequences)
6. Behavioral enactment	Carry out chosen response	Behave aggressively

Based on material in Dodge (1993) and Crick & Dodge (1994).

Social information processors use a database of information about past social experiences, social rules, and social behavior at each step of the process and may skip or repeat steps.

■ **Figure 13.5** Gerald Patterson’s model of the development of antisocial behavior shows how poor discipline and coercive family influence lead to involvement in a deviant peer group and delinquency.

Source: Adapted from Patterson, G. R., DeBaryshe, B. D., & Ramsey, E. (1989). A developmental perspective on antisocial behavior. *American Psychologist*, 44, 329–335.

tantrums, and otherwise being difficult. As both parents and children learn to rely on coercive tactics to avoid or escape unpleasant encounters, parents increasingly lose control over their children’s behavior until even the loudest lectures and hardest spankings have little effect and the child’s conduct problems spiral out of control. It is easy to see how a child who has grown up in a coercive family environment might attribute hostile intent to other people and rely on aggressive tactics to resolve disputes.

Growing up in a coercive family environment sets in motion the next steps in the making of an antisocial adolescent, according to Patterson and his colleagues (see ■ **Figure 13.5**): The child, already aggressive and unpleasant to be around, performs poorly in school and is rejected by other children. Having no better options, he becomes involved in a peer group made up of other low-achieving, antisocial, and unpopular youths, who positively reinforce one another’s delinquency. There is much support for Patterson’s view that ineffective parenting in childhood contributes to behavior problems, poor academic performance, peer rejection, involvement with antisocial peers, and, in turn, antisocial behavior in adolescence (Dodge et al., 2008; Lansford et al., 2014).

Nature and Nurture

However, neither Kenneth Dodge’s social-information processing model nor Gerald Patterson’s coercive family environments model considers the role of genetic endowment in aggression. Some individuals are more genetically predisposed than others to develop difficult, irritable temperaments, impulsive tendencies, psychological disorders, and other response tendencies and personality traits that contribute to aggressive, delinquent, and criminal behavior (Niv & Baker, 2013; Rhee & Waldman, 2002). Genetic differences among us are estimated to account for about 40% of individual differences in antisocial behavior and environmental influences for the remaining 60% of the variation (Rhee & Waldman, 2002). A number of specific genes that affect neurotransmitters and hormones have been identified as contributors to antisocial behavior. Researchers are also discovering *epigenetic effects* of harsh parenting and other stressful early experiences on the expression of certain

genes that play a role in aggressive behavior (Niv & Baker, 2013; Tremblay, 2010).

Genes and environment conspire to produce antisocial youth. Through the mechanism of *gene–environment interaction*, children with certain genetic predispositions are especially likely to become antisocial if they receive poor parenting or, worse, are physically abused (DeLisi, 2016; Dodge, 2009; Kony-Slock & Hudziak, 2013). For example, the monoamine oxidase A (MAO-A) gene, a gene on the X chromosome that affects our ability to control our tempers, has been linked to aggression (Dodge, 2009; Tiihonen et al., 2015). If children have a variant of this gene that results in low MAO-A activity *and* if they are abused or mistreated, they readily attribute hostile intentions to others if provoked, cannot control their anger, lash out impulsively, and show higher levels of antisocial behavior as adults (Caspi et al., 2002; DeLisi, 2016). By contrast, children with this high-risk gene are far less likely to become aggressive if they live in a stable, two-parent home or have nondelinquent friends (Guo, 2011).

Through the mechanism of *gene–environment correlation*, children who have a genetically based predisposition to become aggressive may actually evoke the coercive parenting that Patterson and his colleagues find breeds aggression. This *evocative gene–environment correlation* effect is evident when aggression-prone children who grow up with adoptive parents rather than with their biological parents bring out negativity in their adoptive parents (Fearon et al., 2015). In the end, child antisocial behavior and negative parenting influence one another reciprocally over time: Aggressive children evoke negative, coercive parenting, and negative, coercive parenting further strengthens children’s aggressive tendencies (Larsson et al., 2008; O’Connor et al., 1998).

Many other environmental risk and protective factors can help determine whether or not a child develops a pattern of antisocial behavior (Eisner & Malti, 2015; Guerra & Williams, 2006). Rates of aggression and violent crime are two to three times higher in lower socioeconomic neighborhoods and communities, especially transient and unstable ones, than in middle-class ones (Elliott & Ageton, 1980; Maughan, 2001). Similarly, certain schools have higher rates of delinquency and aggression than others, even when socioeconomic factors are controlled (Barboza et al., 2009; Maughan, 2001).

Finally, some cultural contexts are more likely to breed aggression than others (Eisner & Malti, 2015; Lansford et al., 2012). In Japan, a collectivist culture in which children are taught early to value social harmony, children are less angered by interpersonal conflicts and less likely to react to them aggressively than American children are (Zahn-Waxler et al., 1996). Homicides by youth also occur much less frequently in Asian countries like Japan and in European countries than in North and South America (Eisner & Malti, 2015). Cultural values can make a difference even within a society; for example, Hispanic American youths who have been brought up with traditional Hispanic cultural values such as the importance of family are less likely than those who are more acculturated into American society to engage in antisocial behavior (Cota-Robles, 2003; Soriano et al., 2004). This should not be surprising, as the United States is a relatively violent country: Guns are numerous, homicide rates are high, corporal punishment of children is common, and violence pervades the media (Anderson et al., 2010; Lansford & Dodge, 2008; Lim, Bond, & Bond, 2005).

In sum, we must recognize the contributions of biology and genetic predisposition, psychological factors such as information-processing styles and personality traits, and socio-cultural and contextual factors to aggression. Genes, in combination with environmental influences such as harsh parenting and interaction with antisocial peers, can lead to chronic and serious violence in adolescence and adulthood (Dodge et al., 2008). Unfortunately the antisocial adult who emerges from this developmental process stands a good chance of becoming the kind of harsh, coercive parent who helps raise another generation of aggressive children, who then use the same coercive style with their own children (Conger et al., 2003; Margolin et al., 2016).

Prevention and Treatment

Prevention and treatment of antisocial behavior should clearly be a national priority, but how do we go about it? Many approaches have been tried. **Application 13.1** focuses on the widespread problem of **bullying**, repeatedly inflicting harm through words or actions on a targeted peer, and a prevention program that has been used in many schools to combat it. Other researchers, drawing on Kohlberg's theory of moral development, have involved youth, including juvenile offenders, in discussion of moral dilemmas and democratic decision making in the schools in order to improve their moral reasoning (Gibbs, 2014; Nucci, 2006; Power & Higgins-D'Alessandro, 2008). Dodge's model has been applied to improve the social information-processing skills of juvenile delinquents (Guerra & Slaby, 1990). Others have focused on training to improve self-control and reduce impulsivity (DeLisi, 2016). And Patterson's coercive cycles model has been used to train parents of at-risk youth in positive behavior management techniques (Bank et al., 1991; Patterson, 2005; Reed et al., 2013). All these approaches have had some success, but none has been able to completely

prevent antisocial behavior or turn around the lives of serious juvenile offenders.

Many experts believe that prevention is the key and that it should start early in childhood (Dodge, Coie, & Lynam, 2006; Tremblay, 2010). Since risk factors like harsh parenting and disruptive child behavior reciprocally influence each other, it also makes sense to try to change both the child and the environment (Jaffee, Strait, & Odgers, 2012). For instance, the Fast Track Program, designed by Kenneth Dodge and a large team of researchers (Conduct Problems Prevention Research Group, 2002; Sorensen et al., 2016), began in first grade, extended over 10 years, and used a multipronged approach involving the teaching of social information processing and social skills, efforts to improve academic skills, and behavior management training for parents. It has proven effective in reducing antisocial behavior, including arrests, and preventing diagnoses of conduct disorder and related psychiatric disorders in adolescence and early adulthood (Sorensen, Dodge, & Conduct Problems Prevention Research group, 2016). The program achieves its results, in part, by improving participants' social information-processing and self-regulation skills (Dodge et al., 2013; Sorensen et al., 2016). Even in their 20s, high-risk participants in Fast Track respond more calmly to provocations in the lab such as having items stolen from them; they show lower rises in the male hormone testosterone and, in turn, less aggressive behavior than control adults (Carré et al., 2014).

Finally, still other researchers believe there has been too much emphasis on reducing adolescent problem behavior and too little on helping youth develop in positive directions. **Positive youth development (PYD)** is an approach that emphasizes developing the strengths of youth. In one formulation (Lerner et al., 2005; Lerner, Phelps, Forman, & Bowers, 2009), "five Cs" serve as the goals:

1. Competence (academic, vocational, and so on)
2. Confidence (self-esteem and self-efficacy)
3. Character (moral development, respect for rules)
4. Connection (bonds to family, friends, and institutions like schools and churches)
5. Caring (empathy, prosocial behavior)

PYD programs help youths develop more positive identities, build "five C" strengths, increase their positive contributions to their communities—and yes, reduce their problem behaviors (Jelicic et al., 2007; Lerner et al., 2005; Mueller et al., 2011). For racial and ethnic minority youth, who too often have been viewed more in terms of their vulnerabilities to problems than in terms of their strengths, this "emphasize the positive" approach may be especially welcomed. Indeed, the strengths of particular racial and ethnic groups—racial pride, family values, spirituality—are being incorporated in PYD programs (Evans et al., 2012; Kenyon & Hanson, 2012; Knight & Carlo, 2012). In short, to prevent antisocial behavior we would do well to begin early, use a multipronged approach, and nurture the positive potentials of youth.

● APPLICATION 13.1

Stopping the Bullies

Phoebe Prince, a 15-year-old in Massachusetts who was believed to be moving in on other girls' boyfriends, was taunted mercilessly—jokes about an “Irish slut” on Facebook (she had recently moved to the United States from Ireland), a humiliating accusation in the school cafeteria, kids cruising up next to her in a car as she walked home, throwing an empty soda can at her, and calling her “whore” (Bennett, 2010). Phoebe killed herself.

Bullying, repeatedly inflicting harm through words or actions on a targeted peer, was once written off as just a normal part of growing up but is now a major societal concern (Hwang, Kim, & Leventhal, 2013; Olweus, 1993; Salmivalli & Peets, 2009). The victims can be almost anyone, but recent immigrants, gay and lesbian youth, and youth with disabilities or emotional problems get more than their fair share of bullying (Blake et al., 2012; Burton et al., 2013). Bullying takes many forms, from physical aggression to more indirect or covert forms of aggression such as excluding or gossiping about someone. It includes cyberbullying, which enables bullies to spread rumors, insults, embarrassing photographs, and threats quickly and widely via digital devices (Hinduja & Patchin, 2013; Smith et al., 2008).

We can divide the world of youth into bullies, victims, bully-victims, and neither (Hwang et al., 2013; Zych, Ortega-Ruiz, & Del Ray, 2015). A survey in 40 Western countries revealed that, overall, about 26% of 11- to 15-year-olds report repeatedly bullying and/or being bullied by peers at least two to three times a month (Craig et al., 2009). Rates vary considerably, though, from under 10% in Scandinavian countries like Sweden to around 40% in Baltic countries like Lithuania, with the United States in the middle. Bullying is also a life-span phenomenon; for example, adult bullying in the workplace is also a matter of societal concern (Samnani & Singh, 2012).

The effects of bullying are serious. Being hounded by bullies can lead to becoming a bully and to aggression and delinquency, as

well as to depression, health problems such as stress-related headaches and pains, and self-harmful behavior, including suicide (Barker et al., 2008; Espinoza, Gonzales, & Fuligni, 2012; Hwang et al., 2013; Wolke et al., 2013). Academic performance suffers as well (Cornell et al., 2012; Strøm et al., 2013).

Being bullied as a child may even have long-term implications for adult development. William Copeland and his colleagues (2014) discovered that a marker in the blood indicating inflammation—a sign of an overactive immune system that is associated with a number of chronic illnesses—was at higher levels during childhood and continuing into early adulthood in individuals who had experienced the stress of being bullied during childhood than in those who were not bullied. The more chronic the bullying, the greater the evidence of inflammation. Meanwhile, childhood bullies showed lower levels of inflammation than children who had neither been bullies nor victims, possibly because they achieved status in the peer group through their bullying. This research team also found that bullied children and bully/victims have poorer health, lower incomes, more risky and illegal behavior, and poorer social relationships as young adults than nonbullied individuals—even controlling for family socioeconomic status and child psychiatric problems (Wolke et al., 2013).

So what is being done to stop the bullying? Antibullying laws mandate antibullying programs in the schools and sometimes establish criminal penalties for bullying (Bennett, 2010). Schools now take active steps to combat bullying and to encourage students to report or intervene in bullying incidents rather than reinforcing the bullies (Saarento & Salmivalli, 2015; Beane, 2009). One of the most widely used and well-known interventions is the Olweus Bullying Prevention Program (Olweus, 1993; Olweus & Limber, 2010). Launched in Norway in the wake of three teen suicides attributed to bullying, it is

a comprehensive program with several components. It focuses on the school as a whole (for example, through a school coordinating group with staff and student representatives and teacher training), the class (for example, through posting of rules against bullying and regular class discussions of bullying), the individual (through talks with bullies, victims, and their parents and development of individual action plans for those involved in bullying), and the broader community (through school-community partnerships).

So far, this multifaceted program has had some success reducing bullying and changing attitudes toward it. However, it has proven more effective in Norway and other relatively homogeneous societies than in the more diverse context of the United States (Evans, Fraser, & Cotter, 2014; Olweus & Limber, 2010; Schroeder et al., 2012). If we analyze bullying using Bronfenbrenner's bioecological model (Hong & Espelage, 2012; Chapter 2), we quickly appreciate that a host of problems within the person, family, peer group, school, community, and broader culture must be addressed to stop the bullies once and for all.

● Checking Mastery

1. What is the main change in the level of moral reasoning during adolescence?
2. What are the main contributions of (1) Kenneth Dodge and (2) Gerald Patterson to understanding why some adolescents are highly aggressive?
3. What is an example of the contribution of a gene–environment interaction to the development of aggression?

● Making Connections

1. To demonstrate to yourself that Dodge's social information-processing model can be applied not only to antisocial behavior but to prosocial behavior, picture

a situation in which you are one of the campers in the story at the beginning of this chapter and witness two other campers put the hand of Edward, the camp employee, in a bucket of water while he naps. Show how considerations at each of the six steps of Dodge's model (see Table 13.4) might contribute to your intervening to help Edward—and then how they might keep you from helping.

2. You hear that still another teenage boy has gone on a shooting rampage at his school. Drawing on material in this section, what main hypotheses would you have about why he might have done what he did?

13.6

The Adult

LEARNING OBJECTIVES

- Summarize changes in moral reasoning over the adult years.
- Analyze the limitations of Kohlberg's theory of moral development with reference to cultural differences in moral thinking and dual-process models of moral decision making.
- Distinguish between religiousness and spirituality and discuss their development and relationships to adjustment.

How does moral thinking change during adulthood, and how is it related to moral emotion and moral behavior? And how does moral development intersect with religiousness and spirituality in adults' lives?

Changes in Moral Reasoning

Much research on moral development in adulthood has been guided by Kohlberg's theory. As you have discovered (reexamine Figure 13.3), Kohlberg's postconventional moral reasoning appears to emerge only during the adult years—if it emerges. In Kohlberg's 20-year longitudinal study (Colby et al., 1983), most adults in their 30s still reasoned at the conventional level, although many of them had shifted from Stage 3 to Stage 4. A minority of individuals—one out of six at most—had begun to use Stage 5 postconventional reasoning, showing a deeper understanding of the basis for laws and distinguishing between just and unjust laws. Clearly there is opportunity for continued moral growth in early adulthood.

Do these growth trends continue into later adulthood? Most studies find no major age differences in complexity of moral reasoning, at least when the age groups compared have similar amounts of education (Pratt & Norris, 1999; Pratt et al., 1991, 1996). Older adults are also more likely than younger adults to feel that they have learned important lessons from moral dilemmas they have faced during their lives (Pratt & Norris, 1999). This, then, is further evidence that social cognitive skills hold up relatively well across the life span.

Overall, research based on Kohlberg's influential theory of moral development shows that children think about hypothetical

moral dilemmas primarily in a preconventional manner, that adolescents adopt a conventional mode of moral reasoning, and that a minority of adults shift to a postconventional perspective. Moreover, longitudinal studies of moral growth in several countries show that at least the first three or four of Kohlberg's six stages form an invariant and universal developmental sequence (Colby & Kohlberg, 1987; Gibbs, 2014; Rest et al., 1999).

However, despite Kohlberg's major contributions to the study of moral development, his theory has its limitations. You have already seen that young children are more sophisticated moral thinkers than either Piaget or Kohlberg appreciated. Let us now consider concerns about whether Kohlberg's focus on reasoning about rights and justice adequately captures the nature of moral thinking in non-Western cultures, whether it neglects a much more intuitive or emotional way of responding to moral issues, and whether Kohlberg said enough about influences on how people actually behave when they face moral dilemmas.

Culture and Morality

Are basic aspects of morality universal or are they culture specific? Although support for the early stages of Kohlberg's theory has been obtained in many countries, critics charge that Kohlberg's highest stages reflect a Western ideal of justice centered on individual rights and the rule of law—and that there's more to morality than that. Kohlberg, they argue, did not adequately appreciate that people in non-Western societies often emphasize different moral concepts (Jensen, 2015; Miller & Bland, 2014; Shweder, Mahapatra, & Miller, 1990). Indeed, cross-cultural research suggests that postconventional moral reasoning emerges primarily in Western democracies (Snarey,

1985). Meanwhile, people in *collectivist cultures*, which emphasize social harmony and place the good of the group ahead of the good of the individual, often look like Stage 3 conventional moral thinkers in Kohlberg's system. Yet many have sophisticated concepts of justice that focus on the individual's duty to the group or community and responsibility for others' welfare (Snarey, 1985; Tietjen & Walker, 1985). In **Exploration 13.2**, we look at moral development in India, where moral reasoning based on religious and spiritual concepts can lead to quite different conclusions about what is right or wrong than in Western countries like the United States.

Cross-cultural findings challenge the cognitive-developmental position that moral development proceeds through universal stages. Instead, they support a social learning perspective

on moral development, suggesting that our moral judgments are shaped by the social context in which we develop. Possibly the resolution is this: Individuals all over the world think in more complex ways about moral issues as they get older, as Kohlberg claimed, but they also adopt different notions about right and wrong depending on their culture's teachings (Jensen, 2015; Miller, 2006).

Moral Intuition and Emotion

(Before you read this section, we invite you to read and respond to **Engagement 13.2**.) Developmentalists today are trying to correct for Kohlberg's overemphasis on moral reasoning by exploring the

● EXPLORATION 13.2

Moral Thinking in India

Some time ago, Richard Shweder et al. (1990) studied the moral judgments of children and adults in India and the United States and identified some striking cultural differences in thinking about right and wrong. For example, Hindu children and adults rated a son's getting a haircut and eating chicken the day after his father's death as one of the most morally offensive of the 39 acts they were asked to rate, whereas Americans dismissed it as only a matter of breaking what seemed to them an arbitrary social-conventional rule about appropriate mourning behavior. Meanwhile, Americans viewed a husband's beating of his "disobedient" wife for going to the movies without his permission as a serious moral violation, whereas Hindus viewed it as appropriate behavior. To orthodox Hindus, not showing proper respect for the dead violates a moral rule required by divine law, not an arbitrary social-conventional rule, and it is morally necessary for a man to beat his disobedient wife to uphold his obligations as head of the family. In India, religious and spiritual concepts were integral to moral thinking; yet they had been ignored in Kohlberg's theory of moral development (Shweder et al., 1990).

Based on such cross-cultural studies, Shweder and his colleagues (1997) suggested that three different ethics inform moral thinking around the world and that the balance of them differs from culture to culture:

- an ethic of autonomy (as in Kohlberg's theory, a concern about individual rights and fairness or justice);
- an ethic of community (as in many collectivist cultures, an emphasis on duty,

loyalty, and concern for the welfare of the group); and

- an ethic of divinity (an emphasis on divine law and a quest for spiritual purity).

Niyati Pandya and Rachana Bhangaokar (2015) gave 8- and 11-year-old Indian children moral dilemmas to ponder and found that they often thought about moral issues in religious or spiritual terms. They considered individual rights about as often and the good of the community too, but less often. These children were concerned about what behavior will please or displease God. Talking about why telling a lie would be wrong, for example, an 11-year-old girl said, "We will feel guilty, and our soul will be restless. That means that we are not doing right, we cannot steal or lie while we also worship God or pray for his blessings. . . ." (Pandya & Bhangaokar, 2015, p. 33). Studying Indian adolescents and adults, Kapadia and Bhangaokar (2015) found emphasis on individual autonomy and rights to be greater among adolescents than among adults, but

emphasis on community and divinity themes to be greater among adults.

Lene Arnett Jensen (2015) has used Shweder's three ethics as the basis for a cultural-developmental perspective on morality—a perspective that guided these studies of Indian children and adults. She maintains that individuals in different cultural and subcultural contexts follow different developmental trajectories that involve different mixes of the ethics of autonomy, community, and divinity at different ages. Much remains to be learned about these trajectories, but cross-cultural research has already made an important point: There are more ways to think about moral issues than Kohlberg's rights and justice model suggests.

Runaway Trolleys

We invite you to read and respond to these two moral dilemmas (Greene et al., 2001, p. 2105) and then return to the section Moral Intuition and Emotion.

1. **Switch Dilemma.** A runaway trolley is headed for five people who will be killed if it proceeds on its present course. The only way to save them is to hit a switch that will turn the trolley onto an alternate set of tracks where it will kill one person instead of five. Ought you to turn the trolley in order to save five people at the expense of one?

2. **Footbridge Dilemma.** As before, a trolley threatens to kill five people. You are standing next to a large stranger on a footbridge that spans the tracks, in between the oncoming trolley and the five people. . . . The only way to save the five people is to push this stranger off the bridge, onto the tracks below. He will die if you do this, but his body will stop the trolley from reaching the others. Ought you to save the five others by pushing this stranger to his death?

emotional component of morality more fully. As you have seen already, Martin Hoffman, Grazyna Kochanska, and others have long highlighted the importance of emotions like empathy and guilt in motivating moral action. Now a number of scholars are converging on the idea that gut emotional reactions and intuitions play a critical role in moral decision making (Gibbs, 2014; Greene, 2008, 2013; Haidt, 2008).

Think about whether you would eat your fellow passengers after a plane crash in the mountains if there were nothing else to eat. Most of us say, “Ewww,” finding the idea morally repugnant. We immediately know in our gut, without a need for contemplation, that cannibalism is wrong. Jonathan Haidt (2001, 2008, 2012) argues that we have evolved as a species to have many such quick moral intuitions, often rooted in emotions like disgust. He believes that these intuitions are more important than deliberative reasoning in shaping moral decisions. If deliberate thought of the sort emphasized by Kohlberg plays a role at all, Haidt suggests, it is mainly to rationalize after the fact what we have already decided intuitively. Often, we cannot even come up with logical reasons for our gut reactions.

Like Haidt, Joshua Greene has proposed a **dual-process model of morality** in which deliberate thought and intuition/emotion play distinct roles in morality (see ● **Table 13.5**; and Gibbs, 2014). Greene maintains that both reason and intuition/emotion are important and has tried to figure out why we sometimes make judgments based on quick, emotion-based intuitions and other times make judgments using more deliberative

cognitive processes and what parts of the brain are involved in each. Look again at Engagement 13.2. Despite the similarities between the two trolley car scenarios there, most people would hit the switch in the switch scenario but would not push the stranger off the bridge in the footbridge scenario. Was that your response? Why do you think you reacted that way?

Greene and his colleagues (2001) have proposed that it is because the footbridge dilemma evokes a strong emotional response that the first scenario does not: we are appalled at the idea of directly killing a person with our own hands, possibly because we have evolved to feel such revulsion. Using the fMRI imaging techniques of cognitive neuroscience, Greene and his colleagues have demonstrated that areas of the brain associated with emotion are more active when people think about killing the large man in the footbridge scenario, whereas areas of the brain associated with rational cognition are more active when people weigh the idea of sacrificing the one for the many in the switch problem. Thus the findings were consistent with Greene’s (2008) concept of a dual-process model of morality involving: (1) an emotion-based intuitive process that prompts us, quickly and without awareness, to focus on (and abhor) the harm that would be done if we violated moral principle (as by pushing a stranger to his death); and (2) a more deliberative, cognitive approach in which we weigh the costs and benefits of an action in a cool and calculating manner (and conclude that it is more rational to sacrifice one life than to lose five).

Other evidence supports Greene’s dual-process model and the idea that we use different parts of the brain to make intuitive and deliberative moral decisions (Greene, 2009, 2013; Greene et al., 2008; Moore, Lee, Clark, & Conway, 2011). Much remains to be learned, though. When do we go with our gut reactions and when do we rely on conscious deliberation? How do we integrate signals from the amygdala of the brain (emotion) and the prefrontal cortex (reasoning), especially when they are pulling us in different directions (Shenhav & Greene, 2014)? We do not yet know much about the development of the intuitive and deliberative systems. So far, brain imaging studies suggest that empathic responses may decrease from childhood to adulthood while cognitive appraisal increases. With age, the emotional responses of

● **Table 13.5** Dual-Process Models of Morality

Moral Cognition/ Reasoning (Emphasized by Kohlberg)	Moral Emotion/Intuition (Emphasized by Haidt, Greene)
Rational thought	Intuition
Cold logic	Hot emotion
Controlled processes	Automatic processes
Impartiality	Empathy
Careful deliberation	Quick gut reaction

the amygdala and the cognitive responses of the prefrontal cortex also become better integrated (Decety & Howard, 2014; Decety, Michalska, & Kinzler, 2012). In sum, the dual-processing perspective raises new and interesting questions about the distinct roles of quick, emotion-based intuition and deliberate reasoning in morality—and about how we come to integrate them to guide our behavior.

Predicting Moral Action

Kohlberg focused primarily on moral reasoning rather than moral behavior. But does how one reasons predict how one behaves? Although a person may decide to uphold or to break a law at any of Kohlberg's stages of moral reasoning, Kohlberg argued that more advanced moral reasoners are more likely to behave morally than less advanced moral reasoners are. For example, where the pre-conventional thinker might readily decide to cheat if the chances of being detected were small and the potential rewards were large, the postconventional thinker would be more likely to appreciate that cheating is wrong in principle, regardless of the chances of punishment or reward, because it infringes on the rights of others and undermines social order.

What does research tell us? Individuals determined to be at higher stages of moral reasoning are indeed more likely than individuals at lower stages to behave prosocially and ethically and less likely to behave immorally (Gibbs, 2014; Villegas & Vargas-Trujillo, 2015; Walker, 2004; Wu & Liu, 2014). Yet relationships between stage of moral reasoning and moral behavior are usually fairly weak (Cohen et al., 2014; Wu & Liu, 2014). This is likely because a variety of other factors influence behavior—the situational factors social learning theorists like Bandura emphasize, the gut emotional reactions Haidt and Greene call attention to, the moral ethics and norms that dominate in a given culture, and so on.

In sum, Kohlberg's stage theory has a good deal of support, but it

- underestimates children's moral sophistication;
- fails to appreciate cultural differences in thinking about morality;
- neglects intuition/emotion, as pointed out by dual-process theorists such as Haidt and Greene; and
- says too little about the many influences besides moral reasoning on moral behavior.

In the end, we do best recognizing that the moral reasoning of interest to Piaget and Kohlberg, the moral emotions and intuitions of interest to Freud and Hoffman and more recently Haidt and Greene, and the self-regulatory and moral disengagement processes highlighted by Albert Bandura—together with many other personal and situational factors—all help predict whether a person will behave morally or immorally when faced with an important moral choice.

Religion and Spirituality

Lawrence Kohlberg viewed moral development and religious development as distinct, but they are closely interrelated for the

many people around the world whose religious or spiritual values and beliefs guide their moral thinking and behavior (Cohen, 2015; Nelson, 2009). Indeed, James Fowler (1981; Fowler & Dell, 2006) proposed stages in the development of religious faith from infancy to adulthood that parallel quite closely Kohlberg's stages of moral development. Fowler's stages lead from concrete images of God in childhood, to internalization of conventional religious beliefs during adolescence, to soul searching in emerging or early adulthood, and, for a few, progression to a more abstract, universal perspective on faith in middle age and beyond. This idea of universal stages of religious development, like Kohlberg's stages of moral development, has come into question. However, researchers are more interested than ever in the roles religion and spirituality play in life-span development (Ai, Wink, & Ardel, 2010; King & Boyatzis, 2015; Nelson, 2009; Pargament, Exline, & Jones, 2013). Not only do religious and spiritual beliefs inform people's moral judgments and behavior but they shape their self-perceptions and relationships with other people and groups and affect their adjustment (Cohen, 2015; King & Boyatzis, 2015).

Religiousness has generally been defined as sharing the beliefs and participating in the practices of an organized religion. **Spirituality** is harder to define but involves a quest for ultimate meaning and for a connection with something greater than oneself, whether God, love, nature, or some other cosmic force (see King & Boyatzis, 2015; Nelson, 2009). Spiritual seeking may be carried out within the context of a religion (some people are both religious and spiritual) or outside it (some people say they are spiritual but not religious).

Children often adopt the beliefs of their parents, especially if their parents are religious and are warm and supportive (Power & McKinney, 2013). Children also think on their own about religious and spiritual matters, though, and do so in increasingly complex ways as they get older (Boyatzis, 2013). Adolescence or emerging adulthood is a particularly important time for raising religious and spiritual questions as part of identity formation (Alisat & Pratt, 2012; Good & Willoughby, 2008; Nelson, 2009). For most, the result is staying in the religious tradition in which they were raised but sometimes with a deeper and more personalized understanding. For others, questioning results in rejecting the religious beliefs one was taught as a child, undergoing a spiritual conversion, or developing one's own belief system, whether religious or not. Religious commitment, if it translates into a strong moral identity, can encourage empathy for others and work against antisocial tendencies (Hardy, Walker, Rackham, & Olsen, 2012; King & Boyatzis, 2015).

Is old age also a time for religious and spiritual growth? Most studies suggest that while formal participation in religious activities may decline in late adulthood owing to illness and disability, the importance attached to religion and involvement in more personal forms of participation like prayer remain steady or even increase (Ai et al., 2010). Michelle Dillon and Paul Wink traced changes over the years in both religiousness and spirituality in a sample of adults (Dillon & Wink, 2007; Wink & Dillon, 2002, 2003). The average level of religiousness was high in adolescence; decreased somewhat in middle age, possibly because people had many responsibilities and little time; and

The church is at the center of the African American community and can have both health and mental health benefits for those elderly people who are highly involved in it.

Blend Images/Dream Pictures/Getty Images

rose again in people's late 60s and 70s. Meanwhile, spirituality also increased from middle age to later adulthood (Dillon & Wink, 2007). This was especially true among women, who are generally more religious and more spiritual than men (see also Brown et al., 2012). These findings confirm Erik Erikson's view of old age as centered on the issue of integrity versus despair—as a time for reflecting and finding meaning in life (Atchley, 2009; Nelson, 2009).

Does it benefit people to be highly religious or spiritual? Correlation is not necessarily causation, but both religiousness

and spirituality are positively associated with health, mental health, and well-being (Ai et al., 2010; Greenfield, Vaillant, & Marks, 2009; Spilman et al., 2013; Wink & Dillon, 2008). Why might this be? Perhaps because religiousness and spirituality foster a sense of meaning and purpose in life and provide social support (Ai et al., 2010; Krause, 2013; Nelson, 2009).

Religion and spirituality may be especially important for certain racial and ethnic groups (King & Boyatzis, 2015; Krause, 2013; Mattis & Grayman-Simpson, 2013). For example, both African American and Caribbean Blacks age 55 and older report more religious participation of various types, more use of prayer to cope with stress, and more spirituality than Whites do (Taylor, Chatters, & Jackson, 2007). And compared to older White adults in the United States, older Black adults derive more meaning from their religion, and this sense of meaning is more strongly related for them than for Whites to life satisfaction, self-esteem, and optimism (Krause, 2003). Being highly religious and spiritual also serves to protect African American adults from depression (Cheadle et al., 2015; Ellison & Flannelly, 2009).

In sum, religiousness and spirituality are distinct, and spirituality especially may increase in later life. Moreover, both can contribute positively to a sense of meaning or purpose in life and to social support and, in turn, to good physical and mental health and a sense of well-being.

We have now completed our series of chapters on the development of the person as an individual, having examined the development of self-conceptions and personality (Chapter 11), identities as males or females (Chapter 12), and now social cognition and morality. Our task in upcoming chapters will be to put the individual even more squarely in social and cultural context. It should become clear that throughout our lives we are both independent and interdependent—separate from and connected to other developing persons.

● Checking Mastery

1. How does moral reasoning typically change over the adult years?
2. What are the two distinct processes in dual-process models of morality?
3. What is the main difference between being highly religious and being highly spiritual?

● Making Connections

1. Thinking about all the material on moral development, what do you view as the main strengths and weaknesses of Lawrence Kohlberg's theory of morality and moral development?
2. To what extent do religious or spiritual beliefs enter into your own thinking about moral choices? You might start with your thinking about controversial matters of life and death—abortion, mercy killing, and capital punishment.

Chapter Summary

13.1 Social Cognition

- Social cognition (thinking about self and others) is involved in all social behavior, including moral behavior. Starting in infancy with milestones such as joint attention, understanding of intentions, and pretend play, children develop a theory of mind—a desire psychology at age 2 and a belief–desire psychology at age 4 as evidenced by passing false belief tasks. Developing a theory of mind requires a normal brain and experience communicating about mental states.
- In characterizing other people, preschool children focus on physical features and activities, children 8 years and older on inner psychological traits, and adolescents on integrating trait descriptions to create personality profiles. With age, children also become more adept at perspective taking. Social cognitive skills often improve during adulthood and hold up well but may decline late in life if basic cognitive abilities are taxed or a person becomes socially isolated.

13.2 Perspectives on Moral Development

- Morality has emotional, cognitive, and behavioral components. Sigmund Freud's psychoanalytic theory emphasized the super-ego and moral emotions, and Martin Hoffman has emphasized empathy as a motivator of moral behavior.
- Building on the work of cognitive-developmental theorist Jean Piaget, Lawrence Kohlberg proposed three levels of moral reasoning—preconventional, conventional, and postconventional—each with two stages.
- Social cognitive theorist Albert Bandura focused on how moral behavior is influenced by learning, situational forces, self-regulatory processes, and moral disengagement.
- Evolutionary theorists (Krebs, Tomasello) consider emotion, cognition, and behavior and maintain that humans have evolved to have moral and prosocial tendencies.

13.3 The Infant

- Although infants are amoral in some respects, they begin learning about right and wrong through early disciplinary encounters, internalize rules, and display impressive empathy and prosocial behavior early in life, just as they show antisocial behavior on occasion. Their moral growth is facilitated by a secure attachment and what Kochanska calls a mutually responsive orientation between parent and child.

13.4 The Child

- Kohlberg and Piaget underestimated the moral sophistication of young children (for example, their ability to consider intentions, to distinguish between moral and social-conventional rules, and to seek fairness); still, most children display preconventional moral reasoning.
- Reinforcement, modeling, Hoffman's disciplinary approach of induction, and proactive parenting strategies can foster moral growth, and a child's temperament interacts with the approach to moral training parents adopt to influence outcomes.

13.5 The Adolescent

- During adolescence, a shift from preconventional to conventional moral reasoning is evident, and some adolescents forge a moral identity.
- Adolescent antisocial behavior, both early and late onset, can be understood in terms of Kenneth Dodge's social information-processing model and Gerald Patterson's coercive family environments and the negative peer influences they set in motion. Genetic predisposition interacts with a variety of social–environmental influences. Attempts to prevent or reduce antisocial behavior, including bullying, are varied, including the Fast Track program and the positive youth development movement.

13.6 The Adult

- A minority of adults progress from the conventional to the post-conventional level of moral reasoning; elderly adults typically reason as complexly as younger adults.
- Kohlberg's early stages of moral reasoning form an invariant sequence, but he underestimated children, failed to appreciate cultural differences in bases for moral judgment, and slighted moral emotion and the many other influences on moral behavior.
- Researchers like Haidt and Greene have proposed dual-process models of morality that include both deliberative reasoning and emotion-based intuitions.
- Religiousness and spirituality become stronger in later life and are associated with good physical and mental health and well-being for many people.

Mike Pohle was about to graduate and wanted to find a job close to his fiancée, Marcy Crevonis (Jones, 2007). He slept every night in a Phillies jersey she gave him and had already named the five children they hoped to have. They were soul mates. As Marcy put it, “We were the same person. We shared the same thoughts. We finished each other’s sentences” (Jones, 2007, p. C1).

Mike Pohle was one of the 32 victims of the mass murders at Virginia Tech University, April 16, 2007. Marcy had walked him part of the way to his German class that morning and raced to find him when his class was to end but was blocked by the police. Told of Mike’s death, she went back to his apartment, put on the Phillies jersey, and wept.

The shooter, Seung Hui Cho, had no soul mates. He was an unusually quiet child who did not respond to greetings; one high school classmate recalled the jokes about him: “We would just say, ‘Did you see Seung say nothing again today?’” (Cho & Gardner, 2007, p. A8). Cho spent his lonely days writing stories of violence and death. He had been diagnosed and treated for social anxiety disorder and selective mutism as a child, but he never made this known to Virginia Tech, and deteriorated in college (Schulte & Craig, 2007). As a result, he was almost completely isolated from the human community.

How did their developmental experiences prepare Mike and Marcy to fall in love? What kept Seung from developing close human relationships, and what made him so angry at his fellow humans? Think about Mike Pohle and Seung Hui Cho as you read this chapter. It concerns our emotional lives and closest social relationships and their interrelationships across the life span. We

explore how we develop the emotional security and social competence it takes to interact positively with other people and to enter into intimate relationships with them. We also examine the developmental implications of being deprived of close relationships. We begin by examining the emotions that are so much a part of our close relationships.

14.1

Emotional Development

LEARNING OBJECTIVES

- Distinguish between primary and secondary or self-conscious emotions, giving examples and indicating when they emerge.
- Discuss age-related changes in mastery of emotion regulation skills, the concept of mixed emotions, and display rules for emotion.
- Using socioemotional selectivity theory, explain why older adults typically have greater emotional well-being than adolescents.

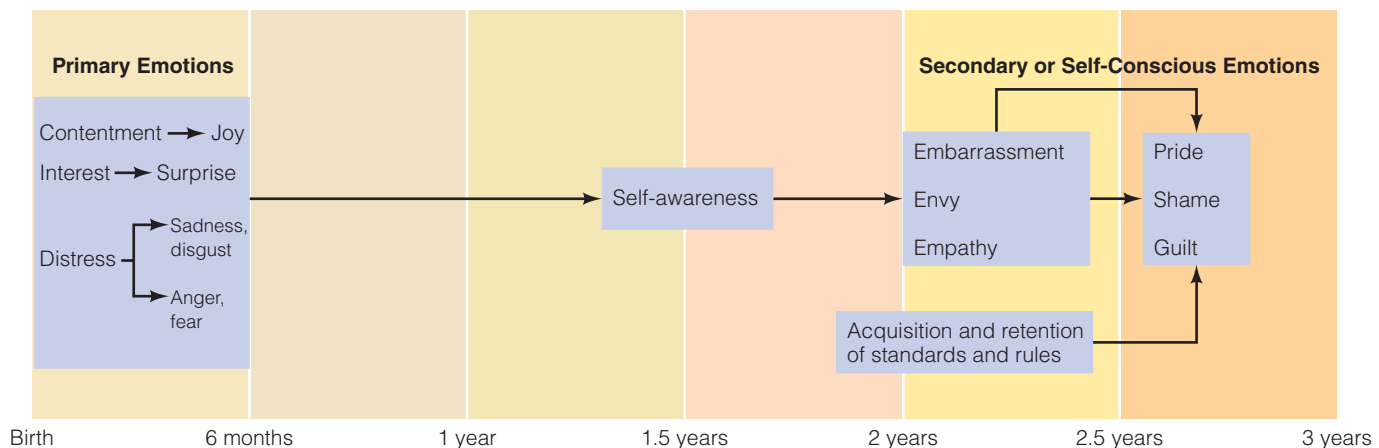

What is an emotion? It is a complex phenomenon that involves a subjective feeling (“I’m mad,” “I feel hot”), physiological changes (a pounding heart), behavior (an enraged face, a door slammed), and often a cognitive appraisal as well (“No wonder I’m mad—He embarrassed me in front of everyone.”) (see Goodvin, Thompson, & Winer, 2015; Gross, 2014). Emotions are detectable in the first days of life, but their character changes as we develop cognitively and as we learn to express and regulate or control them. Parent–child relationships involve strong emotions, and caregivers are critical in shaping the course of emotional development.

First Emotions and Emotion Regulation

Carroll Izard (1982; Izard & Ackerman, 2000) and his colleagues maintain that basic emotions are biologically based, develop early in life, and play critical roles in motivating and organizing

behavior. By videotaping infants’ responses to such events as having a toy taken away or seeing their mothers return after a separation, analyzing specific facial movements (such as the raising of the brows and the wrinkling of the nose), and asking raters to judge what emotion a baby’s face reveals, Izard has established that very young infants express distinct emotions in response to different experiences and that adults can interpret which emotions they are expressing (see also Saarni et al., 2006). The work of Izard and others allows us to piece together an account of the early development of a number of so-called **primary emotions**, distinct basic emotions that emerge within the first 6 months of life (Lewis, 2008, 2015; and see ■ **Figure 14.1**).

At birth, babies show contentment (by smiling), interest (by staring intently at objects), and distress (grimaces in response to pain or discomfort). Within the first 6 months, six specific primary emotions evolve from these three. By 3 months of age or so, contentment becomes joy—pleasure at the sight of something

■ **Figure 14.1** The emergence of different emotions. Primary emotions (joy, surprise, fear, anger, sadness, and disgust) emerge in the first 6 months of life and evolve from there. Once self-awareness or mirror self-recognition is achieved, the first of the secondary or self-conscious emotions (embarrassment, for instance) emerge starting at about 18 months of age. Later in the second year, self-conscious emotions that require evaluating the self against standards (pride, for example) emerge.

familiar such as a big smile in response to Mom's face. Interest becomes surprise, such as when expectations are violated in games of peekaboo. Distress soon evolves into four familiar negative emotions, starting with disgust (in response to foul-tasting foods) and sadness. Angry expressions appear as early as 4 months—about the time infants acquire enough control of their limbs to push unpleasant stimuli away. Now instead of just being distressed when they are physically restrained, they look angrily at the person who is restraining them. Finally, fear is the last to appear.

Next, as Figure 14.1 also shows, come the so-called secondary or **self-conscious emotions** (Lewis, 2015). These emotions require self-awareness and begin to emerge at about 18 months of age, the age when infants become able to recognize themselves in a mirror and may start using words like “I” and “me” (see Chapter 11 on self-recognition). Once they achieve self-awareness, infants may show embarrassment when they are asked to dance or sing for guests. Then, later in the second year, when toddlers become able to judge their behavior against standards of performance, they may display the self-conscious emotions that involve evaluating the self: pride, shame, and guilt (Lewis, 2008). They can feel proud if they catch a ball because they know that's what you're supposed to do when a ball is tossed your way—or guilty if they spill their milk because they know you are not supposed to make messes. Michael Lewis (2015) has gone on to argue that the primary emotions are only action patterns rather than true emotions until children develop self-consciousness and can have thoughts such as, “I'm scared of that dog,” or “I'm mad at that kid!”

Nature, Nurture, and Emotions

Primary or basic emotions such as interest and fear seem to be biologically programmed. They emerge in all normal infants at roughly the same ages and are displayed and interpreted similarly across cultures (Izard, 1982; Malatesta et al., 1989). As Charles Darwin recognized long ago, basic emotions probably evolved in humans because they helped our ancestors appraise and respond

appropriately in certain situations (Cole, Martin, & Dennis, 2004). These emotions also play a central role in the formation of attachments between infants and their caregivers. As John Bowlby, a theorist you will soon meet, emphasized, infants' emotional signals—whether expressions of joy or distress—prompt their caregivers to respond to them and have adaptive value for that reason as well (Kopp & Neufeld, 2003).

Whether an infant tends to be predominantly happy and eager to approach new stimuli or irritable and easily upset depends in part on his genetically influenced temperament (Goldsmith, 2003; Rothbart, 2011). However, caregivers also help shape infants' predominant patterns of emotional expression (Fitness, 2013). Observational studies of face-to-face interactions between mothers and infants suggest that young infants display a range of positive and negative emotions, changing their expressions with lightning speed (once every 7 seconds) while their mothers do the same (Malatesta et al., 1986, 1989). Mothers mainly display interest, surprise, and joy, thus serving as models of positive emotions and eliciting positive emotions from their babies. Mothers also respond selectively to their babies' expressions; over the early months, they become increasingly responsive to their babies' expressions of happiness, interest, and surprise and less responsive to their negative emotions. Through basic learning processes, then, infants are trained to show happy faces more often than grumpy or sad ones—and they do just that over time. This early emotion socialization takes different shapes in different cultures (Friedlmeier, Corapci, & Benga, 2015).

At around 9 months of age, infants also begin to monitor their companions' emotional reactions to stimuli and use this information to decide how they should feel and behave—a phenomenon called **social referencing** (Feinman, 1992). If their mothers are wary when a stranger approaches, they too may be wary and back away. However, if their mothers smile at the stranger, they may approach the stranger eagerly. It is not just that 1-year-olds are imitating their parents' emotions, then; they are using their parents' emotional reactions to decide how to behave in new situations (Kim & Kwak, 2011). Unfortunately, this means that social referencing may be one way in which parents who are socially anxious train their babies to be socially anxious too (Murray et al., 2008).

Parents also socialize their infants' and young children's emotions by talking about emotions in daily life (Fitness, 2013; Thompson, 2014), for example, by saying things like, “What a happy baby you are now!” and “You're mad that you can't have more, aren't you?” Sensitive parents also help children express their feelings so that the parents can respond to their emotional needs. Gradually, in the context of a secure parent–child relationship in which there is plenty of emotional communication, infants and young children learn to understand emotions and express them appropriately (Thompson, 2014).

Emotion Regulation

To conform to their culture's and caregivers' rules about when and how different emotions should be expressed, and, perhaps most importantly, to keep themselves from being overwhelmed by their emotions, infants must develop strategies for **emotion regulation**—the processes involved in initiating, maintaining, and altering emotional responses (see Calkins & Mackler, 2011;

Gross, 2014; Schulz & Lazarus, 2011). Emotion regulation can be accomplished through such tactics as not putting oneself in, or thinking about, situations likely to arouse unwanted emotions (by avoiding monster movies and thoughts of monsters), reappraising or reinterpreting events or one's reactions to them (saying it wasn't really a monster or I wasn't really afraid—I was just surprised), or altering one's emotional responses to events (putting on a brave face to replace a scared face). Emotion regulation often involves suppressing or otherwise controlling negative emotions like anger and fear, but it also includes trying to heighten or prolong positive emotional experiences.

Infants are active from the start in regulating their emotions, but at first they have only a few simple emotion regulation strategies. Very young infants are able to reduce their negative arousal by turning away from unpleasant stimuli or by sucking vigorously on a pacifier (Mangelsdorf, Shapiro, & Marzolf, 1995). By the end of the first year, infants can move away from upsetting events or rock themselves. They also actively seek comfort from their caregivers when they are upset.

By 18–24 months, toddlers will try to control whatever is upsetting them—for example, by pushing a bothersome peer or a noisy mechanical toy away (Mangelsdorf et al., 1995). They may be able to cope with the frustration of waiting for snacks and gifts by playing with toys and otherwise distracting themselves (Grolnick, Bridges, & Connell, 1996), and they may knit their brows or compress their lips in an attempt to suppress their anger or sadness (Malatesta et al., 1989). Finally, as children gain the capacity for symbolic thought and language, they become able to regulate their distress cognitively—for example, by repeating the words, “Mommy home soon, Mommy home soon,” after Mom goes out the door (Thompson, 1994).

The development of emotion regulation skills is influenced by both an infant's temperament and a caregiver's behavior (Grolnick, McMenamy, & Kurowski, 2006). Recall from Chapter 11 that babies differ temperamentally in both how emotionally reactive they are to events and how able they are to exert effortful control over their reactions (Rothbart, 2011). These aspects of temperament matter, but so does parenting. Very young infants who have few emotion regulation strategies of their own rely heavily on caregivers to help them—for example, by stroking them gently or rocking them when they are distressed, by calming them down after a joyful bout of play (Calkins & Hill, 2007; Cole, Michel, & Teti, 1994). As infants age, they gain control of emotion regulation strategies first learned in the context of the parent–child relationship and can regulate their emotions on their own (for example, by rocking themselves rather than looking to be rocked). By being sensitive and responsive caregivers, parents can help keep fear, anger, and other negative emotions to a minimum (Pauli-Pott, Mertesacker, & Beckmann, 2004). Much improvement in emotion regulation occurs at around age 3 to 4 as the prefrontal cortex develops and effortful control improves (Diaz & Eisenberg, 2015). Children who are not able to get a grip on their negative emotions, either because of their temperamental characteristics or because their caregivers do not help them master emotion regulation, tend to experience stormy relationships with both caregivers and peers and are at risk to develop behavior problems (Rothbart, 2011; Saarni et al., 2006).

Emotional Learning in Childhood

Preschool and school-aged children gain still more **emotional competence**; that is, they develop characteristic patterns of emotional expression, greater understanding of emotion, and better emotion regulation skills (Denham, Bassett, & Wyatt, 2007; Denham et al., 2003; Goodvin et al., 2015). Children who express emotions appropriate to the situation and have a good balance of positive to negative emotions, who understand their own and others' feelings and what situations trigger them, and who manage their emotions well make enjoyable companions. Perhaps that is why early emotional competence is a good predictor of social competence as reflected in peer acceptance and teachers' ratings of social adjustment (Denham et al., 2003).

One important advance in understanding emotions is recognizing that people can have mixed emotions about something—for example, that a child can both love and hate her mother. Susan Harter and Bonnie Buddin (1987) showed children aged 4–12 photographs of two different facial expressions of emotion at a time and asked them to explain how someone could have both emotions at once. Preschool children could not think of how to put two emotions together. As one put it, “It's hard to think of two feelings at the same time because you only have one mind” (Harter & Buddin, 1987). At age 8–9, children were better able to explain how two positive or two negative emotions could co-occur—for example, how you could be both sad and mad when a toy breaks. Only by age 11–12, though, were most children able to explain how you could have both a positive and a negative emotion about something simultaneously—for example, how you could be happy you made it to the finals but afraid you would do poorly. As children get older, then, they learn more about different emotions and the situations that arouse them and become more able to integrate different emotions into the same emotional experience (see also Larsen, To, & Fireman, 2007).

As children get older, they also learn about **emotional display rules**—cultural rules specifying what emotions should and should not be expressed under what circumstances (Saarni, 1984; Thompson et al., 2011). Rules such as “Don't laugh when someone falls down,” “Look sad at a funeral,” and “Act pleased when you receive a lousy gift” are examples. As children learn display rules, the gap between what they are experiencing inside and what they express to the world widens (a nice way of saying that they become better liars). They also become more aware of this gap between inner emotions and expressed emotions in themselves and others.

Carolyn Saarni (1984) conducted an interesting study of display-rule learning. Children aged 7, 9, and 11 were rewarded for their labors in a first research session with a nice gift, but after a second research session they received a boring baby toy. Here, then, was a situation (not unlike that faced by children who are given weird gifts from distant relatives for their birthdays) in which our culture's display rule is, “Look pleased about a gift, even if it's a disappointing one.”

Children's reactions were coded as positive (an enthusiastic “thank you,” a big smile), negative (an “ugh,” shrug, wrinkled nose, and so on), and transitional (a lame attempt to follow the display rule such as a mumbled “thank you” or distressed smile). The 7-year-olds in the study, especially the boys, were not skilled at all at masking their disappointment; they said “ugh” a lot. Older children, especially girls, were more able to conform to the display rule by pretending to be

delighted. In order to follow the display rule and regulate their emotions appropriately when given a lousy gift, children must develop (a) the understanding of emotions and emotional display rules needed to know what to do, and (b) the self-control skills needed to hide their negative reactions (Hudson & Jacques, 2014). It may not seem good that children become increasingly able to hide and alter their true feelings as they grow older, but life might be unbearable if adults were as open about their feelings as most young children are!

Display rules and how parents react to and socialize their children's emotions differ from culture to culture (see Friedlmeier et al., 2015; Mesquita, De Leersnyder, & Albert, 2014). For example, parents in individualistic cultures like the United States are more likely than parents in collectivist cultures like

China to encourage the open expression of emotion; they want their children to assert themselves and feel proud when they do well and even to express negative emotions like anger when appropriate. Chinese, Japanese, and other East Asian parents are likely to view such self-centered emotional displays as disruptive to smooth social relationships and to want their children to suppress self-focused emotions like anger. They encourage the expression of other-focused emotions—for example, empathy for someone in distress or shame after letting people down—and point out the negative effects of emotions like anger on others. **Exploration 14.1** examines more closely how parents' beliefs about emotional expression can affect their children's development.

● EXPLORATION 14.1

Emotion Coaching or Emotion Dismissing?

Good emotion coaching starts with noticing that a child is having an emotional experience.

Lisa Spindler Photography Inc/The Image Bank/Getty Images

How emotionally expressive were your parents when you were growing up, and how did they react to your emotional outbursts? Parents differ a good deal in their beliefs about emotions, and these emotional philosophies guide how they express and regulate their own emotions, react to their children's emotions, and teach their children about emotions (Bariola, Gullone, & Hughes, 2011; Halberstadt, 1991; Katz, Maliken, & Stettler, 2012). Moreover, the emotional training they provide their children can be changed through interventions (Gus, Rose, & Gilbert, 2015).

John Gottman and his colleagues (Gottman, Katz, & Hooven, 1996) identified two quite different approaches parents take to emotions.

Emotion coaching involves:

- being aware of even low-intensity emotions;
- viewing children's expressions of emotion, including negative ones, as opportunities for closeness and teaching;
- accepting and empathizing with children's emotional experiences;
- helping children understand and express their feelings; and

- helping children deal with whatever triggered their emotions.

The following example of a mother comforting her 5-year-old son after a frustrating game-playing session with other boys captures the spirit of emotion coaching:

You didn't like that he was bouncing your guy off the game, and that made you really mad. It's hard when you feel so angry. You're going "AAAHH, he's bouncing my guy off there!" right? It makes you sad thinking about it, doesn't it? You know, after you stopped the game, the other guys said, "You know, Joey wasn't really doing so bad." You thought you were losing,

but you weren't (Thompson et al., 2011, p. 238).

Emotion dismissing, by contrast, involves ignoring, denying, or even criticizing or punishing negative emotions or trying to convert them as quickly as possible into positive emotions. Consider a child who is not allowed to express sadness or frustration and anger by well-meaning parents who want nothing but happiness for their child and try to cheer her out of her bad moods or convince her that she is not really upset. This child misses opportunities to learn about anger and how to deal with it and does not get the sense that someone understands and empathizes with her and will help her cope with whatever prompted her emotional reaction.

In studies comparing emotion coaching and emotion dismissing, the emotion coaching approach wins hands down. It is associated with healthy emotional development and fewer emotional and behavioral problems (Katz et al., 2012). An intervention called Tuning in to Kids teaches emotion coaching skills to parents of preschool children and appears to be effective in increasing children's emotional knowledge and reducing their behavior problems (Havighurst et al., 2009, 2010, 2015). "Tuning in to Teens," a similar emotion coaching program for adolescents, has proven successful in improving emotion socialization by parents and, in turn, reducing family conflict and teen acting-out behavior (Havighurst, Kehoe, & Harley, 2015; and see Shortt et al., 2010). Research on emotion coaching provides still more evidence of the power of parents to foster healthy emotional development.

Adolescents' Emotional Lives

Ever since the founder of developmental psychology, G. Stanley Hall, characterized adolescence as a time of *storm and stress*, adolescents have been viewed as moody and emotionally volatile. Although most adolescents do not experience extreme emotional storm and stress, adolescents do seem to experience more negative and mixed emotions and more emotional ups and downs than either children or adults (Larson & Lampman-Petratis, 1989; Riediger & Klipker, 2014). Why might this be?

One reason is that adolescents experience more negative life events than children do and so may simply have more to be depressed, anxious, angry, or moody about (Larson & Ham, 1993; Schulz & Lazarus, 2011). Because they are experiencing more emotional arousal at a time when the executive control centers of their brains have not fully developed, they can also have more difficulty than adults regulating their emotions (Lougheed & Holenstein, 2012; Riediger & Klipker, 2014; Silvers et al., 2012).

But there's another interesting possibility: Teens may have different emotion regulation goals than other age groups. Michaela Riediger and her colleagues (Riediger, Schmiedek, Wagner, & Lindenberger, 2009) called participants ranging in age from 14 to 86 at random times on mobile phones and had them report their emotional experience—specifically, whether they were currently experiencing joyful, contented, interested, angry, nervous, and downhearted feelings. Participants were also asked about their emotion regulation goals at that moment—specifically, whether they were trying to enhance, maintain, or dampen their positive or negative emotions.

As **Figure 14.2** shows, teens showed more “contra-hedonic” motives than adults: Rather than seeking to optimize their

Figure 14.2 Age differences in use of emotion regulation strategies aimed at optimizing positive emotions and minimizing negative ones (prohedonic motivation) versus optimizing negative emotions and minimizing positive ones (contra-hedonic motivation). Also shown is everyday emotional well-being (the balance of positive to negative emotions). Adolescents seem to seek—and experience—lots of negative and mixed emotions, whereas elderly adults have the strongest prohedonic motivation and experience greater emotional well-being than any other age group.

Source: Riediger, M., Schmiedek, F., Wagner, G. G., & Lindenberger, U. (2009). Seeking pleasure and seeking pain. Differences in prohedonic and contra-hedonic motivation from adolescence to old age. *Psychological Science*, 20, 1529–1535, Figure 1, p. 1531.

good moods, they often wanted to maintain or enhance their bad moods or dampen their good ones. At the other extreme, elderly adults were the most “prohedonic” of all age groups, often reporting that they were trying to maintain positive affect and dampen negative affect. As a result, the adolescents had the most mixed emotional lives, and emotional well-being—the difference between positive and negative affect—was lower in adolescence than in old age.

Why did the teens seem to want to go with their negative emotions? A closer look revealed that they often reported positive and negative emotions simultaneously and seemed to crave being able to combine the two, as in being afraid at a horror movie while enjoying the scary experience with friends, or being furious at a classmate but enjoying plotting revenge. Teens may have somewhat more negative emotional lives than children or adults, then, because they lead stressful lives, because they have difficulty regulating their emotions at times, and because they sometimes actively choose to savor negative and mixed emotions (see also Riediger, Wrzus, & Wagner, 2014).

Emotions and Aging

As you have just seen, older adults seem to live more positive emotional lives than other age groups. This is quite surprising to the many people who believe—wrongly—that there is a blunting of emotional experience in old age or that old people are generally miserable because of the losses and health problems that come with aging.

As it turns out, the emotional experiences of younger and older adults are far more similar than different and, when they differ, older adults seem to live more positive emotional lives. For example, the faces of older adults are equally expressive when they are asked to recall events that had made them feel various emotions (Malatesta & Kalnok, 1984; and see Levenson et al., 1991). Older adults are also skilled at emotion regulation, especially at achieving their main emotion regulation goal: maximizing positive emotions and minimizing negative ones (Charles & Carstensen, 2014; Labouvie-Vief et al., 2007; Magai et al., 2006; Mroczek, 2004). The main exception to the rule is this: On occasion, older adults may become emotionally overwhelmed by stressful life events that overtax their resources (Charles & Carstensen, 2014; Wrzus, Müller, et al., 2013).

In an especially revealing study, Laura Carstensen and her colleagues (2000, 2011) sampled the emotional experiences of African American and European American adults between age 18 and age 94 by paging them at random times over a 1-week period as they went about their lives and asking them to report their emotional states. They reassessed these people's daily emotional experiences 5 and 10 years later. In this longitudinal study, frequency of positive emotions did not change much over the years, but negative emotions became less frequent with age. As a result,

overall emotional well-being—the balance of positive to negative emotions—increased with age, until leveling off in very old age.

Older adults also experienced longer-lasting positive emotions and more fleeting negative ones and fewer emotional ups and downs in a day, suggesting that they are more able than younger adults to savor happy emotions while cutting short the sad and angry ones (see also Kliegel, Jager, & Phillips, 2007). As Carstensen et al. (2011), concluded, “Contrary to the popular view that youth is the ‘best time in life,’ . . . the peak of emotional life may not occur until well into the 7th decade (p. 29).” Finally, this study revealed that everyday emotional experience may matter: A positive ratio of positive to negative emotional experiences predicted survival over a 13-year period.

Based on her research, Carstensen (1992) has put forth **socioemotional selectivity theory** to help explain both the positive emotional lives and the changing social relationships of aging adults (see also Charles & Carstensen, 2010; Lang & Carstensen, 2002). According to this view, the perception that one has little time left to live prompts aging adults to put less emphasis on the goal of acquiring information for future use and more emphasis on the goal of fulfilling current emotional needs. As a result, older adults narrow their range of social partners to those who bring them emotional pleasure, usually family members and close friends, and let other social relationships fall by the wayside. By contrast, younger adults, seeing all kinds of time ahead of them, want the social stimulation and new information that strangers and acquaintances provide—and are even willing to sacrifice some emotional well-being to deal with these sometimes unpleasant people.

Carstensen has discovered that older adults achieve their goal of emotional fulfillment in part through what she calls a **positivity effect**: a tendency for older adults to pay more attention to, better remember, and place more priority on positive information than on negative information (Charles & Carstensen, 2014; Reed & Carstensen, 2012). This helps them optimize positive emotions and maintain well-being despite some of the challenges associated with aging. Interestingly, neuroscientists find that two key brain centers involved in emotions—the amygdala and the ventromedial area of the prefrontal cortex—degenerate less with age than the main brain areas involved in cognition (Mather, 2016).

In sum, older adults lead rich and rewarding emotional lives. They are able to experience and express emotions fully but also regulate them effectively to optimize positive feelings and minimize negative ones. Other factors are undoubtedly involved, but Carstensen’s socioemotional selectivity theory and the positivity effect suggest that an emphasis on emotional fulfillment goals and a bias toward positive information contribute. So does continued good functioning by the emotion processing centers of the brain. Indeed, we learn from research on emotions and emotion regulation that, across the life span, humans actively shape their emotional experiences to suit their goals (Riediger & Luong, 2016). We now turn to the social relationships that have so much to do with our emotional lives.

Contrary to stereotype, elderly adults lead rich and generally positive emotional lives, possibly because they see little time left to them and seek emotional gratification in close relationships.

iStockphoto.com/annedehaas

● Checking Mastery

1. What milestone in development must be achieved before an infant will show embarrassment, and what kind of emotion is embarrassment?
2. What is an example of an emotional display rule?
3. According to Carstensen’s socioemotional selectivity theory, why do older adults typically have good emotional well-being?

● Making Connections

1. Describe a couple of instances in your own life when you have displayed the “contra-hedonic motivation” that Michaela Riediger and her colleagues have found to be more common during adolescence than during late adulthood. Explain why you might have sought to enhance a negative emotion or dampen a positive one.
2. Much research suggests that good emotion regulation in childhood is associated with good developmental outcomes. Argue that a child could show too much of this good thing called emotion regulation and suggest some negative effects this could have.

14.2

Perspectives on Relationships

LEARNING OBJECTIVES

- Outline the main argument of Bowlby and Ainsworth’s attachment theory, with emphasis on the role of nature and nurture in attachment and the mechanism through which early attachments have lasting effects on development.
- Discuss two theorists who claim that peers are more important than parents in development.

Developmental theorists agree that social relationships are critical in human development, but they have disagreed about which relationships are most critical. Many noted theorists have argued that no social relationship is more important than the first: the one between parent and child. Sigmund Freud (1930) left no doubt: A warm and stable mother–child relationship is essential for normal personality development. His follower Erik Erikson tended to agree, emphasizing the importance of responsive parenting to the development of trust in the parent–infant relationship. These theorists, in turn, influenced the architects of today’s most influential theory of close human relationships, attachment theory, to focus on the lasting significance of early parent–child relationships.

Attachment Theory

Attachment theory was formulated by British psychiatrist John Bowlby (1969, 1973, 1980, 1988), and it was elaborated on by his colleague Mary Ainsworth, an American developmental psychologist (1989; Ainsworth et al., 1978; and see Cassidy & Shaver, 2016). The theory was based primarily on **ethology**, the study of the behavior of various species in their natural environments and the evolution of that behavior (Archer, 1992). Attachment theory therefore asked how attachment might have helped our ancestors adapt to their environment. Bowlby also drew on concepts from psychoanalytic theory (he was a psychoanalytic therapist who studied the contribution of mother–child relationships to later psychopathology) and cognitive theory (he was interested in expectations about self and other, as you will see).

According to Bowlby (1969), an **attachment** is a strong affectional tie that binds a person to an intimate companion. It is also a behavioral system through which humans regulate their emotional distress when under threat and achieve security by seeking proximity to another person. For most of us, the first attachment we form, around 6 or 7 months of age, is to a parent.

How do we know when a baby becomes attached to his mother? He will try to maintain proximity to her—crying, clinging, approaching, following, doing whatever it takes to maintain the desired closeness to her and expressing his displeasure when he cannot. He will prefer her to other people, reserving his biggest smiles for her and seeking her when he is upset, dis comforted, or afraid; she is irreplaceable in his eyes. He will also be confident about exploring his environment as long as he knows that his mother is there to provide the security he needs.

Notice that an infant attached to a parent is rather like an adult “in love” (like Mike or Marcy at the start of the chapter). True, close emotional ties are expressed in different ways, and

serve different functions, at different points in the life span. Adults, for example, do not usually feel compelled to follow their mates around the house, and they look to their loved ones for more than comforting hugs and smiles. Nonetheless, there are basic similarities among the infant attached to a caregiver, the child attached to a best friend, and the adolescent or adult attached to a romantic partner. Throughout the life span, the objects of our attachments are special, irreplaceable people to whom we want to be close and from whom we derive a sense of security (Ainsworth, 1989).

Nature, Nurture, and Attachment

Drawing on ethological theory and research, Bowlby argued that both infants and parents are biologically predisposed to form attachments because they contribute to survival. It makes sense to think, for example, that young birds tended to survive if they stayed close to their mothers so that they could be fed and protected from predators—but that they starved or were gobbled up, and therefore failed to pass their genes to future generations, if they strayed. Thus, chicks, ducks, and goslings may have evolved to engage in **imprinting**, an innate form of learning in which the young will follow and become attached to a moving object (usually the mother) during a critical period early in life.

Noted ethologist Konrad Lorenz (1937) observed imprinting in young goslings and found that it is automatic and unlearned,

Ethologist Konrad Lorenz demonstrated that goslings would become imprinted to him rather than to their mother if he was the first moving object they encountered during their critical period for imprinting. Human attachment is more complex but is also biologically based.

Nina Leen/Time & Life Pictures/Getty Images

that it occurs only within a critical period shortly after the bird has hatched, and that it is irreversible—once the gosling begins to follow a particular object, whether its mother or Lorenz, it will remain attached to that object. The imprinting response is considered a prime example of a species-specific and largely innate behavior that has evolved because it has survival value. Subsequent research has shown that it is not quite as automatic and different from other learning as originally claimed, that the “critical” period is more like a “sensitive” period, and that imprinting can be reversed (Spencer et al., 2009).

What about human infants? Babies may not become imprinted to their mothers, but they certainly form attachments in infancy and follow their love objects around. Bowlby argued that they come equipped with several other behaviors besides proximity-seeking that help ensure adults will love them, stay with them, and meet their needs. Among these behaviors are sucking and clinging, smiling and vocalizing (crying, cooing, and babbling), and expressions of negative emotion (fretting and crying).

Moreover, Bowlby argued, just as infants are programmed to respond to their caregivers, adults are biologically programmed to respond to an infant’s signals. Just see if you can ignore a baby’s cry or fail to smile when a baby grins at you. Adults are even hormonally prepared for caregiving. **Oxytocin** is a hormone produced primarily in the hypothalamus that plays roles in facilitating caregiving and parent–infant attachment in animals and humans (Feldman, 2016). It affects the muscles that facilitate contractions during labor and the release of milk during breastfeeding. Moreover, mothers with high levels of oxytocin before birth engage in higher levels of positive attachment behavior after the birth, think more about their relationships with their infants, and check more often on their infants than mothers with lower levels of the hormone (Feldman et al., 2007). Oxytocin seems to prime parents (fathers too) to form attachments to their babies, then. Administered by nasal spray, it also seems to increase interpersonal trust among adult partners, although only for some people in some contexts (Bartz, 2016; Schneiderman, Zagoory-Sharon, Leckman, & Feldman, 2012).

Just as the imprinting of goslings occurs during a critical period, human attachments form during what Bowlby viewed as a sensitive period for attachment, the first 3 years of life. But attachments do not form automatically. According to Bowlby, a responsive social environment is critical: An infant’s preprogrammed signals to other people may eventually wane if caregivers are unresponsive to them. Ultimately, the security of an attachment relationship depends on both nature and nurture—on the interaction over time between a biologically prepared infant and a biologically prepared caregiver and on the sensitivity of each partner to the other’s signals.

Attachment and Later Development

Bowlby maintained that the quality of the early parent–infant attachment has lasting impacts on development, especially on later relationships. He proposed that, based on their interactions with caregivers, infants construct expectations about relationships called **internal working models**—cognitive representations of themselves and other people that guide their processing of social information and their behavior in relationships (Bowlby, 1973;

see also Bretherton, 1996). Securely attached infants who have received responsive care will form internal working models suggesting that they are lovable and that other people can be trusted to care for them. By contrast, insecurely attached infants subjected to insensitive, neglectful, or abusive care may conclude that they are difficult to love, that other people are unreliable, or both. Because of their internal working models, insecure infants would be expected to avoid or to be anxious in close relationships later in life. They may, for example, be wary of getting too close to anyone or become jealous and overly dependent if they do.

In sum, attachment theory, as developed by John Bowlby and elaborated with Mary Ainsworth, claims the following:

- The capacity to form attachments is part of our evolutionary heritage.
- Attachments unfold through an interaction of biological and environmental forces during a sensitive period early in life.
- The quality of the attachment between infant and caregiver shapes later development and the quality of later relationships.
- Internal working models of self and others are the mechanism through which early experience affects later development.

Peers: The Second World of Childhood

But what about other kids: Aren’t they also critical to a child’s development? A **peer** is a social equal, someone who functions at a similar level of behavioral complexity—often someone of similar age (Lewis & Rosenblum, 1975). Although the parent–child relationship is undoubtedly important in development, some theorists argue that relationships with peers are at least as significant. In effect, they argue, there are “two social worlds of childhood”—one involving adult–child relationships, the other involving peer relationships—and these two worlds contribute differently to development (Rubin et al., 2015; Youniss, 1980).

From an evolutionary perspective, it makes sense to think that humans evolved to live as members of groups, just as they evolved to form close one-on-one attachments to their parents. And as you saw in Chapter 13, Jean Piaget believed that because peers are equals rather than powerful authority figures, they help children learn that relationships are reciprocal, force them to hone their perspective-taking skills, and contribute to their social cognitive and moral development in ways that parents cannot. Peer relationships are more equal, more voluntary, and less lasting than parent–child relationships, so we simply must learn to get along with peers (Rubin et al., 2015).

Another theorist who believed in the power of peer relationships, especially friendships, was neo-Freudian theorist Harry Stack Sullivan (1953; see also Buhrmester & Furman, 1986). Sullivan stressed that social needs change as we get older and are gratified through different kinds of social relationships at different ages. The parent–child relationship is central up to about age 6 in providing tender care and nurturance, but then peers become increasingly important. At first children need playmates; then they need acceptance by the peer group; and then around age 9 to age 12 they most need intimacy in the form of a close friendship. Sullivan stressed the developmental significance of these **chumships**, or close childhood friendships.

Having a close friend or chum not only teaches children to take others' perspectives but validates and supports children and can protect them from the otherwise harmful effects of a poor parent–child relationship or rejection by the larger peer group. Chumships also teach children how to participate in emotionally intimate relationships and therefore pave the way for romantic relationships during adolescence. Research bears Sullivan out (Bukowski, Motzoi, & Mayer, 2009), as we will see as we now examine the roles of both parents and peers in our changing social worlds.

● Checking Mastery

1. How do ethological theorists explain why imprinting occurs in young goslings?

2. According to attachment theory, what is the mechanism through which early experience affects later social development?
3. Which two theorists believed that peers are at least as important as parents as contributors to development?

● Making Connections

1. Ethological theory and psychoanalytic theory both influenced John Bowlby as he formulated attachment theory. Analyze how each contributed.
2. To whom do you believe you are “attached” right now, and what evidence would you cite that each such relationship is a true attachment?

14.3

The Infant

LEARNING OBJECTIVES

- Discuss how both the caregiver’s attachment and the infant’s attachment grow during the first year of life.
- Distinguish among the four types of parent-infant attachments and explain how a parent’s behavior, an infant’s temperament, and the cultural context can influence which type of attachment develops.
- Summarize the main lessons learned about attachment and later development from studies of infants in deprived institutions, infants separated from parents, infants attending day care, and infants with secure versus insecure attachments.
- Characterize the ability of infants to participate in relationships with peers.

Human infants are social beings from the start, but their social relationships change dramatically once they form close attachments to caregivers and develop the social skills that allow them to coordinate their own activities with those of other infants.

An Attachment Forms

Like any relationship, the parent–infant attachment is reciprocal. Parents become attached to their infants, and infants become attached to their parents.

The Caregiver’s Attachment to the Infant

Parents often begin to form emotional attachments to their babies even before they are born. Moreover, parents who have an opportunity for skin-to-skin contact with their babies during the first few hours after birth often feel a special bond forming, although such **bonding** at birth is neither crucial nor sufficient for the development of strong parent–infant attachments (Goldberg, 1983). Not only are newborns cute, but their early reflexive behaviors, such as sucking, rooting, and grasping, help endear them to their parents (Bowlby, 1969). Smiling is an especially important social signal. Although it is initially a reflexive response to almost any stimulus, it is triggered by voices at 3 weeks of age and by faces at 5 or 6 weeks (Bowlby, 1969; Wolff, 1963).

Over the weeks and months, caregivers and infants develop **synchronized routines** much like dances, in which the partners

Smiling is one of the biologically based behaviors that help ensure adults will fall in love with babies.

zulufoto/Shutterstock.com

take turns responding to each other’s leads (Stern, 1977; Tronick, 1989). Watch the synchrony as this mother plays peekaboo with her infant (Tronick, 1989, p. 112):

The infant abruptly turns away from his mother as the game reaches its “peak” of intensity and begins to suck on his thumb and stare into space with a dull facial

expression. The mother stops playing and sits back watching. . . . After a few seconds the infant turns back to her with an inviting expression. The mother moves closer, smiles, and says in a high-pitched, exaggerated voice, “Oh, now you’re back!”

Synchronized routines are likely to develop when caregivers are sensitive, providing social stimulation when a baby is alert and receptive but not pushing their luck when the infant’s message is “Cool it—I need a break.” When good parent–infant synchrony is achieved, it contributes to a secure attachment relationship (Jaffe et al., 2001) as well as to the development of emotion regulation skills (Feldman, 2007).

The Infant’s Attachment to the Caregiver

Infants progress through four phases in forming attachments (Ainsworth, 1973; Bowlby, 1969):

1. **Undiscriminating social responsiveness** (birth to 2 or 3 months). Very young infants are responsive to voices, faces, and other social stimuli, but any human interests them.
2. **Discriminating social responsiveness** (2 or 3 months to 6 or 7 months). Infants begin to show preferences for familiar companions. They direct their biggest grins and most enthusiastic babbles toward those companions, although they are still friendly toward strangers.
3. **Active proximity seeking or true attachment** (6 or 7 months to about 3 years). Around 6 or 7 months, infants form their first clear attachments. Now an infant will follow her mother, protest when her mother leaves, and greet her mother warmly when she returns. Soon most infants become attached to other people as well—fathers, siblings, grandparents, regular babysitters (Schaffer & Emerson, 1964).
4. **Goal-corrected partnership** (3 years and older). By about age 3, partly because they have more advanced social cognitive abilities, children can participate in a **goal-corrected partnership**, taking a parent’s goals and plans into consideration and adjusting their behavior accordingly. Thus, a 1-year-old cries and tries to follow when Dad leaves the house to talk to a neighbor, whereas a 4-year-old can understand where Dad is going and wait for his return. This final, goal-corrected partnership phase lasts a lifetime.

Attachment-Related Fears

Infants no sooner experience the pleasures of love than they discover the agonies of fear. One form of fear is **separation anxiety**: Once attached to a parent, a baby often becomes wary or fretful when separated from that parent. Separation anxiety normally appears after the first attachment forms, peaks between 14 and 18 months, and gradually becomes less frequent and less intense (Weinraub & Lewis, 1977). Still, even children and adolescents may become homesick and distressed when separated from their parents for a long time (Thurber, 1995).

A second fearful response that often emerges shortly after an infant becomes attached to someone is **stranger anxiety**—a wary or fretful reaction to the approach of an unfamiliar person that can vary in strength from staring and whimpering to screaming

in terror (Schaffer & Emerson, 1964). Anxious reactions to strangers—often mixed with signs of interest—become common late in the first year and then decline (Sroufe, 1996).

How might babysitters, child care workers, and health professionals prevent stranger anxiety? Stranger anxiety is less likely to occur if an attachment figure is nearby (Morgan & Ricciuti, 1969), especially if the attachment figure reacts positively to the stranger and affects the baby’s reactions positively through social referencing. It helps if the setting is a familiar one, but an unfamiliar environment like a doctor’s office can become familiar if infants are given a few minutes to get used to it (Sroufe, Waters, & Matas, 1974). It also helps if the stranger approaches slowly while smiling, talking, and offering a familiar toy or suggesting a familiar activity and if he takes his cues from the infant rather than being pushy (Bretherton, Stolberg, & Kreye, 1981; Mangelsdorf, 1992; Sroufe, 1977). Finally, the stranger should not look any stranger than need be: Infants are most likely to fear strangers who violate their mental schemas or expectations (Kagan, 1972), as by wearing spiked green hair or a surgical mask and stethoscope.

Exploratory Behavior

The formation of a strong attachment to a caregiver also has the positive effect of facilitating exploratory behavior. Ainsworth and her colleagues (1978) emphasized that an attachment figure serves as a **secure base** for exploration—a point of safety from which an infant can feel free to venture—as well as a **safe haven** to which the infant can return for comfort if frightened. Thus Isabelle, a securely attached infant visiting a neighbor’s home with Mom, may be comfortable cruising the living room as long as she can check occasionally to see that Mom is still on the sofa but may freeze and fret and stop exploring if Mom disappears into the bathroom. Isabelle may also beat a hasty retreat to the safe haven Mom provides if stressed by the doorbell, the entry of the neighbor’s German shepherd, or some other unexpected event. Secure attachments allow us to explore the world but they also protect us from it when it becomes too scary.

Stranger anxiety is common at about a year of age but it can be prevented.

Quality of Attachment

Ainsworth's most important contribution to attachment theory was to devise a way to assess differences in the quality of parent–infant attachments. She and her associates created the **Strange Situation**, a now-famous procedure for measuring the quality of an attachment (Ainsworth et al., 1978). It consists of eight episodes that gradually escalate the amount of stress infants experience as they react to the approach of an adult stranger and two departures and returns of their caregiver. On the basis of an infant's pattern of behavior across the episodes, the quality of his attachment to a parent can be characterized as one of four types, one secure and three insecure (resistant, avoidant, and disorganized–disoriented).

1. **Secure attachment.** About 60% of 1-year-olds in the many societies that have been studied are securely attached to their mothers or primary caregivers (Colin, 1996; Howe, 2011). The securely attached infant actively explores the room when alone with his mother because she serves as a secure base. The infant is upset by separation but greets his mother warmly and is quickly comforted by her presence when she returns. The securely attached child is outgoing with a stranger when his mother is present. In the Bowlby–Ainsworth view, the securely attached infant “stays close and continuously monitors [the caregiver’s] whereabouts (*proximity maintenance*), retreats to her for comfort if needed (*safe haven*), resists and is distressed by separations from her (*separation distress*), and explores happily as long as she is present and attentive (*secure base*)” (Hazan, Campa, & Gur-Yaish, 2006, p. 190).
2. **Resistant attachment.** About 10% of 1-year-olds show a resistant attachment, an insecure attachment characterized by anxious, ambivalent reactions (and also called anxious/ambivalent attachment). The resistant infant does not dare venture off to play even when her mother is present; her mother does not seem to serve as a secure base for exploration. Yet this infant becomes distressed when her mother departs, often showing stronger separation anxiety than the securely attached infant. When her mother returns, the infant is ambivalent: she may try to remain near her but is not comforted and does not calm down; she seems to resent the mother for having left, may resist if she tries to make physical contact, and may even hit and kick her in anger (Ainsworth et al., 1978). Resistant infants are also wary of strangers, even when their mothers are present. It seems, then, that resistant or ambivalent infants do all they can to get affection and comfort but never quite succeed.
3. **Avoidant attachment.** Infants with avoidant attachments (up to 15% of 1-year-olds) may play alone but are not very adventuresome, show little apparent distress when separated from their mothers, and avoid contact or seem indifferent when their mothers return. These insecurely attached infants are not particularly wary of strangers but sometimes avoid or ignore them, much as these babies avoid or ignore their mothers. In contrast to resistant infants, avoidant infants seem to have shut down their emotions and distanced themselves from their parents, as if they were denying their need for affection or had learned not to express their emotional needs.

4. **Disorganized–disoriented attachment.** Ainsworth's work initially focused on secure, resistant, and avoidant attachment styles, but some infants do not develop any of these consistent attachment styles. They seem confused. Up to 15% of infants—more in high-risk families—display what is now recognized as a fourth attachment classification, one that is associated with later emotional problems (Main & Solomon, 1990; van IJzendoorn, Schuengel, & Bakermans-Kranenburg, 1999).

Reunited with their mothers after a separation, these infants may act dazed and freeze or lie on the floor immobilized—or they may seek contact but then abruptly move away as their mothers approach them, only to seek contact again. Infants with a disorganized–disoriented attachment have not been able to devise a consistent strategy for regulating their negative emotions; they seem frightened of their parent and stuck between approaching and avoiding this frightening figure (Hesse & Main, 2006). She is clearly not a source of comfort for them.

• **Table 14.1** summarizes the features of these four patterns of attachment. What determines which of these attachment patterns will characterize a parent–infant relationship? The caregiver, the infant, and the cultural and social context all contribute.

The Caregiver's Contributions

According to Freud, infants in the oral stage of psychosexual development become attached to the individual who provides

The wire and cloth surrogate “mothers” used in Harlow’s classic research. This infant monkey has formed an attachment to the cloth mother that provides “contact comfort,” even though it must stretch to the wire mother in order to feed.

● **Table 14.1** Child Behaviors in the Strange Situation Associated with Attachment Types and Related Parenting Styles

Behavior	Type of Attachment			
	Secure	Resistant	Avoidant	Disorganized–Disoriented
Child explores when caregiver is present to provide a secure base for exploration?	Yes, actively	No, clings	Yes, but play is not as constructive as that of secure infant	No
Child responds positively to stranger?	Yes, comfortable if caregiver is present	No, fearful even when caregiver is present	No, often indifferent, as with caregiver	No, confused responses
Child protests when separated from caregiver?	Yes, at least mildly distressed	Yes, extremely upset	No, seemingly unfazed	Sometimes; unpredictable
Child responds positively to caregiver at reunion?	Yes, happy to be reunited, quickly calmed	Yes and no, seeks contact, but resents being left; ambivalent, sometimes angry	No, ignores or avoids caregiver	Confused; may approach or avoid caregiver or do both
Parenting style	Sensitive, responsive	Inconsistent, often unresponsive (e.g., depressed)	Rejecting–unresponsive or intrusive–overly stimulating	Frightened (e.g., overwhelmed) and frightening (e.g., abusive)

them with oral pleasure, and the attachment bond will be most secure if a mother is relaxed and generous in her feeding practices. In a classic study conducted by Harry Harlow and Robert Zimmerman (1959), Freud’s psychoanalytic view was put to the test—and failed. Monkeys were reared with two surrogate mothers: a wire “mother” and a cloth “mother” wrapped in foam rubber and covered with terrycloth. Half the infants were fed by the cloth mother, and the remaining infants were fed by the wire mother. To which mother did these infants become attached? There was no contest: Infants strongly preferred the cuddly cloth mother, *regardless of which mother had fed them*. They spent most of their time clinging to her, ran to her when they were upset or afraid, and showed every sign of being attached to her.

Harlow’s research demonstrated that **contact comfort**, the pleasurable tactile sensations provided by a soft and cuddly “parent,” is a more powerful contributor to attachment in monkeys than feeding. Contact comfort also promotes human attachments (Anisfeld et al., 1990). Moreover, many infants become attached to someone other than the adult who feeds them (Schaffer & Emerson, 1964).

In the end, it is the parent’s behavior that most influences the quality of attachment, as shown in Table 14.1. Infants who enjoy *secure* attachments to their parents have parents who are sensitive and responsive to their needs and emotional signals, just as Bowlby and Ainsworth proposed (Ainsworth et al., 1978; De Wolff & van IJzendoorn, 1997). The importance of sensitive, responsive parenting in creating a secure attachment is one of the most established findings in developmental science.

Babies who show a *resistant* pattern of attachment often have parents who are inconsistent in their caregiving; they react enthusiastically or indifferently, depending on their moods, and are frequently unresponsive (Isabella, 1993; Isabella & Belsky, 1991). Mothers who are depressed, for example, often have difficulty responding

sensitively to their babies’ signals and do not provide the comforting that helps babies regulate their negative emotions (Dawson & Ashman, 2000). The resistant infant may learn to cope with such unreliable caregiving by trying desperately—through clinging, crying, and other attachment behaviors—to obtain emotional support and comfort, and then becomes sad and resentful when these efforts fail.

The parents of infants with an *avoidant* attachment sometimes deserve to be avoided. Some are rejecting; they are impatient, unresponsive, and resentful when the infant interferes with their plans (Ainsworth, 1979; Isabella, 1993). Others have been called “intrusive”; often meaning well, they provide high levels of stimulation even when their babies become uncomfortably aroused and need a break so that they can regain control of their emotions (Isabella & Belsky, 1991). Infants with an avoidant attachment style may learn to avoid and make few emotional demands on adults who either seem to dislike their company or bombard them with stimulation they cannot handle.

Finally, a *disorganized–disoriented* style of attachment is evident in as many as 80% of infants who have been physically abused or maltreated (Carlson et al., 1989; and see Baer & Martinez, 2006) and is also common among infants whose mothers are severely depressed or abuse alcohol and drugs (Beckwith, Rozga, & Sigman, 2002). The parents of infants with a disorganized attachment pattern have been described as frightening and frightened—as fearful adults who are not up to the challenge of caring for an infant and create an unpredictable, scary environment for their babies (Hesse & Main, 2006). Infants with a disorganized attachment are understandably confused about whether to approach or avoid a parent who can be loving one minute but angry and abusive or indifferent the next. You can see each of the four types of attachment, then, as a quite reasonable way of coping with a particular brand of parenting.

The Infant's Temperament

An infant's temperament can also influence the quality of an attachment. Attachments tend to be insecure when infants are by temperament fearful, irritable, or unresponsive (Beckwith et al., 2002). The caregiver's style of parenting and the infant's temperament can also interact to determine the outcome. To illustrate, **Figure 14.3** shows the percentages of 12-month-olds who tested as securely attached as a function of whether they were difficult-to-read infants born prematurely and whether their mothers were depressed (Poehlmann & Fiese, 2001). When a difficult-to-read, premature infant was paired with a depressed mother, the odds of a secure attachment were especially low (see Leerkes, Blankson, & O'Brien, 2009).

So who affects the quality of parent–infant attachment more, the parent or the infant? The parent is clearly more influential. We know the infant's temperament is not the main influence on security of attachment because:

- Relationships between infant temperament and quality of attachment are often quite weak (Roisman & Groh, 2011).
- Many infants are securely attached to one parent but insecurely attached to the other (Kochanska & Kim, 2013; van IJzendoorn & De Wolff, 1997).
- An infant's genetic makeup, although it influences the infant's temperament, has little influence on quality of attachment (Fearon et al., 2006; Raby et al., 2012; Roisman & Fraley, 2008).
- Caregivers who are responsive and adjust to their baby's temperamental quirks are able to establish secure relationships even with temperamentally difficult babies (Leerkes et al., 2009; Mangelsdorf et al., 1990).

Figure 14.3 The combination of a depressed mother and a premature infant means low odds that a secure attachment will form.

Compared with American babies, Japanese infants become more anxious in the Strange Situation because they are rarely separated from their mothers.

kdshutterman/Shutterstock.com

Cultural and Social Context

Finally, the broader social context surrounding caregiver and infant can affect how they react to each other. For example, the stresses associated with living in poverty or experiencing marital conflict may make it difficult for parents to provide sensitive care and may contribute to insecure attachments (Roisman & Booth-LaForce, 2014).

The cultural context in which caregiver and baby interact also colors their relationship. For instance, in Germany, an individualistic culture, parents strongly encourage independence and discourage clingy behavior, fearing that if they are too responsive to cries they will spoil their infants. This may explain why many German infants make few emotional demands on their parents and are often classified as avoidantly attached (Grossmann, Grossmann, & Keppler, 2005). By contrast, babies in the collectivist culture of Japan are rarely separated from their mothers early in life and are encouraged to be dependent on their mothers. They become highly distressed by separations such as those they must endure in the Strange Situation. As a result, they are more likely than American babies to be classified as resistantly attached (Takahashi, 1990; van IJzendoorn & Sagi, 1999).

Could findings like this mean that research on infant attachment is culturally biased? Might those Japanese babies who freak out in the Strange Situation actually be securely attached? Very possibly. In addition, we must appreciate that in many cultures infants do not have a single primary caregiver but instead are passed from caregiver to caregiver during the day. Among the Efe of the Democratic Republic of Congo, for example, infants were observed to be in contact with an average of 9 to 14 different people during a two-hour observation period (Morelli, 2015).

A number of researchers conclude that secure attachment may mean somewhat different things in different societies (Miller, Goyal, & Wice, 2015; Rothbaum & Morelli, 2005). At the same time, many of the key signs of a secure attachment are consistent

across cultures (Posada et al., 2013). And the main predictions of attachment theory—especially the critical importance of parent sensitivity and responsiveness in fostering a secure attachment—are well supported across cultures (see Morelli, 2015; van IJzendoorn & Sagi-Schwartz, 2008). Overall, then, sensitivity and responsiveness of the caregiver (or in many cultures, the caregivers) is the primary influence on the quality of caregiver–infant attachment, but characteristics of both the baby’s temperament and the surrounding cultural and social environment also affect it.

Implications of Early Attachment

From Freud on, psychologists have assumed that a secure parent–child relationship is critical in human development. Just how important is it? Several lines of research offer answers: studies of socially deprived infants; studies of infants who experience separations from their caregivers; and studies comparing the later development of securely and insecurely attached infants.

Social Deprivation

What happens to infants who never have an opportunity to form an attachment? It is better to have loved and lost than never to have loved at all, say studies of infants who grow up in deprived institutional settings where they are unable to form attachments (Leiden Conference, 2012; MacLean, 2003). In the 1990s, children from deprived institutions in Romania were adopted into homes in the United States, the United Kingdom, and Canada after the fall of the Romanian government (Gunnar, Bruce, & Grotevant, 2000). These adoptees reportedly spent their infancies in orphanages with 20–30 children in a room and only one caregiver for every 10–20 children; they spent most of their time rocking in their cribs with little human contact, much less hugs and synchronous routines (Fisher et al., 1997). How did they turn out?

Infants who spent their first several months or more in deprived orphanages displayed a host of problems—poor growth, medical problems, brain abnormalities, and delays in physical, cognitive, and social-emotional development (Leiden Conference, 2012; MacLean, 2003; McCall & Groark, 2015). What of their attachments after they were adopted? The good news is that about 90% had clearly become attached to their adoptive parents 9 months after adoption (Carlson et al., 2014). However, high proportions showed disorganized attachment behavior, as though they saw their parents as both comforting and threatening (see also Bakermans-Kranenburg et al., 2011; Zeanah, Berlin, & Boris, 2011). Many institutionalized children continue to show insecure and atypical attachment behavior as adolescents (Palacios et al., 2014).

A meta-analysis of many studies of institutionalized and otherwise maltreated and neglected children concluded that those who are adopted before 1 year of age have a good chance of becoming as securely attached to their caregivers as other children (van den Dries et al., 2009). However, high rates of insecure and disturbed attachment are observed among children adopted after their first birthday, and the problem is not lack of a single “mother figure.” In adequately staffed institutions and communes, infants cared for by a few responsive caregivers turn out fine (Groark et al., 2005; St. Petersburg-USA Orphanage Research Team, 2008).

Apparently, then, normal development requires sustained interactions with sensitive and responsive caregivers—whether one or a few. Apparently too, children are resilient if they are given a reasonable chance to find someone to love. However, as Bowlby claimed, early social deprivation can leave lasting marks on development.

Separations

Now consider babies who form an attachment but are separated from their caregivers as a result of illness, war, death, divorce, or other circumstances. Bowlby (1960, 1980) discovered that these infants go through a grieving process in which they first protest and search frantically for their loved one, then become sad and listless once they give up, and sometimes then ignore or avoid their caregiver if she returns, only gradually warming up to her again.

Long-term separation of young children from a parent is an issue for military families when a family member is deployed. This can be a Strange Situation-like stress test not only for infants and children but for their parents, whose attachments to their partners are disrupted. Although most families cope well, some infants and children develop emotional and behavioral problems (Maholmes, 2012; Riggs & Riggs, 2011). The most important influence on whether children adapt well is whether the at-home parent or substitute caregiver provides sensitive and responsive care (Posada, Longoria, Cocker, & Lu, 2011). Programs specially designed for military families can help reduce the negative effects of deployment on infants and children (Lester et al., 2012).

Similarly, infants who are permanently separated from an attachment figure caregiver due to death, divorce, or another reason often have adjustment difficulties but normally recover if they have the security of an existing attachment or can form a new one (Bowlby, 1960, 1980; van IJzendoorn & Juffer, 2006). We should worry more about children who experience a series of permanent separations from caregivers, as happens to some infants and children who are

For military families, deployment arouses separation anxiety in all concerned.

AP Images/Heribert Proepper

repeatedly moved from one foster care placement to another. They may have long-lasting attachment problems and psychological disorders as a result of their repeated experiences of loving and losing (Tarren-Sweeney, 2013; Ward, Munro, & Dearden, 2006).

Day Care

What of the daily separations from their parents that infants experience when they are placed in day care centers or in family care homes (in which caregivers take children into their homes)? A major national longitudinal study of child care supported by the National Institute of Child Health and Human Development tracked infants through adolescence (NICHD, 2006; NICHD Early Child Care Research Network [ECCRN], 1997, 2006; Vandell et al., 2010). Overall, infants who experienced routine care by someone other than their mothers were not much different than infants cared for almost exclusively by their mothers in the many aspects of development studied. Most importantly, infants who received alternative care were no less securely attached to their mothers overall than infants who were tended by their mothers (Friedman & Boyle, 2008; Phillips, 2015; NICHD ECCRN, 1997).

Quality of parenting was a much stronger influence on these infants' attachments and later development than whether they had day care experience. Quality of day care also had impacts, though; infants fared poorest if their mothers were insensitive and unresponsive *and* they were subjected to poor-quality day care on top of it (NICHD ECCRN, 1997, 2006; Vandell et al., 2010). In sum, infants and young children who spend time in day care are not less securely attached to their parents than infants and young children cared for at home, on average. However, they are most likely to thrive if they receive both good quality parenting and good quality child care. From a policy perspective, it makes sense to make affordable and high-quality child care available to more families (Phillips, 2015).

Later Development of Securely and Insecurely Attached Infants

Finally, we can assess the importance of early attachment experiences by asking the following question: How much difference does having a secure rather than insecure attachment in infancy make later in life? Three main qualities distinguish children who were securely attached infants from those who were insecurely attached:

- **Intellectual competence.** Children who were securely attached as infants are described by teachers as more curious, self-directed, and eager to learn than insecurely attached children (Waters, Wippman, & Sroufe, 1979) and they are more engaged in classroom activities (Drake, Belsky, & Pasco Fearon, 2014). They have benefitted from having a secure base for exploration.
- **Social competence.** Children who had been securely attached as infants are more able to initiate play activities, are more sensitive to the needs and feelings of other children, and are more popular and socially competent (Booth-LaForce & Kerns, 2009; Waters et al.,

1979). Their positive interactions with caregivers have allowed them to develop good social skills and positive internal working models of self and others.

- **Emotion regulation.** Secure attachment in infancy is also linked to good emotion regulation and coping skills (Gunnar, 1998; Kochanska, 2001). The comforting and help with emotion regulation securely attached babies receive from their sensitive parents make them less reactive to stress than children who had insecure attachments (Diamond & Fagundes, 2010). Good emotion regulation, as you saw earlier, is in turn associated with fewer emotional and behavioral problems in childhood.

In late childhood, adolescence, and even adulthood, children who have enjoyed secure relationships with their parents early in life often continue to be well adjusted and to enjoy good relationships later in life (Elicker, Englund, & Sroufe, 1992; Simpson et al., 2007). In a revealing longitudinal study spanning the years from infancy to the early 20s, Jeffrey Simpson and his colleagues (2007) found that secure attachment in the Strange Situation at 12 months of age was linked to the quality of a child's peer relations in elementary school, which in turn predicted quality of friendships in adolescence, which in turn predicted the emotional quality of romantic relationships in early adulthood. Although quality of attachment during infancy and quality of romantic relationship in adulthood were not significantly correlated, they were indirectly associated through a chain of influence in which the quality of relationships in each developmental period affects the quality of relationships in the next period (see ■ **Figure 14.4**); see also Cassidy & Shaver, 2016; Fraley et al., 2013).

In sum, children are unlikely to develop normally if they never have the opportunity to form an attachment or if their relationships with adults are repeatedly severed. By contrast, a secure attachment during infancy and early childhood has positive implications for later intellectual, social, and emotional development and for the quality of later relationships. Yet you must avoid concluding that infants who are securely attached to their caregivers are forever blessed—or that infants who are insecurely attached to their caregivers are doomed. Early attachments may have few long-term consequences if they change later—and they quite often do. Factors such as a decline in a mother's sensitivity, the departure of a father from the home, and negative life events in the family can change a secure attachment into an insecure one—just as improvements in a mother's sensitivity or a family's circumstances can convert an insecure attachment into a secure one (Roisman & Booth-LaForce, 2014; and see Beijersbergen

■ **Figure 14.4** Simpson et al. (2007) found that relationship quality at each step in development affects relationship quality at the next step.

Source: From Simpson, J. A., Collins, W. A., Tran, S., & Haydon, K. C. (2007). Attachment and the experience and expression of emotions in romantic relationships: A developmental perspective. *Journal of Personality and Social Psychology*, 92, 355–367. © 2007 American Psychological Association. et al., 2012). As Bowlby appreciated, then, internal working models are just that: *working* models, subject to revision in response to later social experiences (Sroufe et al., 2005).

All things considered, the Bowlby–Ainsworth attachment theory is well supported. Studies of the long-term consequences of early attachment support Bowlby’s claim that internal working models formed early in life shape later relationships and development. Still, many of us learn new social skills and different attitudes toward relationships in our later interactions not only with parents but also with peers, friends, lovers, and spouses. It is time, then, to supplement this description of parent–child relations in infancy with a look at the “second world of childhood”—the world of peer relations.

First Peer Relations

Evolution seems to have equipped human infants not only with a capacity for forming attachments to caregivers but also with a capacity for establishing social relationships with peers (Hay, Caplan, & Nash, 2009; Rubin, Bukowski, & Parker, 2006). Infants show an interest in other babies from an early age and show capacities for sharing, cooperation, and empathy as early as their first and second years (see Chapter 13).

Although interested in other babies from start, infants begin to interact with peers in earnest in about the middle of the first year. By then, infants will often smile or babble at their tiny companions, vocalize, offer toys, and gesture to one another, although many of their friendly gestures go unnoticed and unreciprocated (Hay, Nash, & Pedersen, 1983; Vandell, Wilson, & Buchanan, 1980). During their first year, they may share toys nicely one moment but fight over them the next (Hay et al., 2009).

By about 18 months, infants are able to engage in simple forms of reciprocal play with peers (Brownell, Ramani, & Zerwas, 2006; Mueller & Lucas, 1975; Howes & Matheson, 1992). They imitate one another, and they adopt and reverse roles in their play. Thus, the toddler who receives a toy may immediately offer a toy in return, or the one who has been the chaser will become the chasée. Toward the end of the second year, infants have become quite proficient at this kind of turn-taking and reciprocal exchange, especially those who learned turn-taking through secure attachments to their parents (Fagot, 1997). Some infants even form special relationships with certain preferred playmates—friendships (Hay et al., 2009; Rubin et al., 2006).

And we now also know that mere 2-year-olds are ready to participate in peer groups, learn group norms, and conform to their peers. In a clever study (Haun, Rekers, & Tomasello, 2014), 2-year-olds, chimpanzees, and orangutans each played a simple game in which they learned to drop balls through a hole in one of three boxes to earn a treat. Then they were shown three peers who, in turn, played the game but dropped balls in a different hole. What did they do when they had a chance to play again? The apes stuck with their own successful strategy, but most of the 2-year-old children switched to the strategy they saw three other 2-year-olds use. Peer influence and conformity clearly begin much earlier than adolescence! By conforming to peers, young children are socialized quickly into the social norms, rules, and behaviors of those around them. Clearly the caregiver–infant relationship is not the only important social relationship that develops during infancy; peer relations are well under way, too.

Even at a year of age, infants seem ready to engage in social interactions.

● Checking Mastery

1. What are two important types of fear that develop soon after infants form their first attachments?
2. Compare how infants with a resistant attachment and infants with an avoidant attachment react to separations from their caregivers and the reunions that follow.
3. What does research on infants from deprived institutions suggest infants most need in order to develop normally?

● Making Connections

1. Some years ago, a 2-year-old named Baby Jessica made news because she was taken suddenly from the parents who thought they had adopted her and awarded by the court to her biological parents because her biological father had not consented to the adoption. What would attachment theory and research on attachment predict about Jessica’s reactions and later development? Once you answer, speculate about why Jessica reportedly turned into a happy, well-adjusted child instead (Ingrassia & Springen, 1994).
2. Explain how infants with resistant attachments, avoidant attachments, and disorganized attachments are each trying to regulate their emotions as best they can, given the parenting they receive.

14.4

The Child

LEARNING OBJECTIVES

- Describe how parent–child attachments and peer networks change during childhood.
- Explain how play becomes more social, more imaginative, and more rule-governed over the childhood years and what we can conclude about its contributions to development.
- Describe what we learn from sociometric studies of peer acceptance about children who are popular, rejected, or neglected.
- Explain the unique contributions of friendships to child development.

Relationships with parents and peers change from infancy to childhood as children become more involved in play activities and seek acceptance by their peers. These social relationships contribute to development in a variety of ways.

Parent–Child Attachments

Starting at about age 3, according to Bowlby (1969), the parent–child attachment becomes a *goal-corrected partnership* in which parent and child accommodate to each other’s needs. Children become more sensitive partners and grow more independent of their parents. They continue to seek attention and approval from their parents, and it is important that they continue to perceive their parents as psychologically available to them, even when they are not physically present. However, children also look to peers for social and emotional support now and rely on their parents less and their peers more as they get older (Furman & Buhrmester, 1992; Kerns, Tomich, & Kim, 2006).

Peer Networks

From age 2 to age 12, children spend more time with peers and less time with adults; about 10% of social interactions in toddlerhood but 30% of those in middle childhood are with peers (Ellis, Rogoff, & Cromer, 1981; Rubin et al., 2006). American children spend much of their time in day care, preschool, and school classes in which they are segregated by age. Cross-cultural research tells us that children elsewhere consort more with different-age children and adults. As shown in **Figure 14.5**, for instance, Barbara Rogoff and her colleagues found that 2- and 3-year-old Efe children in the Democratic Republic of the Congo and Mayan children in Guatemala spend more time with older children and less with age-mates than children in two U.S. cities do (Rogoff, Morelli, & Chavajay, 2010). Children in traditional cultures are often involved in the day-to-day activities of the community and mingle with people of all ages. The implications are not entirely clear, but American children may miss out on some opportunities to learn from older and wiser children and adults because they grow up in a relatively age-segregated world.

In the United States and in most cultures, children also live in a gender-segregated world (Ellis, Rogoff, & Cromer, 1981; Munroe & Romney, 2006). This gender segregation becomes increasingly strong with age (Martin et al., 2013; and see Chapter 12). Once in their sex-segregated worlds, boys and girls experience different kinds of social relationships, activities, and interactions

Figure 14.5 Involvement of 2- and 3-year-old children with older children versus similar-age children in four cultural settings: Efe children in a nomadic community of foragers in the Democratic Republic of the Congo; Mayan children in San Pedro, Guatemala; and middle-class American children in West Newton, Massachusetts, and Sugarhouse, Utah. Children were observed in naturally occurring activities (lessons, work, play, and conversations). Young children interacted less with older children and more with similar-age children in the United States than in the other two cultures, suggesting that American children live in a relatively age-segregated social world.

that affect their development. Overall, then, children spend an increasing amount of time with peers as they get older, most often peers of the same gender.

Play

Children spend a lot of time playing and play in a variety of ways (Pellegrini, 2009): through locomotor play (as in games of tag or ball), object play (stacking blocks, making crafts), social play (as in mutual imitation or playing board games), and pretend play (enacting roles). So important is play in the life of the child from age 2 to age 5 that these years are sometimes called *the play years*. This is when children hop about the room shrieking with delight, don capes and go off on dragon hunts, and whip up cakes and cookies made of clay, sand, or air. We can detect two major changes in play between infancy and age 5: it becomes more social, and it becomes more imaginative. After age 5 or so, the exuberant and fanciful play of the preschool years gives way

to somewhat more serious, rule-governed and skill-building play (Smith, 2005).

Play Becomes More Social

Years ago, Mildred Parten (1932) classified the types of play engaged in by preschool children of different ages. Her main categories of activity (besides being unoccupied or being an onlooker) are arranged from least to most social, as follows:

1. **Solitary play.** Children play alone, typically with objects, and appear to be highly involved in what they are doing.
2. **Parallel play.** Children play next to one another, doing much the same thing, but they interact little (for example, two girls might sit near each other, both drawing pictures, without talking to each other much).
3. **Associative play.** Children interact by swapping materials, conversing, or following each other's lead, but they are not united by the same goal (for example, the two girls may swap crayons and comment on each other's drawings as they draw).
4. **Cooperative play.** Children join forces to achieve a common goal; they act as a pair or group, dividing their labor and coordinating their activities in a meaningful way (for example, the two girls collaborate to draw a big mural).

The major message of Parten's study (and of others like it) is that play becomes increasingly social and socially skilled from age 2 to age 5 (Barnes, 1971). As shown in **Figure 14.6**, solitary and parallel play become less frequent with age, while associative and cooperative play, the most social and complex of the types of play, become more frequent with age. Solitary and parallel play continue to serve useful functions for older children at times, however (Coplan & Abreau, 2009; Rubin et al., 2011).

Figure 14.6 Frequency of play activities engaged in by preschool children of different ages. With age, solitary and parallel play occur less frequently, whereas associative and cooperative play occur more frequently.

Source: Adapted from Barnes, 1971.

Play Becomes More Imaginative

The first **pretend play**—play in which one actor, object, or action symbolizes or stands for another—occurs around age 1, when an infant may raise an empty cup, or perhaps a forbidden treat, to her lips, smile, give a parent a knowing glance, and make loud lip-smacking sounds (Nicolich, 1977). The earliest pretend play is just like this: The infant performs actions that symbolize familiar activities such as eating, sleeping, and washing. By age 2, toddlers readily join in pretense; if you hand them a towel and suggest that they wipe up the imaginary tea you just spilled at your pretend tea party, they will (Harris & Kavanaugh, 1993)! These toddlers can use their new symbolic capacity to construct a mental representation of a pretend event and act according to this representation.

Pretend play blossoms from age 2 to age 5, increasing in both frequency and sophistication (Howes & Matheson, 1992; Rubin et al., 2006). Most important, children combine their capacity for increasingly social play and their capacity for pretense to create **social pretend play**, play in which children cooperate with others to enact sometimes very sophisticated dramas (Howes & Matheson, 1992). Watch as a 5-year-old (M) tries to convince her partner (E), playing the role of a mother, to leave her babies and come to M's house. The two girls negotiate what will happen next, managing to stay in role and keep in mind the other's role as they do so (Garvey, 1990, p. 137):

M: You come here. The babies are sleeping now and ...
(interrupted).

E: No, they'll cry when I leave 'cause they'll hear the car.

M: Nooo. The car's broken. I have the car.

E: All right, but one baby will have to take care of these little babies.

Although social pretend play is universal, the quality and content of preschoolers' play are culturally influenced (Haight et al., 1999). For example, U.S. children like to play superheroes and act out themes of danger and fantasy, whereas Korean children take on family roles and enact everyday activities (Farver & Lee-Shin, 1997). American children also talk a lot about their own actions, reject other children's ideas, and boss others around, whereas Korean children are more prone to focus on their partners' activities, make polite requests, and agree with one another. Through their play, then, children in the United States (an individualistic culture) learn to assert their identities as individuals, whereas children in Korea (a collectivist culture) learn how to keep their egos and emotions under control to achieve group harmony.

Play Becomes More Rule-Governed

After they enter school, children engage less frequently in pretend play. They become members of peer groups in their neighborhoods or schools—groups that hang out together, have their own norms of behavior, and are often organized into hierarchies or pecking orders with leaders and followers (Rubin et al., 2015). Now children spend more of their time playing organized games with rules—board and computer games, games of tag or hide-and-seek, organized sports, and so on (Smith,

Pretend play during the preschool years contributes to intellectual, social, and emotional development.

Donald Iain Smith/Moment Select/Getty Images

2005). They also develop individual hobbies, such as building model cars, collecting coins, or making scrapbooks, activities that require learning rules and help them acquire skills and knowledge. Partly because of cognitive advances, then, the play of the school-age child is more organized and rule-governed—and less fanciful—than that of the preschool child.

What Good Is Play?

Parents who program their children's days in hopes of molding little Einsteins, like preschool teachers who emphasize learning one's ABCs over playing, may have lost sight of the importance of play in child development (Bartlett, 2011; Hirsh-Pasek et al., 2009; Singer, Golinkoff, & Hirsh-Pasek, 2006). The fact that playful activity occurs among the young of so many species strongly suggests that play is an evolved behavior that helps the young adapt during childhood and prepare for adulthood (Coplan & Abreau, 2009; Pellegrini, 2009). It is easy to see how girls playing house with dolls might be grooming themselves for traditional roles as mothers or how the rough-and-tumble play of boys, like the playful fighting observed in young males of many species, prepares them to compete with other males later in life.

Play allows children to develop and practice many skills. Play is, in fact, associated with development in many domains: motor, cognitive, language, social, and emotional (Pellegrini, 2009; Smith, 2005). For example, physical or locomotor play, from the leg kicking of infants to the soccer playing of children, is associated with neural maturation and the refinement of motor skills. Both Jean Piaget and Lev Vygotsky (see Chapter 7) highlighted the significance of pretend play in cognitive development. Indeed, engaging in lots of pretend play has been linked to better performance on tests of cognitive development, language skills, executive function, and creativity (Lillard et al., 2013). Meanwhile, social pretend play is linked to children's understanding of others' perspectives, social skills, and popularity (Connolly

& Doyle, 1984; Lillard et al., 2013). Finally, play contributes to healthy emotional development by providing opportunities to act out or express bothersome feelings, regulate emotions, and resolve emotional conflicts (Coplan & Abreau, 2009). So it was that Jackie, an abused 5-year-old, coped with his abuse by having an alligator puppet swallow a small child doll and then smashing the alligator with a mallet and burying it in the sandbox (Landreth & Homeyer, 1998).

So, although children play because it is fun, not because it sharpens their skills, they contribute to their own development by playing. Experts agree that young children often learn best when they can do so in self-chosen, hands-on, and playful ways (Hirsh-Pasek et al., 2009; Lillard et al., 2013).

Peer Acceptance

Being accepted by peers means having the opportunity to play and interact with other children and in the process develop normally. Researchers study peer-group acceptance through **sociometric techniques**—methods for determining who is liked and who is disliked in a group (Cillessen, 2009; Cillessen, Schwartz, & Mayeux, 2011). In a sociometric survey, children in a classroom may be asked to nominate several classmates whom they like and several whom they dislike or to rate all their classmates in terms of their desirability or undesirability as companions. It is important to find out both who is liked and who is disliked; this allows children to be classified into the following distinct social categories (Coie, Dodge, & Coppotelli, 1982):

1. **Popular.** Well liked by most and rarely disliked.
2. **Rejected.** Rarely liked and often disliked.
3. **Neglected.** Neither liked nor disliked; these children seem to be invisible to their classmates.
4. **Controversial.** Liked by many but also disliked by many.
5. **Average.** In the middle on both the liked and disliked scales.

Influences on Sociometric Status

Why are some children more popular than others, and why are other children rejected by their peers? Popularity or peer acceptance is affected by some personal characteristics that a child can do little to change—for instance, physical attractiveness and intelligence (Bellanti, Bierman, & Conduct Problems Prevention Research Group, 2000). Social competence—for example, initiating social interactions skillfully, responding positively to peers, resolving interpersonal conflicts, and so on—strongly predicts popularity (Coie, Dodge, & Kupersmidt, 1990; Rubin et al., 2015). Well-liked children are also able to regulate their emotions well (Graziano, Keane, & Calkins, 2007).

What does it take to be rejected or highly disliked by peers? “Rejected” children are often aggressive—pushy, disruptive, annoying, mean. A smaller number are socially isolated, withdrawn children who do not seem to fit in with the peer group's norms (Parkhurst & Asher, 1992; Rubin et al., 2015). Children who fall into the neglected category of sociometric status often have reasonably good social skills but they tend to be shy and unassertive; they may hover around the fringes of a play group

or prefer to play alone, so no one really notices them (Coie et al., 1990; Coplan, Ooi, & Nocita, 2015). Controversial children are interesting: They often have good social skills and leadership qualities, like popular children, but they are also viewed as aggressive bullies, like many rejected children (DeRosier & Thomas, 2003; Miller-Johnson et al., 2003).

In sum, popularity or peer acceptance is affected by many factors. It helps to have an attractive face and a high IQ, but it is probably more important to behave in socially competent ways and to be able to regulate one's emotions. As you have learned, children who have enjoyed secure relationships with their parents tend to become popular children because they have learned social and emotion regulation skills that make for positive relationships with peers.

Implications of Peer Acceptance

Do the outcomes of childhood popularity polls matter? Very much so, especially for the 10%–15% of children who are rejected by their peers (Rubin et al., 2006). Children who are neglected by peers often gain greater acceptance later, maybe because they often have reasonably good social skills (Bierman, 2004; Cillessen et al., 1992). Poorer outcomes would be expected for extremely socially withdrawn children—children whose social anxiety keeps them from interacting with peers and exposes them to victimization (Rubin, Coplan, & Bowker, 2009).

Children who are rejected because of their aggressive behavior are at risk. They are likely to maintain their rejected status from grade to grade (Bierman, 2004; Cillessen et al., 1992). What's more, they may become even more poorly adjusted as a result of the experience of being rejected. Their self-esteem suffers, they lose opportunities to learn social skills, they develop negative attitudes toward others, they are negatively influenced by the other antisocial children they end up hanging out with by default, and their academic performance suffers (Coie, 2004; Prinstein et al., 2009). There is even evidence that the stress of being rejected by peers is associated with inflammatory processes in the body that can contribute to health problems later in life (Murphy, Slavich, Rohleder, & Miller, 2012). Yet social skills training and coaching programs that aim to improve children's interaction skills can improve their acceptance by peers (Bierman & Powers, 2009).

Friendships

Being accepted by the wider peer group and having close friends are distinct and serve different functions for children. Popular children are more likely than unpopular children to have friends, but many unpopular children have at least one reciprocated friendship in which there is mutual affection and many popular children do not (Gest, Graham-Bermann, & Hartup, 2001).

Having at least one friend increases the odds that a child will be happy and socially competent and reduces the odds that a child will be lonely and depressed (Bukowski, Motzoi, & Meyer, 2009; Rubin et al., 2015). This is especially true if

Chumships in late elementary school, said Harry Stack Sullivan, are a training ground for later intimate relationships.

Elena Elisseeva/Shutterstock.com

the friend is well adjusted and supportive (Rubin et al., 2015; Vaughn et al., 2000). As you learned in Section 14.2, psychoanalytic theorist Harry Stack Sullivan (1953) theorized that having a close friend or chum has many developmental benefits, and research bears him out (Bukowski et al., 2009). Chumships teach us how to be emotionally intimate with someone and, as we will see shortly, pave the way for romantic relationships in adolescence. We become attached to friends, who then serve as secure bases and safe havens for us. Friends can provide critical social support and comfort that help children weather stressful events, such as the first day of kindergarten, torment by a bully, or the turmoil of a divorce (Bukowski et al., 2009; Ladd, 1999; Rubin et al., 2015).

● Checking Mastery

1. Which two of Parten's types of play are the most socially complex?
2. What are the two main trends in the development of play over the preschool years?
3. What are three important influences on popularity or sociometric status in childhood?

● Making Connections

1. Addi's parents would like to help advance her physical, cognitive, and social development through play activities, but they do not know how to go about it. Give them some ideas of what they can do with a 1-, 4-, and 8-year-old to provide age-appropriate play experiences.
2. Darren's sociometric status is neglected, whereas Alonzo's is rejected. What training program might you design for each boy to help him become more popular and why?

14.5

The Adolescent

LEARNING OBJECTIVES

- Describe the significance of attachments to parents and friendships in adolescence.
- Distinguish between cliques and crowds and describe their evolution and functions during adolescence.
- Describe four phases in the development of adolescent romantic relationships and the typical effects of dating on adolescent development.

Compared to children, adolescents spend even more time with peers and less time with parents. The quality of a teen's attachment to parents continues to be highly important throughout adolescence, but peers, including both same- and other-sex friends and romantic partners, begin to rival or surpass parents as sources of intimacy and support (Furman & Buhrmester, 1992). As they age, adolescents are constructing and reconstructing internal working models not only for their attachments to their parents but for their attachments to close friends and their attachments to romantic partners. These mental representations differ from one another, each depending most on the quality of interactions within each type of relationship (Furman, Stephenson, & Rhoades, 2014).

Attachments to Parents

Just as infants must have a secure base if they are to explore, adolescents need the security, as well as the encouragement to explore, provided by supportive parents in order to become independent and autonomous individuals (Markiewicz et al., 2006). A balance of exploration and attachment is the key to successful development at this age (Allen, 2008). Adolescents who enjoy secure attachment relationships with their parents generally have a stronger sense of identity, higher self-esteem, greater social competence, better emotional adjustment, and fewer behavioral problems than their less securely attached peers (Allen, 2008; Arbona & Power, 2003; Kenny & Rice, 1995). They are likely to form higher quality attachment to friends—and later to romantic partners—than adolescents with insecure attachments to their parents (Furman & Rose, 2015). They also show better adjustment during the potentially difficult transition to college than students who are insecurely attached (Larose, Bernier, & Tarabulsy, 2005; Mayseless, Danieli, & Sharabany, 1996).

Friendships

Friendships change qualitatively with age. They are based largely on (1) enjoyment of common activities in early childhood, (2) mutual loyalty and caring in late childhood, and (3) intimacy and self-disclosure in adolescence (Collins & Madsen, 2006). Like children, teenagers form friendships with peers who are similar to themselves in physical characteristics (age, gender, and race/ethnicity, for example), as well as in behavior (for example, academic motivation, hobbies). However, adolescents increasingly choose friends whose *psychological* qualities—interests, attitudes, values, and personalities—match their own. In adolescence—and this applies to both males and females and across racial and ethnic

Going to college is a “Strange Situation” that activates attachment behaviors, such as hugging, phoning, Skyping, and texting, designed to maintain contact with attachment figures. Some separation anxiety is normal and usually decreases over the first semester (Berman & Sperling, 1991).

David Burch/Media Bakery

groups—friends become like-minded individuals who understand you and whom you can tell anything, people you can trust with your secrets and count on to be there when you need them (Way & Silverman, 2011).

Although same-sex friendships remain important throughout adolescence, teenagers increasingly form close cross-sex

friendships too. Ruth Sharabany and her colleagues (Sharabany, Gershoni, & Hofman, 1981) found that same-sex friendships were emotionally intimate throughout adolescence but that cross-sex friendships did not attain a high level of emotional intimacy until 11th grade. These findings and others support Harry Stack Sullivan's view that children learn lessons about intimate attachments in their chumships or friendships that they later apply in their romantic relationships (Buhrmester & Furman, 1986; Furman & Rose, 2015).

Sociometric Popularity and Perceived Popularity

In childhood, popular kids have many likable characteristics, but, starting in late childhood and adolescence, it is important to distinguish between **sociometric popularity**, or being liked by many peers, and **perceived popularity**, or being viewed as someone who has status, power, and visibility in the peer group (Mayeux, Houser, & Dyches, 2011; Parkhurst & Hopmeyer, 1998). If you conjure up an image of the “popular” kids in high school, you quickly realize that they had lots of power but that not all were well liked.

Teens with high perceived popularity have good social and leadership skills and are often attractive and well dressed. Some are even very likeable (that is, sociometrically popular). But others seek control and status and sometimes do a lot of damage by snubbing, excluding, bullying, and otherwise being mean to others kids. They often excel at **relational aggression**—subtle and indirect aggression that involves gossiping about and ignoring or excluding others (see Voulgaridou & Kokkinos, 2015).

Just think of Regina George and her clique, the Plastics, in the film *Mean Girls* and you have the idea. Insults, vicious rumors, and betrayals permeated this society of “mean girls.” Apparently relational aggression works: It enhances girls' perceived popularity and makes boys like them more as dating partners (Houser, Mayeux, & Cross, 2015; Rose, Swenson, & Waller, 2004; Smith, Rose, & Schwartz-Mette, 2010). Indeed, adolescents of both sexes may find that aggression, both physical and relational, helps them climb the social status ladder and maintain their position there—at the expense of their victims (Juvonen, Wang, & Espinoza, 2013).

Although being stabbed in the back by someone you thought was your friend is no fun and adolescence can be agonizing as a result, relational aggression seems to serve the positive function of encouraging conformity to group norms and strengthening the peer culture (Killen, Rutland, & Jampol, 2009). Teens with high perceived popularity also blaze the trail toward dating relationships, as you will now see.

Changing Social Networks

Most elementary school children take interest in members of the other sex, talk at length about who likes whom, develop crushes, and in the process prepare themselves for heterosexual relationships (Thorne, 1993). Still, how do boys and girls who live in their own gender-segregated worlds and often seem to hate each other eventually come to date each other?

Some time ago, Dexter Dunphy (1963) offered a plausible account of how peer-group structures change during adolescence to pave the way for dating relationships. His five steps are still helpful today in understanding how peer relations lay the foundation for romantic attachments (see also Brown, 2011; Collins & Madsen, 2006; Furman & Rose, 2015; and Rubin et al., 2015):

1. In late childhood, boys and girls typically become members of same-sex **cliques**, or small friendship groups, and have little to do with the other sex.
2. Boy cliques and girl cliques then begin to interact. Just as parents provide a secure base for peer relationships, same-sex cliques provide a secure base for romantic relationships. For an adolescent boy, talking to a girl at the mall with his friends and her friends there is far less threatening than doing so on his own.
3. In early adolescence, the most popular boys and girls lead the way and form a heterosexual clique.
4. As less popular teens also form mixed-sex cliques of their own, a new peer-group structure, the **crowd**, completes its evolution during the high school years. The crowd, a loose collection of heterosexual cliques with similar characteristics, provides a vehicle for socializing with the other sex through organized social gatherings such as parties. In larger schools, there are likely to be multiple crowds, each with its own distinctive identity and lifestyle. Those adolescents who become members of a mixed-sex clique and a crowd (not all do) have many opportunities to get to know members of the other sex as both friends and romantic partners.
5. More and more couples form and the crowd disintegrates in late high school, having served its purpose of bringing boys and girls together.

Crowds and Their Implications

High school crowds not only bring boys and girls together but give adolescents a social identity and a place in the social order. The names may vary, but most schools have their crowds of, for example, elites (“populars”), academics (“brains”), athletes (“jocks”), and deviants (“druggies,” “goths,” “emos,” and so on), each consisting of adolescents who are similar in some way (Brown & Dietz, 2009; Brown, Mory, & Kinney, 1994). Everyone in high school seems to recognize these differences: “[The brains] all wear glasses and ‘kiss up’ to teachers and after school they all tromp uptown to the library” (Brown et al., 1994, p. 128), “The parties goof off a lot more than the jocks do, but they don't come to school stoned like the burnouts do” (p. 133). In large, diverse high schools, racial or ethnic groups may function as crowds for minority teens (Brown et al., 2008).

An interesting study of high school social networks by Daniel McFarland and his colleagues (2014) shows that characteristics of a school's ecology, such as its size and racial/ethnic composition, strongly influence who hangs out with whom. In a large, diverse school with lots of options, a defined crowd structure with a hierarchy, a pecking order with popular students and groups at the top, is likely to take shape. Students tend to be cliquish, choosing friends similar to themselves in age, gender, race, and social class. In a small school, this hierarchical social structure and sorting

by similarity are less likely. Students in smaller schools are likely to form friendships based on group classwork or school activities, such as sports and music, perhaps because there are fewer students to choose among as friends and because being excluded would carry a huge cost. As a result, they mix more with students from a variety of social backgrounds and racial segregation is less pronounced. Thus the ecology of a high school can make a big difference in where an adolescent fits in the peer culture.

Which crowd or crowds an adolescent belongs to has important implications for her social identity and self-esteem; it is easier to feel good about yourself if you are a “popular” or a “jock” than if you are a “dweeb,” a “burnout,” or a social isolate who does not belong to any crowd (Brown & Lohr, 1987). Indeed, self-perceived crowd membership in high school predicts adjustment in adulthood. In one study, “brains” tended to graduate from college and have high self-esteem at age 24; “basket cases” were more likely than their peers to have seen a psychologist and attempted suicide; “jocks” achieved financial success but shared with “criminals” a tendency to drink too much; and “criminals” were the least well adjusted (Barber, Eccles, & Stone, 2001; see also Doornwaard et al., 2012).

Do crowds really shape adolescents’ future characteristics or does crowd membership merely reflect an adolescent’s existing characteristics? This question concerns the **peer selection versus peer socialization issue**. Crowd membership does partly reflect personality traits, abilities, and values that existed before the adolescent ever got involved with a particular crowd; teens often select or are selected into the crowds that suit them. However, experiences in a crowd then socialize behavior and shape development (Burk, van der Vorst, Kerr, & Stattin, 2012; Giordano, 2003). That is, both selection and socialization contribute to similarity among members of the same crowd. Thus, for example, adolescents who drink often select drinkers rather than teetotalers as friends, but friends then develop even more similar drinking patterns—heavy

or otherwise—as a result of socializing with each other (Burk et al., 2012). Later in adolescence, as adolescents forge their own identities and become more resistant to peer influences, crowds and the group identities they provide become less important (Brown, 2011; Monahan, Steinberg, & Cauffman, 2009).

Peer Influence

A common misconception in our society is that peers are a bad influence on adolescents. As it turns out, peers typically do more to foster important social learning and positive behavior than to encourage antisocial behavior (Rubin et al., 2015). True, at around age 14 or 15, adolescents are more dependent on their peers and more susceptible to peer influence than before or after; they may “go along with the crowd” and take risks that they would not take when alone (Steinberg, 2015). The nature of peer pressure depends on the crowd to which an adolescent belongs, however: “brains” discourage drug use, for example, while “druggies” encourage it (Sussman et al., 2007).

Parents have considerable influence on whether peer influences are good or bad. Getting in trouble by conforming to peers is much less likely among adolescents who have secure attachments to warm and authoritative parents who are neither too lax nor too strict (Brown et al., 1993; Goldstein, Davis-Kean, & Eccles, 2005). These parents are likely to ask where and with whom their kids are going; they do not let their kids run wild, nor do they forbid them from seeing certain friends—a technique that may backfire and increase involvement with deviant peers and delinquent behavior (Keijsers et al., 2012). In sum, the influences of peers and friends on development are usually healthy but can be destructive, depending on what cliques and crowds adolescents belong to, how good their relationships with their parents are, and how much they need the security of peer acceptance.

Dating

As you have seen, the transition to dating takes place in the context of the larger peer group (Collins & Laursen, 2004; Furman & Rose, 2015). Dating relationships in early adolescence are more superficial and short lived than dating relationships in later adolescence and emerging adulthood (Brown, Feiring, & Furman, 1999; Connolly & McIsaac, 2011). In B. Bradford Brown’s (1999) view, adolescent romantic relationships evolve through the following four phases:

1. **Initiation phase.** In early adolescence, the focus is on coming to see oneself as a person capable of a romantic relationship. This is a time of crushes, posturing, and awkward beginnings.
2. **Status phase.** In mid-adolescence, peer approval is what counts; having a romantic relationship, and having it with the “right kind” of partner, is important for the status it brings in the larger peer group.
3. **Affection phase.** In late adolescence, the focus is finally on the relationship rather than on self-concept or peer status. Romantic relationships become more personal and caring.
4. **Bonding phase.** In the transition to emerging adulthood, the emotional intimacy achieved in the affection phase may be coupled with a long-term commitment to create a lasting attachment.

The self-esteem and social identity of adolescents often hinge on which cliques and crowds they belong to. In any era and any group, conformity in dress and behavior helps adolescents fit in and avoid being excluded.

Searching for Love as an LGBT Youth

How does the development of romantic relationships play out for sexual minority youth—lesbian, gay, bisexual, and transgender teens, as well as teens who are not yet sure of their sexual orientation or are open to different possibilities? These teens often try out a variety of types of relationships: sexual experimentation with both same-sex and other-sex partners, including the hookups common among heterosexual youth; passionate friendships that are about emotional intimacy rather than about sex; and dating relationships (Diamond, Savin-Williams, & Dubé, 1999; Shulman & Connolly, 2016).

Sexual minority youth, like straight ones, ultimately seek intimate romantic

relationships. However, they face a number of obstacles to finding them. For one thing, they cannot rely on support from within the larger, heterosexually oriented peer culture to serve as a “secure base for exploration” of relationships. They may be stigmatized and often face higher than average risks of being the victims of peer bullying, sexual harassment, and dating violence (Burton et al., 2013; Reuter, Sharp & Temple, 2015; Williams, Connolly, Pepler, & Craig, 2003). Their parents, especially if they have traditional values, may also react negatively to them when they come out, adding to their challenges (Baiocco et al., 2015).

Yet most sexual minority youth succeed in forming healthy romantic attachments despite such barriers. Moreover, attachment theory applies to LGBT youth just as well as it applies to heterosexual youth and can help us understand how their early experiences in relationships affect their romantic relationships. This was clear in a longitudinal study of LGBT youth aged 16–20 in the Chicago area who were followed over 3.5 years (Starks, Newcomb, & Mustanski, 2015). Just as for heterosexual youths, both secure attachments with parents and secure attachments with friends were linked to better mental health and closer, more satisfying romantic relationships later on.

Brown’s phases were quite evident in an 8-year longitudinal study of German adolescents who were age 13 at the start of the study (Seiffge-Krenke, 2003). The 13-year-olds had romantic relationships that, although emotionally intense, lasted an average of only about 3 months. With age, relationships lasted longer (an average of 21 months by age 21) and became more emotionally intimate and supportive. Supportive relationships with parents proved to be at least as important as supportive relationships with peers in predicting involvement in a love relationship in early adulthood (see also Connolly & McIsaac, 2011; Furman & Rose, 2015; Shulman & Connolly, 2016). **Exploration 14.2** looks at some special challenges faced by sexual minority youth in their search for love.

How does dating affect development and adjustment overall? Dating at an early age seems to have more negative than positive implications for social and emotional adjustment, either because troubled adolescents start dating early or because early daters get hurt or become involved in problem behavior such as sex, drinking, and drug use before their time (Furman & Collibee, 2014; Mendle et al., 2013). By late adolescence or emerging adulthood, having a romantic partner becomes a plus; it is associated with less substance use and fewer emotional and behavioral problems, possibly because finding a romantic partner has become an appropriate developmental task by this age (Furman & Collibee, 2014). In the end, involvement in a steady relationship is good for self-esteem and well-being (although breakups certainly hurt), and adolescents who date tend to be better adjusted than those who do not (Connolly & McIsaac, 2011; Furman & Rose, 2015).

Adolescence is clearly a tremendously important time of change in attachment relationships. As adolescents get older, they look more to peers, both friends and romantic partners, to fulfill

some of the attachment needs that parents fulfilled when they were younger—needs for closeness, a secure base for exploration, and a safe haven in times of trouble (Markiewicz et al., 2006). Secure attachments to friends, like secure attachments to parents, can help adolescents cope with stress, and a lack of such attachments is linked to anxiety and depression (Gorrese, 2016). Even so, parents, especially mothers, remain a critical source of security and support throughout the adolescent years. Moreover, the quality of parent–adolescent relationships and parents’ parenting styles have a lot to do with the quality of an adolescent’s relationships with peers and romantic partners (Brown & Bakken, 2011; Gorrese & Ruggieri, 2012; Oudekerk et al., 2015).

● Checking Mastery

1. What is the difference between a clique and a crowd?
2. Before they are capable of truly caring romantic relationships, what two things do young teens seek from dating relationships, according to B. Bradford Brown’s four phases of dating?

● Making Connections

1. Analyze the clique and crowd structure in your high school, where you fit in it, and how you might have been affected by your experience.
2. How well does Brown’s account of four phases in adolescent dating relationships fit you? Where does your dating history differ, and why might that be?

14.6

The Adult

LEARNING OBJECTIVES

- Explain how social networks change over the adult years and how socioemotional selectivity theory accounts for this change.
- Characterize romantic relationships in terms of the primary basis for partner choice, the triangular theory of love, and the four adult attachment styles.
- Describe the positive effects on adult development of a secure adult attachment style and of having at least one close friend or confidant and the negative effects of social isolation and loneliness.

Relationships with family and friends are no less important during adulthood than they are earlier in life, but they take on different qualities. How do people’s social networks change over the adult years and why, and what is the character of their romantic relationships and friendships?

Social Networks

With whom do adults of different ages interact and what are the implications? Young adults are busily forming romantic relationships and friendships and work contacts. The trend toward greater intimacy in cross-gender relationships that began in adolescence continues (Reis et al., 1993). Young women also continue to form closer friendship ties than men do (Antonucci, Birditt, & Akiyama, 2009). Because of all their social network building, young adults typically have more friends than middle-aged and older adults do.

As adults have children, take on increasing job responsibilities, and age, their social networks of not-so-close friends and acquaintances shrink, but their numbers of close relationships with family and friends stay about the same (Antonucci et al., 2009; English & Carstensen, 2014; Wrzus, Hänel, et al., 2013). The trend toward smaller social networks with age after early adulthood can be seen in many ethnic groups, but ethnic group differences are also evident. For example, from early adulthood on, African American adults’ networks tend to be smaller, to be more dominated by kin, and to involve more frequent contact than those of European Americans (Ajrouch, Antonucci, & Jan-ovic, 2001). Cultural differences are evident too; for example, although their family networks are similar in size, adults in individualistic cultures often have larger networks of friends and acquaintances than adults in collectivist cultures do (Wrzus, Hänel, et al., 2013).

Shrinking social networks in late adulthood may be forced in part by chronic illness and disability. Life events and changes in roles also affect network size; for example, getting married or starting a new job increases social network size, and the death of a spouse decreases it (Wrzus, Hänel, et al., 2013). But as you saw in Section 14.1, Laura Carstensen’s *socioemotional selectivity theory* states that older adults actively choose to shrink their social networks to better meet their emotional needs as they realize that little time is left to them. Consistent with this theory, older adults narrow their social networks to close family and friends to whom they feel very emotionally close and end up with social networks that give them more positive and fewer negative emotional experiences than young adults obtain from their

relationships (Carstensen, 1992; English & Carstensen, 2014; Lang & Carstensen, 1994).

Socioemotional selectivity, loss of roles, and failing health may all lead to shrinking social networks with age, then. However, older adults typically find their relationships satisfying and emotionally fulfilling.

Romantic Relationships

An important developmental task for young adults is to resolve Erikson’s issue of intimacy versus isolation by finding a romantic partner and entering into a committed relationship. How do we choose partners, what does love involve, and how do the internal working models of self and others that we form starting in infancy affect our romantic attachments?

Partner Choice

Many models and schemes have been developed to answer the question of how people choose romantic partners (see Regan, 2008; Strong, DeVault, & Cohen, 2011). Filter theories of mate selection or partner choice have envisioned it as a process in which we progress through a series of filters leading us from all possible partners to one partner in particular (see Regan, 2008; Strong et al., 2011). Assuming two people have an opportunity to meet, similarities in physical appearance, race or ethnicity, education, socioeconomic status, religion, and the like serve as the first filters and provide a basis for dating. Then partners may disclose more about themselves and look for similarity in inner qualities such as values, attitudes, beliefs, and personality traits. If they continue to find themselves compatible, their relationship may survive; if not, it may end. There is little agreement, though, on how many such filters there might be. More importantly, mate selection does not appear to unfold in a neat, steplike manner as filter theories imply (Regan, 2008).

Researchers do agree on one thing: The greatest influence on mate selection is similarity, or **homogamy** (Finkel et al., 2012; Strong et al., 2011). Once homogamy is assured, people may also look for **complementarity**—for partners who are different from them but who have strengths that compensate for their own weaknesses or otherwise complement their own characteristics. However, the saying “birds of a feather flock together” has far more validity than the saying “opposites attract” when it comes to mate selection. Partner choice works much the same in gay and lesbian relationships as in heterosexual relationships (Diamond & Butterworth, 2009).

According to filter theories, we choose romantic partners mainly on the basis of homogamy or similarity—at first surface similarities such as belonging to the same ethnic group may attract us to someone, but we look for psychological similarities as well.

Hero Images/Brand X Pictures/Getty Images

Some online dating sites use algorithms to match partners for similarity and sometimes complementarity as well based on responses to questionnaires. However, research to date suggests that this kind of mechanical matching can go only so far. Why? It ignores the important fact that relationships grow out of partners' interactions over time, that aspects of personality like emotional stability and agreeableness influence the success of relationships, and that in the end it is very hard to predict which relationships will turn into lasting “true love” (Finkel et al., 2012).

Love

Philosophers and poets have struggled for centuries to define love, but it is an elusive concept and there are many kinds of it (Berscheid, 2010; Reis et al., 2013). The concept of romantic love is not just a Western phenomenon or a modern phenomenon, as some people incorrectly believe; it has been documented throughout history and in virtually all of the world's cultures (Hatfield, Mo, & Rapson, 2015; Jankowiak & Fischer, 1992). It is even associated with similar patterns of brain activity across cultures (Acevedo & Aron, 2014). This suggests it is part of our evolutionary heritage that plays a role in committing us to a particular partner and then investing in the rearing of children with that partner (Fletcher et al., 2015). We can think about romantic relationships as a merger of sexual attraction and emotional attachment (Birnbbaum, 2015).

Robert Sternberg (1988b, 2006a) puts some of these ideas together in his **triangular theory of love**, which identifies different types of love based on the strength of three components of love. As shown in ■ **Figure 14.7**, the three components are passion, intimacy, and commitment:

- **Passion** involves sexual attraction, romantic feelings, and excitement. A 24-year-old woman in love expressed it well: “I get so excited when I know that I’m going to see him, and then

■ **Figure 14.7** The three components of love in Sternberg's triangular theory of love. Think about each component being high or low and what the resulting quality of a relationship would be. For example, companionate love has high intimacy and commitment but low passion; infatuation has high passion but low intimacy and commitment.

Source: Adapted from Sternberg, R. J. (1988b). Triangulating love. In R. J. Sternberg & M. L. Barnes (Eds.), *The psychology of love*. New Haven, CT: Yale University Press, p. 122.

when I do see him, I can't breathe I'm so full of want” (Regan, 2008, p. 142).

- **Intimacy** involves feelings of warmth, caring, closeness, trust, and respect in the relationship. It is about emotional togetherness, attachment, and communication.
- **Commitment** involves first deciding that one loves the other person and then committing to a long-term relationship.

Sternberg identified seven types of love that can result depending on whether each of the three dimensions of love is high or low, making the point that love can take a variety of forms. In our culture, couples often experience passion early in a dating relationship and then move on to greater intimacy and finally to commitment as their relationship evolves. In cultures with arranged marriages, commitment may come first, with the parents who arranged the marriage hoping that passion and intimacy will bloom later (Regan, 2008).

If couples are lucky, they will enjoy high levels of passion, intimacy, and commitment—or what is called **consummate love**—all of their days. Adolescents score lower on scales measuring these three aspects of love than young adults do (Sumter, Valkenburg, & Peter, 2013), reinforcing Erikson's idea that early adulthood is the time to establish intimate relationships. Passion, that intense feeling of “being in love,” may have evolved because it lures partners into relationships that will lead to mating and childbearing (Reis & Aron, 2008). However, passion often wanes with time in a relationship, whereas commitment often grows or at least holds steady over the adult years (Ahmetoglu, Swami, & Chamorro-Premuzic, 2010; Sumter et al., 2013). Thus romantic relationships involving

lots of passion in their early stages sometimes evolve into relationships characterized by **companionate love**, friendshiplike, affectionate love defined by high intimacy and commitment but not much passion (Reis & Aron, 2008). Some lucky couples, though, are able to keep all three aspects of love, including passion, alive for many years. Indeed, the reward areas of their brains still “light up” when they look at photos of their partners (Acevedo et al., 2012).

Adult Attachment Styles

Intrigued by parallels between an infant’s attachment to a parent figure and a young adult’s love for a romantic partner, researchers like Phillip Shaver and his colleagues began studying adult romantic relationships from the perspective of attachment theory (Fraley & Shaver, 2008; Mikulincer & Shaver, 2007). Many, though not all, love relationships qualify as attachment relationships; the intimacy component of Sternberg’s triangular theory of love suggests a caring attachment between romantic partners. And signs of attachment anxiety early in a dating relationship are at least as important as passion or sexual desire in predicting whether a serious relationship will evolve (Eastwick & Finkel, 2008). Like the infant who is attached to a parent, the adult who is in love experiences a strong emotional bond to her partner, wants to be close, takes comfort from the bond, is upset by separations, and finds the partner irreplaceable, as illustrated by the story of star-crossed lovers Mike and Marcy at the start of the chapter. Adults often have other attachments, of course: to their children, their parents, and sometimes their best friends.

■ **Figure 14.8** shows how the internal working models that Bowlby theorized we start to construct early in life may affect the quality of our romantic relationships (Bartholomew & Horowitz, 1991; Crowell, Fraley, & Shaver, 1999). It describes the four adult attachment styles that result when view of the self is either positive or negative and view of other people is either positive or negative. These four adult attachment styles can also be described in terms of two dimensions of attachment (Roisman, 2009): anxiety (extent of concern about whether partners will be emotionally available and responsive) and avoidance (extent of discomfort being intimate with and depending on a partner).

Adults with a *secure* working model and adult attachment style feel good about both themselves and others; they are not afraid of entering intimate relationships or of being abandoned once they do. People with a *preoccupied* internal working model have a positive view of other people but feel unlovable. Resembling resistantly attached infants, they crave closeness to others as a means of validating their self-worth, tend to become overly dependent on their partners, and are highly fearful of abandonment; thus, they are high in attachment anxiety but low in avoidance.

Adults with a *dismissing* style of attachment often have a positive view of self but do not trust other people and dismiss

		MODEL OF SELF	
		POSITIVE	NEGATIVE
MODEL OF OTHER	POSITIVE	SECURE <i>Secure attachment history</i> Healthy balance of attachment and autonomy; freedom to explore <i>Low anxiety, low avoidance</i>	PREOCCUPIED <i>Resistant attachment history</i> Desperate for love to feel worthy as a person; worry about abandonment; express anxiety and anger openly <i>High anxiety, low avoidance</i>
	NEGATIVE	DISMISSING <i>Avoidant attachment history</i> Shut out emotions; defend against hurt by avoiding intimacy, dismissing the importance of relationships, and being “compulsively self-reliant” <i>Low anxiety, high avoidance</i>	FEARFUL <i>Disorganized–disoriented attachment history</i> Need relationships but doubt own worth and fear intimacy; lack a coherent strategy for meeting attachment needs <i>High anxiety, high avoidance</i>

■ **Figure 14.8** Adult attachment styles based on internal working models of self and other people arising from early experiences in relationships. These four types of attachment also differ in terms of attachment anxiety (fear of abandonment) and avoidance (discomfort being intimate and dependent) dimensions.

Source: Adapted with permission from Bartholomew, K., & Horowitz, L. M. (1991). Attachment styles among young adults: A test of a four-category model. *Journal of Personality and Social Psychology*, 61, 226–244. © 1991 American Psychological Association.

the importance of close relationships. Like avoidantly attached infants, they defend themselves against hurt by not expressing their need for love. They downplay the importance of relationships, find it hard to trust or depend upon partners, feel that others want them to be more intimate than they wish to be, and keep partners at a distance. That is, they are low in attachment anxiety but high in avoidance. Bowlby (1973) described dismissing or avoidant individuals as “compulsively self-reliant.” Finally, adults with a *fearful* internal working model show both high anxiety and high avoidance, resembling infants with disorganized attachments. They take a dim view of both themselves and other people and display a confusing, unpredictable mix of neediness and fear of closeness. You may wish to see if you can identify the adult attachment styles expressed by the statements in **Engagement 14.1**.

In a pioneering study, Cindy Hazan and Phillip Shaver (1987) demonstrated that adults’ styles of attachment are related to the quality of their romantic relationships (see also Creasey & Jarvis, 2009). For example, adults with a secure attachment style experience a good deal of trust and many positive emotions in their current love relationships, and their relationships tend to last longer than those of adults with insecure attachment styles. Avoidant lovers fear intimacy, whereas resistant individuals tend to be obsessed with their partners and jealous. When engaged

Internal Working Models of Attachment

Which of the internal working models of attachment or attachment styles in Figure 14.8—secure, dismissing, preoccupied, or fearful—is expressed in each of the following statements? And which working model best describes you (Bartholomew & Horowitz, 1991, p. 244; adapted from Hazan & Shaver, 1987)?

- 1. “I want to be completely emotionally intimate with others, but I often find that others are reluctant to get as close as I would like. I am uncomfortable being without close relationships, but I sometimes worry that others don’t value me as much as I value them.”
- 2. “I am somewhat uncomfortable getting close to others. I want emotionally close relationships, but I find it difficult to trust others

completely or to depend on them. I sometimes worry that I will be hurt if I allow myself to become too close to others.”

- 3. “It is relatively easy for me to become emotionally close to others. I am comfortable depending on others and having others depend on me. I don’t worry about being alone or having others not accept me.”
- 4. “I am comfortable without close emotional relationships. It is very important to me to feel independent and self-sufficient, and I prefer not to depend on others or have others depend on me.”

Answers: 1. Preoccupied 2. Fearful 3. Secure 4. Dismissing

and married partners discuss problems in their relationships, those with a secure attachment style calmly share their feelings and thoughts; avoidant-style adults show physiological signs of shutting down or inhibiting their true feelings; and resistant-style adults become highly emotionally aroused (Roisman, 2007).

The quality of the parent–child relationship that an adult experienced earlier in life predicts both adult attachment style and romantic relationship quality (Fraley et al., 2013; Grossmann et al., 2002a; Howe, 2011; Raby et al., 2015). Attachments to friends in childhood and adolescence help account for the link between the quality of early parent–child attachments and later romantic attachments—and they contribute something extra of their own, too (Fraley & Roisman, 2015). Sensitive partners can make a difference too—for example, turning an avoidant/dismissing partner into a more trusting and cooperative one by expressing confidence in him and appreciating his efforts (Farrell et al., 2016; Simpson & Overall, 2014). So, as Bowlby theorized, internal working models of self and others formed on the basis of parent–child interactions—but modified by later experiences—color the quality of later relationships. **Application 14.1** illustrates how attachment theory is being applied to improve both parent–child and couple relationships.

Adults’ attachment styles predict a lot more about adults than the quality of their romantic relationships, though (see Cassidy & Shaver, 2016). A secure internal working model provides a secure base for exploration, predicting the extent to which adults have the confidence and curiosity to explore and master their environments (Elliot & Reis, 2003; Luke, Sedikides, & Carnelley, 2012). Securely attached adults enjoy their work and are good employees in a variety of ways, preoccupied (resistantly attached) adults may need a lot of emotional support and grumble about not being valued enough, and dismissing (avoidantly attached) adults may bury themselves in work and do little socializing with coworkers (Hazan & Shaver, 1990; and see Paetzold, 2015).

Internal working models and attachment styles are also related to an adult’s capacity for caregiving—most importantly, to being a sensitive and responsive parent. Mothers and fathers who had secure relations with their parents tend to interact more

sensitively with their children and form more secure attachments with them than parents whose early attachments were insecure (Roisman & Groh, 2011; Shlafer et al., 2015). Attachment styles also predict the quality of caregiving adults provide to their aging parents (Morse et al., 2011).

Finally, attachment styles are related to well-being and both physical and mental health in later life (Howe, 2011; Waldinger et al., 2015). In a study of 60- to 99-year-olds, Victor Cicirelli (2010) concluded that 50% of the older adults studied could be categorized as secure, most of the rest (38%) dismissing-avoidant, and only 12% preoccupied or fearful. As it turns out, older adults who have either a secure or dismissing-avoidant attachment style tend to be happier with their lives than those with either a preoccupied or fearful attachment style (Magai et al., 2001; Bodner & Cohen-Fridel, 2010). Indeed, across cultures middle-aged and older adults appear to be less anxious than young adults about relationships but more avoidant or dismissing (Chopik & Edelstein, 2014). Whether to cope with the loss of a spouse, cope with an imperfect marriage, or optimize independence and minimize dependency on others, then, many older adults seem to become quite self-reliant in their old age and are happy that way.

We can conclude that a secure attachment style is most likely to be associated with good functioning and high well-being throughout the life span (Van Assche et al., 2013; Waldinger et al., 2015). Secure, preoccupied, dismissing, and fearful adult attachment styles have significant implications for adult development—for quality of romantic relationships, exploratory and mastery behavior at work, parenting and caregiving, and adjustment in later life.

Adult Relationships and Adult Development

As you are learning, adults are better off in many ways when they enjoy close social relationships. Research tells us this: The quality rather than the quantity of an individual’s social relationships is most closely related to that person’s sense of well-being and life

● APPLICATION 14.1

Building Secure Attachments

Attachment theory is increasingly being applied to help parents and children as well as adults develop closer and more developmentally beneficial relationships. For example, programs that teach parents how to be more sensitive and responsive to their infants have contributed to better parenting and better infant and child development in families with stressed, low-income mothers coping with irritable babies (van den Boom, 1995) as well as depressed mothers (Berlin, Zeanah, & Lieberman, 2008; Van Doesum et al., 2008; Velderman et al., 2006). A program aimed at mothers at high risk for maltreating their infants provided 10 sessions that emphasized “providing nurturing care when children are distressed, following children’s lead and expressing delight when children are not distressed, and not behaving in frightening ways,” as abusive

parents often do (Bernard et al., 2012, p. 623). Compared to children whose parents received a control treatment, children in the special program had significantly higher rates of secure attachment (52% vs. 33%) and lower rates of disorganized attachments (32% vs. 57%).

Attachment-based therapy is also being used to treat adolescents and young adults with problems (Diamond et al., 2016; Kobak & Kerig, 2015). For example, attachment-based family therapy—family therapy guided by attachment theory—has proven effective in helping parents provide depressed and potentially suicidal adolescents with a more secure base of support during crises (Ewing, Diamond, & Levy, 2015). It has also helped young adults overcome unresolved anger that they may have toward one of their parents (Diamond et al., 2016).

Finally, attachment theory provides a basis for treating couples with relationship problems (Berry & Danquah, 2016). The emotionally focused therapy developed by Susan Johnson (2004, 2008; Johnson & Wittenborn, 2012), for example, helps partners understand their attachment-related emotions (to appreciate that it is okay to need one another or to be fearful of separation); to communicate their emotions, including painful ones about experiences of betrayal or unresponsiveness; and to collaborate to better meet one another’s emotional needs and heal old wounds. Apparently, then, insecure and troubled relationships can be converted into more secure ones that serve as secure bases for exploration, safe havens in times of stress, and foundations for healthy development across the life span.

satisfaction (Litwin & Shiovitz-Ezra, 2011; Pinquart & Sorensen, 2000). Similarly, perceived social support is more important than the social support actually received (Uchino, 2009). Just as

people can feel lonely despite being surrounded by other people, or deprived of social support even though they receive a lot of it, they can have small social networks and receive little social support yet be quite satisfied.

Most older adults have at least one close friend or confidant—and it is good they do.

Gaby Gerster/laif/Redux

The size of an adult’s social network is not nearly as important as whether it includes at least one **confidant**—a spouse, relative, or friend to whom the individual feels especially attached and with whom thoughts and feelings can be shared (de Jong-Gierveld, 1986; Levitt, 1991). For most married adults, spouses are the most important confidants, and the quality of an adult’s marriage is one of the strongest influences on overall satisfaction with life (Fleeson, 2004). Men are particularly dependent on their spouses; women rely more than men on friends, siblings, and children for emotional support (Gurung, Taylor, & Seeman, 2003). Even in very old age, most adults have at least one close friend and are in frequent contact with them (Ueno & Adams, 2006).

Adults benefit not only from having at least one confidant but also from having interactions that are rewarding rather than stressful (Krause, 1995). Probably because of their personality traits and attachment styles, people who have positive (or

negative) interactions in one relationship tend to have similar experiences in other relationships, creating a constellation of supportive (or stressful) relationships (Krause & Rook, 2003). Relationships with spouses, children, or other significant companions can undermine rather than bolster physical and mental health if they involve mostly conflict and irritation (Newsom et al., 2003; Rook, 2015).

So a small number of close, harmonious, and supportive relationships can improve the quality of an adult's life, whereas negative relationships (or a lack of relationships) can make life miserable, as discussed in **Exploration 14.3** on the widespread

problem of loneliness. It's a matter of life and death: Social support, especially that provided by close family attachments, has positive effects on the cardiovascular, endocrine, and immune systems; improves the body's ability to cope with stress; and contributes to better physical and cognitive functioning and even to a longer life (J. Cacioppo et al., 2015; Pietromonaco, DeBuse, & Powers, 2013; Uchino, 2009). Whatever our ages, our well-being and development hinge considerably on the quality of our ties to our fellow humans—particularly on having a close and gratifying emotional bond with at least one person.

● EXPLORATION 14.3

Lonely Hearts

All the lonely people—Where do they all come from?

—The Beatles, “Eleanor Rigby”

Almost all of us have experienced loneliness at some time in our life, but for some individuals it is a chronic and very painful state. It is a life-span concept that may be caused by being excluded from peer groups, lacking a friend as a child, or being abandoned by friends and lovers as an adolescent or adult (Qualter et al., 2015). Loneliness is reported at all ages but the percentages of people saying they “sometimes” or “often” feel lonely hover around 40–50% and appear to be especially high in adolescence and in old age (Qualter et al., 2015). Lonely people can be almost anyone, even people who are popular and have high status, or people who are surrounded by other people (S. Cacioppo et al., 2015).

It is becoming clear that loneliness takes a significant toll on health and mental health and should be viewed as a major public health problem (Gerst-Emerson & Jayawardhana, 2015). John Cacioppo and his colleagues conclude that humans have evolved to be with other people and that isolation and loneliness stress and wear down the body, affecting genes, stress hormones and responses to stress, and brain functioning. These physical impacts speed the aging process and contribute to such problems as cardiovascular disease, poor immune system functioning, cognitive decline, and depression (J. Cacioppo et al., 2015; Cacioppo & Patrick, 2008; Luo et al., 2012). It does not seem to matter much whether social isolation is real or perceived; measures of social isolation, loneliness, and living alone are all associated with decreased longevity (Holt-Lunstad et al., 2015). But

loneliness and social isolation are distinct, and loneliness can have negative effects on health and mental health independent of the effects of objective social isolation, especially when it is caused by the loss of important attachment figures (J. Cacioppo et al., 2015).

What can be done to help lonely people? A meta-analysis of different approaches to treating loneliness indicates that it may be more effective to change the maladaptive cognitions behind loneliness (for example, “No one cares about me”) than to give people more opportunities for social interaction, increase their social support (for example, through buddy programs), or teach them social skills (S. Cacioppo et al., 2015; Masi et al., 2011). This makes perfect sense if loneliness is mainly a matter of how we perceive our social relationships. With more adults living alone today than ever before, addressing the problem of loneliness is more urgent than ever.

● Checking Mastery

1. What qualities does a companionate love relationship have, according to Sternberg's triangular theory of love?
2. How would you characterize people with a preoccupied internal working model in terms of their (1) views of self and others and (2) position on the dimensions of attachment anxiety and avoidance?
3. What kinds of relationships contribute most to adult well-being?

● Making Connections

1. Laura Carstensen's socioemotional selectivity theory suggests that adults narrow their social networks with age to better meet their emotional needs. Develop some alternative hypotheses about why elderly adults have smaller social networks than young adults.
2. Analyze the internal working models that seem to guide you and your partner in your current (or if you are not in a current relationship, most recent) romantic relationship. What are (were) the implications? To help, you may wish to take the Attachment Styles and Close Relationships surveys at www.web-research-design.net/cgi-bin/crq/crq.pl.

Chapter Summary

14.1 Emotional Development

- Biologically based primary emotions such as anger and fear appear in the first 6 months of life, and secondary or self-conscious emotions at around 18 months of age after self-awareness is achieved. Attachment figures socialize emotions and help infants regulate their emotions until they can develop better emotion regulation strategies of their own.
- Children gain emotional competence (emotional expression, understanding, and regulation) with age; they come to understand that it is possible to have mixed emotions and they learn to follow emotional display rules.
- Adolescents have more negative moods than children or adults, sometimes because they seek them.
- Carstensen's socioemotional selectivity theory and the positivity effect suggest that older adults, realizing that time is short, achieve high emotional well-being by emphasizing emotional fulfillment rather than information seeking and by focusing on positive rather than negative information.

14.2 Perspectives on Relationships

- The developmental significance of early parent-child relationships is emphasized in the Bowlby-Ainsworth attachment theory, which argues that attachments are built into the human species, develop through an interaction of nature and nurture during a sensitive period, and affect later development by shaping internal working models of self and others.
- The second world of childhood, the peer world, was believed to be especially important by Jean Piaget, who emphasized the reciprocal nature of relations with equals, and by Harry Stack Sullivan, who emphasized chumships as a source of social support and a training ground for later intimate relationships.

14.3 The Infant

- Parents typically become attached to infants before or shortly after birth, and parent and child quickly establish synchronized routines. Infants progress through phases of indiscriminating social responsiveness, discriminating social responsiveness, active proximity seeking, and goal-corrected partnership. The formation of a first attachment around 6 or 7 months is accompanied by separation anxiety and stranger anxiety, as well as by exploration from a secure base and retreat to the safe haven the caregiver provides.
- Research using Mary Ainsworth's Strange Situation classifies the quality of parent-infant attachment as secure, resistant, avoidant, or disorganized-disoriented. Harry Harlow demonstrated that contact comfort is more important than feeding in attachment; secure attachment is most closely associated with sensitive, responsive parenting but infant temperament and cultural factors also contribute.
- Repeated long-term separations and social deprivation can make it difficult for an infant to form secure attachments, although recovery is evident. Attending day care normally does not disrupt parent-child attachments, although quality of care matters.

Secure attachments contribute to later cognitive, social, and emotional competence, but attachment quality often changes over time, and insecurely attached infants are not doomed to a lifetime of poor relationships.

- Infants are interested in peers and become increasingly able to coordinate their own activity with that of their small companions; by 18 months, they participate in reciprocal complementary play and may form friendships.

14.4 The Child

- From ages 2 to 12, children participate in goal-corrected partnerships with their parents and spend increasing amounts of time with peers, especially same-sex ones, engaging in increasingly social and imaginative play, including social pretend play, and later in rule-governed games and hobbies.
- Physical attractiveness, intellectual ability, social competence, and emotion regulation skills contribute to popular—rather than rejected, neglected, or controversial—sociometric status. Children who are rejected by their peers and children who have no friends are especially at risk for future problems.

14.5 The Adolescent

- During adolescence, same-sex, and later cross-sex, friendships increasingly involve emotional intimacy and self-disclosure, and a transition is made, led by teens with high perceived popularity, from same-sex cliques, to mixed-sex cliques and larger crowds, and finally to dating relationships, which at first meet self-esteem and status needs and later become more truly affectionate and committed.
- Although susceptibility to negative peer pressure peaks around age 14 or 15, peers are more often a positive than a negative force in development, unless poor relationships with parents lead to association with the wrong crowd.

14.6 The Adult

- Adult social networks, except for family networks, shrink with age, in part because of increased socioemotional selectivity.
- Various filters may be involved in partner choice or mate selection and choices are based mainly on homogamy, with complementarity a lesser consideration. According to Sternberg's triangular theory, love involves passion, intimacy, and commitment and different types of love differ in the amounts of each component.
- Adults have secure, preoccupied, dismissing, or fearful internal working models and adult attachment styles that appear to be rooted in their early attachment experiences and that affect their romantic relationships, approaches to work, caregiving skills, and adjustment in old age.
- At least one close confidant and supportive rather than stressful relationships benefit life satisfaction, physical health, cognitive functioning, and even longevity in adulthood.

15.7 The Problem of Family Violence

Why Does Child Abuse Occur?
What Are the Impacts of Child Abuse?

Listen to the words of Susan Klebold, mother of one of two students, Eric Harris and Dylan Klebold, who, in 1999, killed 12 students and a teacher and injured 24 more students before taking their own lives in a now-infamous massacre at Columbine High School in Colorado (Klebold, 2009, p. 5):

“I was widely viewed as a perpetrator or at least an accomplice since I was the person who had raised a ‘monster.’ In one newspaper survey, 83 percent of respondents said that the parents’ failure to teach Dylan and Eric proper values played a major part in the Columbine killings. If I turned on the radio, I heard angry voices condemning us for Dylan’s actions. Our elected officials stated publicly that bad parenting was the cause of the massacre. . . I tried to identify a pivotal event in his upbringing that could account for his anger. Had I been too strict? Not strict enough? Had I pushed too hard, or not hard enough?”

Susan Klebold has lived every mother's nightmare. By her telling, "Tom and I were loving, attentive, and engaged parents, and Dylan was an enthusiastic, affectionate child," in his early years at least (Klebold, 2016, p. xx). In adolescence, he lost interest in school and became quiet and a little resistant when asked to help around the house, and he and Eric Harris were arrested after they broke into a van, but he was not that different from other teens, was looking into where to attend college, and certainly did not seem deranged. His mother had no idea that Dylan was severely depressed and suicidal and certainly had no idea that he was capable of murder.

Undoubtedly the parents of other mass murderers have experienced anguish similar to Susan Klebold's; we do tend to blame parents when their children do horrible things. But are we justified in doing so? One of the big issues we address in this chapter concerns parenting and the extent to which parents influence how children turn out. You will learn that it's more complex than "blame the parent" thinking would suggest.

The Klebold family's story also illustrates the important concept, put forward by Glen Elder and his colleagues (Elder & Johnson, 2003; Elder & Shanahan, 2006), that we lead **linked lives**—that our lives and development are intertwined with those of other members of our families. Susan Klebold's life, and that of her husband and other son, were changed forever the day of the Columbine massacre. Despite hours of therapy, she is still in anguish over not seeing her son's problem coming so that she could have helped him and prevented the tragedy of Columbine. Just as parents influence their children, then, children influence their parents—for good or bad.

This chapter examines the family and its central roles in human development throughout the life span. How should

Susan Klebold, mother of Columbine High School shooter Dylan Klebold. Does she look like the producer of a mass murderer?

we think about families and how have they changed in recent decades? How do infants, children, and adolescents experience family life, and how are they affected by their relationships with parents and siblings and the parenting they receive? How is adult development affected by such family transitions as marrying, becoming a parent, watching children leave the nest, and becoming a grandparent? Finally, what are the implications of the immense diversity that characterizes today's families—and of such decisions as remaining childless or divorcing?

15.1

Understanding the Family

LEARNING OBJECTIVES

- Discuss the concept of the family as a changing system within a changing world, using the concepts of family systems theory, Bronfenbrenner's bioecological model, and the family life cycle to do so.
- Describe some of the major changes in the family since the 1950s and evaluate which are most positive and most negative.

The family is a system—and a system within other systems. It is also a changing system—and a changing system in a changing world. We invite you to see how much you know about American family life today by completing **Engagement 15.1** before reading on.

The Family as a System within Systems

Despite a Supreme Court ruling on the matter, debate continues to rage in the United States today about whether marriage, the basis for most families, must be between a husband and wife or can be between two men or two women. This controversy illustrates that it may not be possible to define *family* in a way that applies across all cultures and eras of history; many forms of family life have worked and continue to work for humans (Coontz, 2000; Leeder, 2004). However we define family, proponents of **family systems theory** conceptualize the family as

a system. This means that the family, like the human body, is truly a whole consisting of interrelated parts, each of which affects and is affected by every other part, and each of which contributes to the functioning of the whole (Bornstein & Sawyer, 2006; Bowen, 1978; Thoburn & Sexton, 2016). Moreover, the family is a dynamic system—a self-organizing system that adapts itself to changes in its members and to changes in its environment.

The traditional **nuclear family** consists of father, mother, and at least one child. Some scholars think it makes more sense to talk of the "immediate family" consisting of children and whoever cares for them to embrace single-parent families, gay and lesbian families, and so on (McGoldrick, Garcia Preto, & Carter, 2016). In any case, even a simple man, woman, and infant "family system" is complex. An infant interacting with her mother is already involved in a process of reciprocal influence: The baby's smile is greeted by a smile from Mom, and Mom's smile is reciprocated by the infant's grin. However, the presence

● ENGAGEMENT 15.1

Do You Know Today's American Family?

Do you have a good feel for characteristics of American family life today? Fill in the blanks below with a number you would guess is close to the correct percentage and then compare your answers with the statistics in the section "A Changing System in a Changing World" on pages 470–471. Read that section a bit more closely if your guesses are wildly different from the real percentages.

- | | |
|---|--|
| _____ 1. What percentage of adults can be expected to marry at some point in their lives? | _____ 4. What percentage of newly married couples can expect to divorce? |
| _____ 2. What percentage of births are now to unmarried rather than married women? | _____ 5. What percentage of children live with two parents (whether biological, adoptive, or stepparents)? |
| _____ 3. What percentage of women with children younger than age 6 work outside the home? | _____ 6. What percentage of women age 65 and older live alone? |

of both parents means that we must consider husband–wife, mother–infant, and father–infant relationships (Belsky, 1981). Every individual and every relationship within the family affects every other individual and relationship through reciprocal influence.

Now think about how complex the family system becomes if we add another child (or two or six) to it. We must then understand the husband–wife or couple relationship, the relationship between each parent and each of their children, and the relationship between each pair of siblings. The family now becomes a system with subsystems—specifically, the couple, parent–child, and sibling subsystems (Parke & Buriel, 2006). And let's add a fourth subsystem identified by family researchers, **coparenting**, or the ways in which two parents coordinate their parenting and function well (or poorly) as a team in raising their children (Feinberg & Kan, 2016; McHale & Lindahl, 2011; McHale et al., 2002). Do they talk to each other about the children and agree on the basics of child-rearing? Have they worked out a division of responsibility for parenting? Are they consistent in their rules and enforcement of rules? And do they back one another up—or do they undermine each other's parenting, contradict one another, and compete for their children's affection? Mutually supportive coparenting can make a big difference in child development, beyond the impact of a close marital or couple relationship (Lamb & Lewis, 2015).

Now consider the complexity of an **extended family household**, in which parents and their children live with other kin—some combination of grandparents, siblings, aunts, uncles, nieces, and nephews. Extended family households are common in many cultures (Ruggles, 1994). Indeed, it has been suggested that humans evolved to involve the whole "village," or at least many members of the extended family along with a mother and father, in raising children (Hrdy, 2005). In the United States, African Americans, Hispanic Americans, and other ethnic minorities tend to place more emphasis on extended family bonds than European Americans do (Parke & Buriel, 2006). For example, African American single mothers often obtain needed help with child care and social support by living with their mothers (Burton, 1990; Oberlander, Black,

& Starr, 2007). Even when members of the extended family live in their own households, they often interact frequently and share responsibility for raising children, often to the benefit of the children.

The family is also a *system within other systems*; whether it is of the nuclear or the extended type, it does not exist in a vacuum. Urie Bronfenbrenner's *bioecological model*, a systems theory introduced in Chapter 2, emphasizes nicely that the family is a system (a microsystem, if you recall) that is embedded in and interacts with larger social systems such as a neighborhood, a community, a subculture, and a broader culture (Bronfenbrenner & Morris, 2006). The family experience in our culture is different from that in cultures where new brides become underlings in the households of their mothers-in-law or where men can have several wives (Strong & Cohen, 2017). There is an almost infinite variety of family forms and family contexts in the world and so a wide range of developmental experiences within the family.

The Family as a Changing System

It would be difficult enough to study the family as a system if it kept the same members and continued to perform the same activities for as long as it existed. However, family membership changes as new children are born, grown children leave the nest, and parents depart or die. Moreover, each family member is a developing individual, and the relationships between husband and wife, parent and child, and sibling and sibling change in systematic ways over the years. Changes in family membership and changes in any person or relationship within the family affect the dynamics of the whole system.

The earliest theories of family development featured the concept of a **family life cycle**—a sequence of changes in family composition, roles, relationships, and developmental tasks from the time people marry until they die (Duvall, 1977; Hill & Rodgers, 1964). Family theorist Evelyn Duvall (1977), for example, outlined eight stages of the family life cycle, from the married couple without children through the family with children to the aging family, as shown in ● Table 15.1. Each stage has a particular set

● **Table 15.1** Stages of the Family Life Cycle

Stage	Available Roles
1. Married couple without children	Wife Husband
2. Childbearing family (oldest child from birth to 30 months)	Wife–mother Husband–father Infant daughter or son
3. Family with preschool children (oldest child from 30 months to 6 years)	Wife–mother Husband–father Daughter–sister Son–brother
4. Family with school-age children (oldest child up to 12 years)	Wife–mother Husband–father Daughter–sister Son–brother
5. Family with teenagers (oldest child from 13 to 20 years)	Wife–mother Husband–father Daughter–sister Son–brother
6. Family launching young adults (First child gone to last child gone)	Wife–mother–grandmother Husband–father–grandfather Daughter–sister–aunt Son–brother–uncle
7. Family without children (empty nest to retirement)	Wife–mother–grandmother Husband–father–grandfather
8. Aging family (retirement to death)	Wife–mother–grandmother Husband–father–grandfather Widow or widower

Source: Adapted from Duvall, 1977.

of family members, each with distinctive roles (for example, wife, brother) and distinctive developmental tasks—for example, establishing a satisfying relationship in the newlywed phase, adjusting to the demands of new parenthood in the childbearing phase, and adapting to the departure of children in the “launching” phase.

In this chapter, we look at some of these common family transitions, but you will see that an increasing number of people do not experience this traditional family life cycle. Many adults enter into romantic relationships but remain single or childless, marry multiple times, or otherwise follow a different path than the one in which a man and woman form a nuclear family, raise children, and grow old together (Cherlin, 2009; McGoldrick et al., 2016). As a result, many family researchers today find fault with early models of the family life cycle like Duvall’s. They have embraced Duvall’s concept that family systems develop and change. However, they are expanding on the traditional family life cycle concept to describe the tremendous variety in family life cycle experiences today.

A Changing System in a Changing World

Not only is the family a system embedded within systems, and not only is it a developing system, but the world in which it is embedded is ever changing. Since the 1950s, several dramatic

social changes have altered the family experience. Here are some of the trends that have changed family life in the United States (see Cherlin, 2009; Federal Interagency Forum on Child and Family Statistics, 2015; Silverstein & Giarrusso, 2010; Wilmoth & Longino, 2006):

1. **More single adults.** More adults today than in the past are living as singles (never-married, divorced, and widowed adults). About 20% of adults age 25 and older are in the “never married” category, compared to 9% in 1960, and it is projected that more of today’s young singles will still be in the “never married” group when they reach middle age (Wang & Parker, 2014).
2. **More postponed marriages.** Do not conclude that marriage is out of style, though; almost 90% of adults can still be expected to marry at some time in their lives (Cherlin, 2009). It is mainly that marriage is being postponed—a worldwide trend. In 1960, the average age at first marriage was 20 for women and 23 for men; more recently, it is 27 for women and 29 for men (Wang & Parker, 2014).
3. **More unmarried parents.** With marriage being postponed, more and more females, especially less educated ones, are not married when they give birth. About 18% of births in 1980 but a whopping 41% of births by 2013 were to unmarried women, often parenting single-handedly (Federal Interagency Forum on Child and Family Statistics, 2015).
4. **Fewer children.** Today’s adults are also having fewer children than women in the mid-20th century did and therefore spend fewer years of their lives raising children. Increasing numbers of young women are also remaining childless: The percentage has climbed from 10% in the 1970s to almost 20% (Livingston & Cohn, 2010).
5. **More working mothers.** In 1950, 12% of married women with children younger than 6 years worked outside the home; by 2015 the figure had climbed to about 64%, a truly remarkable social change (Bureau of Labor Statistics, 2016). Almost 75% of mothers of children aged 6 to 17 are in the labor force.
6. **More divorce.** The divorce rate increased over the 20th century. More than 40% of newly married couples can expect to divorce (Cherlin, 2010), and up to half of children can expect to experience a divorce at some point in their development (Lansford, 2009).
7. **More single-parent families.** Because of more births to unmarried women and more divorce, more children live in single-parent families. In 1960, only 9% of children lived with one parent, usually a widowed one (Whitehead & Popenoe, 2003). In 2015, although 68% of children younger than 18 years lived with two parents, 24% lived with their mothers only, 4% with their fathers only, and 4% with grandparents or other nonparents (Federal Interagency Forum on Child and Family Statistics, 2015; and see ■ Figure 15.1).
8. **More remarriages.** As more married couples have divorced, more adults have remarried. Often they form new,

Figure 15.1 Percentage of children from birth to age 17 in various living arrangements. In all, 68% of children live with two parents (64% with married parents, 4% with unmarried parents). The rest (32%) do not: 24% live with their mother only, 4% with their father only, and 4% with someone else, most often grandparents.

Source: Data from Federal Interagency Forum on Child and Family Statistics. (2015). *America's children: Key national indicators of well-being, 2015*. Washington, DC: U.S. Government Printing Office. Available at childstats.gov.

reconstituted families, also called blended families, that include at least a parent, a stepparent, and one child.

9. **More years without children.** Because modern couples are having fewer children, because some divorced adults do not remarry, and mainly because people are living longer, adults today spend more of their later years as couples—or, especially if they are women, as single adults—without children in their homes. Older women are more likely than older men to live alone rather than with a spouse (32% vs. 18%), mainly because more women are widowed (Stepler, 2016).
10. **More multigenerational families.** As a result of these same trends, three- and even four-generation families became more common over the 20th century. More children today than in the past know their grandparents and even their great-grandparents, parent-child and grandparent-child relationships are lasting longer, and multigenerational bonds are becoming more important (Bengtson, 2001).
11. **Fewer caregivers for aging adults.** Yet owing to smaller families and increased longevity, more and more aging adults need care from relatives but have fewer children to provide it, some of whom (stepchildren?) may not feel much obligation to provide it (Roberto & Blieszner, 2015; Silverstein & Giarrusso, 2010).

Do you view all these changes in the family as good news or bad news? Some observers view these changes as evidence of a “decline of the family.” They emphasize the often negative effects on children of increased births to unmarried parents, divorce, and single-parent families, and the problem of more elderly adults having fewer children to support them. Some observers also worry because most Americans now view marriage as an institution whose purpose is more to meet the

emotional needs of adults than to nurture children (Cohn et al., 2011; Whitehead & Popenoe, 2003). Family scholar Andrew Cherlin (2009) adds that American children today are being harmed by a dizzying “merry-go-round” of family instability in which their parents switch from one partner to another and from singlehood to cohabitation or marriage and back in their quest for emotional fulfillment. It means that more children are not living with both of their parents, that more parents are not living with their children, and that “the family” is harder to find these days because it is not all living under one roof anymore (Cherlin, 2010).

Can you see any positives in our list of trends in family life? Some scholars can (Connidis, 2010; White & Rogers, 2000). For example, postponing marriage improves its chances of success because partners are more mature and financially stable, men’s and women’s roles in the family are more equal than they used to be now that more women work, and families are better off financially with two wage earners than with only one. Moreover, more children have relationships with their grandparents and great-grandparents. From this perspective, the family is not dying; it is just changing. It can even be characterized as a highly “adaptable institution” in that it has survived despite many social changes that could have done it in (Amato et al., 2003).

Whether it is in decline or not, the American family is more diverse than ever before. Our stereotyped image of the family—the nuclear family with a married couple consisting of a breadwinner—husband/father, a full-time housewife/mother, plus children—has become just that: a stereotype. Clearly, we must broaden our image of the family to include the many dual-career, single-parent, reconstituted, childless, and other types of families that exist today. We must also avoid assuming that families that do not fit the stereotypical family pattern are deficient.

● Checking Mastery

1. What does Urie Bronfenbrenner’s bioecological theory add to our understanding of the family?
2. What are four subsystems in a family with a mother, father, and three children?
3. What are three changes over the 20th century that have resulted in fewer children living their childhoods in a stereotypical nuclear family with a married breadwinner father and homemaker mother?

● Making Connections

1. What does it really mean to be a family? Bearing in mind the diversity of families today, offer a definition of “family” and justify it.
2. In what ways are your family’s experiences traditional and in what ways are they modern and reflective of the trends in family life over the past few decades?

15.2

The Infant

LEARNING OBJECTIVES

- Compare and contrast the traditional roles of mothers and fathers in childrearing and describe how these roles have been changing.
- Define and give an example of good coparenting and of a positive indirect effect of one parent on the other parent's interaction with their infant.

We begin this look at family development by exploring relationships between parenting and the child's development in the family from infancy to adolescence. Later, we will adopt the perspective of this child's parents and see how the family life cycle looks to them. The family is changed when a child is born, becoming a system consisting of mother, father, and infant. The main caregiving role for parents of infants is to nurture them and form secure attachments with them (see Chapter 14).

Mothers and Fathers

Once developmentalists took seriously the idea that the family is a system, they discovered the existence of fathers and began to look more carefully at how both mothers and fathers interact with and influence their children. Gender stereotypes would suggest that fathers are not cut out to care for infants and young children, but the evidence says they are (Lamb, 2013; Lamb & Lewis, 2015). For example, fathers prove to be no less able than mothers to feed their babies effectively (Parke & Sawin, 1976). And fathers, like mothers, provide sensitive parenting, form attachments with their babies, and serve as secure bases for exploration (Cox et al., 1992; Schoppe-Sullivan et al., 2006). We have no basis for thinking that mothers are uniquely qualified to parent or that men are hopelessly inept around babies. Throughout childhood, in fact, there are surprisingly few

differences between mothers and fathers in how they interact with their children (Lamb & Lewis, 2015). However, fathers' capacity for good parenting does not mean that they play the same roles as mothers in their children's lives.

Fathers today are more involved with their children than ever (Bianchi, 2011; Pleck & Masciadrelli, 2004). **Figure 15.2** shows just how much the daily lives of mothers and fathers have changed from 1965 to 2011. As women have increased their involvement in paid work, they have decreased their involvement in housework and somehow managed (by not sleeping?) to spend more time caring for their children than mothers in 1965 did. Fathers have helped make this possible by increasing their involvement in child care from 2.5 to 7 hours a week and their housework time from 4 to 10 hours a week. Some fathers are even sharing responsibility for child care equally with their spouses rather than just "helping," especially if they hold egalitarian views about gender roles (Bulanda, 2004; Deutsch, 2001). As a result, the roles of

Fathers are just as capable as mothers of sensitive, responsive parenting.

Romona Robbins Photography/Image Source/Getty Images

Figure 15.2 Changes in time use of mothers and fathers between 1965 and 2011. Roles are converging.

Source: Parker, K. & Wang, W. (2013). *Modern parenthood: Roles of Moms and Dads converge as they balance work and family*. Pew Research Center Social and Demographic Trends. Retrieved from www.pewsocialtrends.org/2013/03/14/modern-parenthood-roles-of-moms-and-dads-converge-as-they-balance-work-and-family/. Data for 1965 from Bianchi, Robinson, and Milkie, 2006; data for 2011 from Pew Research analysis of the American Time Use Survey.

mothers and fathers are converging. Yet mothers still spend more overall time with children, and more time directly caring for them and interacting with them, than fathers do (Bianchi, 2011). This gender difference in involvement in child care is common across cultures, causing some to argue that it has a biological basis.

Mothers and fathers also differ somewhat in their styles of interacting with young children. When mothers interact with their babies, a large proportion of their time is devoted to caregiving: offering food, changing diapers, wiping noses, and so on. Fathers spend much of their time with children playing (Lamb, 2013). They specialize in tickling, poking, bouncing, and surprising infants, whereas mothers hold, talk to, and play quietly with them (Laflamme, Pomerleau, & Malcuit, 2002; Neville & Parke, 1997). Yet fathers adopt a “motherlike” caregiver role if they have primary responsibility for their children, so their playful parenting may be more about being in the role of the “backup” parent than about being male rather than female (Phares, 1999). The rowdy play style shown by many fathers in our culture does not show up in all cultures, either (Lamb, 2013). It seems, then, that both nature (evolution) and nurture (societal gender-role norms) contribute to mother–father differences in parental involvement and styles of interacting with young children.

In the end, fathers contribute best to development when they, like mothers, are sensitive and responsive caregivers and form secure attachments with their infants. Children fare better cognitively, socially, and emotionally if they have a supportive father in their lives than if they do not (Holden, 2010; Lamb, 2013). However, much the same can be said for any second parent figure, male or female (Biblarz & Stacey, 2010). So fathers are important, but their contribution may not be as unique as once thought (Lamb, 2013).

Although more American fathers are involved in child care than ever before, more fathers also live apart from their children than ever before. As Livingston and Parker (2011) put it, we have “a tale of two fathers,” the engaged kind and the absent kind. What does the fact that 41% of babies are now born to unmarried mothers mean for father involvement? Unmarried fathers who do not live with their child’s mother are usually not very involved parents. However, they can be under some conditions. Studies of low-income, urban fathers over the first 3 years of their child’s life suggest that much hinges on the quality of the relationship between mother and father and on how effectively they coparent even though they do not live together (Cabrera, Fagan, & Farrie, 2008; Fagan & Palkovitz, 2011; Fagan et al., 2009; Palkovitz, Fagan, & Hull, 2013). If mother and father have a good relationship, even if it is no longer a romantic one, and if the father feels supported as a coparent, he is likely to be more involved with his child.

Unmarried mothers and their children clearly benefit when nonresident fathers become involved fathers and develop positive relationships with their children (Adamsons & Johnson, 2013). Meanwhile, becoming an involved father seems to help some young men mature and make positive changes in their lives

(Fagan et al., 2009). Interventions emphasizing the importance of fathers, good parenting, and supportive coparenting can positively affect the child’s development (Cowan et al., 2009; Marczak et al., 2015).

Mothers, Fathers, and Infants: The System at Work

Now let’s view the new family as a three-person system. The mother–child relationship cannot be understood without considering the father; nor can the father–child relationship be understood without taking the mother into account. This is because parents have **indirect effects** on their children by influencing the behavior of their partners. Family members (or subsystems of the family) can have either direct or indirect effects on one another. Direct effects within the family include, for example, a mother’s or a father’s effects on an infant’s development. Indirect effects are instances in which the relationship or interaction between two individuals in the family is modified by the behavior or attitudes of a third family member.

Fathers indirectly influence the mother–infant relationship in many ways. For example, mothers who have close, supportive relationships with their husbands tend to interact more patiently and sensitively with their babies than do mothers who are experiencing marital problems or feel that they are raising their children largely without help (Cox et al., 1992; Lamb & Tamis-Lemonda, 2004). Similarly, mothers indirectly affect the father–infant relationship. For example, fathers who have just had pleasant conversations with their wives are more supportive and engaged when they interact with their children than fathers who have just had arguments with their wives (Kitzmann, 2000). And when the mother of an infant is depressed, the father tends to devote more time to caregiving (Planalp & Braungart-Rieker, 2016). Of course, babies have indirect effects too: A screaming baby can negatively affect a couple’s relationship by causing a stressed father to blow up at his wife.

As you can imagine, infant development goes best when parents get along well. A strong relationship between partners helps both parents engage with their infant (Carlson et al., 2011). When the relationship is good, couples are also likely to coparent effectively (Parke & Buriel, 2006). When parents compete rather than cooperate, their infants may show signs of insecure attachment or may become securely attached to one parent but be blocked from enjoying close relationships with both parents (Caldera & Lindsey, 2006).

It is in the nature of systems to settle into certain patterns of functioning and to resist change, so once an unhealthy pattern of interaction such as fighting between parents becomes established, it can be difficult to change. However, family systems also show a capacity to change in response to changes both within and outside the family, so there is hope for turning maladaptive patterns of interaction into more adaptive ones (Thoburn & Sexton, 2016).

● Checking Mastery

1. In terms of their parenting roles, what is one way in which fathers are similar to mothers and one way in which they are different?
2. Give an example of a negative indirect effect of a father on the mother–infant relationship.

● Making Connections

1. Because of his wife's death during childbirth, Alex suddenly finds himself the sole parent of his infant son, Aaron. Given the material in this section, how do you think this will affect Aaron's welfare and development compared with what would have happened if Alex had been the one who died and his wife had to raise Aaron on her own?

15.3

The Child

LEARNING OBJECTIVES

- Compare and contrast the authoritarian, authoritative, permissive, and neglectful parenting styles in terms of where they fall on the acceptance–responsiveness and demandingness–control dimensions of parenting and how they are likely to affect development.
- Discuss three explanations of why high- and low-SES parents use different parenting styles.
- Define and illustrate with examples the parent effects, child effects, interactional, and transactional models of family influence.
- Summarize the nature of the sibling relationship and its contributions to development.

As children reach age 2 or age 3, parents continue to be caregivers and playmates, but they also become socialization agents. They teach their offspring how (and how not) to behave and how to become contributing members of society using child rearing and discipline techniques, teaching, and other means (Grusec & Davidov, 2010). Siblings also serve as socialization agents and become an important part of the child's developmental experience.

Parenting Styles

How can I be a good parent? Certainly this question is uppermost in most parents' minds. You can go far in understanding which parenting styles are effective by considering just two dimensions of parenting: acceptance–responsiveness and demandingness–control (Baumrind, 2013; Bornstein, 2015; Darling & Steinberg, 1993; Holden, 2010; Maccoby & Martin, 1983; Schaefer, 1959).

Parental **acceptance–responsiveness** refers to the extent to which parents are warm, supportive, sensitive to their children's needs, and willing to provide affection and praise when their children meet their expectations. Accepting, responsive parents are affectionate and often smile at, praise, and encourage their children; they consider their children's perspectives, although they also let children know when they misbehave. Less accepting and responsive parents are often quick to criticize, belittle, punish, or ignore their children and rarely communicate to children that they are loved and valued.

Demandingness–control (sometimes called *permissiveness–restrictiveness*) refers to how much control over decisions lies with the parent as opposed to with the child. Controlling and demanding parents set rules, expect their children to follow them, and monitor their children closely to ensure that the rules are followed. Less controlling and demanding parents make fewer demands and allow their children a great deal of autonomy in exploring the environment, expressing their opinions and emotions, and making decisions about their activities.

By crossing the acceptance and demandingness dimensions, we have four basic patterns of child rearing to consider, as shown in ■ **Figure 15.3**:

1. **Authoritarian parenting.** This is a restrictive parenting style combining high demandingness–control and low acceptance–responsiveness. Parents impose many rules, expect strict obedience, rarely explain why the child should comply with rules, and often rely on power-assertion tactics such as physical punishment to gain compliance.
2. **Authoritative parenting.** Authoritative parents are more flexible; they are quite demanding and exert control, but they are also sensitive to their children. They set clear rules and consistently enforce them, but they have rationales for their rules and explain them, are responsive to their children's needs and points of view, and involve their children in family decision making. They are reasonable and democratic in their approach; although it is clear that they are in charge, they communicate respect for their children.
3. **Permissive parenting** (sometimes called *indulgent parenting*). This style is high in acceptance–responsiveness but low in demandingness–control. Permissive parents are child-centered; they have relatively few rules and make relatively few demands, encourage children to express their feelings and impulses, and rarely exert control over their behavior.
4. **Neglectful parenting** (sometimes called *disengaged* or *uninvolved parenting*). Finally, parents who combine low demandingness–control and low acceptance–responsiveness are relatively uninvolved in their children's upbringing. They seem not to care much about their children. They may be hostile and rejecting or indifferent—or they may be so overwhelmed by their own problems that they cannot devote sufficient energy to expressing love and setting and enforcing rules (Maccoby & Martin, 1983).

		Parental acceptance–responsiveness	
		High	Low
Parental demandingness–control	High	Authoritative Reasonable demands, consistently enforced, with sensitivity to and acceptance of the child	Authoritarian Many rules and demands; few explanations and little sensitivity to the child's needs and perspectives
	Low	Permissive Few rules and demands; children are allowed much freedom by indulgent parents	Neglectful Few rules and demands; parents are uninvolved and insensitive to their children's needs

Figure 15.3 The acceptance–responsiveness and demandingness–control dimensions of parenting. Which combination best describes your parents' approach?

Source: From Maccoby, E. E., & Martin, J. A. (1983). Socialization in the context of the family: Parent–child interaction. In E. M. Hetherington (Vol. Ed.), P. H. Mussen (Ed.-in-Chief), *Handbook of child psychology: Vol. 4, Socialization, personality, and social development* (4th ed.). Copyright © 1983 by Wiley. Reprinted with permission.

We assume that you have no difficulty deciding that parental acceptance and responsiveness are preferable to parental rejection, hostility, neglect, or insensitivity. As you have seen in this book, warm, responsive parenting is associated with secure attachments to parents, academic competence, high self-esteem, good social skills, peer acceptance, a strong sense of morality, good mental health, and many other virtues. The benefits of perceived parent acceptance are clear across the life span (Holden, 2010; Khaleque & Rohner, 2012).

The degree of demandingness and control shown by parents is also important. The authoritarian, authoritative, and permissive parenting styles were originally identified and defined by Diana Baumrind (1967, 1977, 1991, 2013). In a pioneering longitudinal study, Baumrind found that children raised by authoritative parents were the best adjusted: They were cheerful, socially responsible, self-reliant, achievement oriented, and cooperative with adults and peers. Children of permissive parents were often impulsive, aggressive, self-centered, rebellious, aimless, and low in independence and achievement. Given little guidance, they did not learn self-control and self-direction. Children of authoritarian parents tended to be moody and unhappy, relatively aimless, and unpleasant to be around. They had little opportunity to learn self-reliance and lacked confidence in their own decision-making skills.

Subsequent research has shown that the worst developmental outcomes are associated with the neglectful, uninvolved style of parenting. Children of neglectful parents display behavioral problems such as aggression and frequent temper tantrums and tend to become hostile and antisocial adolescents who abuse alcohol and drugs and get in trouble (Lamborn et al., 1991; Miller et al., 1993; Weiss & Schwarz, 1996). Parents who provide little guidance and communicate that they do not care breed children who

are resentful and prone to strike back at their uncaring parents and other authority figures.

In short, children develop best when they have both love and limits. The link between authoritative parenting and positive developmental outcomes is evident in most ethnic groups and socioeconomic groups in the United States (Sorkhabi & Mandara, 2013; Steinberg, 2001) and in a variety of other cultures (Sorkhabi & Mandara, 2013; Vazsonyi, Hibbert, & Snider, 2003). Nonetheless, the effectiveness of different parenting approaches can differ depending on the cultural or subcultural context in which they are used. Much seems to hinge on how common a parenting style is in a culture or subculture and whether children view it as normal and acceptable (see Grolnick & Pomerantz, 2009; Lansford et al., 2005; Sorkhabi & Mandara, 2013). Case in point: African American parents living in high-crime poverty areas in the United States sometimes rely on authoritarian and even harsh parenting in an effort to protect their children from harm. Their children tend to view this as a sign that their parents care rather than as a sign of hostility and rejection. As a result, this authoritarian parenting style does not have as many negative effects as it has in middle-class communities (Deater-Deckard, Dodge, & Sorbring, 2005; Laird et al., 2009; McElhaney & Allen, 2012). We further explore the importance of cultural context in influencing the effectiveness of parenting styles in **Exploration 15.1**.

Social Class, Economic Hardship, and Parenting

Over the past few decades, economic inequality has increased in our society as a result of technological advances, globalization, and other major societal changes. Wealthy families have accumulated still more wealth while other families have seen little improvement in their finances and, in many cases, have lost what they had as a result of unemployment, housing foreclosures, and evictions (Amato, Booth, & McHale, 2015; Duncan, Magnuson, & Votruba-Drzal, 2015). As sociologist Robert Putnam (2015) demonstrates vividly in his book *Our Kids*, growing economic inequality translates into a growing gap between rich and poor kids in their developmental experiences and life outcomes. How exactly does a family's economic fortunes affect development?

Start with the fact that parents of different socioeconomic (SES) levels rely on different parenting styles in raising children—with some important implications. Compared with middle-class and upper-class parents, lower-class and working-class parents tend to place more emphasis on obedience and respect for authority. They are often more restrictive and authoritarian, reason with their children less frequently, and show less warmth and affection (Conger & Dogan, 2007; McLoyd, 1990). Parents dealing with poverty and economic hardship tend to be especially harsh and inconsistent, sometimes to the point of being abusive and/or neglectful (Brooks-Gunn, Britto, & Brady, 1999; Seccombe, 2000). You will find a range of parenting styles in any social group, of course. However, these average social-class differences in parenting help explain social-class differences in developmental outcomes such as school achievement, adjustment, and life success (Conger & Dogan, 2007).

Culture and the Tiger Mother

Sophia and Lulu could never attend sleepovers or have playdates, watch television or play computer games, get a grade less than A, or choose their own extracurricular activities or musical instruments. Their mother rejected the birthday cards they made for her one year because they were poorly done. Their mother once called Sophia “garbage” for disrespecting her. And poor 7-year-old Lulu: After she tore her musical score for “Little White Donkey” to bits during a long battle over playing the difficult piano piece, her mother put her doll-house in the car and said she’d donate it to the Salvation Army, threatened no dinner and no birthday parties for years, and called her lazy and pathetic.

Not exactly our image of the perfect parent. Amy Chua, a law professor at Yale, caused a firestorm with her book, *Battle Hymn of the Tiger Mother* (Chua, 2011a, 2011b). This “Tiger Mother” described raising her daughters, Sophia and Lulu, in what struck most American parents as an almost abusively demanding, controlling, and unresponsive manner: Authoritarian parenting to the max. Chua, meanwhile, accused American parents (including her husband) of being too child-centered and spineless. They worry too much about their children’s self-esteem, she charged, and protect their children from struggling with difficult challenges and facing criticism. They don’t view children as obligated to obey their parents and make them proud, as Chinese parents do, and they bow to their children’s desires rather than relying on their own judgment about what is best for children.

Lulu did finally play the piano piece correctly after hours more work on it, beamed at her hard-won accomplishment, and celebrated with her mother. As far as we can tell, both Sophia and Lulu have turned out pretty well: Both went to Harvard and both not only appreciated their Tiger Mother but planned to become Tiger Mothers themselves, pushing their children to be the best they can be (Carey, 2016). Is this really the model parents

should follow if they want high-achieving children?

Perhaps not. Chua admits that she went too far at times; she moved toward a more moderate parenting style, partly in response to Lulu’s rebellion. What this Tiger Mother did is also not representative of what most Chinese parents do, although they do tend to be more strict and controlling than most European American parents (Ng, Pomerantz, & Deng, 2014). How do we square the generally positive outcomes of a traditional Chinese upbringing with mounds of research suggesting that the warmer and more reasonable authoritative parenting style is the best way to raise children? Why aren’t Chinese children stressed, moody, and incapable of making their own decisions rather than achievement oriented and accomplished?

Plenty of studies say that the authoritative parenting style works well, not only for European Americans but for children from a variety of cultural and ethnic backgrounds, including Chinese-American children like Tiger Mother’s daughters (Kim et al., 2013; Sorkhabi & Mandara, 2013). Su Yeong Kim and her colleagues (2013) did an interesting study of 444 Chinese-American youth over the 8 years from early adolescence to emerging adulthood. She looked at both positive aspects of parenting (warmth, reasoning, monitoring, and democratic approach) and negative aspects (hostility, control, shaming, and punitiveness). The goal was to identify different parenting profiles. It turned out that almost half the parents fit a “supportive” profile, much like the authoritative style, in which they showed high warmth and reasonable control. Another 28% were “tiger parents” (defined as high on both positive and negative scales), 20% were easy going (low across scales), and only 7% were harsh (low warmth, high control).

As in most studies, children with supportive, authoritative parents fared best overall, academically and otherwise. By comparison, tiger parents’ children had lower grade

point averages, felt more academic pressure, experienced more depressive symptoms, and felt more alienated. At least in these Chinese-American families and with adolescents, then, tiger parenting was neither the most common approach nor the best approach. Moreover, there seems to be more acceptance and warmth to the typical Chinese parenting approach than Tiger Mother let on.

Ruth Chao (1994, 2000) concluded from her research that we must look more closely at what Chinese parenting involves and understand it in its cultural context. She maintains that Chinese parents are not really authoritarian in our Western sense of the term. In Chinese culture, training children entails parent involvement and self-sacrifice, along with an emphasis on hard work, discipline, and doing well to uphold the family’s honor. Parents are indeed demanding; they offer clear and specific guidelines for behavior, believing that this is the best way to express their love and train their children properly. Children understand that their parent’s strictness is an expression of love and that their responsibility as a child is to obey, work hard, and meet their parents’ high expectations. Parents may not explain their rules or involve their children in decision making—but children do not expect them to. Although the Chinese style seems overly controlling to European American eyes, Chinese parents and children view it as warm and caring—and thus more like authoritative parenting than like the colder, more arbitrary authoritarian style). Children respond well to it as a result.

Parents in many cultures around the world adopt a more traditional, controlling approach to parenting and get good results with it. The real moral of the Tiger Mother story is that we must always interpret parenting in its cultural and subcultural context and understand that styles that do not look acceptable to us may be acceptable and effective in other sociocultural settings.

Why do these socioeconomic differences in parenting styles and child outcomes exist? Three major explanations, all with some truth to them, center on SES differences in financial stress, resources invested in children, and cultural values and socialization goals (see Conger & Dogan, 2007; Duncan et al., 2015).

Financial Stress

One well-established explanation, developed by Glen Elder, Rand Conger, and their colleagues and called the **family stress model**, centers on the negative effects of financial stresses on parent mental health, parenting, and, in turn, child development (Conger & Dogan, 2007; Donnellan, Martin, Conger, & Conger, 2013). As shown in ■ **Figure 15.4**, Conger and his associates (1992, 2002; Conger, Patterson, & Ge, 1995) have found that parents who experience financial problems feel economic pressure, which tends to make them depressed, which increases conflict between the couple, which disrupts each partner's ability to be an effective parent. Financially stressed parents tend to be less warm and nurturant, more authoritarian, and less consistent. This breakdown in parenting then contributes to negative child outcomes such as low self-esteem, poor school performance, poor peer relations, and adjustment problems such as aggression and depression. The family stress model seems to have good support and applies across ethnic groups and cultures (Nepl, Senia, & Donnellan, 2016; Donnellan et al., 2013). It is also useful in explaining the effects of a variety of stressors on low-income parents and, in turn, children—for example, the effects of living in a dangerous neighborhood or being immigrant parents who do not speak English or understand the culture well (Duncan et al., 2015; White et al., 2009).

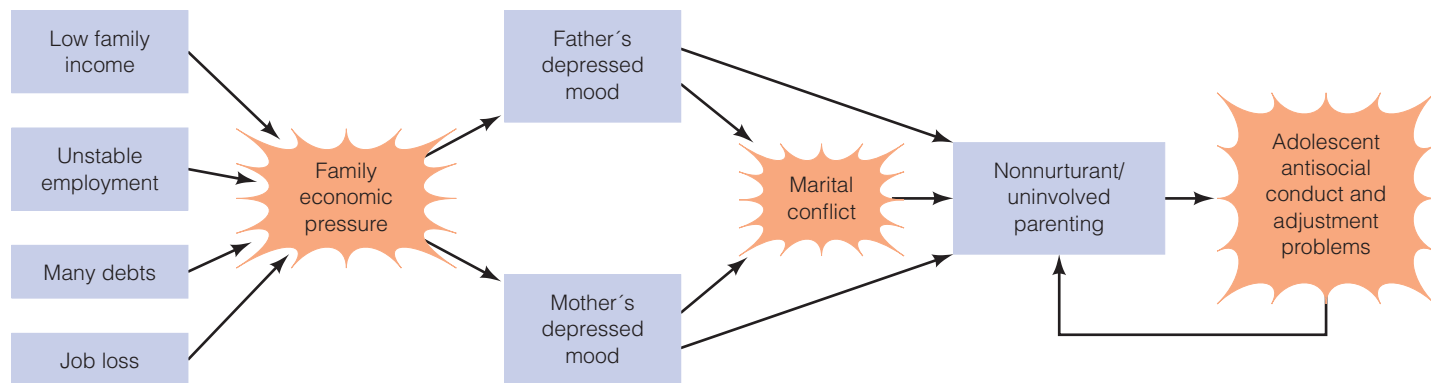

Now consider the even worse effects of poverty on development. About 20% of children in the United States—one in five—live in poverty today, more than in other Western nations (Federal Interagency Forum on Child and Family Statistics, 2015). Those affected are disproportionately children under 6, children in female-headed homes (where 46% are poor), and

minority children (39% of Black, non-Hispanic children and 30% of Hispanic children, compared to 11% of White, non-Hispanic children). Stresses are magnified for families living in poverty or moving in and out of poverty as a result of job loss and other economic crises. Both parents and children experience stress as they cope with a physical environment characterized by pollution, noise, and crowded, unsafe living conditions and a social environment characterized by family instability and violence (Duncan et al., 2015; Evans, 2004).

As noted previously, parents coping with poverty tend to be harsh, punitive, and inconsistent. Partly owing to its effects on parenting, poverty is associated with child health problems, emotional and behavioral problems, and academic failure (Bradley & Corwyn, 2002; Evans, 2004; Evans & Kim, 2013). We also know that the many chronic stressors associated with poverty can alter children's stress response systems in ways that pave the way for health and mental health problems later in life and can disrupt the development of regions of the brain that are involved in attention and self-regulation and that are therefore important in coping with challenges (Duncan et al., 2015; Evans & Kim, 2013). The negative effects of poverty on development are most severe when poverty is experienced early in life and over many years (Duncan et al., 2015; Wagmiller, 2015).

Resource Investment

A second explanation of social-class differences in parenting and child outcomes is that low-SES parents have fewer resources to invest in their children's development than high-SES parents do (Conger & Dogan, 2007; Donnellan et al., 2013; Duncan et al., 2015). Wealthier parents can invest more money and time in getting their children a good education; providing books, computers, and other learning materials in the home; taking their children to educational events; and devoting time to interacting with their children and stimulating their minds. They can also spend more on good nutrition, child care, and health care.

Cultural Values and Socialization Goals

Third and finally, high- and low-SES parents may have different values and socialization goals in socializing their children (Conger & Dogan, 2007; Duncan et al., 2015). As **Table 15.2** shows, for example, poor parents have more worries about their children’s welfare than wealthier parents do, especially when it comes to the possibility that their children could be the victims of violence, become teen parents, or get in trouble with the law. These concerns may contribute to their more authoritarian, controlling style of parenting.

High- and low-SES parents may also parent in ways that prepare their children for the kinds of jobs the parents hold. Wealthier parents may reason more with their children and foster initiative and creativity because these are the attributes that count for business executives, professionals, and other white-collar workers. Parents from lower socioeconomic groups may be authoritarian and emphasize obedience to authority figures in part because that is what is required in jobs like their own (Kohn, 1969).

In sum, low family SES and economic hardship may be associated with poor developmental outcomes because of (1) economic stresses that result in less warm and nurturant, more authoritarian, and less consistent parenting; (2) limited investment of resources, mainly money and time, in children’s development; and (3) socialization goals centered more on keeping children

out of trouble and preparing them to obey a boss rather than be the boss. These are important things to know in the wake of the economic recession of 2008 and its continuing negative effects on parents and children (Adrian & Coontz, 2010; Donnellan et al., 2013). Experimental programs designed to boost the incomes of families living in poverty can change these negative influences, putting children on a path to better achievement in school and better life outcomes (Duncan et al., 2015).

Models of Influence in the Family

So far, you have seen that parents, through their parenting, affect their children’s development. But there are other ways of thinking about influence in the family and they give us a more sophisticated understanding. Consider four different models of influence in the family: the parent effects, child effects, interactional, and transactional models.

Parent Effects Model

The study of human development has been guided through most of its history by a simple **parent effects model** of family influence (Holden, 2010; Maccoby, 2007). This model assumes that influences run one way, from parent—particularly mother—to child. This is the “blame the parents” model that Susan Klebold encountered after her son became a mass murderer. You have just reviewed research demonstrating positive and negative effects of different parenting styles on child development. But what if you turn things around: Could it be that a child’s behavior influences the style of parenting his parents adopt and that what appear to be parent effects are instead child effects?

Child Effects Model

A **child effects model** of family influence highlights the influences of children on their parents (Crouter & Booth, 2003; Sanson, Hemphill, & Smart, 2004). One good example of a child effect is the influence of a child’s age and competence on the style of parenting used with that child. For example, infants in their first year of life require and elicit sensitive care, whereas older infants who are asserting their wills and toddling here and there force parents to set limits (Fagot & Kavanaugh, 1993). Normally parents then become less restrictive as their children mature and gradually, with parental guidance, become capable of making their own decisions. As children develop, then, parenting shifts from parent regulation of the child, to parent and child coregulation of the child, to self-regulation by a now more capable child (Holden, 2010).

A child’s genetic makeup and personality also influence the parenting she receives. Is it not possible that easygoing, manageable children cause their parents to be warm and authoritative? Could not difficult, stubborn, and aggressive children help mold parents who are rejecting rather than accepting—and who either rule with an authoritarian iron hand or throw up their hands in defeat and become neglectful? The *gene–environment correlations* discussed in Chapter 3, especially evocative ones in which children evoke certain reactions from other people, are examples of

● **Table 15.2** Comparison of Parents’ Concerns for Their Children Based on Family Income Levels

Concern that your child(ren) might:	Family Income		
	\$75,000+	\$30,000–\$74,999	\$30,000
Be bullied	61%	62%	60%
Struggle with anxiety or depression	55	55	55
Be kidnapped	44	51	59
Get beat up or attacked	38	44	55
Get pregnant/Get a girl pregnant as a teenager	43	40	50
Have problems with drugs or alcohol	44	36	41
Get shot	22	29	47
Get in trouble with the law	21	25	40

Source: Parker, K., Horowitz, J. M., & Rohal, M. (2015, December 17). *Parenting in America. Outlooks, worries, aspirations are strongly linked to financial situation*. Pew Research Center, p. 49. Retrieved from www.pewsocialtrends.org/files/2015/12/2015-12-17_parenting-in-america_FINAL.pdf.

child effects. Indeed, evidence is accumulating that children’s genetically influenced characteristics can influence not only parenting styles but marital relationships and the behavior of siblings—the whole family system (Reiss & Neiderhiser, 2011).

In a clever experiment to detect child effects, Barbara Keller and Richard Bell (1979) had female college students attempt to convince 9-year-old girls to behave altruistically (for example, to spend more time sewing a pillow for a handicapped child than sewing a pillow for themselves). The girls had been coached to respond either attentively or inattentively. As expected, college students confronted with an attentive child used what Chapter 13 called induction, explaining how other children might feel if the child behaved selfishly. By contrast, college students who interacted with an inattentive child relied on power-assertion techniques such as promising rewards for altruism and threatening penalties for selfishness.

Interactional Model

The **interactional model** improves on the parent effects and child effects models by recognizing that parent and child characteristics may combine in certain ways to influence development. The concept of *gene–environment interaction* (see Chapter 3) illustrates the interactional model; for example, aggressive behavior is most likely to develop if a child has a variant of the MAO-A gene associated with temper control problems *and* is raised by an abusive parent (Caspi et al., 2002; Dodge, 2009). It takes the combination of an at-risk child and an abusive environment. There appear to be many examples of such interactions between child characteristics and characteristics of the child-rearing environment (Dodge & Rutter, 2011). They tell us that the effect of a particular parenting approach depends on the child with whom it is used, and that the effect of a particular child characteristic depends on how a child with that characteristic is parented.

Transactional Model

The interactional model is a step forward, but it focuses on what characteristics child and parent bring to their interactions—not how they change each other as they interact. In the **transactional model** of family influence, both parent effects and child effects are at work as parent and child influence one another reciprocally over time (Sameroff, 1975, 2009). Child problems may develop when *the relationship* between parent and child somehow goes bad as the two interact. We could imagine a pretty average child and a pretty average parent somehow getting off on the wrong foot and developing a toxic relationship that has increasingly negative effects on the child’s development. By the same token, healthy child development could result when, whatever characteristics parent and child bring to the relationship, the transactions between them evolve in a more positive direction over time.

As Chapter 13 revealed, antisocial behavior can result when a child who behaves aggressively elicits negative, coercive parenting and when that parenting contributes further to the child’s aggression—that is, when an escalating *coercive cycle* of influence develops (Ge et al., 1996; O’Connor et al., 1998; Williams &

Steinberg, 2011). When such a destructive family process evolves, it becomes difficult to say who is more influential, parent or child. It also becomes clear that changing the child’s problem behavior requires focusing on both parent and child.

Demonstrations of child effects, interactional effects, and transactional effects within the family are tremendously important. They mean that parents are not solely responsible for whether their children turn out “good” or “bad.” True, parents probably have more influence overall than children do on how the parent–child relationship unfolds (Holden, 2010; Kuczynski & Parkin, 2007). Yet the transactional model captures best the concept that the family is a system in which family members lead linked lives and influence one another. ● **Table 15.3** compares the models of family influence discussed in this section.

Sibling Relationships

A family system consisting of mother, father, and child is changed by the arrival of a new baby and becomes a new—and considerably more complex—family system. How do children adapt to a new baby in the house, how does the sibling relationship change as children age, and what do brothers and sisters contribute to each other’s development in the final analysis?

A New Baby Arrives

When Judy Dunn and Carol Kendrick (1982; see also Dunn, 1993, 2007) carefully studied young children’s reactions to a new sibling, they found that mothers typically pay less attention to their firstborns after the new baby arrives than before its birth. Why shouldn’t firstborns find being “dethroned” an unpleasant experience? They sometimes become more difficult and demanding, or more dependent and clingy, and they may develop problems with their sleeping, eating, and toileting routines. Most of their battles are with their mothers, but a few firstborns are not above hitting, poking, and pinching their younger brothers or sisters. Secure attachments can even become insecure (Teti et al., 1996). Although positive effects such as an increased insistence on doing things independently and helping out are also evident, it is clear that some firstborns resent losing their parents’ attention.

● **Table 15.3** Models of Family Influence

Model	Pattern of Influence
Parent effects model	Parent influences child
Child effects model	Child influences parent
Interactional model	The combination of a particular kind of child with a particular kind of parent determines developmental outcomes
Transactional model	The reciprocal influence of parent and child on one another over time determines how the parent–child relationship and the child’s development unfold

Just how common are jealous responses? Brenda Volling and her colleagues (2014) observed how 2- to 3-year-old firstborns reacted when their mothers, and separately their fathers, interacted positively with their 1-month-old siblings. The researchers expected that this stress test would arouse the attachment systems of firstborns, causing them to reduce their exploratory behavior and seek proximity to their parent. Most firstborns (60%) coped well: They watched closely and sometimes approached but often just sat quietly. Another 31% clearly found the experience threatening: They watched very intently and seemed unable to play by themselves constructively or to approach their parent for comfort. Only 3% were disruptive, actively protesting and being aggressive. Another small number (6%) were very anxious and clingy. Reactions were quite similar whether mother or father interacted with the baby. The 30% of firstborns who were clearly threatened and the 3% who were disruptive showed the most behavior problems a few months later. Overall, then, this study and others suggest that entry of a new family member perturbs the family system, but that most firstborns take interest in and adapt well to a new sibling while a minority have difficulty coping temporarily (Volling, 2012).

How can adjustment problems be minimized? It helps if both parents have good mental health and a sense of self-efficacy as parents and if they have good social support to help them cope with the challenges of parenting (Volling, 2012). Adjustment to a new sibling is also easier if the marital relationship is good and remains good after the birth and if the firstborn had secure relationships with both parents before the younger sibling arrived—and continues to enjoy close relationships with them afterward (Dunn, 2007; Teti et al., 1996). If parents continue to provide love and attention to their firstborn and maintain the child's routines as much as possible—a cause helped greatly if the father increases his involvement in child care and the two parents coparent effectively—things are likely to go well (Song & Volling, 2015; Volling, 2005).

Ambivalence in Sibling Relationships

Although most older siblings adjust well and fairly quickly to the arrival of a new brother or sister, **sibling rivalry**—the spirit of competition, jealousy, and resentment between brothers and sisters—is a normal part of sibling relationships. It may be rooted in an evolutionary fact: Although siblings are genetically related, they compete with one another for their parents' time and resources to ensure their own survival and welfare (Bjorklund & Pellegrini, 2002). Siblings may also be at odds because they live in close proximity but lack the mature social skills needed to resolve conflicts and because they often feel they are treated differently by their parents (Holden, 2010). For all these reasons, perhaps, sibling relationships typically involve both closeness and conflict and are therefore best described as ambivalent.

The number of skirmishes between very young siblings can be as high as 56 per hour (Dunn, 1993). Jealousies, bouts of teasing, shouting matches, and occasional kicks and punches continue to be part of the sibling relationship throughout childhood; squabbles are most often over possessions (McGuire et al., 2000). Thankfully, levels of conflict normally decrease after early adolescence as teenagers spend more time away from home (Furman & Buhrmester, 1992; Larson et al., 1996).

Most firstborns adjust well to the arrival of a new sibling, but sibling relationships are ambivalent—both close and rivalrous.

0 M/Shutterstock.com

Sibling relationships are friendlier and less conflicted if mothers and fathers get along well as a couple and if they respond warmly and sensitively to all their children rather than unfairly favoring one over another (Dunn, 2007). Children are wise enough to accept that differences in treatment can be fair if they are based on differences in age and competencies, but they resent seemingly unfair differences in treatment (Kowal et al., 2002).

Sibling Influences on Development

Despite its element of sibling rivalry, the sibling relationship is generally close, interactions with siblings are mostly positive, and siblings play mostly positive roles in one another's development (McHale, Updegraff, & Whiteman, 2012). Four important functions of siblings stand out:

- **Emotional support.** Brothers and sisters confide in one another, often more than they confide in their parents (Howe et al., 2000). They protect and comfort one another in rough times. Even preschoolers jump in to comfort their infant siblings when their mothers leave or when strangers approach (Stewart & Marvin, 1984).
- **Caregiving.** Siblings babysit and tend young children. Indeed, in a study of 186 societies, older children were the principal caregivers for infants and toddlers in 57% of the cultures studied (Weisner & Gallimore, 1977; and see Rogoff, 2003).
- **Teaching.** Although older brothers and sisters are not always as skilled at teaching as parents are (Perez-Granados & Callanan, 1997), they clearly feel a special responsibility to teach, and younger siblings actively seek their guidance.
- **Social experience.** Having at least one sibling to interact with can have positive effects on a child's social cognitive skills and social competence (Dunn, 2007; McHale, Kim, & Whiteman, 2006; and see Chapter 13). In their interactions with siblings, especially all those skirmishes, children learn how to take others' perspectives, read others' minds, express feelings, negotiate, and resolve conflicts.

In many societies, older siblings are major caregivers for young children. This girl in Laos looks after her brother every day.

iStockphoto.com/presdigital

So siblings provide emotional support, caregiving, teaching, and social experience. However, siblings also hold the power to affect one another negatively—as when they develop a hostile relationship or, as teens, influence one another to use drugs or engage in delinquent acts (Sisler & Ittel, 2015). And siblings can affect each other not only directly but also through the indirect effects they have on their parents—for good or ill. In an excellent illustration, Gene Brody (2003, 2004) discovered that if an older sibling is competent, this contributes positively to his mother’s psychological functioning, which makes her more likely to provide supportive parenting to a younger sibling, which in turn increases the odds that the younger sibling will also be competent. By contrast, an incompetent older sibling can set in motion a negative chain of influence in the family system leading to less

supportive parenting and less positive outcomes for the younger sibling. Interventions aimed at improving the parenting of siblings and the quality of sibling relationships can benefit the whole family (Updegraff et al., 2016).

● Checking Mastery

1. Referring to the dimensions of acceptance–responsiveness and demandingness–control, how would you characterize an authoritative parenting style?
2. What are two reasons that low-SES parents might use a more authoritarian and less warm and nurturing parenting style than high-SES parents do?
3. How would you distinguish between the interactional model and the transactional model of family influence?
4. How would you characterize the most common response of a firstborn to a new sibling?

● Making Connections

1. Alison, a 16-year-old teenager who was drunk at the time, plowed the family car into a Dairy Queen and is being held at the police station for driving under the influence. Her father must pick her up. What would you expect an authoritarian, authoritative, permissive, and neglectful father to say and do in this situation? What implications might these contrasting approaches to parenting have for this young woman’s development?
2. If only the child effects model of family influence were at work, what behavior by children do you think would be most likely to push parents to use each of the four main parenting styles: authoritarian, authoritative, permissive, and neglectful?

15.4

The Adolescent

LEARNING OBJECTIVES

- Describe how the parent–child relationship both changes and remains the same in early adolescence.
- Discuss how parents can best foster autonomy and how the process may differ in individualistic versus collectivist cultures.

When you picture the typical relationship between a teenager and her parents, do you envision a teenager who is out all the time with friends, resents every rule and restriction, and rolls her eyes or talks back at every opportunity? Do you imagine parents wringing their hands in despair and wondering if they will survive their children’s adolescent years? Many people believe that the period of the family life cycle during which parents have adolescents in the house is a particularly stressful time, with close parent–child relationships deteriorating into bitter tugs-of-war. How much truth is there to these characterizations?

Ripples in the Parent–Child Relationship

Contrary to belief, most parent–adolescent relationships are close, and most retain whatever quality they had in childhood (Collins & Laursen, 2006). It is rare for a parent–child relationship to suddenly turn bad at adolescence; more likely, a troubled parent–adolescent relationship has grown out of a troubled parent–child relationship and has been shaped by both the parent’s parenting and the child’s personality and behavior (Eisenberg et al., 2008).

Parent–child conflict escalates in early adolescence, but it is generally about minor issues.

Corbis/SuperStock

Yet the parent–child relationship does change during adolescence. Time spent together decreases as adolescents become more involved with peers. This can make adolescents feel less involved with and supported by their parents (Collins & Laursen, 2006; De Goede, Branje, & Meeus, 2009). Parent–child conflict also increases temporarily in early adolescence, around the onset of puberty (McGue et al., 2005; Shanahan et al., 2004). Young adolescents assert themselves, and they and their parents squabble more. The bickering is mainly about minor matters such as disobedience, homework, household chores, and privileges (Collins & Laursen, 2006). These skirmishes in early adolescence alter the parent–child relationship—not so much its closeness as the balance of power between parents and adolescents, as we will now see.

Achieving Autonomy

A key developmental task of adolescence is achieving **autonomy**, or the capacity to make decisions independently and manage life tasks without being overly dependent on other people. If adolescents are to “make it” as adults, they cannot be rushing home for reassuring hugs after every little setback or depending on parents to get them to work on time or manage their checkbooks. Achieving autonomy is about establishing an identity separate from one’s parents and preparing to leave the nest and fly on one’s own.

As children reach puberty and become more physically and cognitively mature and more capable of acting autonomously, they assert themselves more. As they do so, their parents give up some of their power, adolescents assume more control of their lives, and the parent–child relationship becomes more equal (De Goede et al., 2009; Steinberg, 2011). It is usually best for the development of autonomy if adolescents maintain close attachments with their parents and

parents maintain authoritative control but also gradually grant teens more responsibility for decision making (Lamborn & Steinberg, 1993; Longmore, Manning, & Giordano, 2013). Gaining some separation from parents is healthy; becoming detached from them is not (Beyers et al., 2003). A blend of autonomy and attachment, or independence and interdependence, is the goal.

From this point of view, it is healthy for teens to argue some with their parents. True, fighting can be damaging if it goes too far and results in mutual hostility and Patterson’s coercive cycles (see Chapter 13). However, in most families parent–adolescent conflict fosters autonomy by helping teens formulate their own values and beliefs and learn how to negotiate and resolve conflicts (Noller & Atkin, 2014).

How much autonomy adolescents want and how much parents grant differ from culture to culture. In individualistic cultures like ours, autonomy is clearly prized, whereas in collectivist cultures maintaining respect for parents and family harmony are valued more (McElhaney & Allen, 2012; Pomerantz et al., 2011). Studying different ethnic groups in the United States, Andrew Fuligni (1998) discovered that Filipino and Mexican American adolescents are more likely than European American adolescents to believe that they should not disagree with their parents, and Chinese American adolescents are less likely to expect the freedom to go to parties and to date at a young age. In collectivist Asian cultures like China, parents continue to be in command, the balance of power does not shift as much, and the quest for autonomy is less evident, at least during early and middle adolescence, than in the United States. Yet most adolescents in both individualistic and collectivist cultures strive for—and will eventually achieve—more autonomy than they displayed as children.

Across cultures, adolescents are most likely to become autonomous, achievement oriented, and well-adjusted if their parents consistently enforce a reasonable set of rules, involve their teenagers in decision making, recognize their need for greater autonomy, monitor their comings and goings, gradually loosen the reins, and continue to be warm, supportive, and involved throughout adolescence (Holden, 2010; Lamborn et al., 1991; Longmore et al., 2013). In short, the winning approach is usually authoritative parenting.

When parents are extremely strict and controlling and stifle autonomy, or when they are extremely lax and fail to guide and monitor their adolescents, teens are likely to become psychologically distressed, rebel, socialize with the wrong crowds, and get into trouble (Goldstein, Davis-Kean, & Eccles, 2005; Lamborn et al., 1991; Van Petegem, 2015). Keep in mind, though, that in some cultural and subcultural contexts a more authoritarian style or a more permissive style may also produce good outcomes (Garcia & Gracia, 2009; McElhaney & Allen, 2012; Steinberg, Dornbusch, & Brown, 1992). In **Exploration 15.2**, we ask an interesting question: Does the helicopter parenting favored by some American parents today interfere with the development of autonomy among their college-aged children?

Helicopter Parents and the Quest for Autonomy

Are your parents helicopter parents? The term **helicopter parenting** refers to developmentally inappropriate levels of control and assistance to late adolescents and emerging adults—also called overparenting (Segrin et al., 2013, 2015). Helicopter parents try to micromanage their children’s lives during the college years, and often beyond, through such tactics as closely monitoring their children’s activities through frequent texting and calling, looking into job opportunities and arranging dentist appointments and activities for them, calling their professors about unfair grades, trying to settle disputes with their roommates, and generally removing obstacles in their paths and orchestrating their success. Some helicopter parents may fit the authoritarian parenting profile, but most seem to be

loving and mostly authoritative parents who try too hard to be good parents. By hovering over their children and solving problems for them, do they help their children succeed or do they inhibit the development of autonomy and self-reliance?

Parent involvement in children’s lives is generally a good thing, but overinvolvement may not be. College students who report on scales that their parents engage in helicopter parenting tactics also report negative self-perceptions and low self-efficacy (Bradley-Geist & Olson-Buchanan, 2014; LeMoyné & Buchanan, 2011; van Ingen et al., 2015). They are prone to use medication for anxiety and depression (LeMoyné & Buchanan, 2011), and they are not very engaged in school (Padilla-Walker & Nelson, 2012). They tend to show high levels

of narcissism (an inflated sense of self and sense of entitlement) and poor coping skills (Segrin et al., 2013). Importantly, they have low levels of self-perceived autonomy and competence, which, in turn, are linked to more depression symptoms and lower life satisfaction (Schiffirin et al., 2014).

So helicopter parents may do more harm than good. They may inhibit the growth of autonomy in their adolescent and emerging adult children and might do better encouraging their children to rely on themselves rather than on their parents. Without longitudinal research, however, we cannot rule out the possibility that child effects are operating. That is, students who are struggling to cope with life may prompt their parents to hover over them.

● Checking Mastery

1. What do the parent–adolescent conflicts of early adolescence generally concern?
2. What parenting style is most likely to foster autonomy, and why?

● Making Connections

1. At age 13, Miki moved from Japan to the United States with her family and now finds her relationship with her

parents strained. Drawing on the material in this section, how would you analyze what is going on?

2. Analyze how your parents (or those of one of your high school friends) handled (or mishandled) the parenting challenge of maintaining a close relationship with their teen, maintaining reasonable authoritative control, and allowing for greater autonomy. Use specific examples to illustrate your points.

15.5

The Adult

LEARNING OBJECTIVES

- Characterize the major effects on couples of the first year of marriage, new parenthood, raising two or more children, entering the empty nest phase of family life, and grandparenting.
- Summarize how marital, sibling, and parent–child relationships are likely to change during adulthood.

So far we have offered a child’s-eye view of family life. How does it look to adults? We will follow a couple through the establishment, new-parenthood, child-rearing, empty nest, and grandparenthood phases of the family life cycle.

Establishing a Marriage

In U.S. society, almost 90% of adults choose to marry at some point in their lives (Cherlin, 2009). Although love and marriage go together in most modern societies today, in many traditional

societies marriages are not formed on the basis of love. They are arranged by leaders of kin groups who are concerned with acquiring property, allies, and the rights to any children the marriage produces (Ingoldsby & Smith, 1995; Regan, 2008). So in reading what follows, remember that the modern, Western way of establishing families is not the only way.

Marriage is a significant life transition for most adults: it involves taking on a new role (as husband or wife) and adjusting to life as a couple. We rejoice at weddings and view newlyweds as supremely happy beings. Indeed, they feel on top of the world,

The honeymoon is great, but for many couples marital satisfaction declines somewhat during the first year of marriage.

Elyse Lewin/Photographer's Choice/Getty Images

their self-esteem and sense of mastery rise, and their emotional distress level drops (Chen, Enright, & Tung, 2016; Mernitz & Kamp Dush, 2016).

However, Ted Huston and his colleagues have found that the honeymoon is often short (Huston, 2009; Huston, McHale, & Crouter, 1986; Huston & Melz, 2004; Huston et al., 2001). In their longitudinal study of newlywed couples, perceptions of the marital relationship became less favorable and marital satisfaction declined during the first year after the wedding. Behavior changed as well: “One year into marriage, the average spouse says, ‘I love you,’ hugs and kisses their partner, makes their partner laugh, and has sexual intercourse about half as often as when they were newly wed” (Huston & Melz, 2004, p. 951). Although partners spend only slightly less time together, more of that time is devoted to getting tasks done and less to having fun or just talking.

Most couples are far more satisfied than dissatisfied with their relationships after the “honeymoon” is over. Moreover, high marital satisfaction holds steady for some couples while it is declining for others (Lavner & Bradbury, 2010; Lorber et al., 2015). Still, adapting to marriage clearly involves some strains. Blissfully happy relationships often evolve into still happy but more realistic ones. Whether this happens because couples begin to see “warts” that they did not notice before the marriage when they were “blinded by love,” stop trying to be on their best behavior, have run-ins as an inevitable part of living together and coping with life’s problems, or start taking each other for granted, it is normal.

Does the quality of a couple’s relationship early in their marriage have implications for their later marital adjustment? Newlyweds believe their blissful feelings will endure or even increase, even though these feelings will, in fact, decline on average (Lavner, Karney, & Bradbury, 2013). However, Huston and his colleagues found that, compared with couples who were happily married after 13 years, couples who remained married but were unhappy had had relatively poor quality relationships all along (Huston et al., 2001; Huston, 2009). Even as newlyweds these couples acted more negatively toward each other than couples

who stayed married and remained happy in their marriages. Couples who divorced early were even more negative toward each other early in their relationship.

So the establishment phase of the family life cycle involves a modest loss of enthusiasm on average, although not for all. Couples seem most likely to survive when they can maintain a high level of positive and supportive interaction to help them weather the conflicts that inevitably arise in any relationship (Fincham, 2003; Gottman, 2011).

New Parenthood

By age 40, 85% of women have given birth to a child and 76% of men have fathered one (Martinez, Daniels, & Chandra, 2012). How does the arrival of a new baby affect a mother, a father, and their relationship? (Gay and lesbian families are discussed in Section 15.6.) Some people believe that having children draws a couple closer together; others believe that children strain a relationship. Which is it?

On average, new parenthood is best described as a stressful life transition that involves both positive and negative changes (Cowan & Cowan, 2000; Nomaguchi & Milkie, 2003). On the positive side, parents claim that having a child brings them joy and fulfillment and contributes to their own growth as individuals (Emery & Tuer, 1993; Palkovitz, 2002). But couples have added new roles (as mothers and fathers) to their existing roles (as spouses, workers, and so on), and new parents often find juggling work and family responsibilities challenging. They not only have a lot of new work to do as caregivers, but they also lose sleep, worry about their baby, find that they have less time to themselves, and sometimes face financial difficulties. All of this adds up to stress.

In addition, couples often adopt more traditional gender-role attitudes and divide their labors along more traditional lines—a phenomenon called the *parental imperative* (see Chapter 12). She specializes in the “feminine” role by becoming the primary caregiver and housekeeper, often reducing her involvement in work outside the home and increasing her hours of labor inside the home, while he emphasizes his “masculine” role as provider and works harder in his job (Cowan & Cowan, 2000; Katz-Wise, Priess, & Hyde, 2010; McClain & Brown, 2016). As Figure 15.2 suggested, mothers’ and fathers’ roles are converging. Yet time-use diaries suggest that, even among highly educated and dual-career couples that equally share tasks before the birth, new mothers take on more than 2 hours of added work a day, compared to 40 minutes more for new fathers (Yavorsky, Kamp Dush, & Schoppe-Sullivan, 2015).

What are the effects of increased stress and of sharper gender-role differentiation? Marital satisfaction typically declines somewhat in the first year after a baby is born and continues to decline thereafter (Doss et al., 2009; Gottman & Notarius, 2000; Mitnick, Heyman, & Smith Slep, 2009). This decline is often steeper for women than for men, mainly because they usually do the lion’s share of child care (Levy-Shiff, 1994; Noller, 2006), and it’s steeper when couples do adopt more traditional gender roles (McClain & Brown, 2016). Especially for mothers, self-esteem and sense of mastery, which rise when adults marry, fall when they become parents (Chen et al., 2016). Yet some new parents experience the transition as a bowl of cherries, others as the pits—as a

New parenthood brings joy, but it is also a stressful transition involving new challenges.

Cultura Creative (RF)/Alamy Stock Photo

full-blown crisis in their lives. What might make this life event easier or harder to manage? Characteristics of the baby, the parent, and the social context all count.

A baby who is difficult (for example, cries endlessly because of colic) creates more stresses and anxieties for parents than an infant who is quiet, sociable, responsive, and otherwise easy to love (Levy-Shiff, 1994; Russell & Lincoln, 2016). Parent characteristics matter too. Parents who have good problem-solving and communication skills, are in good mental health, and find adaptive ways to restructure their lives to accommodate a new baby adjust well (Cox et al., 1999; Levy-Shiff, 1994). Similarly, parents who have realistic expectations about parenthood and about infants and children tend to adjust more easily than those who have an unrealistically rosy view (Kalmuss, Davidson, & Cushman, 1992). It also helps to have a sense of self-efficacy as a parent, something women are more likely to have than men (Fillo et al., 2015; Gross & Marcussen, 2016).

Finally, the social context can make a big difference to the new parent. Most important is social support, possibly from friends and relatives but especially from a partner. Things go better for a new mother when she has a good relationship with her partner and when he does his fair share of child care and housework than when she has no partner or an unsupportive one (Demo & Cox, 2000; Levy-Shiff, 1994). When a mother feels that she has less

quality time with her partner and thinks that the division of labor is unfair, her marital satisfaction drops (Dew & Wilcox, 2011). Well aware that new parenthood is a stressful transition for many couples, developmental scientists have developed preventive interventions to help expecting mothers and fathers prepare realistically for the challenges ahead and support each other as they deal with these challenges (Schulz, Cowan, & Cowan, 2006). Strengthening supportive coparenting—helping couples work as a team—can improve the couple’s relationship, their relationships with the new child, and their child’s development (Feinberg & Kan, 2016; McClain & Brown, 2016).

In sum, parents who have an easy baby to contend with; who possess positive personal qualities and coping skills; and who receive support from their partners and other people are in the best position to cope adaptively with new parenthood, a transition that is normally both satisfying and stressful and that can undermine marital satisfaction.

The Child-Rearing Family

Having a second child is more likely when the experience of having the first child is positive (Margolis & Myrskylä, 2015). What can parents look forward to during their child-rearing years if they do have additional children? A heavier workload! The stresses and strains of caring for a toddler are greater than those of caring for an infant, and the arrival of a second child means added stress (O’Brien, 1996). Parents complain of the hassles of cleaning up food and toys, constantly keeping an eye on their children, and dealing with their perfectly normal but irritating demands for attention, failures to comply with requests, and bouts of whining. A mother who is raising multiple children as a single parent or a mother whose partner is not very involved may find herself without a moment’s rest as she tries to keep up with two or more active, curious, mobile, and dependent youngsters.

Because the workload increases when a second child is born, fathers often become more involved in child care (Dunn, 2007). Indeed, now that most mothers work outside the home, half or more of both moms and dads in dual-career families say they find it difficult to balance work and family; it’s no longer just a woman’s problem (Parker & Wang, 2013). Work-family conflict is especially common when children are young (Erickson, Martinengo, & Hill, 2010). Working parents are also subject to **spillover effects**—positive or negative effects of events at work on family life and effects of events at home on work (Barnett, 1994; Crouter, 2006). After parents have a stressful day at work, for example, they tend to be withdrawn from their spouse and children and angry and irritable if provoked (Repetti, Wang, & Saxbe, 2009). By contrast, a rewarding, stimulating job can have positive effects on a parent’s interactions within the family (Greenberger, O’Neil, & Nagel, 1994).

Additional challenges sometimes arise for parents when their children enter adolescence. As you saw earlier, parent–child conflicts escalate for a while in early adolescence. Moreover, parents’ conflicts with each other over how to raise their adolescent children can stress their marriage (Cui & Donnellan, 2009). When the firstborn child in the family reaches puberty, marital love and satisfaction often decline further (Whiteman, McHale, &

Crouter, 2007). Mothers of middle school students have a lower sense of well-being than either mothers of infants or mothers of adult children (Luthar & Ciciolla, 2016).

Middle-aged parents are also affected by how well adjusted their children are. They may have difficulty maintaining a sense of well-being if their children are experiencing problems or are having trouble launching themselves successfully into adulthood (Greenfield & Marks, 2006). The negative effects on parents' mental health of a child's problems as a teenager can still be detected in old age (Milkie, Norris, & Bierman, 2011). Here, then, is another example of child effects within the family system. But it works the other way, too: When parents are unhappy or are experiencing marital problems, parenting and parent-child relationships can deteriorate, placing teens at greater risk for problems such as delinquency, alcohol and drug use, anxiety, depression, and emotional distress (Chung, Flook, & Fuligni, 2009; Cui, Conger, & Lorenz, 2005).

Children clearly complicate their parents' lives by demanding everything from fresh diapers and close monitoring to college tuition. By claiming time and energy that might otherwise go into nourishing the marital relationship and by adding stress to their parents' lives, children seem to have a negative—although typically only slightly negative—effect on marital satisfaction through the child-rearing years (Gorchoff, John, & Helson, 2008; Kurdek, 1999; Rollins & Feldman, 1970). Yet when parents are interviewed about parenthood, they emphasize the positives, saying that parenthood has contributed a great deal to their personal development and made them more responsible and caring people (Palkovitz, 2002).

The Empty Nest

As children reach maturity, the family becomes a “launching pad” that fires adolescents and young adults into the world to work and start their own families. The term **empty nest** describes the family after the departure of the last child. It can bring moments of deep sadness:

Pamela automatically started to toss Doritos and yucky dip into her cart—and then remembered. “I almost burst into tears,” she recalls. “I wanted to stop some complete stranger and say, ‘My son’s gone away to college.’ I had such a sense of loss.” (Span, 2000, p. 15)

But it brings moments of celebration to other parents:

We can find the TV remote. The only dirty dishes are in the dishwasher. No doors slam at 2 a.m. The floors are clothes-free zones. We always know where the car keys are. Grocery bills are mere double-digits. (Kelly, 2013, p. B2)

On balance, parents react more positively than negatively to the emptying of the nest. Whereas the entry of children into the family causes modest decreases in marital satisfaction, the departure of the last child seems to be associated with increases, especially for women (Bouchard, 2014; Gorchoff et al., 2008; White & Edwards, 1990). After the nest empties, women often feel that their marriages are more equitable and that their spouses are more accommodating to their needs (Mackey & O'Brien, 1995; Suitor, 1991). Only a

minority of parents find this transition disturbing or depressing and suffer from what has been called “empty nest syndrome.”

Why are parents generally not upset by the empty nest? First, they have fewer roles and responsibilities and therefore experience less stress and strain. Second, they have more opportunity to focus on their relationship; for women, increased enjoyment of time with their partners is a key reason for increased marital satisfaction (Gorchoff et al., 2008). Third, parents are likely to view the emptying of the nest as evidence that they have done their job of raising children well and have earned what Erik Erikson called a sense of generativity (Mitchell & Lovegreen, 2009). One 44-year-old mother put it well: “I have five terrific daughters who didn't just happen. It took lots of time to mold, correct, love, and challenge them. It's nice to see such rewarding results.” Finally, most parents continue to enjoy a good deal of contact with their children after the nest empties, so it is not as if they are really losing the parent-child relationship (White & Edwards, 1990).

What if the children don't leave or come flying back? In recent years, an increasing number of adult children have been remaining in the nest, or leaving and then refilling it in a kind of “boomerang effect.” In fact, for the first time in modern times, living with parents has become the most common living arrangement for 18-to-34-year olds in the United States (Fry, 2016). In 1960, only about 20% of Americans aged 18 to 34 lived with parents, whereas 62% lived with a spouse or partner (Fry, 2016). Now 32.1% live with parents, 31.6% with a spouse or partner. More years in school, lack of financial means to live independently, and postponement of marriage have all played a role in this change. Over 40% of Canadians and Europeans in this age range live with their parents, so the United States may only be catching up to the rest of the Western world (Rampell, 2016).

Boomerang children who return home are often unemployed, have limited finances, are divorced or separated, or have experienced other difficulties or delays getting their adult lives off the ground (Bouchard, 2014; Ward & Spitze, 1992; White & Rogers, 1997). Most empty nest parents adapt well to their children's return, especially if they are responsible young adults who are attending school, working, or otherwise making progress toward flying on their own (Aquilino, 2006; Parker, 2012; Ward & Spitze, 2004).

Grandparenthood

Although we tend to stereotype grandparents as white-haired, jovial elders who knit mittens and bake cookies, most adults become grandparents when they are middle-aged, not elderly (Conner, 2000; Connidis, 2010). Becoming a first-time grandparent can be a wonderful milestone in an adult's life; Leslie Stahl (2016), reporter on the program *60 Minutes*, said this: “I nearly swooned, staring at her like a lover. . . Aha! There it was. We grandmas literally, actually, fall in love” (p. 63).

Grandparenting styles are diverse, as illustrated by the results of a national survey of grandparents of teenagers that identified three major styles of grandparenting (Cherlin & Furstenberg, 1986):

1. **Remote.** Remote grandparents (29% of the sample) were symbolic figures seen only occasionally by their grandchildren. Primarily because they were geographically distant, they were emotionally distant as well.

2. **Companionate.** This was the most common style of grandparenting (55% of the sample). Companionate grandparents saw their grandchildren frequently and enjoyed doing things with them. They only rarely played a parental role and liked it that way. As one companionate grandparent put it, “I’m happy to see them when they come and I’m happy to see them go” (Bates & Taylor, 2013, p. 59).
3. **Involved.** Finally, 16% of the grandparents took on a parent-like role. Like companionate grandparents, they saw their grandchildren frequently and were playful with them, but unlike companionate grandparents, they often helped with child care, gave advice, and played other practical roles in their grandchildren’s lives. Indeed, some involved grandparents lived with and served as substitute parents for their grandchildren because their daughters or sons could not care for the children themselves. More and more grandparents today, especially in African American and Hispanic families, are the primary parent figures for their grandchildren (Hayslip, 2009).

You can see, then, that grandparenting takes many forms but that most grandparents see at least some of their grandchildren frequently and prefer a companionate role that is high in enjoyment and affection but low in responsibility. Most grandparents find the role gratifying, especially if they *do* see their grandchildren frequently (Connidis, 2010; Hayslip et al., 2015). Although being a grandparent does not in itself boost life satisfaction, contact with grandchildren does, for grandmothers at least (Bouchard & McNair, 2016). Yet parents control grandparents’ access to their grandchildren, and grandparents may suffer if they suddenly lose all contact with their grandchildren because their child loses a custody battle or they fall out of favor with a son- or daughter-in-law (Bates & Taylor, 2013; Hayslip et al., 2015).

Grandparents have been called “the family national guard” because they must be ever ready to come to the rescue when

there is a crisis in the family and they never know when they will be called (Hagestad, 1985). Grandmothers often help their daughters adjust to new parenthood and aid with child care when their grandchildren are very young—or step in to raise grandchildren when an unmarried teenage daughter gives birth or a son or daughter divorces, cannot make it in a bad economy, develops a drug problem, or dies (Dunn, Fergusson, & Maughan, 2006; Seltzer & Yahirun, 2013).

Grandparents who do get “called to duty” often contribute greatly to their grandchildren’s development. Indeed, maternal grandmothers have probably been the most important helpers of mothers throughout history and continue to be important today (Coall & Hertwig, 2011). A grandmother who mentors a young single mother and coparents with her can help her gain confidence and competence as a parent and optimize her grandchildren’s development (Dunifon, 2013; S. E. Oberlander et al., 2007). A close grandparent–grandchild relationship can also protect the child of a depressed mother from becoming depressed (Silverstein & Ruiz, 2006). And although teenagers raised by single mothers tend to have low educational attainment and high rates of problem behavior on average, they resemble children raised by two parents if they are raised by a single mother and a grandparent (DeLeire & Kalil, 2002; Dunifon, 2013).

Involved grandparenting can take a toll on grandparents, however. These grandparents are often poor or have health problems and sometimes suffer from stress, depression, and deteriorating health when grandchildren move in with them and they must become the primary parents (Hayslip et al., 2015; Musil et al., 2011).

Changing Family Relationships

What becomes of relationships between spouses, siblings, and parents and children over the adult years? All family relationships develop and change with time.

Marital Relationships

As you have seen, marital satisfaction dips somewhat after the honeymoon period is over, dips still lower in the new-parenthood phase, continues to drop during the child-rearing years, and may recover only when the children leave the nest, especially for women. This U-shaped curve in marital satisfaction over the phases of the family life cycle does not affect all but does suggest that parenthood takes something away from a couple’s relationship.

The character of marital relationships also changes over the years. Frequency of sexual intercourse often decreases (see Chapter 12), and the love relationship often changes from one that is passionate to one that is companionate, more like a best-friends relationship (Bierhoff & Schmohr, 2003; Reis & Aron, 2008). With age, couples become more affectionate and experience fewer negative emotions (Carstensen, Levenson, & Gottman, 1995; Smith et al., 2009).

Overall, though, knowing what stage of the family life cycle an adult is in does not tell us much about how satisfied that person is with his marriage. Personality is far more important. Happily married people have more agreeable personalities than unhappily

Most grandparents prefer and adopt a companionate style of grandparenting in which the idea is to have fun.

Blend Images - KidStock/Brand X Pictures/Getty Images

married people; for example, they are more emotionally stable and vent negative feelings less often (Robins, Caspi, & Moffitt, 2000). Moreover, in happy marriages, the partners' personalities are similar and are likely to remain so or become even more similar over the years, as each partner reinforces in the other the traits that brought them together in the first place (Caspi, Herbener, & Ozer, 1992; Gonzaga, Campos, & Bradbury, 2007).

Over the years, romantic partners affect each other's development. For example, having a conscientious spouse is related to occupational success for both men and women—apart from the effects of their own conscientiousness (Solomon & Jackson, 2014). This may be because a conscientious partner contributes to a satisfying life at home. Meanwhile, Denis Gerstorff and his colleagues (2009) studied older married couples averaging 75 years of age over a 10-year period. If a husband had good memory skills, his wife was less likely to suffer a decline in memory performance over the next 2 years. If a wife was depressed, her husband was likely to experience increased symptoms of depression and decreased memory performance. These and other studies show that we really do lead linked lives and that, consistent with the transactional model of family influence, we influence and are influenced by our partners in close relationships.

By the time they reach age 65 or older, about 72% of men are married and live with their wives but only 42% of women are married and live with their husbands (Federal Interagency Forum on Aging Related Statistics, 2012). Marriages face new challenges when one of the partners becomes seriously ill or impaired and needs care. As our upcoming discussion of caregiver burden will suggest, wives may develop physical and mental health problems and become socially isolated when they must care for a dying husband. However, they typically manage to cope with their spouse's death and rebuild their lives (Connidis, 2010; and see Chapter 17). The family life cycle ends with widowhood.

Without question, the marital relationship is centrally important in the lives and development of most adults (Finkel et al., 2015). Overall, married adults tend to be “happier, healthier, and better off financially” than unmarried adults and are likely to remain so if they can weather bad times in their marriages (Waite & Gallagher, 2000). Married adults even live longer (Robles et al., 2014).

Sibling Relationships

The sibling relationship is typically the longest-lasting relationship we have, linking us to individuals who share many of our genes and experiences throughout our lives (Cicirelli, 1991; Connidis, 2010; Greif & Woolley, 2016). Today, of course, sibling relationships involve not only biological siblings but often half siblings, stepsiblings, and adoptive siblings. These relationships too can be close, conflicted, or, for most of us, ambivalent.

Relationships between siblings often change for the better once they no longer live together in the same home. In a recent study asking 261 adults age 40 and older about their sibling relationships (Greif & Woolley, 2016), it was clear that conflict and rivalry had decreased and feelings of warmth and equality had increased since childhood. Whereas 46% reported fighting and arguing with their sibs as children, only 12% reported conflict in their current relationships. Moreover, these adults generally trusted their siblings, viewed them as supportive, and appreciated their importance.

Some of the ambivalence that characterizes sibling relationships during childhood carries over into adulthood, however (Cicirelli, 1995; Connidis, 2010). Siblings may compete with one another as they build their lives. And whereas siblings who enjoyed a close relationship during childhood are likely to be drawn closer after significant life events such as a parent's illness or death, siblings who had poor relationships during childhood may clash in response to the same life events—for example, bickering about who is doing more to help an ailing parent or how a deceased parent's estate should be divided (Lerner et al., 1991; Ross & Milgram, 1982). Adult siblings who perceive that their parents played favorites when they were children or play favorites now do not get along as well as those who believe their parents have treated them equitably—evidence that parents have an indirect effect on the quality of sibling relationships (Greif & Woolley, 2016; Suito et al., 2009).

Parent–Child Relationships

Parent and child generations in most families are in close contact and enjoy affectionate give-and-take relationships throughout the adult years. When aging parents eventually need support, children are there to help.

Evolving Relationships. Even after emerging adults have left the nest, there are likely to be some tensions along with the love in most parent–child relationships (Birditt & Fingerman, 2013). Parents can become stressed when their adult children have problems or when they are asked to help solve those problems; children can become irritated when their parents try to meddle in their lives or demand more of them than they want to give (Birditt et al., 2009; Blieszner, 2006; Connidis, 2010). Because parents and children are at different points in the life cycle, parents are often more invested in the parent–child relationship than children who are busy building their own families are. As a result, the well-being of parents is often positively affected when their children marry or become parents, but negatively affected when their children experience divorce or other negative events (Kalmijn & De Graaf, 2012).

Adult children have an opportunity to negotiate a new phase of their relationship with their parents in which they move beyond playing out roles as child and parent, see their parents as “real people” with flaws, understand them better, get past any strains in their relationship during adolescence, and become more like friends (Birditt & Fingerman, 2013; Birditt et al., 2008; Tasi, Telzer, & Fuligni, 2013). A more mutual, friendlike relationship is especially likely to evolve if parents were supportive, authoritative parents earlier in the child's life (Belsky et al., 2001). Young adults whose parents are highly supportive of them tend to be better adjusted than those who lack continued parent support (Fingerman et al., 2012).

When children are middle-aged and their parents are elderly, the two generations typically continue to care about, socialize with, and help each other (Umberson & Slaten, 2000). Aging mothers enjoy closer relations and more contact with their children, especially their daughters, than aging fathers do (Umberson & Slaten, 2000). And Hispanic American, African American, and other minority group elders often enjoy more supportive relationships

Many Hispanic American families benefit from close relationships and lots of mutual support across generations.

Tim Mantoani/Masterfile

with their families than European Americans typically do, especially when it comes to living together or near one another and providing mutual help (Bengtson, Rosenthal, & Burton, 1996; Sarkisian, Gerena, & Gerstel, 2007).

Typically, relationships between the generations are not only close but equitable: Each generation gives something, and each generation gets something in return (Conner, 2000; Markides, Boldt, & Ray, 1986). If anything, aging parents give more (E. Brody, 2004; Fingerma n & Birditt, 2011). Aging families do *not* typically experience what has been called **role reversal**, in which the parent becomes the child and the child becomes the caregiver. Only when parents reach advanced ages and develop serious physical or mental problems does the parent–child relationship sometimes become lopsided like this and usually it is only for a short time (Connidis, 2010; Fingerma n & Birditt, 2011).

Caring for Aging Parents. Elaine Brody (1985, 2004) uses the term **middle generation squeeze** (others call it the *sandwich generation* phenomenon) to describe the situation of middle-aged adults pressured by demands from both the younger and the older generations simultaneously (see also Grundy & Henretta, 2006; Zarit & Talley, 2013). Imagine a 55-year-old woman caring for her daughter’s children (and maybe even her granddaughter’s children) as well as for her own ailing parents (and possibly her grandparents). That’s middle generation squeeze!

Adults with children who still depend on them increasingly find themselves caring for their aging parents too; about one-third of women ages 55–69 report helping members of both the older and younger generations (Grundy & Henretta, 2006). As a result of the global economic recession of 2008, more middle-aged parents in many countries are being called upon to provide more financial support for longer to their young adult children while also helping their aging parents (Parker & Patten, 2013).

Spouses or partners are the first in line to care for frail elders. The burden of caregiving can be especially heavy for aging and sometimes frail husbands and wives (Zarit & Heid, 2015). One 84-year-old

woman who had been caring for her 86-year-old husband was driven to suicide and explained her suicide attempt this way:

As he got worse, it got very, very bad, . . . mentally, for me to cope . . . But I didn’t ever say anything because that’s just what I had to do. . . I could not stand another 24 hours. . . I asked my husband more than once, wouldn’t he like some of those people to come in and help him? At least bathe and things like that. . . He said no. (Adelman et al., 2014, p. 1052, 1054)

If spouses are not available or up to the challenge, caregiving responsibility falls on adult children (Silverstein & Giarrusso, 2010). Daughters spend more time than sons providing emotional support to aging parents and in-laws and carry more of the burden overall, although sons are about as involved as daughters in providing help with practical tasks and financial assistance (Chesley & Poppie, 2009). Traditional gender-role norms call for women to be the **kinkeepers** of the family—the ones who keep family members in touch with each other and handle family problems when they arise (Brody, 2004).

In our society, most aging parents strongly resist having to live with and be dependent on their children. They prefer to live close to but not with their children; they enjoy their independence and do not want to burden their children when their health fails (Connidis, 2010; Brody, 2004). However, families remain the major providers of care for the frail elderly today. We see little support for the view that today’s families have abandoned or failed to meet their responsibilities to their oldest members. However, concerns are now being expressed about whether children whose parents divorced or stepchildren will be as supportive of older adults, especially fathers and stepfathers, in future years (Silverstein & Giarrusso, 2010; Stein, 2009). **Exploration 15.3** looks at how the Chinese government’s one-child policy and rapid industrialization have affected care of elders in China.

Middle-aged adults who must foster their children’s development while tending to their own development and caring for aging parents sometimes find their situation overwhelming. They may experience **caregiver burden**—psychological distress associated with the demands of providing care for someone with physical or cognitive impairments (Adelman et al., 2014; Knight & Losada, 2011; Zarit & Talley, 2013). Caring for an ailing loved one can be rewarding and can even have beneficial effects on health and well-being (Brown et al., 2009). Yet many adult children providing such care experience emotional, physical, and financial strains and suffer for it (Pinquart & Sorensen, 2006). A woman who is almost wholly responsible for a dependent elder may feel angry and resentful because she has no time for herself. She may experience role conflict between her caregiver role and her roles as wife, mother, and employee (Stephens et al., 2001, 2009). This can undermine her sense of well-being and put her at risk for depression.

Caregiver burden is likely to be heavier if:

- the recipient of care has Alzheimer’s disease or another form of dementia rather than physical health problems and engages in the disruptive and socially inappropriate behavior that often accompanies dementia (Chiao, Wu, & Hsiao, 2015; Pinquart & Sorensen, 2003);

● EXPLORATION 15.3

Caring for Aging Parents in China

Qilai Shen/Getty Images

In the collectivist society of China, daughters-in-law have traditionally been the first choice as caregivers for aging parents. Aging parents have often been taken in by a son, usually the oldest,

and cared for by his wife (Youn et al., 1999). But this tradition is changing. The Chinese government's long-running policy of allowing only one child per family has limited the number of potential caregivers available to aging parents. Meanwhile, rapid industrialization has meant that many of these children, especially in rural areas, have left to find work in the cities (Raymo et al., 2015; Zhang, 2009). For many Chinese elders, then, the emptying of the nest, which is happening more often now than in the past, is not the positive milestone

it is for many American parents. Instead, it tends to be associated with a sense of abandonment and with loneliness, depression, low life satisfaction, and low income (Bouchard, 2014; Gao et al., 2014; Zhai et al., 2015).

Chinese elders in urban areas are faring better. Although they do not as often live with their children as they used to, they have better pensions, medical care, and housing than rural elders. And more and more are living together and providing one another with support. Yet with about a third of the Chinese population expected to be older than 60 by 2050, a crisis looms: One child may need to support two parents and up to four grandparents without sufficient help from the government (Beech, 2013). This may be one reason the Chinese government has now relaxed its one-child-per-family policy. Yet as more countries' aging populations balloon, more societies will face challenges like China's.

- the caregiver lacks personal resources such as a secure attachment style (Karantzas, Evans, & Foddy, 2010; Morse et al., 2011);
- the caregiver lacks social support—especially in the form of a supportive marriage (Brody et al., 1992; Scharlach, Li, & Dalvi, 2006; Stephens et al., 2009);
- cultural and contextual factors do not support caregiving; for example, white caregivers devote fewer hours to care but feel more burdened by it than African American caregivers do, possibly because of differences in cultural norms regarding family responsibility for elder care (Kosberg et al., 2007).

In short, the caregivers most likely to experience caregiver burden are those who must care for parents or spouses with dementia and associated behavioral problems, who lack personal resources such as a secure attachment style, and who lack social and cultural support for caregiving.

What can be done for burdened caregivers? Behavior management training, anger management training, and cognitive behavioral therapy can help caregivers sharpen their caregiving skills, teach their aging parents self-care skills, learn to react less negatively to the difficult behavior often shown by elderly adults with dementia, and cope with the stress associated with their role and the conflicts that may arise between it and their other roles (Zarit, 2009; Zarit & Talley, 2013). Respite services that give caregivers a break now and then can also be tremendously important. Mainly,

family caregivers need to be recognized as the most important sources of care for aging adults and integrated into long-term care service systems for aging adults (Qualls, 2016).

● Checking Mastery

1. Compare how new parenthood and the empty nest affect marital satisfaction.
2. What are three factors that can make new parenthood a stressful transition?
3. Which of the three main grandparental roles do grandparents prefer, and what does it involve?
4. What are two factors that might increase the caregiver burden on a middle-aged woman caring for her ailing mother?

● Making Connections

1. Martha has just married George and wonders how her experience of the events in the traditional family life cycle is likely to differ from his. Can you enlighten her?
2. You may want to ask your mother, but to what extent does the research on changes in the marital relationship and in parent-child relationships (relationships with both parents and children) apply to your mother? If there are differences, why do you think they arose?

15.6

Diverse Family Experiences

LEARNING OBJECTIVES

- Describe the “typical” implications of never marrying, cohabiting with a partner, remaining childless, living in a dual-career family, and living in a gay or lesbian family.
- Discuss the “typical” effects of divorce on parents and children and what factors are likely to make for good adjustment.

Useful as it is, the traditional family life cycle concept does not capture the tremendous diversity of family experiences today. Some adults never marry, and some of those live alone, whereas others cohabit with a romantic partner, heterosexual or homosexual, sometimes raising children together, sometimes not. Some, married or not, never have children. And an increasing number of adults change their family circumstances—for example, marrying, divorcing, and then cohabiting or remarrying. Let us examine some of these variations in family life.

Singles

It is nearly impossible to describe the “typical” single adult. This category obviously includes young adults who have not yet married. Because adults have been postponing marriage, the number of young, single adults has grown considerably (Cohn et al., 2011). Singles also include middle-aged and elderly people who never married or who experienced divorce or the death of a spouse. Overall, as **Figure 15.5** shows, the percentage of adults

Figure 15.5 The percentage of U.S. adults who are married fell between 1960 and 2010, while the percentages of never married and divorced or separated adults rose. Postponement of marriage accounts for much, but not all, of the drop in the percentage of adults who are married.

Source: Cohn, D., Passel, J. S., Wang, W., & Livingston, G. (2011). *Barely half of U.S. adults are married—A record low*. Washington, DC: Pew Research Center Social & Demographic Trends. Retrieved from www.pewsocialtrends.org.

who are married has dropped considerably since 1960, whereas the percentages of never-married and divorced or separated adults have grown.

What do we know about the 10% or so of adults who never marry? Stereotypes suggest that they are miserably lonely and mal-adjusted. However, single adults often make up for their lack of spouse and children by forming close bonds with siblings, friends, or younger adults who become like sons or daughters to them (Connidis, 2010; Rubinstein et al., 1991). It is divorced or widowed rather than never-married single adults who tend to be least happy with their singlehood in old age (Pudrovskaya, Schieman, & Carr, 2006).

Many single adults enter into romantic relationships that may or may not lead to marriage. **Cohabitation**, living with a romantic partner without being married, is on the rise, to the point that most marriages are now preceded by cohabitation (Cohan, 2013). Unmarried people live together for a variety of reasons (Cohan, 2013; Connidis, 2010):

- **Convenience:** They are in a romantic relationship and want an affordable living arrangement or get tired of commuting to be together.
- **Trial marriage:** They live together to find out whether they are compatible enough to marry.
- **Alternative to marriage:** They have no intention to marry. Some reject the concept of marriage. Some are older adults who want companionship but do not want to jeopardize their financial situation or upset their children by remarrying (Brown, Bulanda, & Lee, 2012; Connidis, 2010). Some of these older adults decide instead to “live apart together,” maintaining their own households but staying at each other’s places with some frequency (Benson & Coleman, 2016).

It makes sense to think that couples who live together before marrying would have more opportunity than those who do not to determine whether they are truly compatible before they tie the knot. Yet couples who live together and then marry are, on average, more dissatisfied with their marriages and more likely to divorce than couples who do not live together before marrying (Cohan, 2013). How can this be?

One explanation is that cohabiters are different from people who marry without cohabiting; for example, they tend to be younger and lower in income and they may have less conventional family attitudes and less commitment to marriage as an institution (Booth & Johnson, 1988; Cohan, 2013). This is less likely to be the reason, though, as more and more couples cohabit. Indeed, in European countries where cohabitation is widespread and well-accepted and gender attitudes are more egalitarian,

cohabiting women are no less happy than married women (Lee & Ono, 2012).

A second explanation is that many adults who cohabitate do not go into it with an intention to marry but end up marrying anyway, largely out of inertia (Stanley et al., 2010). That is, some couples whose relationship is not very strong may slide into more nights in the same bed without a commitment to each other and marry only because their lives and assets have become entangled and it has become difficult to leave (Cohan, 2013; Stanley et al., 2010).

If partners are engaged before they decide to live together, if they have not cohabited with other partners before, and if they do not have a child before they marry, their odds of marital success improve (Cohan, 2013; Tach & Halpern-Meehin, 2009). But if couples who live together have characteristics that make them poor bets for marital success or if they marry out of inertia rather than true love, their marriages are more likely to fail.

Many cohabiting couples have children. Even when biological parents cohabit, they are more likely than a married couple to break up and to have limited income. As a result, their children tend to perform more poorly in school and have more mental health and behavior problems on average than children of married parents (Ganong, Coleman, & Russell, 2015).

Childless Married Couples

Many married couples who remain childless want children but cannot have them. However, a growing number of adults voluntarily decide to delay having children or to be “child free” (Abma & Martinez, 2006; Allen & Wiles, 2013; Keizer, Dykstra, & Jansen, 2008).

Trying and failing to conceive a child is a difficult and demoralizing experience (Schwerdtfeger & Shreffler, 2009). Yet childlessness generally does not diminish the well-being of adults and sometimes boosts it (Umberson, Pudrovska, & Reczek, 2010). Indeed, the marital satisfaction of childless couples tends to be higher than that of couples with children during the child-rearing years (Hansen, 2012; Kurdek, 1999). And middle-aged and elderly childless couples are no less satisfied with their lives than parents whose children have left the nest (Rempel, 1985; Bures, Korpcekyj-Cox, & Loree, 2009). Children apparently do not guarantee happiness; nor does not having children doom people to an unhappy adulthood (Connidis, 2010).

Gay and Lesbian Families

What are the family experiences of gay men, lesbian women, and other sexual minority adults like? They are most notable for their diversity (Goldberg, 2009; Peplau & Fingerhut, 2007; Rith & Diamond, 2013). Generally, gay and lesbian relationships evolve through the same stages of development, are satisfying or dissatisfying for the same reasons, and are typically as rewarding as those of married or cohabiting heterosexuals (Kurdek, 1995, 2006; Peplau & Fingerhut, 2007). Sexual minority couples end their relationships more than married heterosexual couples do but at about the same rate as cohabiting heterosexual couples (Rith & Diamond, 2013). We know very little about the relationships of LGBT adults in later life (Kimmel, Hinrichs, & Fisher, 2015).

This lesbian couple has twins, thanks to a sperm donation. Research tells us that the children of gay and lesbian parents generally turn out much like children of heterosexual couples on average. The secret to success in any family is good parenting.

67 Photo/Alamy Stock Photo

In the United States, several million gay men and lesbian women are parents, most through previous heterosexual relationships, others through adoption, artificial insemination, or surrogate parents. Some no longer live with their children, but others raise them as single parents and still others raise them in families that have two mothers or two fathers. Other gay men and lesbian women live as singles or as couples without children throughout their lives, some forming families that consist of a group of friends (Diamond & Butterworth, 2009).

Gay and lesbian families face special challenges, as evidenced by our continuing national struggles over gay marriage even after the Supreme Court ruling legalizing it. These families are often not fully recognized as families by society and are sometimes victims of discrimination (Peplau & Fingerhut, 2007; Rith & Diamond, 2013). For example, a gay or lesbian person's life partner may not be embraced as a full member of the family, allowed to make life-and-death decisions if their partner becomes ill, or given custody of the partner's children if the partner dies (Connidis, 2010). In one study, the well-being of the children of sexual minority individuals was linked to the extent to which the social climate of the area in which they lived was supportive of sexual minorities (Lick et al., 2012).

Contrary to myth, gay and lesbian couples usually do not have one adopt the traditional “husband” role and the other the “wife” role (Rith & Diamond, 2013). Instead, relationships are usually egalitarian; partners share responsibilities equally and tend to work out a division of labor based on who is especially talented at or does not mind doing certain tasks (Huston & Schwartz, 1995). After they become parents, most couples report that their child has two very involved parents, although the biological parent usually takes the lead role (Goldberg & Perry-Jenkins, 2007; Rith & Diamond, 2013).

What are the implications for children of being raised by gay or lesbian parents? Comparing lesbian mothers with heterosexual

mothers in two-parent and single-parent homes, Susan Golombok and her colleagues (2003) discovered that lesbian mothers tend to hit children less and to engage in imaginative and domestic play more but are otherwise similar to heterosexual mothers. Moreover, children who lived with two parents of the same sex had better developmental outcomes than children living with a single mother, and they were no different than children living with two heterosexual parents. Lesbian couples are more likely than either gay couples or heterosexual couples to engage in supportive coparenting—a factor associated with good child adjustment (Farr & Patterson, 2013). These studies and others suggest that gay and lesbian adults who raise children are at least as likely as heterosexual parents to parent effectively and to produce competent and well-adjusted children (Farr, Forssell, & Patterson, 2010; Ganong et al., 2015; Goldberg, 2009; Rith & Diamond, 2013). Moreover, their children are typically no more likely than the children of heterosexual parents to develop a homosexual or bisexual orientation, although they may become more flexible in their thinking about sexual identity issues (Ganong et al., 2015).

Divorcing Families

Progress through the family life cycle is disrupted when a married couple divorces. Divorce is not just one life event. Rather, divorce—and the same can be said of the separation of a cohabiting couple—is a series of stressful experiences for the entire family that begins with difficulties before the divorce or separation and includes a complex series of life changes as the relationship unravels and family members reorganize their lives (Amato, 2000, 2010; Demo & Fine, 2010; Hetherington & Kelly, 2002). Why do couples divorce (or separate)? What effects does divorce typically have on family members? And how can we explain why some adults and children thrive after a divorce whereas others experience persisting problems?

Before the Divorce

Scholars have pieced together a profile of the couples at highest risk for divorce (Amato, 2010; Demo & Fine, 2010; Kitson, 1992; Teachman, 2002). Generally they are young adults, in their 20s and 30s, who have been married for an average of only about 7 years (hence the term “seven year itch”?) and who often have young children. Couples are especially likely to divorce if they married as teenagers, had a short courtship, conceived a child before marrying, and are of low SES—all factors that might suggest an unreadiness for marriage and unusually high financial and psychological stress accompanying new parenthood. Difficult personalities and alcohol or drug abuse often play a role as well.

Couples typically divorce because they feel their marriages lack communication, emotional fulfillment, or compatibility. Wives tend to have longer lists of complaints than their husbands do and often have more to do with initiating the breakup (Hewitt, Western, & Baxter, 2006; Thompson & Amato, 1999). Whereas, historically, divorce was considered a drastic step taken only when adultery, desertion, abuse, or a similar crisis was involved, starting in the late 20th century it came to be viewed as an action to be taken when people do not feel fulfilled in their relationship (Cherlin, 2009). Most divorcing couples experience a few years

of marital distress and often try separations before they make the final decision to divorce (Demo & Fine, 2010; Kitson, 1992).

After the Divorce

Most families going through a divorce experience it as a genuine crisis—a period of considerable disruption that often lasts at least 1–2 years (Amato, 2000; Demo & Fine, 2010; Hetherington, 2006). The wife, who usually ends up as the primary caregiver for any children, is likely to be distressed, although she is often relieved as well. The husband is also likely to be distressed, particularly if he did not want the divorce and feels shut off from his children. Both individuals must revise their identities and their relationship. Both may feel isolated from former friends and unsure of themselves in new romantic relationships. Divorced women with children are likely to face the added problem of getting by with considerably less money (Amato, 2000). Because of these stressors, divorced (or separated) adults are at higher risk than married adults for depression and other forms of psychological distress, physical health problems, and even death (Amato, 2000; Kamp Dush, 2011, 2013; Sbarra, Law, & Portley, 2011).

As you might suspect, psychologically distressed adults do not make the best parents. Moreover, children going through a divorce do not make the best children because they too are suffering. They are often angry, fearful, depressed, and guilty, especially if they believe that they were somehow responsible for their parents’ breakup (Buehler, Lange, & Franck, 2007; Hetherington, 1981). They may be whiny, dependent, disobedient, and disrespectful.

Mavis Hetherington and her associates (Hetherington, Cox, & Cox, 1982; Hetherington & Kelly, 2002) have found that stressed custodial mothers often become impatient and insensitive to their children’s needs. In terms of parenting styles, they tend to become less authoritative and less consistent; they occasionally try to seize control of their children with a heavy-handed, authoritarian approach, but more often they fail to carry through in enforcing rules and make few demands that their children behave maturely (see also Demo & Buehler, 2013). Noncustodial fathers, meanwhile, are likely to be overly permissive, indulging their children during visitations (Amato & Sobolewski, 2004). Good coparenting becomes a challenge.

This is not the formula for producing well-adjusted, competent children. A vicious circle of the sort described by the transactional model of family influence can result: Children’s behavioral problems make effective parenting more difficult, and deterioration in parenting aggravates children’s behavioral problems. When this breakdown in family functioning occurs, children are likely to display academic problems and adjustment difficulties at school, behavior problems ranging from aggression to depression, and strained relations with peers (Ehrenberg et al., 2014; Hetherington, 2006).

Families typically begin to pull themselves back together about 2 years after the divorce, and by the 6-year mark most differences between children of divorce and children of intact families have disappeared (Hetherington & Kelly, 2002). Yet even after the crisis phase has passed, divorce can leave a residue of negative effects on as many as 25% of children into adulthood (Amato, 2006; Hetherington & Kelly, 2002). For example, as adolescents,

children of divorce are less likely than other youth to perceive their relationships with their parents, especially their fathers, as close and caring (Amato, 2010; Woodward, Fergusson, & Belsky, 2000). Adults whose parents divorced are also less likely than adults from intact families to marry and more likely to experience relationship problems and divorce or separation if they do (Afifi & Denes, 2013; Amato, 2006).

However, some of the problems observed in children of divorce are evident before the divorce and are actually the result of marital conflict rather than divorce (Demo & Buehler, 2013; Lansford, 2009). Mark Cummings and his colleagues have shown that couples who fight all the time become irritable parents, which in turn causes their children to become emotionally upset and poorly adjusted (Cummings & Davies, 2010).

Moreover, not all families experience divorce as a major crisis with negative effects; some even grow as a result of their experience (Demo & Fine, 2010; Hetherington & Kelly, 2002). Some adults feel better about themselves and their lives after extracting themselves from a bad marriage. And children may benefit when they escape a conflict-ridden two-parent family, which is more detrimental to a child's development than a cohesive single-parent family (Afifi & Denes, 2013; Amato, 2006). In short, the impacts of divorce vary widely; it is not always best to “stay together for the good of the children.”

Influences on Adjustment

Several factors can help facilitate a positive adjustment to divorce and prevent lasting damage (Demo & Fine, 2010; Ehrenberg et al., 2014; Ganong et al., 2015):

1. **Adequate financial support.** Families fare better after a divorce if the noncustodial parent, usually the father, pays child support and the family has adequate finances (Amato & Sobolewski, 2004; Marsiglio et al., 2000).
2. **Good parenting by the custodial parent.** If the custodial parent can manage to remain authoritative and consistent, children are far less likely to experience problems (Hetherington, 2006; Weaver & Schofield, 2015).
3. **Good parenting by the noncustodial parent.** Children may suffer when they lose contact with their noncustodial parent over time, as a quarter or so of children living with their mothers do (Cheadle, Amato, & King, 2010; Demo & Cox, 2000). Continued father involvement is generally a plus so long as the father is not a harsh, hostile person (Coley, Carrano, & Lewin-Bizan, 2011; Elam et al., 2016).
4. **Minimal conflict between parents.** Children should be protected from continuing marital conflict and efforts by parents to undermine each other in their children's eyes after the divorce (Elam et al., 2016; Ganong et al., 2015; Lansford, 2009). When parents can agree on joint custody, both parents' and

Most children adjust to being part of a reconstituted family, but it can be challenging for a while, especially when both partners bring children to remarriage.

Catchlight Visual Services/Alamy Stock Photo

children's adjustment tends to be better (Bauserman, 2002, 2012). When the mother has custody, supportive coparenting in which parents coordinate and cooperate can help keep fathers close to and involved with their children and reduce behavior problems (Amato, Kane, & James, 2011; Sobolewski & King, 2005).

5. **Additional social support.** Divorcing adults are less depressed if they have close confidants than if they do not (Menaghan & Lieberman, 1986). Children also benefit from support from close friends (Lustig, Wolchik, & Braver, 1992).
6. **Minimal other changes.** Generally families do best if additional changes are kept to a minimum—for example, if parents do not have to move, get new jobs, and so on (Buehler et al., 1985–1986). It is easier to deal with a couple of stressors than a mountain of them.
7. **Personal resources.** Finally, personal resources such as intelligence, emotional stability, and good coping skills often put some individuals—even some members of the same family—on a more positive trajectory than others after a divorce (Demo & Fine, 2010; Lansford, 2009).

Interventions for divorced parents can improve their parenting skills and, in turn, their children's adjustment (Forgatch & DeGarmo, 1999; Sandler et al., 2015). Children can benefit from school-based programs in which they and other children of divorce can share their feelings and learn positive coping skills (Grych & Fincham, 1992; Pelleboer-Gunnink et al., 2015). As Paul Amato (1993) concludes, adjustment to divorce will depend on the “total configuration” of stressors the individual faces and on the resources he has available to aid in coping, including both personal strengths and social supports.

Reconstituted Families

Within 3–5 years of a divorce, about 75% of single-parent families experience yet another major transition when a parent remarries and the children acquire a stepparent—and sometimes new siblings (Hetherington & Stanley-Hagan, 2000; and see McGoldrick et al., 2016; Teachman & Tedrow, 2008). Because about 60% of remarried couples divorce, an increasing number of adults and children today find themselves on a merry-go-round of cohabitation or marriage, conflict, separation or divorce, and remarriage or cohabitation (Cherlin, 2009).

How do children fare when their custodial parent remarries? The first few years are a time of disruption as a new family system takes shape and new family roles and relationships are ironed out (Hetherington & Stanley-Hagan, 2000). The difficulties are likely to be worse if both parents bring children to the family than if only one parent does (Hetherington, 2006). Girls sometimes have more trouble adjusting

than boys: They are often so closely allied with their mothers that they may resent either a stepfather competing for their mother's attention or a stepmother attempting to play a substitute-mother role. Most adapt with time, but on average adolescents in reconstituted or blended families with children from more than one marriage, like children in single-parent families after a divorce, are less well-adjusted than adolescents in intact two-parent families (Hetherington, 2006). Stepparents too may suffer (Pace & Shafer, 2015).

There is hope, though. Outcomes are better when children whose mothers remarry maintain good relationships with both their mother and stepfather (Amato, King, & Thorsen, 2016; King, Amato, & Lindstrom, 2015). And training for parents in newly reconstituted families can improve parenting skills, strengthen coparenting, and reduce child behavior problems at school, as well as enhance the couple's relationship (Bullard et al., 2010).

What should we conclude overall about the implications of today's diverse families for child development? It's quite simple. As Mavis Hetherington (2006) concludes, "It is family process rather than family structure that is critical to the well-being of children" (p. 232). That is, children and adolescents can thrive in any type of family as long as they receive good parenting.

● Checking Mastery

1. What are two main reasons that cohabitation before marriage is associated with later marital problems?
2. What kind of parenting should divorcing parents provide if they want to prevent adjustment problems in their children?
3. After a divorce, how does a custodial parent's remarriage typically affect the children?

● Making Connections

1. Three months after her divorce from Alex, Blanca has become depressed and increasingly withdrawn. Her son Carlos, age 7, has become a terror around the house and a discipline problem at school. How might (a) the parent effects model, (b) the child effects model, (c) the interactional model, and (d) the transactional model of family influence explain what is going on in this single-parent family?
2. Suppose you are a counseling psychologist and Blanca comes to you for advice on how she and her family can deal most effectively with their divorce. What would you tell her based on research on factors affecting adjustment to divorce?

15.7

The Problem of Family Violence

LEARNING OBJECTIVES

- Describe the various forms that family violence can take.
- Illustrate how characteristics of the abuser, child, and social context can all contribute to child abuse.
- Summarize the effects of child abuse on victims and two approaches to preventing abuse.

As this chapter makes clear, family relationships are as basic to human development through the life span as food and water. At the same time, families can be the cause of much anguish and of development gone astray. Nowhere is this more obvious than in cases of family violence:

From a young age, I have had to grow up fast. I see families that are loving and fathers who care for their children, and I find myself hating them. . . . I have nightmares pertaining to my father. I get angry and frustrated when family is around. (St. George, 2001, p. A20)

These sobering words were written by Sonyé Herrera, an abused adolescent who for years had been hit, threatened with guns, choked, and otherwise victimized—and had witnessed her mother abused—by an alcoholic father. The abuse continued even after the couple divorced. At age 15, unable to stand any more, Herrera had her father charged with assault, but he returned one afternoon, hit her, and shot and killed both her and her mother before turning his gun on himself (St. George, 2001).

Child abuse, mistreating or harming a child physically, emotionally, or sexually, is perhaps the most visible form of family violence. Every day, infants, children, and adolescents are burned,

bruised, beaten, starved, suffocated, sexually abused, or otherwise mistreated by their caretakers (Del Vecchio, Eckardt Erlanger, & Smith Slep, 2013; Miller & Knudsen, 2007). Accurate statistics are hard to come by because much abuse goes unreported, but official statistics for the United States suggest that, in 2013, 1 of every 100 children under age 18 was the victim of substantiated **child maltreatment**, a broad term that includes both child abuse and neglect of the child's basic needs (Federal Interagency Forum on Child and Family Statistics, 2015). Of all maltreated children, 76% overall are neglected, 17% physically abused, 8% sexually abused, 8% emotionally or psychologically abused, and 9% experience other types of maltreatment. Many children experience more than one of these types of maltreatment, which is why the percentages add up to more than 100%. Rates of maltreatment decrease with the age of the child.

Child abuse commands a good deal of attention and tugs at our heartstrings, but the potential for abuse exists in all possible relationships within the family system (Tolan, Gorman-Smith, & Henry, 2006). Children and adolescents batter, and in rare cases kill, their parents (Agnew & Huguley, 1989). Siblings, especially brothers, abuse one another in countless ways, especially if there is violence elsewhere in the family (Hoffman, Kiecolt, &

Child abuse occurs in all ethnic and racial groups, often when a vulnerable parent is overwhelmed by stress.

iStockphoto/Sturti

Edwards, 2005). And spousal or intimate partner abuse appears to be the most common form of family violence worldwide. Globally it has been estimated that about one-third of women are beaten, coerced into sex, or emotionally abused by their partners (Murphy, 2003). In the United States, surveys suggest that about 15% of couples experience physical violence in a year, ranging from pushing to use of weapons (Heyman, Foran, & Wilkinson, 2013; Straus & Gelles, 1990). This means that millions of children witness domestic violence and are harmed by what they see (Grych, Oxtoby, & Lynn, 2013; McDonald et al., 2006).

Elderly adults are targets of family violence too. Frail or impaired older people are physically or psychologically mistreated, neglected, financially exploited, and stripped of their rights—most often by stressed adult children or spouses serving as their caregivers (Jayawardena & Liao, 2006; Nerenberg, 2008). Around 5% of elderly adults are probably neglected or abused in various ways (Tolan, Gorman-Smith, & Henry, 2006).

Family violence is not a pretty picture. Here is a social problem of major dimensions that causes untold suffering and harms the development of family members of all ages. What can be done to prevent it, or to stop it once it has started? To answer this question, we must understand why family violence occurs.

Why Does Child Abuse Occur?

Various forms of family violence have many similarities, and the contributors are often similar (Tolan et al., 2006). Because child abuse, especially physical abuse, has been studied the longest, we will look at what has been learned about how characteristics of the abuser, the abused, and the social context contribute to it.

The Abuser

The abusive parent is most often a young mother who is likely to have many children, to live in poverty, to be unemployed, and to have no partner to share her load (U.S. Department of Health and Human Services, 2007; Wolfner & Gelles, 1993). Yet child

abusers come from all races, ethnic groups, and social classes. Many of them appear to be fairly typical, loving parents—except for their tendency to become extremely irritated with their children and to do things they will later regret.

A few reliable differences between parents who abuse their children and those who do not have been identified. First, *child abusers tend to have been abused as children*. Although most maltreated children do not abuse their own children when they become parents, a relatively high percentage, about 30%, do (Institute of Medicine & National Research Council, 2014). Adults who have been abused and neglected as children are also more prone than those who were not maltreated to engage in other forms of violence—partner violence and violent crime (Milaniak & Widom, 2015).

This “cycle of violence” is an example of a broader phenomenon, the **intergenerational transmission of parenting**, or the passing down from generation to generation of parenting styles, whether abusive or positive (Conger, Belsky & Capaldi, 2009). What is behind the intergenerational transmission of abusive parenting? One possibility, suggested by Albert Bandura’s social cognitive theory, is observational learning—for example, of a harsh style of parenting and the use of force. Genetics (for example, genes associated with an explosive temper and aggression passed from parent to child) may also contribute. And epigenetic effects cannot be ruled out; the stress of being abused could alter the expression of genes that affect parenting and make for an over-reactive stress response system later in life (McGowan et al., 2009; Moore, 2015; and see Chapter 3 on epigenetic effects).

Notice that the intergenerational transmission of abusive parenting does *not* occur for about 70% of abuse victims, though. Some harshly treated children are protected from becoming abusive by their temperament (Scaramella & Conger, 2003). Others have supportive partners who keep them from becoming overly harsh parents (Conger, Schofield, & Neppl, 2012). Still others seek psychotherapy and are helped by it (Maxwell et al., 2016).

Second, *abusive mothers are often battered by their partners* (Coohey & Braun, 1997; McCloskey, Figueredo, & Koss, 1995). Many abusive mothers may have learned through their experiences both as children and as romantic partners that violence is the way to solve problems, or they may take out some of their frustrations about being abused on their children.

Third, *abusers often have mental health problems*. Only about 1 in 10 has a severe psychological disorder (Jaffee, 2013; Kempe & Kempe, 1978). However, many are insecure individuals with low self-esteem, and many struggle with depression and substance abuse (IOM & NRC, 2014). These adults see themselves as victims, feel powerless as parents, and find the normal challenges of parenting stressful and threatening (Bugental, 2009; Bugental & Beaulieu, 2003).

Fourth, *abusive parents often have distorted perceptions of the normal behavior of infants and young children* (Haskett, Johnson, & Miller, 1994). For example, when infants cry to communicate needs such as hunger, abusive mothers may infer that the baby is somehow criticizing or rejecting them (Egeland, 1979; Egeland, Sroufe, & Erickson, 1983). One mother interpreted her 3-month-old’s babbling as “talking back” (Bugental, 2009). (See why the study of human development is useful?)

In short, abusive parents tend to have been exposed to harsh parenting as children and to abusive romantic relationships, suffer from mental health problems and low self-esteem, and misinterpret normal child behavior as ego threatening. Still, it has been difficult to identify a particular kind of person who is highly likely to turn into a child abuser. Could some children bring out the worst in parents?

The Abused

An abusive parent sometimes singles out only one child in the family as a target; this offers a hint that child characteristics might matter (Gil, 1970). No one is suggesting that children are to blame for being abused, but some children appear to be more at risk than others. For example, children who have medical problems or who have difficult temperaments are more likely to be treated harshly or abused than quiet, healthy, and responsive infants who are easier to care for (Bugental & Beaulieu, 2003; Ganiban et al., 2011). Yet many difficult children are not mistreated, and many seemingly cheerful and easygoing children are.

Just as characteristics of the caregiver cannot fully explain why abuse occurs, then, neither can characteristics of children. But could parent and child characteristics interact? In support of an interactional model of family influence, we now know that the combination of a high-risk parent and a challenging child can spell trouble. For example, a mother who feels powerless to deal with children, and who must raise a child who has a disability or illness or is otherwise challenging, is prone to overreact emotionally when the child cannot be controlled and use harsh discipline (Bugental, 2009; Martorell & Bugental, 2006). Such powerless parents experience higher levels of stress than most parents, as indicated by high cortisol levels and fast heart rates, when interacting with children who are unresponsive. Consistent with the transactional model of family influence, their uneasiness can make such children even less responsive, provoking even more use of power tactics by the parent. So, even the match between child and caregiver may not be enough to explain abuse; as the transactional model suggests, relationships between parents and children sometimes evolve in bad directions over time as each influences the other.

The Context

We must also consider the ecological context of abuse (Cicchetti & Toth, 2015). Abuse is most likely to occur when a parent is under great stress and has little social support (Cano & Vivian, 2003; Egeland et al., 1983). Life changes such as the loss of a job or a move can disrupt family functioning and contribute to abuse or neglect (Berger et al., 2011; Wolfner & Gelles, 1993). Abuse rates are also highest in deteriorating neighborhoods where families are poor, transient, socially isolated, and lacking in community services and informal social support (Korbin, 2001).

Finally, the larger macroenvironment is important. Ours is a violent society in which the use of physical punishment is common and the line between physical punishment and child abuse can be difficult to draw (Crouch & Behl, 2001; Lansford & Dodge, 2008). Child abuse is less common in societies that discourage or outlaw physical punishment of children (Holden, Vittrup, & Rosen, 2011; Levinson, 1989).

As you can see, child abuse is a complex phenomenon with many causes and contributing factors. It is not easy to predict who will become a child abuser and who will not, but abuse seems most likely when a vulnerable individual faces overwhelming stress with insufficient social support. Much the same is true of intimate partner abuse, elder abuse, and other forms of family violence.

What Are the Impacts of Child Abuse?

Physically abused and otherwise maltreated children tend to have problems in virtually every area of development: physical injuries, health problems, atypical brain development, cognitive deficits, social, emotional, and behavioral problems, and psychological disorders (Cicchetti & Toth, 2015; Del Vecchio et al., 2013; IOM & NRC, 2014). Our information on the effects of abuse comes from correlational rather than experimental studies, of course, so it is difficult to firmly establish cause-effect relationships between abuse and development.

Maltreatment can have damaging effects on the developing brain, the stress response system, and other biological systems that affect psychological functioning (IOM & NRC, 2014). Intellectual deficits and academic difficulties are common among mistreated children (Cicchetti & Toth, 2015; Malinosky-Rummell & Hansen, 1993; Shonk & Cicchetti, 2001). Social, emotional, and behavioral problems are also common (Cicchetti & Toth, 2015; Flores, Cicchetti, & Rogosch, 2005). Maltreated children tend to have poor understanding of emotions, experience many negative emotions, and have difficulty regulating their emotions (Cicchetti & Toth, 2015). Some are explosively aggressive youngsters, rejected by their peers for that reason (Bolger & Patterson, 2001); others are anxious, depressed, and withdrawn. Some also fail to display empathy in response to the distress of others. Whereas toddlers typically show concern and offer comfort when a peer cries, abused toddlers are likely to become angry and attack the crying child, reacting to the distress of peers much as their abusive parents react to their distress (Main & George, 1985).

As we saw in Chapter 14, abused children form attachments to their abusive parents but the attachments are often of the disorganized type, suggesting that these children need but also fear their caregivers and are unsure whether to approach or avoid these scary people. They tend to have negative views of both their parents and themselves (Cicchetti & Toth, 2015). Even as adults, individuals who were abused as children tend to have higher-than-average rates of depression, anxiety, and other psychological problems (Nemeroff & Binder, 2014). They still show deficits in the processing of emotion (Young & Widom, 2014). Their marriages are more negative and less satisfying and their relationships with their families are less emotionally close (Nguyen, Karney, & Bradbury, 2016; Savla et al., 2013).

Remarkably, though, some maltreated children—between 10% and 25%—are resilient and get back on an adaptive developmental path (Cicchetti & Toth, 2015). Some appear to have genes that protect them—that make them stress resistant, confident, and able to cope effectively (Caspi et al., 2002; Cicchetti & Toth,

2015; Kim-Cohen & Gold, 2009). Environment matters too: An attachment to at least one nonabusive adult may be especially important (Houshyar, Gold, & DeVries, 2013).

Clearly family life can make us or break us. **Application 15.1** explores approaches to preventing and treating child maltreatment.

Meanwhile, we hope this examination of diverse family experiences has convinced you that we do indeed live linked lives throughout the life span and that the family is centrally important in human development. Our next chapter looks more closely at some of the many ways in which development can go awry.

● APPLICATION 15.1

How Do We Stop the Violence?

Knowing what we know about child abuse, what can be done to prevent it, stop it, and undo the damage? What would you propose?

Home visitation programs to help new parents cope with their babies and their lives can prevent maltreatment (IOM & NRC, 2014). For example, Daphne Bugental and her colleagues (Bugental, 2009; Bugental & Beaulieu, 2003; Bugental et al., 2002) developed a program to empower stressed, low-income parents who are at high-risk to become abusive because they feel helpless in the face of the challenge of raising a child who is unresponsive and difficult. Home visitors taught mothers to analyze the causes of caregiving problems without blaming either themselves or their children and to devise, try out, and evaluate the effectiveness of solutions to these caregiving problems.

After the intervention period, mothers who received empowerment training had a greater sense of power than mothers in control groups did. Most importantly, their rate of physical abuse, including spanking and

slapping, was only 4%, compared with 23% in a home visitation group that was given no empowerment training and 26% in a group that was referred to the usual community services. Moreover, the children in the empowerment group were in better health and were better able to manage stress (see also Bugental, Corpuz, & Schwartz, 2012; Bugental & Schwartz, 2009).

Another effective approach to prevention and treatment is to teach parents positive parenting skills—for example, through behavior management programs that apply principles of positive reinforcement to prevent or weaken coercive cycles in the family (Chen & Chan, 2016; Forgatch, Patterson, & Gewirtz, 2013; Knerr, Gardner, & Cluver, 2013). Psychotherapy can help too: A trauma-focused form of cognitive behavior therapy helps both abusive parents and their abused children deal with their memories of abuse and overcome maladaptive beliefs about themselves (IOM & NRC, 2014).

Ultimately, a comprehensive, ecological approach designed to convert a pathological family system into a healthy one is likely to be most effective. Abusive parents need emotional support and the opportunity to learn more effective parenting, problem-solving, and coping skills. Victims of abuse need day care programs, developmental training, and psychotherapy to help them overcome the many negative effects of abuse (Leenarts et al., 2013; Malley-Morrison & Hines, 2004). Change is also needed in families' neighborhoods and communities to ensure that families have the services and supports they need (Dodge & Coleman, 2009). Interventions guided by a "Communities That Care" approach, for example, mobilize community leaders and whole communities to decrease risk factors and increase protective factors affecting the community's children and to change the whole ecology surrounding abuse (Salazar et al., 2016). Stopping the violence requires determination and funding, but there is hope.

● Checking Mastery

1. Identify one characteristic of the parent, one characteristic of the child, and one contextual factor that could contribute to child abuse.
2. What are two explanations of the intergenerational transmission of abusive parenting?

● Making Connections

1. Given what you now know about the roles of the abuser, the abused, and the context in child abuse, how do you think these three sets of factors enter into intimate partner violence?

2. Given the societal problems that stem from abuse and neglect of children, what do you think about the idea of licensing parents, much as we license drivers, to ensure that they have the appropriate knowledge and skills and possibly even temperament? Licensing could involve pledging to support children financially and to refrain from maltreating them; it could even involve being of a certain age or passing a parenting skills course (see Holden, 2010). What do you see as the pros and cons of such a policy?

Chapter Summary

15.1 Understanding the Family

- The family, whether nuclear or extended, is best viewed, as suggested by Bronfenbrenner's bioecological perspective, the family life cycle concept, and family systems theory, as a changing social system embedded in larger social systems that are also changing. Social changes in the past half century or more have resulted in more single adults, later marriage, more unmarried parents, fewer children, more women working, more divorce, more single-parent families, more reconstituted families, more empty nest years, more multigenerational families, and fewer caregivers for aging adults.

15.2 The Infant

- Infants affect and are affected by their parents. Fathers are capable parents but have been less involved in caregiving than mothers, although the roles of mothers and fathers have been converging.
- Developmental outcomes are likely to be positive when parents engage in supportive coparenting and have positive indirect effects on child development through their positive influences on each other.

15.3 The Child

- Parenting styles can be described in terms of the dimensions of acceptance–responsiveness and demandingness–control; children are generally most competent when their parents adopt an authoritative style rather than an authoritarian, permissive, or neglectful style. Socioeconomic status and economic hardship, as illustrated by the family stress model, as well as culture and subculture, affect parenting styles.
- Research on four models of family influence—the parent effects, child effects, interactional, and transactional models—tells us that children's problem behaviors are not always solely caused by ineffective parenting.
- When a second child enters the family system, firstborns may find the experience stressful but usually adapt; sibling relationships are characterized by ambivalence, and siblings play important roles as providers of emotional support, caregiving, teaching, and social experience and can have indirect effects on the parenting their siblings receive.

15.4 The Adolescent

- Parent–child relationships typically remain close in adolescence but involve increased conflict around puberty.
- Parent–child relationships are renegotiated to become more equal as adolescents strive for autonomy; the goal of autonomy is best supported by authoritative parenting.

15.5 The Adult

- Marital satisfaction declines somewhat, on average, as newlyweds adjust to each other and undergo the positive but stressful transition to new parenthood and raise children, whereas the empty nest transition often increases marital satisfaction. A companionate style of grandparenting is generally a positive experience but involved grandparents can find raising grandchildren burdensome.
- In adulthood, siblings have less contact but often continue to feel both emotionally close and at least somewhat rivalrous.
- Young adults often establish more mutual relationships with their parents, and most middle-aged adults continue to experience mutually supportive relationships with their elderly parents until some experience middle generation squeeze, caregiver burden, and possibly a short period of role reversal.

15.6 Diverse Family Experiences

- Inadequately described by the traditional family life cycle concept are single adults (some of whom cohabit with partners for a variety of reasons), childless married couples, and gay and lesbian families.
- Divorce creates a crisis in the family for 1 or 2 years; most adjust, but some children of divorce living in single-parent and reconstituted families experience not only short-term but longer-term adjustment problems, although many factors can make the experience better.

15.7 The Problem of Family Violence

- Parent characteristics such as having been abused, child characteristics such as a difficult temperament, and contextual factors such as lack of social support all contribute to child maltreatment. Child abuse has serious and often long-lasting effects on development, but some victims show considerable resilience.

Aging and Dementia

Peggy, a 17-year-old female, was referred by her pediatrician to a child psychiatry clinic for evaluation of an eating disorder. She had lost 10 pounds in 2 months and her mother was concerned. . . . At the clinic she stated that she was not trying to lose weight, had begun to sleep poorly about 2 months ago unless she had several beers, and that she and friends “got trashed” on weekends. Her relationship with her parents was poor; she had attempted suicide a year previously with aspirin and was briefly hospitalized. The day before this evaluation she had taken a razor to school to try to cut her wrists, but it was taken away by a friend. She admitted being depressed and wanting to commit suicide and finally told of discovering that she was pregnant 4 months earlier. Her boyfriend wanted her to abort, she was ambivalent, and then she miscarried spontaneously about 2 months after her discovery. After that, “It didn’t really matter how I felt about anything” (Committee on Adolescence, 1996, pp. 71–72).

Does Peggy have any diagnosable psychological disorders? It would seem from this description that she may have diagnosable problems with substance abuse and depression and possibly even an eating disorder. However, her pregnancy and miscarriage may have provoked her symptoms: How do we differentiate between psychological disorders and normal responses to negative life events? How did Peggy's problems unfold and where might they lead?

We do not all have as many problems as Peggy, but it is the rare person who makes it through the life span without having at least some difficulty adapting to the challenges of living. Each

phase of life poses unique challenges, and some of us inevitably run into trouble mastering them. This chapter is about psychological disorder—about some of the ways in which human development can go awry. It is about how development influences psychopathology and how psychopathology influences development. By applying a life-span development perspective to the study of psychological disorders, we understand them better. And by learning more about divergent patterns of development, we gain new perspectives on the forces that guide and channel—or block and distort—human development more generally.

16.1

What Makes Development Abnormal?

LEARNING OBJECTIVES

- Describe three broad criteria of abnormal behavior and the approach taken by DSM-5 in diagnosing disorders such as major depressive disorder.
- Define developmental psychopathology and contrast the developmental psychopathology perspective to a medical or disease perspective.
- Explain and illustrate the diathesis–stress model of psychopathology.

Clinical psychologists, psychiatrists, and other mental health professionals struggle to define the line between normal and abnormal behavior and diagnose psychological disorders, often guided by three broad criteria in doing so:

- **Statistical deviance.** Does the person's behavior fall outside the normal range of behavior? By this criterion, a mild case of the “blahs” or “blues” would not be diagnosed as clinical depression because it is so statistically common, but a more enduring, severe, and persistent case might be.
- **Maladaptiveness.** Does the person's behavior interfere with adaptation or pose a danger to self or others? Psychological disorders disrupt functioning and create problems for the individual, other people, or both.
- **Personal distress.** Does the behavior cause personal anguish or discomfort? Many psychological disorders involve personal suffering and are of concern for that reason alone.

Although these general guidelines provide a start at defining atypical behavior, they are vague. We must identify specific forms of statistical deviation, maladaptiveness, and personal distress.

DSM Diagnostic Criteria

Professionals who diagnose and treat psychological disorders use the more specific diagnostic criteria in the *Diagnostic and Statistical Manual of Mental Disorders*. The newest version, **DSM-5**, was published in 2013 (American Psychiatric Association, 2013). It spells out defining features and symptoms for numerous psychological disorders. Some hope that advances in genetics, brain imaging, blood testing, and other diagnostic approaches will allow better identification of the biological state or disease underlying a disorder's symptoms, much as doctors can test for the HIV virus when someone appears to have symptoms of AIDS. That goal will be difficult to achieve, though (Addington & Rapoport, 2012). As you'll learn, rather than having one clear biological cause,

most psychological disorders in DSM-5 have many variations and many contributors, both biological and environmental.

Because depression is so common across the life span, we will highlight it in this chapter and use it here as an example of how DSM-5 defines disorders. Depression is a family of several affective or mood disorders, some relatively mild and some severe. One of the most important is **major depressive disorder**, defined in DSM-5 as at least one episode of feeling profoundly depressed, sad, and hopeless, and/or losing interest in and the ability to derive pleasure from almost all activities, for at least 2 weeks (American Psychiatric Association, 2013). To qualify as having a major depressive episode, the individual must experience at least five of the following types of symptoms, including one of the first two, persistently during a 2-week period:

- Depressed mood (or irritable mood in children and adolescents) nearly every day
- Greatly decreased interest or pleasure in activities most of the day
- Significant weight loss when not dieting or weight gain (or for children, failure to achieve expected weight gains)
- Insomnia or sleeping too much
- Agitation or restlessness, or sluggishness and slowing, of behavior
- Fatigue and loss of energy
- Feelings of worthlessness or extreme guilt
- Decreased ability to think or concentrate or indecisiveness
- Recurring thoughts of death, recurring suicidal ideas, or a suicide attempt or plan to commit suicide

By DSM-5 criteria, a man suffering from major depression might feel extremely discouraged, no longer seem to care about his job or even about sexual relations with his wife, lose weight or have difficulty sleeping, speak and move slowly as though lacking the energy to perform even the simplest actions, have trouble getting his work done, dwell on how guilty he feels about his many failings, and begin

As the story of Peggy illustrates, major depressive disorder involves statistical deviance, maladaptiveness, and personal distress.

Amazingmikael/Shutterstock.com

to think he would be better off dead. A woman with major depressive disorder described it this way: “Like living behind glass. You can see life, but you can’t hear it or feel it” (Rowan, 2015, p. E4). Major depressive disorder would not be diagnosed if an individual is merely a little “down”; many more people experience depressive symptoms than qualify as having a clinically defined depressive disorder.

DSM-5 notes that both cultural and developmental considerations should be taken into account in diagnosing major depressive disorder. For example, some studies find that Asians who are depressed are likely to complain of **somatic symptoms** (body symptoms such as tiredness and aches) more than psychological symptoms such as guilt and may be underdiagnosed if this cultural difference is not taken into account (Sue et al., 2012). And although DSM-5 takes the position that depression in a child is fundamentally similar to depression in an adult, it points out that some depressed children express their depression by being irritable rather than sad. An interesting question we’ll ask in this chapter is how the flavor of depression changes over the life span.

Developmental Psychopathology

Psychologists and psychiatrists have long brought major theories of human development to bear in attempting to understand and treat psychological disorders. Freudian psychoanalytic theory once guided most thinking about psychopathology and clinical practice; behavioral theorists have applied learning principles to understand and treat behavioral problems; and cognitive psychologists have called attention to how individuals interpret their experiences and perceive themselves. More recently, evolutionary psychologists have been asking whether psychological disorders may have evolved because they sometimes served adaptive functions for our ancestors. For example, might depression be an adaptive response to loss? After all, it allows us to conserve energy, avoid additional stressors, and analyze what went wrong (Mealey, 2005; Rottenberg, 2014).

There is now an entire field devoted to the study of abnormal behavior from a developmental perspective—**developmental**

psychopathology (Cicchetti & Toth, 2009; Cummings & Valentino, 2015; Lewis & Rudolph, 2014; Sroufe, 2009, 2013). As defined by pioneers L. Alan Sroufe and Michael Rutter (1984), developmental psychopathology is the study of the origins and course of maladaptive behavior. Developmental psychopathologists appreciate the need to evaluate atypical development in relation to typical development and to study the two in tandem. They want to know how disorders arise and how their expression changes as the individual develops, and they search for causal pathways and mechanisms involving genes, the nervous system, the person, and the social environment that lead to normal or abnormal adjustment. In doing so, they bring life span, interdisciplinary, and systems perspectives to the study of psychopathology, looking at the interplay among biological, psychological, and social factors over the course of development.

Psychopathology as Development, Not Disease

Some developmental psychopathologists fault DSM-5 and similar diagnostic systems for being rooted in a medical or disease model of psychopathology that views psychological problems as disease-like entities that people either have or do not have. Alan Sroufe (2009) puts it this way:

Psychopathology is not a condition that some individuals simply have or are born to have; rather, it is the outcome of a developmental process. It derives from the successive adaptations of individuals in their environment across time, each adaptation providing a foundation for the next. (p. 181)

■ **Figure 16.1** illustrates the concept of psychopathology as development. It portrays progressive branchings that lead development on either an optimal or a less-than-optimal course. Start with the assumption that typical human genes and typical human environments push development along an adaptive course and pull it back on course if it strays (Grossman et al., 2003). Some individuals—even some whose genes or experiences put them at risk to develop a disorder—manage to stay on a route to competence and good adjustment. Some start out poorly but get back on a more adaptive course later; others start off well but deviate later. Still others start on a maladaptive course due to genes and early experience and deviate further from developmental norms as they age because their early problems make it harder and harder for them to master later developmental tasks and challenges (Kendler, Gardner, & Prescott, 2002).

Now picture Figure 16.1 with many more roadways. In this developmental pathways model, change is possible at many points, and the lines between typical and atypical development are blurred. A number of different pathways can lead to the same disorder, and the same risk factors can lead to a variety of different outcomes (Cicchetti & Toth, 2009). A model of this sort may seem complex, but it fits the facts of development.

More is being learned every day about relationships among genes, neural circuits and neurotransmitters, and behaviors associated with psychological disorder. As a result, many experts view psychological disorders as life-span *neurodevelopmental* disorders (Davis, 2012; Hyde, 2015). This neurodevelopmental perspective requires looking at typical and atypical pathways of brain development and

their implications for functioning. It involves using genetic and brain imaging techniques in diagnosing disorders in hopes of intervening early with individuals who are at risk for various disorders to put them on a healthier developmental trajectory.

Social Norms and Age Norms

Developmental psychopathologists appreciate that behaviors are abnormal or normal only within the social and cultural contexts that help shape them (Causadias, 2013; Chen, Fu, & Leng, 2014). **Social norms** are expectations about how to behave in particular social contexts—whether a culture, a subculture, or an everyday setting like a church. What is normal in one social context may be abnormal in another. For example, John Weisz and his colleagues (1997) discovered that Thai children are more likely than American children to report (or to be reported by their parents to have) symptoms of inner distress such as anxiety and depression and are less likely to engage in aggression and other forms of “acting out.” One reason for the difference may be that the Thai culture places high value on emotional control and socializes children to control rather than vent their negative emotions (see also Chen et al., 2014; Weiss et al., 2009).

Another example of the need to consider cultural norms concerns one of the behaviors used in diagnosing autism (see later section): lack of normal eye contact. But what is normal eye contact? In China and certain other East Asian cultures, it is viewed as rude to look directly into someone’s eyes; looking at the nose area is more culturally appropriate (Norbury & Sparks, 2013). If an evaluator is not attentive to such cultural differences, an incorrect diagnosis could be made. As such examples hint, the definitions, meanings, symptoms, rates, and developmental courses and correlates of psychological disorders are likely to vary from culture to culture, from subculture to subculture, and from historical period to historical period (Norbury & Sparks, 2013; Serafica & Vargas, 2006).

In addition, developmental psychopathologists are very aware that atypical behavior must be defined in relation to *age norms*—societal expectations about what behavior is appropriate or normal at various ages. The 4-year-old boy who frequently cries, acts impulsively, wets his bed, is afraid of the dark, and talks to his imaginary friend may be perceived as—and may be—normal. The 40-year-old who does the same things needs help! You simply cannot define atypical behavior and development without having a solid grasp of typical behavior and development.

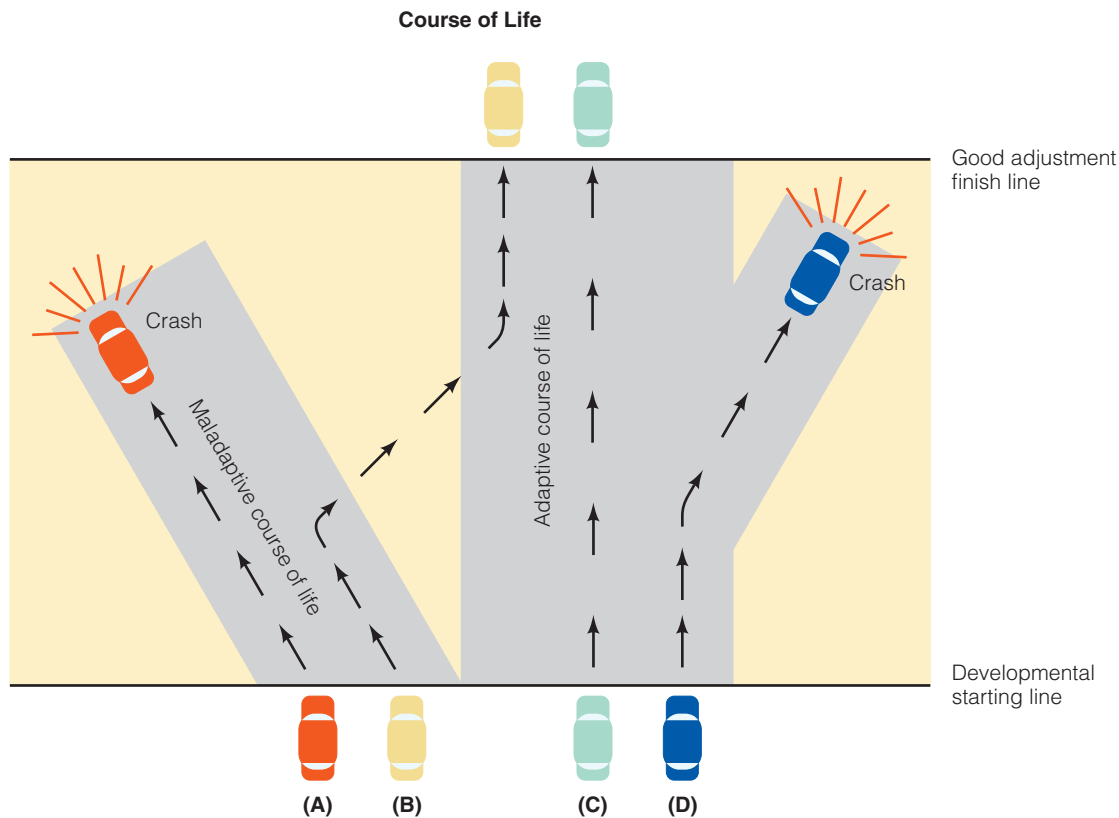

Figure 16.1 Developmental pathways leading to typical and atypical developmental outcomes. Some individuals start on a maladaptive course and deviate further from developmental norms as they age (route A); some start poorly but return to a more adaptive course later (route B); others stay on a route to competence and good adjustment all along (route C); and still others start off well but deviate later in life (route D). Now imagine many more roads and on and off ramps.

In Thailand, boys like this one are socialized to restrain their expressions of emotion rather than act them out. As a result, children there are more prone to depression and anxiety but less aggressive than children in the United States.

Developmental Issues

As they attempt to trace developmental pathways to adaptive or maladaptive functioning, developmental psychopathologists grapple with the same developmental issues that have concerned us throughout this book—most notably, the nature–nurture issue and the issue of continuity and discontinuity in development (see Chapter 2). Addressing the nature–nurture issue involves asking important questions such as these:

- How do biological, psychological, and social factors interact over time to give rise to psychological disorders?
- What are the important risk factors for psychological disorders—and what are the protective factors that keep some individuals who are at risk from developing disorders?

Addressing the continuity–discontinuity issue means asking these sorts of questions:

- Are most childhood problems passing phases that have no bearing on adjustment in adulthood, or does poor functioning in childhood predict poor functioning later in life?
- How do expressions of psychopathology change as the developmental status of the individual changes?

The Diathesis–Stress Model

In their efforts to understand how nature and nurture contribute to psychopathology, developmental

psychopathologists have long found a **diathesis–stress model** of psychopathology useful (Coyne & Whiffen, 1995; Ingram & Price, 2001). This model proposes that psychopathology results from the interaction over time of a vulnerability to psychological disorder (called a *diathesis*, which can involve a predisposing genetic makeup, physiology, set of cognitions, personality, or a combination of these) and the experience of stressful events. The diathesis–stress concept should remind you of the concept of gene–environment interaction.

Consider depression. We know that certain people are genetically predisposed to become depressed. Genetic factors account for about 40%–60% of the variation in a group of people in symptoms of major depressive disorder (Garber, 2010). A genetic vulnerability to depression manifests itself as imbalances in serotonin, dopamine, and other key neurotransmitters that affect mood and in such characteristics as high emotional reactivity to stress, including high production of the stress hormone cortisol, and self-defeating patterns of thinking in the face of negative events (Beck & Bredemeier, 2016; Gotlib et al., 2006).

According to the diathesis–stress model, however, individuals predisposed to become depressed are not likely to do so unless they experience significant losses or other stressful events, as illustrated in **Figure 16.2**. One stressful life event is usually not enough to trigger major depression, but when negative events pile up or become chronic, a vulnerable person may succumb. Meanwhile, individuals who do not have a diathesis—a vulnerability to depression—may be able to withstand high levels of stress without becoming depressed.

Researchers can now pinpoint many specific diathesis–stress interactions. For example, inheriting a particular variant of a gene involved in controlling levels of the neurotransmitter serotonin and experiencing multiple stressful events results in an especially high probability of major depression (Caspi, Sugden, Moffitt, et al., 2003; and see Petersen et al., 2012). Among people with one or two of the

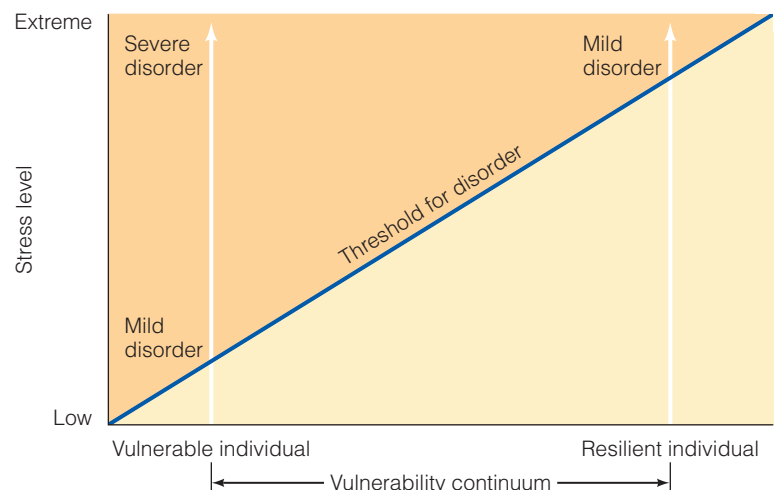

Figure 16.2 The diathesis–stress model. For a vulnerable individual, even mild stress can result in disorder. For an individual who does not have a vulnerability or diathesis to disorder, it would take extremely high levels of stress to cause disorder; even then, the disorder might be only mild and temporary.

Source: Adapted from Ingram & Price, 2001.

high-risk genes, about 10% became depressed if they experienced no negative life events between ages 21 and 26, but 33% became depressed if they experienced four or more such events. By comparison, even when exposed to many stressful events, only 17% of individuals with two low-risk versions of the gene became depressed.

Depressive disorders (and many other psychological disorders) often evolve from an interaction of diathesis and stress—or, to use familiar developmental terms, from an interaction between genes and environment. It is messier than Figure 16.2 implies, though. For example, genes not only predispose some people to depression but also influence the extent to which they experience stressful life events (Rice, Harold, & Thapar, 2003). Moreover, the relationship between stress and disorder is reciprocal: Life stress aggravates disorder, but disorder also makes life more stressful (Garber, 2010; Grant et al., 2004). Finally, in a person genetically predisposed to depression, a depressive episode early in life in response to intense stress may bring about changes in gene activity and in the neurobiology of the stress-response system (the hypothalamic–pituitary–adrenal [HPA] axis). These changes may lower the threshold for a future depressive episode (the diagonal line in Figure 16.2) so that later in life depression may reoccur even in response to less stressful experiences (Grossman et al., 2003; Monroe & Reid, 2009).

This chapter will now illustrate the concepts of developmental psychopathology in action by examining a few developmental problems associated with different phases of the life span—for

example, autism to illustrate disorders arising in infancy; ADHD to illustrate childhood disorders; anorexia nervosa and substance abuse to illustrate disorders arising in adolescence; and Alzheimer’s disease to illustrate disorders of old age. In addition, we look at depression in every developmental period to see how its symptoms and significance change over the life span.

● Checking Mastery

1. What are two of the three broad criteria useful in defining when a psychological disorder is present?
2. Jake says psychological disorders are diseases that some people have and other people don’t. What might a developmental psychopathologist tell Jake?
3. What is a diathesis and why is it important?

● Making Connections

1. Dr. Blinderson is used to diagnosing depression in American college students. Think through what this psychologist might want to consider if he began to diagnose major depression among both preschool children and elderly adults.
2. Revisit the case of Peggy at the start of the chapter and hypothesize about how the diathesis–stress model might apply to her.

16.2

The Infant

LEARNING OBJECTIVES

- Describe the two defining features and main characteristics, including brain functioning, of autism spectrum disorder.
- Explain why rates of autism spectrum disorder are increasing, how nature and nurture may contribute to it, and what can be done to treat it.
- Explain why there is controversy about whether infants can have true depressive disorders and what factors contribute to depression symptoms in infancy.

Adults worry about infants who do not eat properly, who cry endlessly, or who seem overly withdrawn and timid. Because infant development is strongly channeled by biological maturation supported by a nurturing family environment, few infants develop severe psychological problems. Yet psychological disorder exists in infancy, and its effects can be profound.

Autism Spectrum Disorder

Jeremy, 3½ years old, has big brown eyes and a sturdy body. His mother carries him down the corridor toward the examiner, who greets them. Jeremy glances at the examiner’s face but does not smile or say hello. They walk together into a playroom. Jeremy’s mother puts him down, and he sits on the carpet in front of some toys. He picks up two blocks, bangs them together, and begins to stack the blocks, one on top of the other, not stopping until he has used the entire set. Jeremy does not look at the examiner or his mother while he works, nor when he finishes. And he does not make a sound. The examiner

asks him to give her a red block. He does not respond. On their way out, Jeremy and his mother stop to look at a poster of a waterfall surrounded by redwood trees. “Yosemite Valley,” Jeremy reads out—the name beneath the picture. His voice sounds automated, almost robotic. (Sigman & Capps, 1997, p. 1)

Autism was first identified and described by Leo Kanner in 1943. Now diagnosed as **autism spectrum disorder (ASD)**, it usually begins in infancy and is characterized by abnormal social and communication development and restricted interests and repetitive behavior. Picture the typical infant that we have described in this book: a social being who responds to others and forms close attachments starting at 6 or 7 months of age, a linguistic being who babbles and later uses one- and two-word sentences to converse with companions, and a curious explorer who is fascinated by new objects and experiences. Now consider the two defining features of autism highlighted in DSM-5 (and see Waterhouse, 2013):

- **Social and communication deficits.** Autistic children have difficulty responding appropriately to social cues, sharing

experiences with other people, and participating in social interactions. Some autistic children are mute and quite asocial; others acquire language skills with varying degrees of success but are socially awkward and have difficulty carrying on true, back-and-forth conversations (Tager-Flusberg, 2014; Waterhouse, 2013).

- **Restricted and repetitive interests and behavior.** Autistic children seek sameness and repetition. They may become obsessed with particular objects and interests—bug collecting, for example—and may repeat phrases over and over. They may engage in stereotyped behaviors such as rocking, flapping their hands in front of their faces, or spinning toys. If they are more intellectually able, they may carry out elaborate rituals and routines such as a particular sequence of getting-dressed activities. They resist change and can become highly distressed when their physical environment is even slightly altered.

The social impairments associated with ASD strike us most. Like Jeremy, some children with ASD seem to live in a world of their own. They are far less likely than other infants to make eye contact, jointly attend to something with a social partner, seek other people for comfort, snuggle when held, and make friends. They also have great difficulty reading other people's minds and emotions, responding with empathy when others are distressed, and demonstrating self-awareness and self-conscious emotions such as embarrassment and guilt. Although over half of autistic children form secure attachments to their parents (Rutgers et al., 2004), a higher than average number develop what Chapter 14 described as disorganized–disoriented attachments (Sigman & Capps, 1997).

It is critical to recognize that individuals with ASD vary tremendously in the degree and nature, as well as the causes, of their deficits. As a result, some experts talk of “autisms” rather than autism, believing that ASD is actually a number of different underlying disorders (Hu, 2013; Jones & Klin, 2009). Others conclude that even the “autisms” perspective is flawed because the symptoms, brain deficits, and causes of ASD are so unique to the individual (Waterhouse, 2013). There's a saying in the autism community, attributed to Dr. Stephen Shore: “If you've met one person with autism, you've met one person with autism.”

The concept of ASD was devised to reflect this diversity. In DSM-5, previously distinct disorders are all diagnosed as ASD, which can vary from mild to severe. As a result, ASD is now the diagnosis given to individuals who show classic autism as well as those who used to be diagnosed as having **Asperger syndrome**, a mild form of ASD. The child with Asperger's syndrome has normal or above-average intelligence, good verbal skills, and a clear desire to establish social relationships but has deficient social cognitive and social-communication skills. Affected children are sometimes called “little professors” because they talk rather stiffly and formally, and sometimes at mind-numbing length, about the

Children with autism spectrum disorder benefit from special training to help them do what typically developing children do naturally: take part in the give-and-take of social relationships.

Sergey Novikov/Shutterstock.com

particular subjects that obsess them. Their strength is that they see the trees very clearly; their weakness is that they often miss the forest (Grandin & Panek, 2013; Pellicano, 2010). Many have been largely invisible until recently; rather than being diagnosed with a disorder, they were simply viewed as odd and socially awkward.

Is There an Epidemic?

Rates of autism are rising. DSM-III-R, published in 1987, indicated that autism affected about 4 or 5 of every 10,000 children (American Psychiatric Association, 1987). The rate has been climbing dramatically since, to 1 in 68 children age 8 (about 1.5%) in the latest survey of community sources in the United States that diagnose and educate or treat children with the condition (Autism and Developmental Disabilities Monitoring Network, 2014). An even higher rate was discovered in a survey of parents in the United States in 2014 about whether a doctor or health professional had ever told them that a target child in the family had ASD: Here, the estimated rate of ASD was 1 in 45, or over 2.2% (Zablotsky et al., 2015). There are four or five affected boys for every girl, and white children are more likely to be diagnosed than Hispanic or African-American children.

Why have rates of autism been rising so steeply over the past few decades? If you have heard that the vaccine infants receive for measles, mumps, and rubella is the culprit, forget what you have heard. There is no support for this claim, which unfortunately has made some parents fear having their children immunized and has bumped up rates of childhood diseases (Waterhouse, 2013). The main research study linking vaccinations to autism was found to be fraudulent and incorrect (Editors of *The Lancet*, 2010). Still, because some celebrities have spread this myth, and

perhaps because the vaccination is normally given to infants at about 15 months of age when symptoms of autism are often first being recognized, the dangerous vaccine myth has persisted.

Why are rates of ASD increasing, then? Most researchers believe that increased rates are mainly a result of increased awareness of the condition, a broader definition that includes the entire autistic spectrum (including more mild cases), increased diagnosis of children who were previously diagnosed with language impairments or learning disabilities or simply considered to be odd children, and policy changes in the 1990s that made children with ASD eligible for educational and medical services (Benaron, 2009; Waterhouse, 2013).

In sum, the recent rise in the prevalence of ASD seems to be more about detection of cases that were there all along than about new cases and causes. Variations in diagnostic practices probably contribute not only to increased rates of ASD in recent years but also to large differences in rates of ASD across cultures—from as low as 1 or 2 per 10,000 in Oman to as high as 260 in 10,000 in South Korea (Norbury & Sparks, 2013). Although ASD is not often diagnosed in China, for example, the rate zooms higher when the same diagnostic methods used in Western countries are applied to Chinese children (Sun et al., 2015). Still, no one can quite rule out the possibility that there has been a true increase in the prevalence of ASD associated with some as yet unidentified cause (Autism and Developmental Disabilities Monitoring Network, 2014; Waterhouse, 2013).

Characteristics

Most children with ASD are probably autistic from birth. However, because they often seem to be typically developing babies in their first year, and because physicians are slow to make the diagnosis even when parents express concerns about their child's development, many autistic children are not diagnosed until they are 4 or older, even though they could be diagnosed at 2 or possibly even at 1 (Autism and Developmental Disabilities Monitoring Network, 2014; Benaron, 2009; Klin et al., 2004). Researchers are working feverishly to improve early diagnosis because the earlier these children receive treatment, the more likely it is that they can be steered onto a more typical developmental pathway.

By age 1, autistic infants may be given away by their lack of normal interest in and responsiveness to social stimuli—for example, by failure to display normal infant behaviors such as orienting to someone calling their name, preference for human over nonhuman stimuli, eye contact, visual focus on faces in a scene (autistic babies tend to focus on objects in the background), joint attention (a key precursor of theory-of-mind skills), imitation, and turn taking, as in mutual smiling and peekaboo games (Ingersoll, 2011; Klin et al., 2004; Zwaigenbaum et al., 2005). Checklists of such abilities can be used to screen 1-year-olds for ASD (Pierce et al., 2011; Tager-Flusberg, 2014). Still others are using brain imaging techniques to try to identify these babies (Wolff et al., 2012) and are looking for diagnostically useful biomarkers in the blood (Glatt et al., 2012).

Complicating efforts to understand ASD is the fact that it is often **comorbid** with—that is, co-occurs with—other disorders such as intellectual disability, language disorders, ADHD,

epilepsy, anxiety disorders, and more (Waterhouse, 2013). Consider intellectual functioning. Almost half of children with ASD have average or above-average IQs, but the rest have below average IQs, some low enough to qualify for a diagnosis of intellectual disability (Autism and Developmental Disabilities Monitoring Network, 2014; Ingersoll, 2011). Meanwhile, a minority of autistic individuals, whether their IQs are high or low, show *savant abilities*—that is, special talents such as the ability to quickly calculate days of the week corresponding to dates on the calendar or to memorize whole train schedules (see Heaton & Wallace, 2004; and the description of *savant syndrome* in Chapter 9). Consider Ezra, age 15. Obsessed with animated films (he memorized the release dates of hundreds of them), animals, and breakfast cereals, he would greet people he knew with unusual conversation openers like, “Hi, Bonnie! You had Post Honeycombs in your kitchen in August of 2004!” (Fields-Meyer, 2011). Yet he could not seem to remember the names of the seven children in his classroom at school.

Autism used to be viewed as a prime example of development that is qualitatively different from typical development. No more. Because we know more about the milder end of the autism spectrum, autism is now located at the extreme end of a continuum of social responsiveness, quantitatively rather than qualitatively different from typical social behavior (Baron-Cohen, 2010; Robinson et al., 2011). In other words, many of us have some of the traits associated with autism to some degree.

Brain Functioning

Many autistic children display neurological abnormalities (Volkmar et al., 2004; Waterhouse, 2013). However, the neurological abnormalities are varied, and it is not yet clear which, if any, best explains the characteristics of individuals with ASD. We'll highlight here (a) *early brain overgrowth*, and (b) *later underconnectivity* between areas of the brain involved in social cognition.

As you may recall from Chapter 5, neurons typically proliferate during the prenatal period and early infancy. In at least some infants who later develop ASD, neurons in the frontal cortex and certain other areas of the brain proliferate wildly during this early sensitive period for brain development (Courchesne, Carper, & Akshoomoff, 2003; Schumann et al., 2009). Analyses of the brains of young infants with ASD show a higher than usual volume of neurons and number of connections among them. Moreover, areas of the cortex have disorganized patches of neurons within them (Stoner et al., 2014).

Neural growth then seems to slow and the usual pruning process does not go as it should. By early childhood and beyond, connections among key brain regions involved in social information processing are noticeably underdeveloped (Solso et al., 2016; Wolff et al., 2012). Many brain areas are called into action and must communicate well with others in key neural networks for us to interact smoothly with other people. Thus underconnectivity among brain areas helps explain the social and communication impairments associated with ASD (Pelphrey et al., 2011). It has been suggested that the brains of individuals with ASD take a “second hit” during adolescence that makes teens with ASD struggle with the peer and romantic relationships so

important in adolescence as well as with the development of self-control and autonomy (Picci & Scherf, 2015). Important regions of their brains are experiencing neural loss in adolescence at a time when other adolescents' brains are undergoing a growth spurt and reorganizing.

Like most hypotheses, though, the early brain overgrowth and later underconnectivity hypothesis does not fit all children with ASD (Waterhouse, 2013). Moreover, although abnormalities in early brain development may cause later social information-processing deficits, we cannot rule out that the possibility that a shortage of early social experience contributes to atypical brain development (Pelphrey et al., 2011). We can at least agree that atypical patterns of brain development are evident in individuals with ASD and that they affect a number of important areas of development.

Suspected Causes

Early theorists suggested that rigid and cold parenting by “refrigerator moms” caused autism, but this harmful myth has long been put to rest (Achenbach, 1982). It is now understood that interacting with an autistic child can easily cause parents to be tense and frustrated. Moreover, the parents of autistic children, because ASD is genetically influenced, sometimes have mild autistic spectrum traits themselves. Bad parenting is not responsible for autism.

Genes do contribute strongly to autism (Curran & Bolton, 2009; Yoo, 2015). Almost 19% of 3-year-olds who have an older sibling with ASD have it too; 32% have it if more than one older sibling has it (Ozonoff et al., 2011). In twin studies, if one identical twin is autistic, the other is autistic in 60–70% of the cases, whereas fraternal twins are hardly alike at all (Yoo, 2015). But since one identical twin can have ASD when the other does not, nonshared environmental factors must also be at work (Ronald & Hoekstra, 2011). And in one twin study (Hallmayer et al., 2011), shared environmental influences were also evident—possibly prenatal or postnatal experiences that could make even fraternal twins similar.

Hundreds of genes on several chromosomes, each with small effects, have been implicated (Waterhouse, 2013). Most likely, individuals with autism inherit from their parents, or acquire through new mutations, several genes that interact with each other and with environmental influences to put them at risk (Yoo, 2015). In some cases too, segments of DNA that affect neural communication appear to have been copied too many or too few times during cell division (Yoo, 2015). Autism occurs more often when parents, especially fathers, are older; this is because as we age, genetic mutations and copy number variations become more common, especially in the formation of sperm (Hultman et al., 2011; O’Roak et al., 2012). When these genetic errors occur, the processes through which genes and experience guide the development of the brain and its neural connections can be disrupted.

Early environmental influences also contribute to ASD (Mandy & Lai, 2016; Tordjman et al., 2014; Waterhouse, 2013). An environmental trigger such as a virus or chemicals in the environment can interact with a genetic predisposition to cause

autism. For example, the combination of genetic copy number variants associated with ASD and a maternal infection during pregnancy is associated with more severe ASD symptoms (Mazina et al., 2015). Prenatal exposure to teratogens such as rubella, alcohol, and thalidomide are known to contribute to ASD. Autism also occurs more frequently when there is maternal bleeding or other complications during pregnancy (Gardener, Spiegelman, & Buka, 2009). *Epigenetic effects* are probably at work too: Early environmental influences can alter the expression of genes that guide brain development (Hall & Kelley, 2014; Tordjman et al., 2014). In short, there are about as many possible environmental contributors to ASD as genetic ones.

Developmental Outcomes and Treatment

What becomes of children with autism as they get older? A small minority outgrow their autism and function like typically developing children (Fein et al., 2013). However, although most individuals with ASD improve in functioning with age, they are usually autistic to some extent for life. Fewer than half are totally independent as adults in the sense of living away from their parents and having a job; few marry and many have physical and mental health problems. Positive outcomes are most likely among those who have IQ scores above 70 and reasonably good communication skills by age 5. We know almost nothing about what happens to adults with ASD in old age (Howlin & Moss, 2012).

Can treatment help? Absolutely! Researchers continue to search for drugs that will correct the brain dysfunctions of individuals with ASD, but there is probably no “magic pill.” The most effective approach to treating ASD is intensive and highly structured behavioral and educational programming, beginning as early as possible, continuing throughout childhood, and involving the family (Schreibman et al., 2015). The goal is to make the most of the plasticity of the young brain during its sensitive period for development.

O. Ivar Lovaas and his colleagues pioneered the use of **applied behavior analysis (ABA)**, the application of reinforcement principles to teach skills and change behavior, to shape social and language skills in children with autism (Lovaas & Smith, 2003). In an early study, Lovaas (1987) trained student therapists to use reinforcement principles to reduce these children’s aggressive and self-stimulatory behavior and to teach them developmentally appropriate skills such as how to imitate others, play with toys and with peers, and use language. Parents were taught to use the same behavioral techniques at home. Lovaas reported astounding results for a 40-hours-a-week intervention—for example, IQ scores were about 30 points higher in the treatment group than in the comparison group that received much less of this training.

Subsequent research suggests that early behavioral interventions usually do not convert children with ASD into typically functioning children. Nonetheless, many children with autism, especially those who are young and do not have severe intellectual disabilities, make impressive gains if they receive intensive cognitive and behavioral training and comprehensive family services starting early in life (Dawson et al., 2010; Reichow & Wolery, 2009). Newer early intervention programs that build on both

applied behavior analysis and developmental science focus on training foundational social communication skills such as pointing, joint attention, and imitation and use more natural reinforcers to do so (Hardan et al., 2015; Schreibman et al., 2015). Thus, where Lovaas and his colleagues might have given a child a cereal bit for saying “car,” a therapist would now give the child a car to play with. The therapist would also try to develop a relationship with the child in which the child learns to initiate and participate in give-and-take interactions. Typically family members become trainers too, so that the training becomes embedded in the child’s everyday life.

In an especially well-conducted study with random assignment of children to treatment and control groups, one of these more modern ABA programs, called the Early Start Denver Model, was evaluated (Dawson et al., 2012). It not only increased IQ scores, language, and social skills but also changed brain functioning, making ASD children’s neural responses to faces like those of typically developing children. And its positive effects were still evident when 18- to 30-month-olds, who were trained for two years, were reassessed at age 6 (Estes et al., 2015). We know that the young brain is very plastic, so there is a good chance that such early intervention programs, by increasing a child’s social interaction, change the course of brain development. But ASD remains a lifelong disorder for many and a growing number of adults with autism need training and services too (Turcotte et al., 2016).

Depression

Does it seem possible to you that an infant could experience major depressive disorder as defined in DSM-5? Infants are not capable of the negative cognitions common among depressed adults—the low self-esteem, guilt, worthlessness, hopelessness, and so on. After all, until late infancy, they have not yet acquired the capacity for symbolic thought or self-awareness that would allow them to reflect on their experience. Yet infants *can* exhibit some of depression’s behavioral symptoms (such as loss of interest in activities or psychomotor slowing) and somatic, or physical, symptoms such as weight loss (Garber, 2010; Luby & Belden, 2012).

DSM-5 allows diagnosis of major depressive disorder in childhood but is silent about infancy. While psychologists and psychiatrists are debating whether true depression can occur in infancy, a small number of babies are clearly experiencing serious depressive states and symptoms (Garber, 2010; Luby, 2009). Moreover, young children who receive diagnoses of major depressive disorder are often said by their parents to have shown symptoms such as tearfulness, irritability, and a lack of joy even as infants (Luby & Belden, 2012). Indeed, babies can experience a whole range of mental health problems—problems involving feeding, sleeping, anxiety, attachment, and more (Keren et al., 2010; Zeanah, 2009). As a result, a special DSM-like diagnostic system has been developed by the Zero to Three Project to help infant mental health specialists better identify psychological disorders in infants so that they can be treated (Northcutt & McCarroll, 2014; Zero to Three, 2005). The developers of this system believe that major depressive disorder can indeed occur in infancy, contrary to what

the authors of DSM-5 suggest. The developers also know that diagnosing infants and young children is challenging.

Why would a baby become depressed? Depressive symptoms are most likely to be observed in infants who are abused or neglected, have an all-important attachment severed, or have a depressed caregiver (Boris & Zeanah, 1999). Infants who display a disorganized pattern of attachment, in which they do not seem to know whether to approach or avoid their caregiver (see Chapter 14)—an attachment style common among abused children—are especially likely to show symptoms of depression (Egeland & Carlson, 2004). And infants who are permanently separated from their mothers between 6 and 12 months of age have long been known to be at risk to become sad, weepy, listless, unresponsive, and withdrawn and to show delays in virtually all aspects of development (Spitz, 1946).

Infants whose mothers—or fathers—are depressed are also at risk (Gotlib et al., 2006). These babies adopt an interaction style that resembles that of their depressed caregivers; they vocalize little and look sad, even when interacting with women other than their mothers, and they show developmental delays (Field, 1995). They are at increased risk of becoming clinically depressed themselves later in life and of developing other psychological disorders. This may be because of a combination of genes and stressful experiences with their unpredictable caregivers (that is, because of diathesis–stress). Stress early in life, we now know, can produce children with an overactive stress-response system who are easily distressed, cannot regulate their negative emotions, are more reactive to stress later in life, and are more likely to develop psychological disorders (Bruce et al., 2013; Gunnar & Quevedo, 2007).

In sum, mental health problems in infants can often be traced to a family environment in which parent–infant attachment and interaction are maladaptive (Keren et al., 2010). Intervening to change the family system—for example, to treat a depressed mother so that she can parent more effectively—helps both her and her child (Cuijpers et al., 2015).

What are the implications for this baby of growing up with a depressed mother? Infants whose mothers are depressed may show heightened reactivity to stress and develop depression symptoms of their own.

SpeedKingz/Shutterstock.com

● Checking Mastery

1. What two major groups of symptoms would you expect to see in a child with autism spectrum disorder?
2. How does brain development in children with ASD appear to differ from that in typically developing children?
3. What are two early experiences that could contribute to depressive symptoms in an infant?

● Making Connections

1. What are two myths about autism that have been discredited, and how might they have arisen or have seemed believable?
2. If you were trying to judge whether Baby Baboo is depressed, what would you look for? Refer to the DSM-5 definition of major depressive disorder in Section 16.1.

16.3

The Child

LEARNING OBJECTIVES

- Distinguish between externalizing and internalizing problems and discuss nature/nurture and continuity/discontinuity issues pertaining to childhood problems.
- Characterize ADHD in terms of its symptoms, developmental course, suspected causes, and treatment.
- Discuss the importance and challenges of recognizing depression in children.

Many children experience developmental problems—fears, recurring stomachaches, temper tantrums, and so on. A smaller proportion qualify as having a psychological disorder and a smaller proportion still are diagnosed as having a psychological disorder and treated for it.

Externalizing and Internalizing Problems

Many developmental problems of childhood can be placed in one of two broad categories that reflect whether the child's behavior is out of control or overly controlled (Achenbach & Edelbrock, 1978). When children have **externalizing problems**, they lack self-control and act out in ways that disturb other people and violate social expectations. They may be aggressive, disobedient, difficult to control, or disruptive. We discussed conduct disorder and aggressive behavior in Chapter 13 and will discuss ADHD here as an example. In **internalizing problems**, negative emotions are internalized, or bottled up, rather than externalized, or expressed. Internalizing problems include anxiety disorders (such as persistent worrying about separation from loved ones), phobias, severe shyness and withdrawal, and depression.

Externalizing behaviors decrease from age 4 to age 18, whereas internalizing difficulties increase (Bongers et al., 2003). Externalizing problems are typically more common among boys, whereas internalizing problems are more prevalent among girls—a gender difference evident across cultures (Crijnen, Achenbach, & Verhulst, 1997). Yet cultural differences in values and parenting behavior make for cultural differences in how children's problems are expressed. For example, children in collectivist Asian cultures tend to show more depression, anxiety, and other internalizing symptoms than children in individualistic Western countries like the United States and Canada, whereas rates of externalizing problems such as aggression and disruptive behavior are higher in Western societies (Chen et al., 2014). Finally children from low socioeconomic status (SES) families show more externalizing and internalizing problems than children from higher SES families, partly because their environments are more stressful (Amone-P'Olak et al., 2009).

How do externalizing and internalizing problems arise, and to what extent do such problems in childhood spell trouble later in life? These questions concern the issues of nature–nurture and continuity–discontinuity in development.

Nature and Nurture

Most of us have a strong belief in the power of the social environment, particularly the family, to shape child development. This belief in a *parent effects model* of family influence (see Chapter 15) often leads us to blame parents—especially mothers—if their children are sad and withdrawn, uncontrollable and “bratty,” or otherwise different from most children. Parents whose children develop problems often draw the same conclusion, feeling guilty because they assume they are at fault. If instead we view developmental disorders from a family systems perspective and apply a *transactional model* of family influence, we appreciate how emerging problems both affect and are affected by family interactions. We understand that parents are important but that they both influence and are influenced by their children (Cowan & Cowan, 2006; Cummings & Valentino, 2015).

It is true that youngsters with depression, conduct disorder, and many other psychological disorders tend to come from families in which there is a history of psychological disorder, marital conflict, child maltreatment, or other problems (Connell & Goodman, 2002; Cummings & Valentino, 2015). However, a child in such a family may have a genetically based predisposition to disorder that would be expressed even if the child were adopted into another home early in life (Plomin et al., 2013). Moreover, “bad parenting” is sometimes the effect of a child's disorder rather than its cause (Cowan & Cowan, 2006).

Unquestionably, stress on a family and the ineffective or even abusive parenting that sometimes results from it contribute to and aggravate many childhood problems. In addition, children who are at genetic risk for psychological disorders may or may not develop disorders depending on whether they are parented effectively (Johnson et al., 2001; Sentse et al., 2009). As the

diathesis–stress model suggests, then, disorders often arise from the toxic interaction of a genetically based vulnerability and stressful experiences. Atypical development, like typical development, is the product of the interplay of nature and nurture.

Continuity and Discontinuity

The parents of children who develop psychological problems often most want to know this: Will my child outgrow these problems or will they persist? These parents are understandably concerned with the issue of continuity versus discontinuity in development. You have already seen that ASD persists beyond childhood in most individuals, but what about the broader range of childhood problems?

Consider some of the findings of a remarkable project called the Great Smoky Mountains Study (Costello, Copeland, & Angold, 2016). This study involved conducting psychiatric diagnostic interviews nine times by questioning a sample of children and their parents in the southeastern United States between the ages of 9 and 21 (Copeland et al., 2011). By age 21, 61% of participants had met the criteria for a psychological disorder at some point in their young lives. Another 21% at some point had shown evidence of what DSM calls disorders “not otherwise specified,” or mixed pictures of symptoms, bringing the grand total of individuals who had experienced at least one psychological disorder in childhood and adolescence to a whopping 82%. Although the percentage of youth with a disorder at any particular point in time is much lower, apparently abnormal behavior is very normal. Most of us clearly move back and forth between “normal” and “abnormal” developmental pathways over our lives.

The Great Smoky Mountains researchers have also examined connections between having a disorder at one age and having the same disorder, or possibly a different one, at a later age (Copeland et al., 2013). Overall, having a disorder early was associated with at least three times the risk of having it at a later time. Continuity was especially strong for externalizing problems such as ADHD, less strong for internalizing problems such as depression and anxiety. Quite often, an early disorder was also linked to a different kind of problem in adolescence or adulthood; for example, conduct disorder in childhood predicted a later substance use disorder, and anxiety in adolescence predicted depression in adulthood. This may have to do with the fact that comorbidity among psychiatric disorders is very common, especially in childhood. Overall, there was a good deal of continuity of psychological disorders from childhood to early adulthood—sometimes continuity of a particular disorder over time, other times continuity of a pattern of maladaptation that expressed itself differently in different life periods.

Finally, this project shed light on the implications of problems in childhood for adult adjustment by assessing adverse outcomes in early adulthood: psychiatric and health problems, legal problems such as incarceration, financial problems such as losing jobs, and social problems such as lack of social support (Costello et al., 2016; Copeland et al., 2015). About 60% of participants with one or more childhood psychiatric disorder had at least one adverse outcome in adulthood, compared to only about 20% of those without any childhood diagnoses.

There is room for discontinuity along with the continuity in development, however: Some children outgrow their problems.

For example, in another study of children and adolescents with behavioral and emotional problems, about 40% still had significant problems in adulthood, but most did not (Hofstra, Van der Ende, & Verhulst, 2000). So, having psychological problems as a child is a risk factor for later problems but it does not doom an individual to a life of maladjustment. If children have mild rather than severe problems and if they receive help, their difficulties are more likely to be overcome (Essex et al., 2009).

Indeed, some children show remarkable **resilience**, functioning well despite exposure to risk factors for disorder or overcoming even severe early problems to become well adjusted (Garmezy, 1994; Masten & Tellegen, 2012). Resilient children appear to benefit from protective factors such as their own competencies (especially intellectual ability and social skills) and strong social support (especially a stable family situation with at least one caring and effective parent figure). Overall, research on continuity and discontinuity in psychopathology brings home the importance of identifying and treating children with psychological problems early so that their developmental trajectories can be altered.

With the nature–nurture and continuity–discontinuity issues in mind, let us now focus on two illustrative childhood problems: attention deficit hyperactivity disorder, an externalizing disorder, and depression, an internalizing disorder.

Attention Deficit Hyperactivity Disorder

Upon entering high school I was determined to make high honor roll every quarter. It didn't quite work out that way though. . . . I was completely lost. I couldn't focus on work, I couldn't pay attention in class, and I couldn't concentrate on homework, rarely completing it as a result. . . . I was completely frustrated because I didn't understand why I was having such trouble. . . . My teachers knew I had the potential to do well, but they just figured I was lazy and not motivated. My parents were angry with me because my teachers told them I never did my homework. . . . I would try to sit down and write a paper, but there were too many thoughts in my head and too many things going on around me to even get a paragraph down. I would sit in the front row of my math class, with my notebook open and ready to take notes, but then something would catch my eye out the window and I'd miss the whole lesson. (Stone, 2009)

In this story, Rachel Stone describes her struggles with sustaining and focusing her attention, illustrating a key feature of **attention deficit hyperactivity disorder (ADHD)**. ADHD is diagnosed if either one of the following two sets of symptoms, or a combination of the two, is present (American Psychiatric Association, 2013 [DSM-5]; see also Hinshaw & Ellison, 2016; Selikowitz, 2009; Weyandt, 2007):

1. **Inattention.** The individual does not seem to listen, is easily distracted, makes careless errors, has trouble following instructions, misses details, is distractible, does not stick to activities and finish tasks, and tends to be forgetful and unorganized.
2. **Hyperactivity and Impulsivity.** The individual is restless, perpetually fidgeting, finger tapping, or chattering, and

Most children with attention deficit hyperactivity disorder show inattention but not hyperactivity; they often seem “spaced out” in the classroom.

Wolfgang Flamisch/Getty Images

has trouble remaining seated; he or she acts impulsively before thinking, cannot wait to have a turn in an activity, and may talk too much, blurt things out, and interrupt others.

ADHD is common—and like autism spectrum disorder, it is becoming more common now that it is better known and makes an affected child eligible for educational and medical services. Based on parent reports, 11% of children aged 4 to 17 in 2011 had been diagnosed as ADHD at some point in their lives, compared to 7.8% in 2003 (Visser et al., 2014). At least two boys for every girl have the disorder, although girls have often been underdiagnosed because they often show inattention rather than the more easily observable and often exasperating hyperactive behavior that boys more often show (Hinshaw & Ellison, 2016). The primarily inattentive form of ADHD is roughly twice as common as the primarily hyperactive-impulsive form (Froehlich et al., 2007). Most children with ADHD also have other comorbid conditions ranging from conduct disorder to anxiety and depression.

Developmental Course

ADHD expresses itself differently at different ages. When the predominant symptom is hyperactivity/impulsivity, the condition may reveal itself in infancy, though it cannot be diagnosed until about age 4. As infants, children with ADHD are typically very active, have difficult temperaments, and show irregular feeding and sleeping patterns (Teeter, 1998). As preschool children, they are in perpetual motion, quickly moving from one activity to another. Because most young children are energetic and have short attention spans, behavior must be judged in relation to developmental norms; otherwise, we might mistake most average 3- and 4-year-olds for hyperactive children. Finally, by

the grade-school years, overactive behavior is less of a problem, but children with ADHD are fidgety, restless, and inattentive to schoolwork (American Psychiatric Association, 2013).

What becomes of hyperactive children later in life? It used to be thought that they outgrew their problems. Most children with ADHD do outgrow their overactive behavior. However, as illustrated by Rachel’s story, adolescents with ADHD continue to be restless, to have difficulty concentrating on their academic work, and to behave impulsively; on average, they perform poorly in school and are prone to car accidents, substance abuse, and reckless delinquent acts (Hinshaw & Ellison, 2016). Those able to go on to college may need extra help to make the transition successfully (Weyandt & DuPaul, 2013).

The picture is somewhat more positive by early adulthood.

Yet many individuals with ADHD get in trouble because of disorganization, lapses of concentration, impulsive decisions, and procrastination (Schmidt & Petermann, 2009; Volkow & Swanson, 2013). In one study following ADHD and control children from about age 7 to age 21, the adults who had been identified as ADHD in childhood had lower educational attainment and achievement, had become involved in sexual activity and parenthood earlier, had been fired more and received lower performance ratings from their employers, and had fewer close friends and more problems in social relations (Barkley et al., 2006; and see Schmidt & Petermann, 2009).

In a national study, about half of children diagnosed with ADHD continued to meet the diagnostic criteria for ADHD as adults; inattention problems persisted more than hyperactivity/impulsivity problems (Kessler, Green et al., 2010). This evidence of continuity in ADHD across the life span is consistent with findings that over 4% of adults in the United States have diagnosable ADHD (Kessler et al., 2006). ADHD is evident even in old age (Brod et al., 2012); it is clearly not “kid stuff.” If you complete the short assessment in **Engagement 16.1**, you can see whether you show some of the behaviors characteristic of adult ADHD.

Suspected Causes

What causes this disorder? Russell Barkley (1997, 2015) has put forth the view that the frontal lobes of individuals with ADHD do not function as they do in typically developing children; this results in difficulties in **executive functions**—higher level control functions based in the prefrontal cortex of the brain that are critical in self-control—most importantly, difficulty inhibiting responses and organizing and regulating one’s emotions and behavior. Low levels or inefficient use of the neurotransmitters dopamine and

Could You Have ADHD?

Check the box that best describes how you have felt and conducted yourself over the past 6 months.

	Never	Rarely	Sometimes	Often	Very Often
1. How often do you have trouble wrapping up the final details of a project once the challenging parts have been done?					
2. How often do you have difficulty getting things in order when you have to do a task that requires organization?					
3. How often do you have problems remembering appointments or obligations?					
4. When you have a task that requires a lot of thought, how often do you avoid or delay getting started?					
5. How often do you fidget or squirm with your hands or feet when you have to sit down for a long time?					
6. How often do you feel overly active and compelled to do things, like you were driven by a motor?					

Add up the number of check marks in the shaded boxes. If you have four or more checks in the shaded boxes, then you may want to talk to a professional about your behaviors and feelings to determine if you might have ADHD. Remember that this self-assessment is not a definitive diagnosis and needs follow-up if your answers are suggestive of ADHD.

norepinephrine, which are involved in communication among neurons in the frontal lobes, seem to be at the root of the inattention, executive function impairments, and other differences in cognitive functioning that individuals with ADHD show (Hinshaw & Ellison, 2016). The frontal cortexes of children with ADHD may also be slower to mature than those of other children and may or may not catch up by adulthood (Shaw et al., 2012).

Genes predispose some individuals to develop ADHD and probably underlie the differences in brain functioning associated with it. Genes account for as much as 60–90% of the variation among individuals in whether they have ADHD (Scerif & Baker, 2015; Waldman & Gizer, 2006). First-degree relatives of someone with ADHD have 4 to 5 times the usual risk (Thapar, 2003). There is not one ADHD gene, however. There may be 100 or more gene variants common in individuals with ADHD that influence levels of dopamine and other relevant neurotransmitters in their brains.

Environmental influences are also important, as they help determine whether a genetic risk turns into a reality and whether the individual adapts well or poorly as she develops (Hinshaw & Ellison, 2016). The myth that ADHD is due to consuming sugar has long been put to rest (Weyandt, 2007). There is still some uncertainty about whether food colorings or dyes contribute. It seems clear that food dyes are not a major cause of ADHD, but they may have small negative effects on some children (Arnold, Lofthouse, & Hurt, 2012; Kleinman et al., 2011). Low birth weight and teratogens such as maternal smoking and alcohol use and exposure to lead, air pollution, and other toxic chemicals during pregnancy appear to contribute to some cases of ADHD (Banerjee, Middleton, & Faraone, 2007; Hinshaw & Ellison, 2016). And

genes and environment interact: Individuals who inherit genes that lower dopamine levels in the brain and who also experience family adversity show more ADHD symptoms than children who do not have both genes and environment working against them (Laucht et al., 2007). Meanwhile, parents who are able to remain authoritative parents in the face of the challenges of raising a child with ADHD are likely to end up with a more manageable child than parents who respond negatively and harshly to their children's behavior (Hinshaw & Ellison, 2016).

Treatment

Most children with ADHD are prescribed stimulant drugs (often Ritalin or Adderall), and most are helped by these drugs. Although it may seem odd to give overactive children stimulants, the brains of individuals with ADHD are actually underaroused. These drugs increase levels of dopamine and other neurotransmitters to normal levels and, by doing so, allow these children to concentrate (Hinshaw & Ellison, 2016). Listen to Rachel Stone again:

I was put on the medication Adderall one month before sophomore year concluded. I was able to pull up all my grades. . . . Things only got better with junior year. . . . With the Adderall, I was able to focus in class and remember how much I liked math! I ended up with the highest average in the pre-calculus classes. . . (Stone, 2009)

Yet controversy surrounds the use of stimulants with ADHD children. Some critics argue that these drugs are prescribed to too many children, including many who do not actually have ADHD (Mayes, Bagwell, & Erkulwater, 2009). Other critics are concerned

that stimulant drugs have undesirable side effects such as loss of appetite and headaches and may do longer-term damage that we do not yet know about (Mayes et al., 2009). What's more, stimulant drugs do not cure ADHD; they improve functioning only until their effects wear off.

Behavioral treatment is also used to treat ADHD. The Multimodal Treatment Study of Attention Deficit Hyperactivity Disorder (MTA), a carefully conducted national study of 579 children with ADHD ranging in age from 7 to 9, pitted medication and behavioral treatment against each other (Jensen et al., 2001; Molina et al., 2009). The study randomly assigned children to receive optimally delivered medication, state-of-the-art behavioral treatment (a combination of parent training, child training through a summer program, and school intervention), a combination of the two approaches, or routine care in the community over 14 months. The findings were clear: Medication alone was more effective than behavioral treatment alone or routine care in reducing ADHD symptoms such as inattention (see also Scheffler et al., 2009). However, a combination of medication and behavioral treatment was superior to medication alone when the goal was defined as not only reducing ADHD symptoms but also improving academic performance, social adjustment, and parent-child relations. A multi-pronged approach is generally recommended now (Chronis, Jones, & Raggi, 2006; Hinshaw & Ellison, 2016):

- medication;
- behavioral programming designed to teach children with ADHD to stay focused on tasks, control their impulsiveness, and interact socially;
- parent training designed to help parents understand and manage the behavior of these often-difficult youngsters; and
- interventions at school to make the learning environment more structured and increase motivation.

A caveat, though: An 8-year follow-up of children in the Multimodal Treatment Study revealed that differences among the treatment groups had faded by the time these children were adolescents and that, regardless of which treatment they received, children with ADHD had more academic and social problems than comparison children who did not have ADHD (Molina et al., 2009). Most children who had received medication during the study had since stopped using it but were doing as well as those who continued their medication. Overall, then, the study suggests that, while medication and behavior treatment can significantly improve functioning in the short term, achieving long-term improvement is more challenging. This means that some individuals with ADHD may need to continue taking medication or receiving psychotherapy during adulthood (Volkow & Swanson, 2013).

Depression

As you saw earlier, the depressive symptoms displayed by some infants may or may not qualify as major depressive disorder. When, then, can children experience true clinical depression? For years many psychologists and psychiatrists, especially those influenced by psychoanalytic theory, argued that young children simply could not be depressed. Feelings of worthlessness, hopelessness, and self-blame were not believed to be possible until the

child was older (Garber, 1984). Besides, childhood is supposedly a happy, carefree time, right?

It is now clear that children as young as 3 can meet the same DSM criteria for major depressive disorder used in diagnosing adults (Garber, 2010). Depression in children is rarer than depression in adolescents and adults, but an estimated 2% of children have diagnosable depressive disorders (Gottlib & Hammen, 1992). Their depression is often comorbid with other disorders, especially anxiety disorders, but also conduct disorder, oppositional defiant disorder, and ADHD (Garber, 2010; Whalen et al., 2015). Such comorbidity, so common in childhood, not only makes it difficult to diagnose psychological problems but raises larger questions about how distinct different DSM disorders really are.

Depression expresses itself differently in a young child than in an adult. Like depressed infants, depressed preschool children are more likely to display the behavioral and somatic symptoms of depression (losing interest in activities, eating poorly, and so on) than to talk about feeling depressed or hopeless (Kaslow et al., 2000). Yet as early as age 3 some children who are depressed express excessive shame or guilt—claiming, for example, that they are bad (Luby et al., 2009). In diagnosing depression, the main characteristics to look for are either sadness or irritability (children may express their depression either way) along with the lack of interest in usually enjoyable activities that depressed adults display (Garber, 2010; Luby et al., 2006).

Suicide Attempts?

Some young children—about one in ten 3- to 7-year-olds in one study—also have suicidal thoughts or act out themes of death and suicide in their play (Whalen et al., 2015). What may not have occurred to you is that children as young as 3 are also capable of

Even young children can experience a major depressive episode.

Jeges-Varga Ferenc/Shutterstock.com

not only thinking about suicide but attempting it (Rosenthal & Rosenthal, 1984; Shaffer & Pfeffer, 2001):

- At age 3, Jeffrey repeatedly hurled himself down a flight of stairs and banged his head on the floor; upset by the arrival of a new brother, he was heard to say, “Jeff is bad, and bad boys have to die” (Cytryn & McKnew, 1996, p. 72).
- An 8-year-old, after writing her will, approached her father with a large rock and asked in all seriousness, “Daddy, would you crush my head, please?” (Cytryn & McKnew, 1996, pp. 69–70).
- Other children have jumped from high places, run into traffic, and stabbed themselves, often in response to abuse, rejection, or neglect.

Moreover, children who attempt suicide once often try again (Shaffer & Pfeffer, 2001). Very few children actually commit suicide (Westfeld et al., 2010), but the moral is clear: Parents, teachers, and human service professionals need to appreciate that childhood is not always a happy, carefree time and that children can develop serious depressive disorders and suicidal tendencies. Children’s claims that they want to die should be taken dead seriously.

Carryover of Depression

Do depressed children tend to have recurring bouts of depression, becoming depressed adolescents and adults? Most children make it through mild episodes of sadness, and carryover of depression problems from childhood to adulthood is not as strong as carryover from adolescence to adulthood. However, there is indeed carryover of depression from the preschool years to the school years and from the school years to adolescence (Luby et al., 2014). It is estimated that half of children and adolescents diagnosed as having major depressive disorder have recurrences in adulthood (Kessler, Avenevoli, & Merikangas, 2001).

Is it possible to identify in early childhood individuals who may not be diagnosable as depressed yet but who are at risk to become depressed in adolescence or adulthood? Major depression in a parent and traumatic early experiences such as being abused are clear warning signs, but neuropsychologists are also looking for biological signs of a predisposition to depression. To illustrate, one group of researchers (Luking et al., 2016b) is focusing on the brain’s response to reward. People who are depressed do not seem to derive pleasure from their experiences. Brain imaging studies show that the reward centers of their brains show a blunted response to rewards such as candy, a happy face image, or acceptance of an invitation to chat by a peer. This blunted response to reward can also be observed in adolescents who have not been diagnosed with depression but who are at risk for it because a parent has experienced major depression.

Katherine Luking and her colleagues (2016a) used fMRI to look for a blunted response to reward in the brains of children aged 7–10 as they played a game in which they guessed whether the number on a card was more or less than 5 and got candy if they were correct but lost candy if they were wrong. Children whose mothers had had major depression showed the same blunted response to reward that adolescents of depressed mothers had shown. Interestingly, they also showed a heightened sensitivity to losing, suggesting that neural responses to the loss of rewards may be even more important than responses to reward in identifying children who are at risk for depression. Think about

the implications: If researchers can identify, through brain imaging or other methods, children who show biological signs of risk for depression, it may become possible to intervene early to prevent depression as well as to prevent the further changes in brain development that result from depression (Luby et al., 2016).

Treatment

Most depressed children—and children with other psychological disorders too—respond well to psychotherapy (Carr, 2009; Kazdin, 2003). **Cognitive behavioral therapy**, a well-established psychotherapy approach that identifies and changes distorted thinking and the maladaptive emotions and behavior that stem from it, has proved especially effective (Brent & Maalouf, 2009; Weisz, McCarty, & Valeri, 2006). But since preschool children have limited cognitive and linguistic skills, might there be a more developmentally appropriate way to treat them? This question is explored in **Application 16.1**.

Depressed children have also been treated with antidepressant drugs called selective serotonin reuptake inhibitors, such as Prozac (fluoxetine), that correct for low levels of the neurotransmitter serotonin in their brains. These drugs can help correct for biased information processing that emphasizes negative emotional material and for overreactivity to stress (Gotlib, Joormann, & Foland-Ross, 2014). However, antidepressant drugs do not appear to be as effective with children as with adults, and a warning that they may increase suicidality in children and adolescents who take them was issued by the U.S. Food and Drug Administration in 2004 (Vitiello, Zuvekas, & Norquist, 2006). Antidepressants are still prescribed in some cases for seriously depressed youth who are likely to be at even greater risk of suicide if they are not treated with medication, but antidepressant drugs are now prescribed less often and with more careful monitoring of the child’s reactions (Nemeroff et al., 2007). In sum, both ADHD and major depression can significantly alter the course of development in childhood and beyond, so detecting and treating these problems early is important.

● Checking Mastery

1. How would you describe the main difference between an externalizing and an internalizing disorder in childhood?
2. What two major sets of symptoms characterize ADHD?
3. What is the agreed-upon best way to treat ADHD and in what way is it limited?
4. How is major depression in a preschool child similar to and different from major depression in an adult?

● Making Connections

1. Focusing on depression in childhood and citing evidence, what do you conclude about the nature/nurture and continuity/discontinuity issues as they pertain to depression?
2. Some experts believe that ADHD is overdiagnosed and over-treated with medications. Others, however, believe that not enough cases of ADHD are being treated with medications. What is your position on diagnosis and treatment of ADHD and how does the material in this chapter support—and fail to support—your view?

● APPLICATION 16.1

How Do You Treat a Depressed 3-Year-Old?

So, children as young as 3 years can be diagnosed with major depressive disorder, but how in the world do you treat a depressed preschool child? Antidepressant drugs are generally not advisable at this age, and many forms of “talking” therapy designed for adults are simply not usable with children because of their limited verbal and cognitive skills. We do not know much yet about the effectiveness of treatments for depression and anxiety disorders in the preschool years (Luby, 2013). However, Joan Luby and her colleagues have developed one promising approach that illustrates how psychotherapy can be adapted to the developmental characteristics of young children.

Luby and her associates started with a child therapy approach called **Parent–Child Interaction Therapy (PCIT)** that was originally developed by Sylvia Eyberg and her colleagues (see Eyberg & Bussing, 2010) to treat children with disruptive behavior. The PCIT approach centers on modifying the parent–child relationship and building more effective parenting skills. Parents first learn to let their children take the lead in play while giving them positive attention and reinforcement; in a second phase, they learn to lead the child’s activity

using effective discipline techniques (for example, getting them to comply with requests). Through parent training, especially coaching by the therapist through a wireless system while parent and child interact, the parent becomes the vehicle for changing the quality of parent–child interactions and the child’s behavior.

Luby, Lenze, and Tillman (2012) adapted PCIT to treat depression in young children, creating what they called Parent–Child Interaction Therapy—Emotional Development (PCIT-ED). They added to the usual PCIT components a component focused on enhancing the child’s emotional development and emotion regulation skills. Because depression involves too much negative affect and too little positive affect, parents are taught to help their children recognize, express, and regulate negative and positive emotions—for example, to minimize sad feelings and intensify happy feelings. In other words, parents learn to be good emotion coaches (see Chapter 14).

Children aged 3 to 7 who had been diagnosed with major depression were randomly assigned to either the PCIT-ED treatment or to a control intervention in which small groups of parents learned about child development. After

some families dropped out, especially from the control group, the researchers were left with only 19 children in the PCIT-ED group and 10 in the control group, groups too small to provide a definitive test. However, compared to the control children, the children treated with PCIT-ED showed better emotion recognition skills and executive functioning and fewer symptoms of depression. Meanwhile, their parents scored lower on a measure of parenting stress as well as on a measure of their own depression symptoms, a finding that might be significant for future parent–child interactions given what we know about the negative effects of parent depression on parent–child interactions and child development.

Because depression in the preschool years predicts major depressive disorder later in childhood (Luby et al., 2014), it makes great sense to be on the lookout for depressed children and get them the treatment they need before their condition becomes more firmly rooted. It also makes sense to mobilize their parents as therapists. The PCIT approach is also being applied successfully to treat preschool children with conduct problems (Niec et al., 2016) as well as those with anxiety disorders (Carpenter et al., 2014).

16.4

The Adolescent

LEARNING OBJECTIVES

- Evaluate the “storm and stress” view of adolescence and discuss the factors that contribute to a peaking of risky problem behaviors in adolescence.
- Summarize the nature, causes, and preferred treatment of anorexia nervosa.
- Describe substance use in adolescence and how the cascade model accounts for the development of substance use problems.
- Explain why depression rates climb in adolescence, especially among females.
- Describe gender differences in adolescent suicidal behavior and explain why some adolescents attempt or commit suicide.

If any age group has a reputation for having problems, it is adolescents. This is supposedly the time when angelic children are transformed into emotionally unstable, uncontrollable delinquents. The view that adolescence is a time of emotional storm and stress was set forth by the founder of developmental psychology, G. Stanley Hall (1904). It has been with us ever since.

Storm and Stress?

Are adolescents really more likely than either children or adults to experience psychological problems? On one hand, adolescents have a worse reputation than they deserve. Most adolescents are not emotionally disturbed and do not engage in serious problem behaviors such as drug abuse and chronic delinquency. Instead,

significant mental health problems—real signs of storm and stress in the form of diagnosable disorders—characterize a minority of adolescents, adolescents like Peggy, described at the beginning of the chapter (Merikangas et al., 2010). Moreover, many of these adolescents were maladjusted before they reached puberty and continue to be maladjusted during adulthood (Reinherz et al., 1999).

Yet there is some truth to the storm-and-stress view. Adolescence is a period of risk taking, of problem behaviors such as substance abuse and delinquency, and of heightened vulnerability to certain forms of psychological disorder (Cicchetti & Rogosch, 2002; Steinberg, 2011). The Centers for Disease Control and Prevention (2013) estimates that 13% to 20% of children aged 3 to 17 experience a psychological disorder in a given year and that rates of disorder climb with age from childhood to adolescence. It is estimated that about 25% of adults are affected by a disorder in a given year (Kessler & Wang, 2008).

Teenagers face greater stress than children; they must cope with physical maturation, changing brains and cognitive abilities, tribulations of dating, changes in family dynamics, moves to new and more complex school settings, societal demands to become more responsible and to assume adult roles, and more (Cicchetti & Rogosch, 2002). Most adolescents cope with these challenges remarkably well, maintain the level of adjustment they had when they entered adolescence, and undergo impressive psychological growth. Many feel depressed, anxious, and irritable occasionally, though, and as many as one in five experiences a diagnosable psychological disorder. These adolescents' problems should not be dismissed as a "phase" they are going through.

Adolescent Problem Behaviors

Many adolescents get themselves into trouble by binge drinking and using drugs, having risky sex, engaging in vandalism and other law-breaking behavior, and displaying other so-called adolescent problem behaviors. Adolescents are more likely than either children or adults to engage in some of these risky behaviors (Defoe et al., 2015). Adolescent problem behaviors usually do not reach the level of seriousness to qualify as psychological disorders, but they are of concern nonetheless (Boles, Biglan, & Smolkowski, 2006; Jessor, 1998).

Why do problem behaviors increase in adolescence? First, these behaviors often grow out of normal developmental tasks of adolescence: establishing an identity, establishing autonomy and independence from parents, and gaining acceptance by peers and romantic partners. Teens experiment with lots of new behavior to find out who they are, challenge their parents' authority, and impress other kids. Second, puberty and the hormonal changes that come with it appear to contribute to increases in both internalizing and externalizing problems (Mendle, 2014). And third, the timetable for brain development makes risk taking especially likely in adolescence. As you learned in Chapter 5, adolescents' brains combine strong sensation- and reward-seeking tendencies with immature prefrontal cortexes and therefore limited capacities for self-regulation (Albert, Chein, & Steinberg, 2013; Shulman et al., 2016; and see Chapter 5). The result is sometimes impulsive risk taking in pursuit of excitement and enjoyment without much self-control or thought of the likely consequences. Such risky behavior is most likely when

adolescents are with friends and when their emotions are aroused. Children, whose prefrontal cortexes are also underdeveloped, often show as much risk taking as adolescents do in laboratory settings. However, in the real world adolescents have much more opportunity than children to take risks because they are more often around temptations and out of the sight of adults (Defoe et al., 2015). Advice to parents: Recognize that your teens have immature brains and do what you can to minimize their opportunities to take risks that can hurt themselves or others (Steinberg, 2015).

In sum, adolescence is a challenging period of the life span; problem behaviors such as substance use and delinquency increase—the result of risk taking fueled by needs for identity, autonomy, and peer acceptance, the hormonal changes of puberty, and incomplete brain development. Partly for these same reasons, certain diagnosable disorders also become more prevalent in adolescence. Having discussed adolescent externalizing problems like aggression and conduct disorder in Chapter 13, let us look here at eating disorders such as anorexia nervosa that can make the adolescent period treacherous and even fatal; experimentation with alcohol and drugs that can turn into substance abuse; and depression, whose rate increases dramatically from childhood to adolescence. These problems interfere with adolescent development; yet they become far more understandable when viewed in the context of adolescence.

Eating Disorders

Perhaps no psychological disorders are more closely associated with adolescence than the eating disorders that disproportionately strike adolescent females, especially during the transition from childhood to adolescence at around age 14 and again during the transition from adolescence to emerging adulthood at around age 18 (Bryant-Waugh, 2007; Eddy, Keel, & Leon, 2010). Eating disorders—*anorexia nervosa*, *bulimia nervosa*, *binge eating disorder* (a new distinct disorder starting in DSM-5), and related conditions—have become more common in industrialized countries in recent decades (Eddy et al., 2010; Milos et al., 2004). They are serious—indeed, potentially fatal—conditions that are difficult to cure.

Anorexia nervosa, which literally means “nervous loss of appetite,” is characterized by:

- body weight that is less than minimally normal for the person's gender, height, and age;
- a strong fear of becoming overweight or behavior that interferes with gaining weight; and
- a tendency to feel fat despite being emaciated, to be overly influenced by weight or shape in evaluating the self, and to fail to appreciate the seriousness of one's low body weight (American Psychiatric Association, 2013).

Bulimia nervosa, the so-called binge-purge syndrome, involves recurrent episodes of consuming huge quantities of food followed by purging activities such as self-induced vomiting, use of laxatives, rigid dieting and fasting, or obsessive exercising (Pinhas et al., 2007). **Binge eating disorder** involves binge eating without the purging.

A study of adolescent females involving annual diagnostic interviews administered from age 13 to age 21 revealed that by age 20 over

5% of these young women had experienced at least one of these three disorders (Stice, Marti, & Rohde, 2012). A total of 13% had experienced either one of these eating disorders or a less clearcut, “sub-threshold” form of eating disorder. We will focus here on anorexia, the least common but most life threatening of the three disorders.

The typical individual with anorexia may begin dieting soon after reaching puberty and simply continue, insisting, even when she weighs only 60 or 70 pounds, that she needs to lose a few more pounds (Hsu, 1990). Praised at first for losing weight, she becomes increasingly obsessed with dieting and exercising and may gain a sense of control by resisting the urgings of parents and friends to eat more (Levenkron, 2000).

There are about 11 affected females for every 1 affected male (van Hoeken, Seidell, & Hoek, 2003), a huge gender difference. It is a myth that anorexia nervosa is restricted to European American females from upper-middle-class backgrounds. It occurs at all socioeconomic levels and in all racial and ethnic groups. African American females are less affected, however, probably because they are more satisfied with their bodies and less concerned than European American and Asian American females with dieting and being thin (Franko & George, 2009).

Suspected Causes

Nature and nurture contribute in complex ways to eating disorders. On the nurture side, sociocultural factors are significant. Rates of eating disorders vary widely around the world, being highest in Western or Westernized countries and in urban areas within

Anorexia can be life threatening.

Angela Hampton Picture Library/Alamy Stock Photo

countries (Anderson-Fye, 2009; Culbert, Racine, & Klump, 2015). We live in a society obsessed with thinness as the ideal of physical attractiveness—a society that makes it hard for young women to feel good about their bodies (Eddy et al., 2010; Keel & Klump, 2003). As the Western thinness ideal has spread to other countries, rates of eating disorders in those countries have risen. Interestingly, exposure to television on the island of Fiji converted girls raised to view plump bodies as a status symbol associated with the generous sharing of food into girls who feel too fat and try to lose weight (Becker et al., 2002).

Well before they reach puberty, starting as early as preschool, girls in our society begin to associate being thin with being attractive, fear becoming fat, and wish they were thinner (Hill, 2007; Ricciardelli & McCabe, 2001). They play with ultrathin Barbie dolls and see ultrathin models and celebrities on television and in magazines (Dittmar, Halliwell, & Ive, 2006; Dohnt & Tigge-mann, 2006). These kinds of cultural messages about the **thin ideal** help explain why about a fourth of second-grade girls in one study said they dieted (Thelen et al., 1992; and see Hill, 2007).

Genes, though we are not sure which ones, serve as a diathesis, predisposing certain individuals to develop eating disorders (Eddy et al., 2010; Keel & Klump, 2003). Twin and adoption studies suggest that around half of the variation in risk for eating disorders is attributable to genes; the remainder is mostly tied to nonshared or individual experiences rather than to experiences shared with siblings (Culbert, Racine, & Klump, 2015).

Biochemical abnormalities have been detected in individuals with anorexia that may underlie their symptoms. For example, low levels of the neurotransmitter serotonin, which is involved in both appetite and mood and has been linked to both eating disorders and mood disorders, may be involved (Klump & Culbert, 2007). The neurotransmitter dopamine, important in the brain’s reward system, has also been implicated; eating disorders, like alcohol and drug addiction, may involve compulsive behavior that becomes reinforcing (Halmi, 2009; and see Klump & Culbert, 2007). Genes also contribute, along with environment, to a personality profile that puts certain individuals at risk; females with anorexia tend to be obsessive perfectionists and score high on measures of negative emotionality or neuroticism (Culbert, Racine, & Klump, 2015).

Why is adolescence the prime time for the emergence of eating disorders in females? Here, too, we must consider both social and biological factors. As girls steeped in the thinness ideal experience normal pubertal changes, they naturally gain fat and become, in their minds, less attractive just when the pressure is on to be more attractive (Murnen & Smolak, 1997). Genetic and hormonal influences also help explain why some girls are so susceptible to eating disorders when they reach puberty. Kelly Klump and her colleagues have discovered in twin studies that, among prepubertal girls, genes have little to do with eating attitudes and behaviors; but among girls who have reached puberty, genes explain over 50% of the variation in eating attitudes and behaviors (Klump, McGue, & Iacono, 2003; Klump et al., 2012). In boys, by contrast, genetic influences on eating attitudes and behaviors are evident before puberty, during puberty, and after puberty (Klump et al., 2012). Possibly, then, increases in female hormones during puberty activate a genetically based risk for eating disorders in certain girls (Culbert et al., 2015; Klump et al., 2010, 2012).

Yet anorexia still may not emerge unless a genetically predisposed adolescent girl living in a weight-conscious culture also experiences an environment that fosters eating problems and a buildup of stressful events (Eddy et al., 2010). Girls who are overly concerned about their weight sometimes come from families that are preoccupied with weight, where mothers may model and reinforce disordered eating or even have eating disorders themselves (Eddy et al., 2010; Micali et al., 2015; Sim et al., 2009). Some experience pressure and criticism at home; family environment may then interact with genetic makeup to increase the risk of an eating disorder (Culbert et al., 2015). It often takes stressors or traumatic events of some kind to push a vulnerable young woman over the edge (Reyes-Rodríguez et al., 2011).

In anorexia nervosa, then, we have another clear example of the diathesis–stress model at work. A young woman who is at risk for it partly because of her genetic makeup and the hormonal changes associated with puberty may not develop anorexia unless she also grows up in an environment that overvalues thinness and faces overwhelming stress.

Prevention and Treatment

Can eating disorders be prevented before they start? Eric Stice and his colleagues have been testing the effectiveness of what they call the Body Project, a preventive program that can be administered either on the Internet or in groups (Stice & Presnell, 2007; Stice et al., 2009). The program attempts to get adolescent girls and college women who have body image concerns to stop buying into the thin ideal by having them critique it in essays, role plays, and other exercises. The cognitive dissonance created by coming out against the thin ideal is expected to motivate these young women to stop pursuing thinness as their goal.

In an intervention study with 306 adolescent girls who had body image concerns, the researchers compared a school-based version of their cognitive dissonance program with an educational brochure on eating disorders. The program proved effective in reducing internalization of the thin ideal and, in turn, reducing body dissatisfaction, dieting efforts, and eating disorder symptoms. An Internet-based version of the program and group sessions led by peer leaders have also proven effective with both high school and college students (Stice et al., 2012; Stice, Becker, & Yokum, 2013). The program even results in neural responses assessed through fMRI that suggest less valuing of thin models as compared to average-weight models (Stice, Yokum, & Waters, 2015). Here, then, an ounce of prevention may be worth at least a pound of cure.

What can be done for individuals who develop eating disorders? Effective treatment of individuals who have anorexia typically starts with behavior modification designed to bring their eating behavior under control, help them gain weight, and deal with any medical problems they may have, in a hospital or treatment facility if necessary (Patel, Pratt, & Greydanus, 2003). Then it is possible to move on to such options as psychotherapy designed to help them understand and gain control of their problem and medication for depression and related psychological problems (see Grilo & Mitchell, 2010).

Family therapy approaches appear to be more effective in the long run than individual treatment (Couturier, Kimber, & Szatmari, 2013). In the well-regarded Maudsley Hospital approach

developed in London, the goal is to involve parents and other family members as part of the treatment team, help them respond more constructively to the patient's eating behavior in order to facilitate weight gain, and once weight is under control, help them focus on broader family or individual issues such as the adolescent's need for more autonomy (Blessitt, Voulgari, & Eisler, 2015; Hurst, Read, & Wallis, 2012).

Substance Use Disorders

She lost count of the vodka shots. It was New Year's Eve . . . , and for this high school freshman, it was time to party. She figured she'd be able to sleep it off—she'd done it before. But by the time she got home the next day, her head was still pounding, her mouth was dry, and she couldn't focus. This time, the symptoms were obvious even to her parents. After that night, she realized the weekend buzzes had gone from being a maybe to a must. (Aratani, 2008, p. C1)

One of the ways in which some adolescents explore their identities, strive for peer acceptance, and reach toward adulthood is by experimenting with smoking, drinking, and drug use. For some, like this high school freshman (and Peggy at the start of the chapter), substance use moves beyond experimentation to abuse. In DSM-5 language, **substance use disorders** occur when a person continues to use a substance, whether alcohol, marijuana, or something else, despite adverse consequences such as putting the individual in physically dangerous situations, interfering with performance in school or at work, or contributing to interpersonal problems. People with substance use disorders may crave a substance or substances, be unable to control their use of substances or quit, develop an increased tolerance for a substance, and experience withdrawal symptoms if use is terminated.

The tolls of substance use disorders on development can be heavy. As noted in Chapter 5, for example, teens under the influence of alcohol are likely to make additional risky choices that can have negative consequences for themselves or others: smoking, having risky sex, driving under the influence, getting into fights, and engaging in illegal behavior, for example. Concerns also include effects of drinking, especially binge drinking, on the nervous system during a period of important brain development when the brain is vulnerable to being rewired in ways that make negative effects on cognitive abilities and future addiction more likely (Conrod & Nikolaou, 2016; Lisdahl et al., 2013; Spear, 2015). Similar evidence of negative effects of marijuana on brain development, cognitive functioning, and motivation in adolescence is emerging (Volkow et al., 2016). Indeed, both heavy alcohol use and heavy marijuana use in adolescence have negative impacts on occupational and financial success and the quality of interpersonal relationships in adulthood (Cerdá et al., 2016; Chassin et al., 2010; Volkow et al., 2016).

Substance Use Rates

Just how widespread is substance use in adolescence? For years, the Monitoring the Future study has tracked rates (Johnston et al.,

2016). The percentages of adolescents at various grade levels who reported in 2015 that they had used different substances are shown in ■ **Figure 16.3**. These percentages are not as high as those reported in the 1970s and early 1980s, but they indicate that some experimentation with alcohol and marijuana is quite common and increases with age.

Alcohol has long been the most widely used substance. By 12th grade (age 17 or 18), about two thirds of teens have had a drink, and 17% report binge drinking in the past 2 weeks—drinking five or more drinks on one occasion (Johnston et al., 2016). Binge drinking is an even more serious problem among college students; about 35% reported binge drinking in the two weeks before they were surveyed (Johnston et al., 2015). The risk of brain damage and even death from this kind of drinking to get drunk, especially for teens, is real. One emergency room physician put it this way: “We’re seeing kids coming in with blood alcohol levels in the mid-.3s, even .4, which is four to five times the legal limit for driving. That’s the level at which 50% of people die” (Listfield, 2011, p. 7).

Males have traditionally had higher rates of substance use and abuse than females, but the gap has narrowed over the years (Johnston et al., 2016). Ethnic differences in substance use are also evident: Native American youth have high rates of use, Hispanic white and non-Hispanic white youth have medium rates, and Asian American and African American youth have the lowest rates (Johnston et al., 2016; Woo & Keatinge, 2008).

■ **Figure 16.3** Percentages of adolescents in grades 8, 10, and 12 who report ever using various substances. Alcohol use and marijuana use are common and increase with age. The other illicit drugs besides marijuana that were studied, such as cocaine, heroin, and amphetamines, have each been tried by under 10% of the adolescents.

A Cascade of Contributors

It is now evident that the developmental pathway to adolescent substance use and abuse begins in childhood. A major study by Kenneth Dodge and others (2009) attempted to integrate what is known about contributors to the use of illicit drugs in adolescence in a **cascade model of substance use**. Similar cascade models have been formulated to help account for the development of a variety of problems (Dodge et al., 2008; Masten et al., 2005; and see Chapter 13 on aggression). A cascade model is a transactional, multifactor model that envisions development as a flow of water over a series of waterfalls, gaining momentum as it goes, as each influence along the way helps realize the previous factors and contributes to the next influence in the chain of influence. Dodge’s cascade of substance use begins with:

1. a child who is at risk due to a difficult temperament, born into
2. an adverse family environment characterized by such problems as poverty, stress, and substance use, who is
3. exposed to harsh parenting and family conflict, and therefore develops
4. behavior problems, especially aggression and conduct problems, and therefore is
5. rejected by peers and gets into more trouble at school, so that
6. parents give up trying to monitor and supervise their now difficult-to-control adolescent, which contributes to
7. involvement in a deviant peer group, where the adolescent is exposed to and reinforced for drug taking and other deviant behavior.

The cascade model was tested in a longitudinal study that entailed annual assessments of 585 children from prekindergarten through 12th grade. Substance use was measured in grade 7 to grade 12 as any use of marijuana, inhalants, cocaine, heroin, or another illicit drug. Use clearly increased with age, from 5% in grade 7 to 22% in grade 10 to 51% in grade 12. The seven groups of factors in the cascade model each predicted both the next step in the cascade and involvement in substance use. All in all, the model captures well the developmental concept that adolescent problem behaviors and psychological disorders do not spring out of nowhere. Instead, they grow out of the accumulating effects of transactions between an individual and parents, peers, and other aspects of the social environment over many years. The model points to the possible value of substance abuse prevention programs targeting at-risk children long before adolescence. Although it becomes harder to stop the cascade toward substance use as the years go by, there are new opportunities to intervene at each step. We know that preventive interventions to delay drinking and drug use in adolescence can head off problematic substance use in adulthood (Spoth et al., 2009; and see Sloboda, 2009).

How can this cascade model be improved? Many explanations of substance use and abuse put more emphasis on genetics. Because of their genes, some individuals are more vulnerable to substance abuse as well as to the effects of environmental influences described in the cascade model (Dick, Prescott, & McGue,

2009; Sartor et al., 2010). Moreover, what we often assume are peer socialization effects on substance use (effects of friends on an adolescent's substance use) need to be studied more closely, as they could instead be peer selection effects (effects of an adolescent's substance use tendencies, possibly genetically based, on whether she chooses drinking or nondrinking friends). As **Exploration 16.1** illustrates, this **peer socialization/peer selection issue** is important in gauging whether peers truly influence us. In the end, alcohol and drug abuse are the developmental outcomes of interactions among many genes and a cascade of many environmental factors.

Depression and Suicidal Behavior

Before puberty, boys and girls have similarly low rates of depression; after puberty, rates climb, and the rate of depression for females becomes twice that of males in adolescence and adulthood—in our society and in others (Garber, 2010). In one study of female adolescents, the rate of major depressive disorder at some time in the individual's life was 1% among girls younger than age 12 but 17% among young women age 19 and older (Glowinski et al., 2003). Adolescent depression looks more like adult depression, with cognitive symptoms such as hopelessness (Garber, 2010; Mendle, 2014). However, depressed adolescents sometimes act out and look more like delinquents than like

● EXPLORATION 16.1

Peer Socialization or Peer Selection?

If we don't blame adolescent problem behaviors on bad parenting, we tend to blame them on negative peer influences. We say, for example, that someone got into trouble with alcohol and drugs because she got in with the "wrong crowd." But are similarities between adolescents and their friends in, say, alcohol use the result of *peer socialization* (peer influence on adolescents) or *peer selection* (the tendency of adolescents to choose friends who are like themselves, whether they are heavy drinkers or teetotalers). Much tells us that peer selection is a real phenomenon—that birds of a feather flock together. And often both socialization and selection are at work in adolescent substance use (Cruz, Emery, & Turkheimer, 2012; Hill et al., 2008; Simons-Morton & Farhat, 2010).

Using the twin study approach, for example, Jennifer Cruz and her colleagues (2012) established that the level of alcohol use in an adolescent's peer network predicted changes over time in the adolescent's

drinking, even with genetic factors controlled. In fact, when identical twins differed in their drinking habits, the twin whose peer group drank a lot drank more than the twin whose peer group drank less—solid evidence of a true peer socialization effect. At the same time, there was evidence that certain teens, due to a genetic predisposition to drink, chose drinking friends more often than other teens did—support for the selection hypothesis.

Here, then, is another illustration of the need to take genes into account before jumping to conclusions about environmental (whether parent or peer) influence on development. It appears that an adolescent's substance use can indeed be influenced by friends' use of substances—but that to establish that we have to rule out the fact that an adolescent's genetic makeup influences who that adolescent selects as friends.

The same peer socialization/peer selection issue arises in studying peer influence on

other psychological disorders. For example, studies suggest that hanging out with weight-conscious friends leads to disordered eating attitudes and behavior. But does it? Recent studies of adolescent female twins suggest that girls select friends with levels of weight consciousness similar to their own and that much of what looked like peer socialization influence in previous studies may reflect peer selection at least as much as peer socialization (O'Connor et al., 2016; VanHuyse et al., 2016). Similarly, researchers find that yes, adolescents who affiliate with antisocial peers develop externalizing problems but that having externalizing problems also results in selecting antisocial friends (Samek et al., 2016). In short, to fully understand peer influences on psychopathology and development more generally, we must grapple repeatedly with the peer socialization/peer selection issue. Both processes often seem to be at work: We select friends who are like us and then become even more like them due to their influence on us.

victims of depression. They also may show more “vegetative” symptoms such as lacking energy and sleeping all the time.

Factors in Depression

Why is adolescence a depressing period for some? For one thing, genetic influences on depression seem to become more powerful after puberty than they were in childhood (Conley & Rudolph, 2009; Ge et al., 2003; Scourfield et al., 2003). For example, in one study, a gene-environment interaction—a combination of risky variants of the *5-HTTLPR* gene associated with difficulty handling stress and interpersonal stress such as a lack of friends plus conflict-ridden relationships—pushed adolescents, but not children, to depression (Hankin et al., 2015).

As it turns out, girls are more likely than boys to experience an accumulation of stressful events in early adolescence (Ge et al., 1994; Mezulis et al., 2011). Experiencing such events—especially interpersonal ones such as relationship break-ups and fights with family or friends—predicts increases in depressive symptoms (Ge, Natsuaki, & Conger, 2006; Hamilton et al., 2015). The greater interpersonal stress experienced by girls also contributes to their being more likely than boys to engage in **ruminative coping**, dwelling unproductively on their problems, often by co-ruminating about their woes with their friends (Hamilton et al., 2015; ; Nolen-Hoeksema, 1990; Rose, Carlson & Waller, 2007). Compared to coping tactics favored by boys, such as distraction and active problem solving, ruminative coping and co-rumination can make depression and anxiety worse. Indeed, heavy reliance on ruminative coping is now viewed as a risk factor not only for depression but for anxiety, substance use, and eating disorders (Nolen-Hoeksema & Watkins, 2011; Nolen-Hoeksema et al., 2007).

Suicidal Behavior

As depression becomes more common from childhood to adolescence, so do suicidal thoughts, suicide attempts, and actual suicides. Individuals with major depression are more likely to make suicide attempts during adolescence than before or after (Rohde et al., 2013). Indeed, suicide is the second leading cause of death for 15- to 24-year-olds, behind accidental injuries and ahead of assaults or homicides (Heron, 2016). For every adolescent suicide, there are many unsuccessful attempts. Suicidal thoughts are even more common (Shaffer & Pfeffer, 2001). Almost 12% of male and 19% of female high school students in the United States seriously considered suicide in the past year; 6% of males and almost 10% of females attempted it (Eaton et al., 2012).

Before you conclude that adolescence is the peak time for suicidal behavior, however, consider the suicide rates for different age groups shown in **Figure 16.4**. It is clear that adults are more likely to commit suicide than adolescents are. The suicide rate for non-Hispanic white women peaks in middle age, and the

Figure 16.4 Number of suicides per 100,000 people by age and sex among European Americans, African Americans, and Hispanic Americans in the United States.

Source: National Center for Health Statistics (2016). *Health, United States, 2015. With special feature on racial and ethnic health disparities*. Hyattsville, MD: U.S. Department of Health and Human Services, Centers for Disease Control and Prevention, National Center for Health Statistics. Retrieved from www.cdc.gov/nchs/nus.htm.

suicide rate for non-Hispanic white men peaks in old age and is considerably higher than that of other groups. Rates for minority group members, especially minority females, are very low by comparison.

Overall, males are more likely to commit suicide than females, by a ratio of at least three to one—a difference that holds up across most cultures studied (Girard, 1993; Shaffer & Pfeffer, 2001). When we look at suicide attempts, this ratio is reversed, with females leading males by a ratio of about three to one. Apparently, then, females attempt suicide more often than males do, but males more often commit suicide when they try. This is mainly because men use more lethal techniques (especially guns).

Suicide rates are very much influenced by their sociohistorical context. In the United States, they decreased from 1986 to 1999 but have increased since then (Curtin, Warner, & Hede-gaard, 2016). The recent increases have been especially steep among middle-aged women and men, possibly because the 2008 economic recession hit them hard.

If suicide rates are higher in adulthood than in adolescence, why do we hear so much about teenage suicide? Probably because adolescents attempt suicide more frequently than adults do. The typical adolescent suicide attempt has been characterized as a “cry for help”—a desperate effort to get others to notice and help resolve problems that have become unbearable (Berman & Jobes, 1991; Lester, 1994). The adolescent who attempts suicide often wants a better life rather than death. This by no means suggests that adolescent suicide attempts should be taken lightly. Their message is clear: “I’ve got serious problems; wake up and help me!”

Suicidal behavior in adolescence is the product of diathesis-stress. Four key risk factors are youth psychological disorder,

family pathology and psychopathology, stressful life events, and access to firearms (Gould et al., 2003; and see Beautrais, 2003):

- More than 90% of adolescent suicide victims, partly because of genetic predisposition, suffered from depression, a substance-use disorder, an anxiety disorder, or another diagnosable psychological problem at the time of their deaths (Shaffer & Pfeffer, 2001). And the more problem behaviors an adolescent displays, the more likely she is to go from thinking suicidally to taking action (Miller & Taylor, 2005).
- Many suicide attempters also have histories of troubled family relationships, and often psychopathology and even suicide run in the family.
- In the period leading up to a suicide attempt, the adolescent has often experienced a buildup of stressful life events that breeds a sense of helplessness—deteriorating relationships with parents and peers, academic and social failures, run-ins with the law (Berman & Jobes, 1991; Woo & Keatinge, 2008).
- The availability of firearms makes it easy to act on suicidal impulses.

Engagement 16.2 shows some of the behavioral warning signs that can help you recognize that someone you know may be planning to commit suicide and needs help. The adolescent who attempts suicide once may try again if he receives little help (Rotheram-Borus et al., 2000). Although, as we have seen, adolescence is not a time of “storm and stress” for most, it is a period in which biological, psychological, and social influences can conspire to make several mental health problems more likely.

● ENGAGEMENT 16.2

Is Anyone You Know Suicidal? Know the Warning Signs

Do you have any friends, relatives, or acquaintances who you think might be suicidal? If so, see if they show the following warning signs of suicidality in young people, compiled by a committee of suicide experts (Rudd et al., 2006) and disseminated by the U.S. government’s Substance Abuse and Mental Health Services Administration (SAMHSA, 2012):

Call 9-1-1 or seek immediate help from a mental health provider when you hear, say, or see any one of these behaviors:

- Someone threatening to hurt or kill themselves

- Someone looking for ways to kill themselves: seeking access to pills, weapons, or other means
- Someone talking or writing about death, dying, or suicide

Seek help by contacting a mental health professional or calling 1-800-273-TALK for a referral should you witness, hear, or see anyone exhibiting any one or more of these behaviors:

- Hopelessness
- Rage, anger, seeking revenge
- Acting reckless or engaging in risky activities, seemingly without thinking

- Feeling trapped—like there’s no way out
- Increasing alcohol or drug use
- Withdrawing from friends, family, or society
- Anxiety, agitation, unable to sleep, or sleeping all the time
- Dramatic changes in mood
- No reason for living; no sense of purpose in life

Source: Rudd, M. D., Berman, A. L., Joiner, T. E. Jr., Nock, M. K., Silverman, M. M., Mandrusiak, M., . . . Witte, T. (2006). Warning signs for suicide: Theory, research, and clinical applications. *Suicide and Life-Threatening Behavior*, 36 (3), Table 2, p. 259.

● Checking Mastery

1. What does the fact that 20% or so of adolescents have diagnosable psychological disorders say for and against the notion that adolescence is a period of storm and stress?
2. How does the sociocultural environment contribute to anorexia nervosa?
3. Judging from the cascade model of substance use, what are three factors you might look for if you want to identify children who are at risk for illicit drug use when they become adolescents?
4. How do males and females differ with respect to (a) suicide attempts and (b) completed suicides?

● Making Connections

1. How would you characterize your own mental health during adolescence? Consider whether the concept of “storm and stress,” as well as adolescent problem behaviors and specific diagnoses we have discussed in this section, apply to you.
2. Peggy, the young woman described at the beginning of the chapter, attempted suicide. Using the material on suicide in this section, develop a theory of why she might have done so, showing how both diathesis and stress may have contributed.

16.5

The Adult

LEARNING OBJECTIVES

- Explain how depression is related to age, gender, and ethnicity in adulthood.
- Describe the major characteristics of dementia and Alzheimer's disease in particular.
- Summarize what we know about the biology and the causes of and contributors to Alzheimer's disease.
- Explain how one can distinguish between irreversible dementias like Alzheimer's disease and reversible dementias, delirium, depression, and normal aging.

As you have seen, by the time we reach adulthood, most of us have already had at least one diagnosable psychological disorder, whether it was recognized and treated or not (Copeland et al., 2011). Most adult psychological disorders originate in childhood or adolescence, but rates and forms of disorder change over the adult years.

Stress and Disorder

Many psychological problems in adulthood emerge when a vulnerable individual faces overwhelming stress. When do adults typically experience the greatest number of life strains and stressors? No question about it: in early adulthood (Almeida et al., 2011; McLanahan & Sorensen, 1985; Pearlin, 1980). Life strains decrease from early to middle adulthood, perhaps as many adults settle into more stable lifestyles and stop changing residences, jobs, and relationships so much. Meanwhile, despite their increased health problems, elderly adults report fewer hassles and strains overall than middle-aged adults do (Almeida & Horn, 2004; Martin, Grunendahl, & Martin, 2001). This may be because they have fewer roles and responsibilities to juggle or because they have learned to take many problems in stride.

Age differences in stressful experiences help explain age differences in rates of psychological disorder. Diagnostic interviews with adults age 18 or older in the United States reveal that rates of affective disorders (major depression and related mood disorders), alcohol abuse and dependence, schizophrenia, anxiety disorders, and antisocial personality all decrease from early adulthood to late adulthood (Myers et al., 1984; Robins & Regier, 1991). The only category of disorder that increases with age is cognitive impairment, as increasing numbers of older adults develop Alzheimer's disease and other forms of dementia (to be described shortly). Overall, about 25% of American adults are judged in clinical interviews to have experienced a psychological disorder in the past year (Kessler & Wang, 2008).

With that as background, we can look more closely at one of the disorders to which young adults are especially susceptible, depression, and then turn to an examination of Alzheimer's disease and related cognitive impairments in later life.

Depression

Major depression and other affective disorders are among the most common psychological problems experienced by adults. Who gets depressed, and what does this reveal?

Age, Gender, and Ethnic Differences

The average age of onset of major depression is in the early 20s (Woo & Keatinge, 2008). Contrary to stereotypes of older adults, they tend to be less vulnerable to major depression and other severe affective disorders than young or middle-aged adults are (Hybels, Blazer, & Hays, 2009; Kessler et al., 2010). Still, there are good reasons to be concerned about depression in old age. First, depressed elderly adults are more likely than depressed adolescents to take their own lives. Second, reports of depression symptoms, though not diagnosable disorders, increase when people reach their 70s and beyond (Nguyen & Zonderman, 2006; Teachman, 2006). Although only about 1%–2% of elderly adults have major depressive disorder at a given time, somewhere between 15% and 25% experience symptoms of depression (Hybels et al., 2009; Knight et al., 2006). These individuals are most likely to be very old women who are physically ill, poor, and socially isolated, and many could benefit from treatment (Blazer, 1993; Falcon & Tucker, 2000).

Might some of these mildly depressed and demoralized elders have a more serious but undiagnosed depressive disorder? It's quite possible. Depression can be difficult to diagnose in later life (Charney et al., 2003; Edelstein et al., 2015). Think about it: Symptoms of depression include fatigue and lack of energy, sleeping difficulties, weight loss, cognitive deficits, and somatic (body) complaints. What if an 80-year-old woman and/or her doctor interpret these symptoms as nothing more than aging, as the result of the chronic illnesses so common in old age or medications for them, or as signs of dementia? A case of depression could be missed. To complicate diagnosis, elderly adults sometimes deny that they are sad, guilty, or suicidal and may instead report the very somatic symptoms that can easily be misinterpreted as signs of physical illness if the individual's physical health status is not carefully reviewed (Edelstein et al., 2015; Nguyen & Zonderman, 2006). So clinicians working with older adults need to be sensitive to the lines between normal aging, physical disease, and psychopathology.

As noted already, women are twice as likely as men to be diagnosed with depression. This gender difference probably stems from a variety of factors (Kuehner, 2003; Nolen-Hoeksema, 2002): female hormones and biological reactions to stress; levels of stress (including more interpersonal stress among women); ways of expressing distress (women being more likely to express classic depression symptoms, men being more likely to become angry

Although few elderly adults have diagnosed depression, a sizable minority experiences at least some symptoms of depression.

Mark Richards/PhotoEdit

or overindulge in alcohol and drugs); and styles of coping with distress (especially the tendency for women to engage in counterproductive ruminative coping).

Ethnic differences in depression are also evident. In a national study of adults age 55 and older (Woodward et al., 2012), the percentages of adults who had been affected by mood disorders, including major depressive disorder, during their lifetime were quite high for Latinos (13.9%) and non-Hispanic Whites (13.8%), and much lower for African Americans (5.4%) and Asian Americans (6.4%). Possibly elderly Latino adults who are recent immigrants to the United States feel socially isolated and stressed as younger members of their families become acculturated (Jimenez et al., 2010). Older African Americans who are religious may be protected from depression by their religious faith and the social support they receive through their churches (Jimenez et al., 2010). African Americans are also more likely than other groups to go undiagnosed and untreated when they are depressed (Akincigil et al., 2012). Older Asian Americans may also be underdiagnosed; for example, they tend to view mental illness in terms of somatic symptoms and may be hesitant to admit that they have psychological problems or seek help for them (Jimenez et al., 2010; Sue et al., 2012). Whatever the reasons, we can expect rates of depression to be highest among young adults, females, and both Hispanic and non-Hispanic whites.

Treatment

One of the biggest challenges in treating adults with major depression and other psychological disorders is getting them to seek treatment; many eventually do but often after going years without help (Wang et al., 2005). Older adults are especially likely to go undiagnosed and untreated, particularly if they are minority group members (Karel, Gatz, & Smyer, 2012; Neighbors et al., 2007). Meanwhile, few psychologists and psychiatrists are specially trained to treat a growing global population of older adults.

Despite these barriers, depressed elderly adults who seek psychotherapy or begin taking antidepressant medications benefit (Edelstein et al., 2015). For older and younger depressed adults alike, the most effective approach is often a combination of drug treatment and psychotherapy, especially cognitive behavioral therapy aimed at addressing carefully identified problems.

Aging and Dementia

Perhaps nothing scares us more about aging than the thought that we will become “senile.” **Dementia** is a progressive deterioration of neural functioning associated with cognitive decline—for example, memory impairment, declines in tested intellectual ability, poor judgment, difficulty thinking abstractly, and often personality changes as well (see La Rue, 2015; Lyketsos, 2009). The term dementia has been dropped from DSM-5 in favor of the term “neurocognitive disorder,” although we will continue to refer to dementia here. Different causes of neurocognitive disorder such as Alzheimer’s disease are distinguished as subtypes, and each has “major” and “minor,” or more and less severe, forms (American Psychiatric Association, 2013; Bajenaru et al., 2012).

Developing dementia is not part of typical aging. Yet rates of dementia increase steadily with age, making old age the biggest risk factor for dementia. Overall, dementia affects up to 10% of adults age 65 and older (Karel et al., 2012). Rates climb steeply with age, as shown in ■ **Figure 16.5**—from less than 2% at age 65–69 to over 35% at age 90 and older.

Dementia is not a single disorder. Much damage can be done by labeling any older person with cognitive impairments senile—or even as having Alzheimer’s disease—and then assuming that he is a lost cause. Many different conditions can produce symptoms we associate with senility, and some of them are curable or reversible. Let us look at the leading cause of dementia, Alzheimer’s disease, and then at related conditions.

■ **Figure 16.5** Percentage of older adults with dementia by age group.

Alzheimer's Disease

With Alzheimer's disease, you just know you're going to forget things, and it's impossible to put things where you can't forget them because people like me can always find a place to lose things and we have to flurry all over the house to figure where in the heck I left whatever it was. . . . It's usually my glasses. . . . You've got to have a sense of humor in this kind of business, and I think it's interesting how many places I can find to lose things. . . . [People with Alzheimer's] want things like they used to be. And we just hate the fact that we cannot be what we used to be. It hurts like hell. (Cary Henderson, age 64, former history professor diagnosed with Alzheimer's disease at age 55; Rovner, 1994, pp. 12–13)

Alzheimer's disease is the most common subtype of dementia, or major neurocognitive disorder, accounting for over half the cases, including those of former president Ronald Reagan and, more recently, famed women's basketball coach Pat Summitt, who died of it in 2016 (Castro & Smith, 2015; Geldmacher, 2009; Qui & Fratiglioni, 2009). The disease can strike in middle age but becomes increasingly likely with advancing age, and it affects about twice as many women as men, partly because they live longer. Because more people are living into advanced old age, more will end up with Alzheimer's disease unless ways of preventing it or slowing its progression are found.

Alzheimer's disease leaves two telltale signs in the brain: *senile plaques* (masses of dying neural material outside neurons with a toxic protein called **beta-amyloid** at their core), and *neurofibrillary tangles* (twisted strands made of neural fibers and the protein **tau** within the bodies of neural cells). The effects of these physical changes—loss of connections between neurons, deterioration and death of neurons, increasingly impaired mental functioning, and personality changes—are progressive and irreversible or incurable. The disease typically begins to affect the brain in middle adulthood, maybe earlier, long before cognitive functioning is affected and even longer before the disease is diagnosed. The first noticeable symptoms of Alzheimer's, detectable 2–3 years before dementia can be diagnosed, are usually difficulties remembering recently encountered material such as new acquaintances' names or yesterday's lunch menu (Geldmacher, 2009).

The individual on a path to Alzheimer's may be recognized as having *mild cognitive impairment (MCI)*, discussed in Chapter 8. MCI is often—though not always—an early warning that dementia will follow (Castro & Smith, 2015). Similar to what is now called minor neurocognitive disorder in DSM-5, it is more serious than the slower cognitive functioning and minor memory problems common among typically aging adults. If all it took to warrant a diagnosis of MCI or dementia were occasional episodes of misplacing keys or being unable to remember someone's name, many young and middle-aged adults, not to mention textbook writers, would qualify!

In the early stages of Alzheimer's disease, warning signs include getting lost, having trouble managing money and paying bills, telling and retelling the same stories to the same people or repeatedly asking the same questions, and losing items but not being able to retrace one's steps to find them. As the disorder progresses, people

Positron emission tomography (PET scanning) shows metabolic activity in the brain and reveals areas of high brain activity (in red and yellow) and low brain activity (in blue or black). Here we see more activity in a normally functioning brain (left) than in the brain of a person with Alzheimer's disease (right).

Dr. Robert Friedland/Science Source

with Alzheimer's may have trouble remembering not only recently acquired but old information, have more trouble coming up with the words they want during conversations, and forget what to do next midway through making a sandwich or getting ready for bed. If tested, they may be unable to answer simple questions about where they are, what the date is, and who the president of the United States is. Eventually they become incapable of caring for themselves; no longer recognize loved ones; lose all verbal abilities; and die some years after they are diagnosed.

Not only do patients with Alzheimer's disease become increasingly unable to function, but they also often test the patience of caregivers by forgetting they have left something cooking on the stove, wandering away and getting lost, accusing people of stealing the items they have misplaced, or taking off their clothes in public. Some become highly agitated and uncontrollable; large numbers suffer from depression and become apathetic; and some experience psychotic symptoms such as hallucinations (Geldmacher, 2009).

Causes and Contributors. What causes Alzheimer's disease? It has a genetic basis, but there is no single "Alzheimer's gene" (Gatz, 2007). Alzheimer's disease strikes repeatedly and early in some families, and researchers have identified genetic mutations on three chromosomes that cause early-onset Alzheimer's disease (before age 60). Anyone who inherits just one of these dominant genes will develop the disease. However, these genes account for less than 5% of all cases of Alzheimer's disease (Gatz, 2007).

Genetic contributors to late-onset Alzheimer's disease, which is by far more common than the early-onset variety, are not as clear-cut. Rather than making Alzheimer's disease inevitable, a large number of genes increase a person's risk slightly (Gatz, 2007; National Institute on Aging, 2015). *APOE e4* is the most famous of these susceptibility genes; having two of the risk-inducing *APOE e4* variants of the *APOE* gene means having up to 15 times the normal risk of Alzheimer's disease (Lyketsos, 2009). It is believed that the *APOE e4* gene is linked to an increased buildup of

beta-amyloid—the damaging substance in senile plaques—and speeds the progression of Alzheimer’s disease (National Institute on Aging, 2015). Yet not everyone with the *APOE e4* gene, or even a pair of them, develops Alzheimer’s disease, and many people with Alzheimer’s disease lack this risky gene variant.

Overall, genes account for about 60% of the variation in Alzheimer’s, which means that environmental factors are also involved (Qui & Fratiglioni, 2009). It has not been easy to pinpoint environmental contributors, however (Gatz, 2007). Epigenetic effects—environmental influences on the expression of genes involved in beta-amyloid production, for example—are now believed to be important (Chouliaras et al., 2010; National Institute on Aging, 2015). Traumatic brain injuries, such as those suffered by some boxers and football and soccer players, increase the risk of Alzheimer’s disease, especially in combination with risky genes such as *APOE e4* (Delano-Wood et al., 2015). Other risk factors include unhealthy lifestyle factors such as a poor diet, smoking, and inactivity—and conditions linked with them such as obesity, diabetes, high blood pressure, and cardiovascular disease (La Rue, 2015).

Researchers are also becoming more aware of the importance of **cognitive reserve**—extra brain power or cognitive capacity that some people can fall back on as aging and disease begin to take a toll on brain functioning (Delano-Wood et al., 2015; Sharp & Gatz, 2011). People who have advanced education and high intelligence and have been mentally, physically, and socially active over the years have more cognitive reserve than less active people. As a result, if they do develop Alzheimer’s disease, their more elaborate neural connections may allow them to continue functioning well even as the disease begins to damage their brains.

Prevention and Treatment. What can be done to prevent, or at least slow the progression of, and treat Alzheimer’s disease? Since the same lifestyle factors that contribute to cardiovascular disease and to metabolic disorders such as diabetes and obesity contribute to dementia as well, the same healthy lifestyle recommendations are appropriate in staving off Alzheimer’s disease: eat a healthy diet, control smoking, exercise regularly (La Rue, 2015). Physical exercise—and cognitive exercise as well—can delay cognitive decline in later life and slow the progression of dementia (Hertzog et al., 2009; La Rue, 2015). Researchers are searching frantically for more precise methods of diagnosing Alzheimer’s disease earlier, through brain imaging and biomarkers in the blood or cerebrospinal fluid, in hopes of intervening to slow or even halt the disease’s progression before much damage is done (National Institute on Aging, 2015). While we wait, the best advice is to take good care of your health throughout the life span.

Drugs are regularly prescribed for individuals who have Alzheimer’s disease (for example, Aricept [donepezil] to alter neurotransmitter levels and Namenda [memantine] to combat amyloid plaques). Drugs can modestly improve cognitive functioning, reduce behavioral problems, and slow the progression of the disease in some patients (Castro & Smith, 2015; La Rue, 2015). However, they are not very effective and are certainly not a cure. The search for more effective drugs continues (National Institute on Aging, 2015).

However, even though deterioration leading to death must be expected in today’s Alzheimer’s patients, a great deal can be done to make the disease more bearable for them and their caregivers.

This woman with Alzheimer’s disease is visited by her grandson.

Ocskaymark/Getty Images

Memory training and memory aids (for example, reminder notes around the house), the use of behavioral management techniques and medications to deal with behavioral problems, and educational programs and psychological interventions for both patients and their caregivers to help them understand and cope with dementia and function better can all contribute (La Rue, 2015).

Other Causes of Cognitive Impairment

Many other conditions can result in cognitive impairment in aging adults. Another common type of neurocognitive disorder, often occurring in combination with Alzheimer’s disease, is **vascular dementia** (Nyenhuis, 2015; Szoeki et al., 2009). Also called multi-infarct dementia, most cases are caused by a series of minor strokes that cut off the blood supply to areas of the brain. Whereas Alzheimer’s disease usually progresses slowly and steadily, vascular dementia often progresses in a steplike manner, with further deterioration after each small stroke. And whereas Alzheimer’s disease is more strongly influenced by genes, vascular dementia is more closely associated with lifestyle risk factors for cerebrovascular diseases that affect blood flow in the brain.

Rivaling vascular dementia as the second or third most common type of neurocognitive disorder behind Alzheimer’s disease is **Lewy body dementia**, which involves fluctuations in cognitive functioning, visual hallucinations, and often motor and balance problems (Sperling, Geneser, & Manning, 2015). It is caused by protein deposits in neurons called Lewy bodies, which are also involved in Parkinson’s disease. Some other causes of neurocognitive disorder are described in • Table 16.1. Patients may have more than one of these diagnoses.

Careful diagnosis is critical because certain treatable conditions can be mistaken for irreversible dementia. First, some individuals—as many as 10%—have **reversible dementias**, cases of significant cognitive decline that can be treated and cured (La Rue, 2015; Lipton & Weiner, 2003). Reversible dementias can be caused by alcoholism, toxic reactions to medication, infections,

Comedian and actor Robin Williams, who committed suicide in 2014 at the age of 63, had recently been diagnosed with Parkinson’s disease and may have been in the early stage of dementia—either Parkinson’s disease dementia or dementia with Lewy bodies (Porcher, 2014). Both are associated with the presence of protein deposits called Lewy bodies in the brain (Porcher, 2014). Williams was experiencing depression, anxiety, and paranoia at the time of his death—symptoms that often accompany both types of dementia.

● **Table 16.1** Some Common Forms and Causes of Dementia, or Neurocognitive Disorder, Besides Alzheimer’s Disease

Name	Description
Vascular dementia	Also called multi-infarct dementia. Caused by minor strokes that cut off blood supply to areas of the brain; results in steplike deterioration after each stroke; functioning depends on location and extent of brain damage.
Lewy body dementia	May be as common as vascular dementia. Caused by protein deposits called Lewy bodies in neurons. Motor problems, as in Parkinson’s disease; visual hallucinations, attention and alertness problems, unpredictable cognitive functioning.
Frontotemporal dementia	Early-onset dementia associated with shrinking of the frontal and temporal lobes. Executive function problems (e.g., impulsive behavior) and poor judgment are more common than memory problems. The best known type is Pick’s disease.
Parkinson’s disease dementia	Lewy bodies in subcortical areas of the brain contribute to motor problems (tremors, slowing/freezing while walking); treatment of Parkinson’s disease with the drug L-dopa to make up for dopamine deficiency is effective, but some patients go on to develop what is called Parkinson’s disease dementia in the later stages.
Huntington’s disease	Caused by a single dominant gene (see Chapter 3). Subcortical brain damage results in involuntary flicking movement of the arms and legs; hallucinations, paranoia, depression, personality changes.
Alcohol-related dementia	Caused by alcohol abuse; memory problems are the primary symptom in what is called Wernicke–Korsakoff’s syndrome.
AIDS dementia complex or ADC	Caused by HIV virus infection. Encephalitis, behavioral changes, decline in cognitive function, progressive slowing of motor functions.

Note: The first two conditions in the table are the most common causes of dementia besides Alzheimer’s disease; the rest are rarer.

Sources: La Rue (2015); www.alz.org/dementia/types-of-dementia.asp; www.dementiacarecentral.com/node/576; www.ninds.nih.gov/disorders/dementias/detail_dementia.htm#2300219213.

metabolic disorders, vitamin deficiencies, and malnutrition. If these problems are corrected—for example, if the individual is taken off a recently prescribed medicine or is placed on a nutritious diet—a once “senile” person can be restored to normal mental functioning. By contrast, if that same person is written off as a hopeless case of Alzheimer’s disease, a potentially curable condition may become a progressively worse and irreversible one.

Second, some elderly adults are mistakenly diagnosed as suffering from dementia when they are actually experiencing **delirium**. This treatable neurocognitive disorder, which emerges more rapidly than dementia and comes and goes over the course of the day, is a disturbance of consciousness characterized by periods of disorientation, wandering attention, confusion, and

hallucinations (American Psychiatric Association, 2013; Na & Manning, 2015; Weiner et al., 2009). One 66-year-old woman with a history of seizures, for example, called 911 repeatedly because she believed burglars were in her home; in her agitated state, she even threatened her housemate with a knife (Weiner et al., 2009). After she was taken to the hospital, she continued to be highly agitated, moving and talking constantly, not trusting the staff. Her episode of delirium appeared to be the result of a urinary infection combined with early Alzheimer’s disease, and she was able to return home after 5 days in the hospital.

Hospital patients of any age—but especially elderly ones—experience delirium in reaction to any number of stressors—illness,

surgery, drug overdoses, interactions of drugs, and malnutrition (Na & Manning, 2015). It is critical to watch for signs of delirium, identify possible causes, and intervene to change them quickly. Unfortunately the condition often goes undetected or misdiagnosed. When elderly patients experience delirium but are not identified and are sent home from the hospital without treatment for it, they are at high risk to show worsening dementia or to die (Kakuma et al., 2003; Na & Manning, 2015).

Third, elderly adults who are depressed are sometimes misdiagnosed as suffering from dementia (Edelstein et al., 2015; Butters et al., 2004). After all, depression's symptoms include cognitive impairments such as being forgetful and mentally slow. Treatment of depression with antidepressant drugs and psychotherapy can significantly improve the functioning of such individuals. However, if their depression goes undetected and they are written off as senile, they may deteriorate further.

Fourth, relatives who do not understand dementia may mistake the cognitive declines that many people experience as part of typical aging for incurable dementia. The moral is clear: It is critical to distinguish among irreversible dementias (most notably, Alzheimer's, vascular dementia, and Lewy body dementia), reversible dementias, delirium, depression, and other conditions that may be mistaken for irreversible dementias—including aging itself. This requires a thorough assessment, including a medical history, physical and neurological examinations, and assessments of cognitive functioning (La Rue, 2015). Only after all other causes, especially potentially treatable ones, have been ruled out should a diagnosis of Alzheimer's disease be made.

So ends our tour of psychopathology across the life span. It can be discouraging to read about the countless ways in which genes and environment can conspire to make human development go awry and about the high odds that most of us will experience a psychological disorder sometime during our lives. Yet research provides an increasingly solid basis for intervening to prevent developmental psychopathology through a two-pronged

strategy of eliminating risk factors (such as abusive parenting and stress) and strengthening protective factors (such as effective parenting and social support). If prevention proves impossible, most psychological disorders and developmental problems can be treated successfully, enabling the individual to move onto a healthier developmental pathway.

● Checking Mastery

1. In which adult age group, gender, and ethnic groups would you expect the highest rates of major depressive disorder?
2. How does Alzheimer's disease progress with regard to the timing of plaques and tangles in the brain, cognitive deficits, diagnosable dementia, and death?
3. What are two approaches used to treat Alzheimer's disease?
4. What are two key differences between delirium and dementia?

● Making Connections

1. So now that you have read this whole chapter, what do you think of the DSM-5's position that major depressive disorder is basically the same from early childhood to old age? Argue for the DSM-5 position and then argue against it.
2. Grandpa Fred is starting to display memory problems: Sometimes he asks questions that he just asked, leaves water boiling on the stove, and cannot come up with the names of visiting grandchildren. Fred's son Will is convinced that his father has Alzheimer's disease and is a lost cause. What possibilities would you like to rule out before accepting that conclusion—and why?

Chapter Summary

16.1 What Makes Development Abnormal?

- To diagnose psychological disorders, clinicians may consider broad criteria such as statistical deviance, maladaptiveness, and personal distress and apply DSM-5 criteria to diagnose specific disorders based on their symptoms.
- Developmental psychopathology is concerned with the origins and course of maladaptive behavior and contrasts with a medical or disease model.
- A diathesis–stress model has proved useful in understanding how nature and nurture contribute to many psychological disorders

16.2 The Infant

- Autism spectrum disorder is characterized by social and communication impairments and by restricted and repetitive interests and behavior. It is genetically influenced, involves atypical early

brain growth and connectivity, and responds well to early and intensive behavioral training.

- Infants who have been maltreated, separated from their attachment figures, or raised by a depressed caregiver may display symptoms of depression.

16.3 The Child

- Many childhood disorders can be categorized as externalizing (acting out) or internalizing (bottling up) problems; they are often a product of diathesis–stress, they are common, and externalizing problems especially often predict problems in adolescence and adulthood.
- Attention deficit hyperactivity disorder (ADHD) involves inattention and/or hyperactivity/impulsivity, often continues into adulthood, and can be treated most effectively through a combination of stimulant drugs and behavioral intervention.

- Major depressive disorder and suicidal behavior can occur during early childhood; depression manifests itself somewhat differently in childhood and tends to recur but can be treated.

16.4 The Adolescent

- Adolescents are more vulnerable than children but no more vulnerable than adults to psychological disorders; 20% or so at any given time experience the “storm and stress” of a psychological disorder and many more engage in risky problem behaviors as they seek to complete developmental tasks of adolescence with raging hormones and immature brains.
- Anorexia nervosa arises when a genetically predisposed female who lives in a society that values the thin ideal experiences stressful events.
- Substance use disorders can grow out of adolescent experimentation with substances; according to the cascade model, the developmental pathway toward illicit drug use begins in childhood.
- The risks of depression rise during adolescence, especially among females. Adolescents, in a cry for help, are more likely to

attempt but less likely to commit suicide than adults, older white men being the group most likely to commit suicide.

16.5 The Adult

- Young adults experience both more stressful life events and more psychological disorders, including depression, than older adults.
- Diagnosing depression among older adults can be tricky if their symptoms are attributed to aging, chronic disease, or dementia; older adults have low rates of diagnosable depression but 15%–25% suffer some symptoms of depression.
- Dementia, now called major neurocognitive disorder, is a progressive deterioration in neural functioning associated with significant cognitive decline that increases with age. Alzheimer’s disease, the most common cause of dementia, and vascular dementia and Lewy body dementia, other irreversible dementias, must be carefully distinguished from correctible conditions such as reversible dementia, delirium, and depression.

Taking Our Leave

On Sunday, June 12, 2016, at the Pulse nightclub in Orlando, Florida, friends and relatives desperately sought news of their loved ones in the wake of the deadliest mass shooting in U.S. history. When it was over, 49 people had been murdered and 53 injured, most of them Latino and gay. Eddie Meltzer, the son of a German father and Costa Rican mother, witnessed much confusion in the waiting area set up for loved ones after the shooting:

“There was a woman who came in, she didn't speak English, and they were reading some names, and she was like, ‘Oh, thank God, my son is alive!’” said Meltzer, who had left Pulse five minutes before the shooting began. “And I had to say, ‘I'm sorry, ma'am, but that is the list of people who didn't make it.’”

The woman wailed and began to hit him. “You're lying!” she screamed in Spanish.

Instead of pushing her away, he wrapped his arms around her, holding on as the rage transformed to grief (Santich & Salazar, 2016).

Images of 9/11, Virginia Tech, Aurora, Sandy Hook, the Boston Marathon bombing, Charleston, San Bernardino, Orlando, and other tragedies in the United States—along with massacres in Brussels, Paris, Nice, Istanbul, Baghdad, and elsewhere around the world—have come to symbolize for many of us the horror of death. Whether we are 4, 24, or 84 when death strikes a loved one, death hurts. By adulthood, most of us have experienced a significant loss, even if it was “only” the death of a beloved pet. Even when death is not striking so closely, it is there, lurking somewhere in the background as we go about the tasks of living—in the newspaper, on television or the Internet, fleeting through our minds. Some psychologists argue that much of human behavior and human culture is an effort to defend against the terror of death (Park & Pyszczynski, 2016; Pyszczynski, Solomon, & Greenberg, 2003). Yet sooner or later we all face the ultimate developmental task: the task of dying.

This chapter explores death and its place in life-span human development, starting with a discussion of the meanings and causes of death. You will discover that death is part of the human experience throughout the life span, but that each person’s experience of it depends on his level of development, personality, life circumstances, and sociocultural context.

Friends and family release doves and balloons at the funeral for Franky Jimmy De Jesus Velazquez in his hometown of Caguas, Puerto Rico, June 21, 2016. He was one of the 49 victims of the Pulse nightclub shooting on June 12, 2016, near Orlando, Florida.

17.1

Matters of Life and Death

LEARNING OBJECTIVES

- Discuss the biological definition of death and the issues it raises.
- Distinguish between active euthanasia, passive euthanasia, and physician-assisted suicide and attitudes toward them.
- Illustrate how social reactions to death differ in different cultures and racial/ethnic groups.
- Analyze trends in the likelihood of death and causes of death across the life span.

What is death, biologically and socially? When are we most vulnerable to it, and what kills us?

What Is Death?

There is a good deal of confusion and controversy in our society today about when life begins and when it ends. Proponents and opponents of legalized abortion argue vehemently about when life really begins. And we hear similarly heated debates about whether a person in an irreversible coma is truly alive and whether a terminally ill patient who is in agonizing pain should be able to choose to die. Definitions of death as a biological phenomenon change; so do the social meanings attached to death.

Biological Death

Biological death is hard to define because it is not a single event but a complex process. Different systems of the body die at different rates, and some individuals who have stopped breathing or who lack a heartbeat or pulse, and who would have been declared dead in earlier times, can now be revived before their brains cease to function. Moreover, basic body processes such as respiration and blood circulation can be maintained by life-support machines

in patients who have fallen into a coma and whose brains have ceased to function.

In 1993, the Uniform Determination of Death Act in the United States defined biological death in terms of brain functioning. The Act insisted that, in cases where there is uncertainty, death cannot be said to have occurred until there is **total brain death**, defined as an irreversible loss of functioning in the entire brain, both the higher centers of the cerebral cortex that are involved in conscious awareness and thought and the centers in the brain stem that control basic life processes such as breathing.

As further elaborated by the American Academy of Neurology, determining brain death requires extensive testing following specific guidelines (Wijdicks et al., 2010; but see Greer et al., 2016, on wide variations in application of the guidelines across the country). A person in a coma must be observed to be totally unresponsive to stimuli, show no movement in response to noxious stimuli, and have no reflexes such as a constriction of the eye’s pupils in response to light. An electroencephalogram (EEG) or other measures should indicate an absence of electrical activity in the cortex of the brain. Because a coma is sometimes reversible if the cause is a drug overdose or an abnormally low body temperature, these and certain other conditions must be ruled out before a

person in a coma is pronounced dead. This definition means that a coma patient whose heart and lungs are kept going only through artificial means such as a mechanical ventilator but who has no sign of functioning in the brain stem is dead.

Since the definition of brain death was settled upon, there has been continued debate about people in comas. In the mid-2000s, one young woman in a coma, Terri Schiavo, spurred a ferocious national debate (Cerminara, 2006; Foley, 2011). In 1990 Ms. Schiavo had suffered a cardiac arrest that caused irreversible and massive brain damage. She was unconscious but her brain stem allowed her to breathe, swallow, and undergo sleep–wake cycles. After losing hope of a recovery as the years passed, her husband wanted to remove her feeding tube as he believed she would have wanted. However, her parents believed that she retained some awareness of her environment and wanted to keep her alive. After receiving medical testimony, a Florida court ruled that her feeding tube should be withdrawn. Finally, after the issue was debated at length in legislative bodies (including Congress), courts (including the Supreme Court), and the media, the tube was removed when appeals of the court’s decision failed. Ms. Schiavo died at the age of 41 in 2005.

Famous right-to-die cases like the Terri Schiavo case highlight the different positions people can take on the issue of when a person is dead. The definition of death as total brain death is quite conservative. By this definition, Ms. Schiavo was not dead, even though she was in an irreversible coma, because her brain stem was still functioning enough to support breathing and other basic body functions. Shouldn’t we keep such seemingly hopeless patients alive in case we discover ways to revive them? A more liberal position is that a person should be declared dead when the cerebral cortex is irreversibly dead, even if some body functions are still maintained by the more primitive portions of the brain. After all, is a person really a person if she lacks any awareness and if there is no hope that conscious mental activity will be restored?

Do you believe Terri Schiavo, who could breathe on her own but suffered massive brain damage, should or should not have been taken off her feeding tube? Her husband Michael thought she should be taken off it, but her parents fought him.

Getty Images

But are we sure there is no awareness? Defining the line between life and death has become more complicated since Adrian Owen and his colleagues (2006) demonstrated that at least some people who are in “vegetative states” may have more awareness than suspected. Unlike coma patients, who lack both awareness and wakefulness, people in vegetative states (a dehumanizing term if there ever was one) lack awareness but experience sleep–wake cycles, may open their eyes, and move now and then. Owen asked a young woman who had been in a vegetative state for 5 months as a result of a car accident to imagine playing tennis or visiting the rooms of her house. Brain imaging with fMRI techniques showed that her brain responded exactly as healthy adults’ brains respond to these tasks, suggesting that this woman could understand and respond intentionally to instructions and implying that she had some degree of consciousness. Subsequent studies have confirmed that a small proportion of people in vegetative states are most likely treated as if they were dead when they are mentally alive (Cruse et al., 2011, 2013; Graham et al., 2015; Monti et al., 2010).

Life and Death Choices

Cases such as these raise issues concerning **euthanasia**—a term meaning “happy” or “good” death that usually refers to hastening the death of someone suffering from an incurable illness or injury. *Active euthanasia*, or “mercy killing,” is deliberately and directly causing a person’s death—for example, by administering a lethal dose of drugs to a pain-racked patient in the late stages of cancer or smothering a spouse who has advanced Alzheimer’s disease. *Passive euthanasia*, by contrast, means allowing a terminally ill person to die of natural causes—for example, by withholding extraordinary life-saving treatments (as happened when Terri Schiavo’s feeding tube was removed). Between active euthanasia and passive euthanasia is **assisted suicide**—not directly killing someone, as in active euthanasia, but making available to a person who wishes to die the means by which she may do so. This includes physician-assisted suicide—for example, a doctor’s writing a prescription for sleeping pills at the request of a terminally ill patient who has expressed his desire to die (Foley, 2011).

How do we as a society view these options? We invite you to explore your own views in **Engagement 17.1**. There is overwhelming support among medical personnel and members of the general public for passive euthanasia (Shannon, 2006; Stillion & McDowell, 1996). And 68% of adults in the United States support physician-assisted suicide when a disease cannot be cured and the patient is in severe pain and requests help in committing suicide—a figure that has risen recently, especially among young adults (Dugan, 2015). African Americans and other minority group members are often less accepting of actions to hasten death than European Americans, possibly because they do not trust the medical establishment or possibly for religious or philosophical reasons (Kwak & Haley, 2005; Werth et al., 2002).

What does the law say about end-of-life interventions? Although active euthanasia is still treated as murder in the United States and most countries, it is legal in most states to withhold extraordinary life-extending treatments from terminally ill patients and to “pull the plug” on life-support equipment when that is the wish of the dying person or when the

● ENGAGEMENT 17.1

Life and Death Attitudes

Imagine that you have terminal cancer and are told that there is no more that can be done for you and no hope of recovery. What would be your answers to the following questions? There are no right or wrong answers.

1. Who would you want with you and what would you want to do with your last days or weeks?
2. Would you want to spend your last days or weeks in a hospital, in a hospice facility for terminally ill people, or at home?
3. Would you want the doctors to do all that is possible to keep you alive as long as possible, in case a new treatment is discovered?
4. Would you choose to take large doses of pain medicine even though it might limit your ability to think clearly and interact with people?
5. Would you want the following applied to you to keep you alive: (a) resuscitation if your heart stops, (b) a respirator to keep you breathing if you stop breathing on your own, (c) a feeding tube inserted in your nose or abdomen to provide nourishment if you can no longer take food through your mouth?
6. Would you want to be able to ask your doctor for and receive a drug with which you could end your own life if you desired?

immediate family can show that the individual expressed, when she was able to do so, a desire to reject life-support measures (Cantor, 2001). A **living will**, a type of advance directive in which people express their wishes after death, allows people to state that they do not want extraordinary medical procedures applied to them if they become hopelessly ill. (You can download state-specific advance directives at Caring Connections, www.caringinfo.org.)

In 1997, Oregon became the first state to legalize physician-assisted suicide. Following strict guidelines, terminally ill adults in Oregon who have 6 or fewer months to live can request lethal medication from a physician, as patients in European countries such as the Netherlands, Belgium, and Luxembourg can do. The few people in Oregon who have taken this option—70 some a year—have usually had terminal cancer and believed that they faced only hopeless pain and suffering and a loss of dignity with no chance of recovery (Angell, 2014). Washington State, Vermont, Montana (with court approval), and California have since moved to allow assisted suicide under certain conditions (Gostin & Roberts, 2016; Medina, 2016), but a number of other states have enacted laws *against* assisted suicide (Glascock, 2009). As a result, there is a big gap between supportive public attitudes and the laws of most states (Allen et al., 2006; Cohen et al., 2013). There is also a big gap between public attitudes and the views of doctors, most of whom oppose physician-assisted suicide (Angell, 2014). Brittany Maynard, a 29-year-old with incurable brain cancer, brought considerable attention to the issue in 2014 by moving from California to Oregon to obtain a prescription to hasten her death (Angell, 2014). In part in reaction, California enacted a physician-assisted suicide law (Gostin & Roberts, 2016).

On such life-or-death issues, right-to-die advocates, who maintain that terminally ill people should have a say in how and when they die, fight right-to-life advocates, who say that everything possible should be done to maintain life and that nothing should be done to cut it short. It makes sense to think through these issues now in case you must someday decide whether you or a loved one should live or die (see Shannon, 2006).

Brittany Maynard focused attention on the right-to-die issue by deciding at age 29 that she did not want to suffer any longer from the seizures and pain caused by her terminal brain cancer. She moved from California to Oregon to seek legal physician-assisted suicide and died as planned in November 2014. “I did this,” she said, “because I want to see a world where everyone has access to death with dignity, as I have had” (Bever, 2014). Here, her husband tells of their experience.

Social Meanings of Death

Death is not only a biological process but also a psychological and social one. The social meanings attached to death vary widely from historical era to historical era and from culture to culture (Parkes, Laungani, & Young, 2015; Rosenblatt, 2015b). True, people everywhere die, and people everywhere grieve deaths. Moreover, all societies have evolved some manner of reacting to this universal experience—of interpreting its meaning, disposing of corpses, and expressing grief. Beyond these universals, however, the similarities end.

Historical Change. As Philippe Ariès (1981) has shown, the social meanings of death have changed over the course of history. In Europe during the Middle Ages, people were expected to recognize that their deaths were approaching so that they could bid their farewells and die with dignity surrounded by loved ones. Since the late 19th century, Ariès argues, Western societies have engaged in a “denial of death.” We have taken death out of the home and put it in the hospital and funeral parlor to be managed by physicians and funeral directors; as a result, we have less direct experience with it than our ancestors did (Röcke & Cherry, 2002; Taylor, 2003).

Right-to-die and death-with-dignity advocates have been arguing that we should return to the old ways, bringing death into the open, allowing it to occur more naturally, and making it again a normal life experience to be shared with family rather than a medical failure. As you will see later, this is just what the hospice movement has aimed to achieve.

Cultural Variation. The experience of dying also differs from culture to culture. Societies take different stands, for example, on whether to support frail elders or speed their deaths. Anthony Glascock (2009) found that in 21 of 41 cultures he examined, practices that hastened the death of frail elderly people existed—practices such as depriving ailing elders of food, driving them from their homes, or stabbing them upon their request. Only 12 of the societies were entirely supportive of frail elders and had no death-hastening practices.

If we look at how people in other cultures grieve and mourn a death, we quickly realize that there are many alternatives to our Western ways and no single, biologically mandated grieving process (Klass, 2001; Park & Pyszczynski, 2016; Rosenblatt, 2008, 2015b). Yes, sadness is a common response, but there are no universal emotional responses to death. Depending on the society, “funerals are the occasion for avoiding people or holding parties, for fighting or having sexual orgies, for weeping or laughing, in a thousand different combinations” (Metcalf & Huntington, 1991, p. 24). In most societies, there is some concept of spiritual immortality. Yet here, too, there is much variety, from concepts of heaven and hell to the idea of reincarnation to a belief in ancestral ghosts who meddle in the lives of the living (Rosenblatt, 1993).

We need not look beyond North America to find considerable variation in the social meanings of death. Different ethnic and racial groups clearly have different rules for expressing grief. For example, it is customary among Puerto Ricans, especially women, to display intense emotions after a death (Cook & Dworkin, 1992), and Mexican American mourners do more viewing, touching, and kissing of the deceased than European Americans (Bonanno, 2009). Japanese Americans, by contrast, are socialized to restrain their grief—to smile so as not to burden others with their pain and to avoid the shame associated with losing self-control (Cook & Dworkin, 1992).

Different ethnic and racial groups also have different mourning practices. Irish Americans have traditionally believed that the dead deserve a good send-off, a wake with food, drink, and jokes—the kind of party the deceased might have enjoyed (McGoldrick et al., 1991). African Americans tend to regard the funeral not as a time for rowdy celebration but as a forum for expressing grief, in

some congregations by wailing and singing spirituals (McGoldrick et al., 1991; Perry, 1993). Jewish families are even more restrained; they quietly withdraw from normal activities for a week of mourning, called *shivah*, then honor the dead again at the 1-month and 1-year marks (Cytron, 1993).

In short, the experiences of dying individuals and of their survivors are shaped by the historical and cultural contexts in which death occurs. Death may be universal, and the human tendency to mourn a loss may be too (Parkes, 2000). Otherwise, death is truly what we humans make of it; there is no one “right” way to die or to grieve a death.

What Kills Us and When?

As Chapter 5’s discussion of basic theories of aging and death revealed, genes and environment conspire to ensure that all

The dama funeral ceremony practiced by the Dogon people of Mali in western Africa involves a masquerade that leads the souls of the deceased to their final resting places in the next world. Mourning rituals differ considerably from culture to culture.

humans not only develop but age and die. How long are we likely to live, and what is likely to kill us?

Life Expectancy

In the United States the life expectancy at birth—the average number of years a newborn can be expected to live—is almost 79 years (Miniño & Murphy, 2012). This average life expectancy disguises important differences between males and females, among racial and ethnic groups, and among social classes. As shown in **Figure 17.1**, the life expectancy for males is generally lower than that for females: 76 years versus 81 years overall. Female hormones seem to protect women from high blood pressure and heart problems, and they are less exposed than men to violent deaths and accidents and to health hazards such as smoking and drinking (Kajantie, 2008; Kaplan & Erickson, 2000). Ethnic differences are evident as well: Life expectancy is highest for Hispanics, medium for non-Hispanic whites, and lowest for African Americans, more of whom experience the stressors and health hazards associated with poverty. Across racial and ethnic groups, life expectancies are lower in poor areas than in affluent areas (Malmstrom et al., 1999).

Despite historical improvements in longevity in all regions of the world, however, life expectancies in some parts of the world lag far behind life expectancies in others. In some less developed countries plagued by malaria, famine, AIDS, and other such killers, many of them in Africa, the life expectancy is barely above 50 (Central Intelligence Agency, 2015). Among these countries are Chad, Somalia, Swaziland, and Afghanistan. By contrast, the life expectancy at birth is over 80 now in about 40 highly developed and affluent countries such as Japan, Hong Kong, and Singapore in Asia and Iceland, Italy, Sweden, and Switzerland in Europe (Central Intelligence Agency, 2015).

Death across the Life Span

Death rates change over the life span, as illustrated by the “Total Deaths” statistics for different age groups in **Table 17.1**. Infants are relatively vulnerable; infant mortality in the United States has dropped considerably in recent years, however, and

Figure 17.1 Life expectancy at birth for males and females of different racial and ethnic groups in the United States in 2010. Females outlive males; Hispanics have the longest, African Americans the shortest life expectancy.

Source: Miniño, A. M., & Murphy, S. L. (2012, July). *Death in the United States, 2010*. NCHS Data Brief, No. 99. U.S. Department of Health and Human Services, Centers for Disease Control and Prevention, National Center for Health Statistics. Retrieved from: www.cdc.gov/nchs/data/databriefs/db99.htm

now stands at a bit over 6 out of 1,000 live births (Miniño & Murphy, 2012). Assuming that we survive infancy, we have a relatively small chance of dying during childhood or adolescence. Death rates then climb steeply and steadily throughout adulthood.

What kills us? The leading causes of death change dramatically over the life span, as also shown in **Table 17.1** (Heron, 2016).

Table 17.1 Leading Causes of Death for Different Age Groups in the United States

Age Group	Total Deaths, 2013	No. 1 Cause	No. 2 Cause	No. 3 Cause
Younger than 1 year	23,440	Congenital abnormalities	Short gestation, low birth weight	Maternal complications of pregnancy
1–4 years	4,068	Accidents (unintentional injuries)	Congenital abnormalities	Assault (homicide)
5–9 years	2,427	Accidents	Cancers	Assault (homicide)
10–14 years	2,913	Accidents	Cancers	Suicide (self-harm)
15–19 years	9,480	Accidents	Suicide	Assault (homicide)
20–24 years	19,006	Accidents	Suicide	Assault (homicide)
25–44 years	115,036	Accidents	Cancers	Heart diseases
45–64 years	515,851	Cancers	Heart diseases	Unintentional injuries
65 years and older	1,904,640	Heart diseases	Cancers	Chronic respiratory diseases

Source: Heron, M. (2016, February 16). Deaths: Leading causes for 2013. *National Vital Statistics Reports*, 63(2). Retrieved from: www.cdc.gov/nchs/data/nvsr/nvsr65/nvsr65_02.pdf

Infant deaths are mainly associated with congenital abnormalities that infants bring with them to life, low birth weight or short gestation, and complications of pregnancy. The leading cause of death among preschool and school-age children is unintentional injuries or accidents (especially car accidents but also poisonings, falls, fires, drownings, and so on). Adolescence and early adulthood are generally periods of good health. Accidents (especially car accidents), suicides, and homicides are the leading killers of adolescents and emerging adults, making this a time for sudden and traumatic death.

Accidents and cancers kill young adults, and heart diseases also begin to take a toll. In the 45–64 age group, cancers have become the leading cause of death, followed by heart diseases. These and other chronic illnesses brought on by some combination of genetic risk and environmental factors become more likely causes of death as age increases. Among adults 65 and older, heart diseases lead the list by far, followed by cancers and chronic respiratory diseases, with strokes close behind.

In sum, life expectancies are higher than ever. After we make it through the vulnerable period of infancy, we are at low risk of death through adolescence and are most likely to die suddenly in an accident if we do die. As we age, we become more vulnerable to chronic diseases—and the often slower and more expected deaths associated with them.

● Checking Mastery

1. Why was Terry Schiavo not dead according to the total brain death definition of death?
2. What would be most likely to kill a 10-year-old? A 70-year-old?

● Making Connections

1. What would you have decided about whether Terri Schiavo should have been taken off her feeding tube and why—and what does your answer imply about how you think death should be defined?
2. An 85-year-old British man and his 74-year-old wife, who was dying of terminal liver and pancreatic cancer, paid an organization in Switzerland to help them achieve an assisted suicide in which they both drank poison and lay down to die together (Gibbs, 2009). The husband had weak vision and hearing but no major health problems; he mainly did not want to go on living without his beloved wife. Do you believe that (1) the wife and (2) the husband should be able to choose death in circumstances like these? Why or why not?

17.2

The Experience of Death

LEARNING OBJECTIVES

- Assess Elisabeth Kübler-Ross's stages of dying and the limitations of her view of the dying person's experience.
- Assess the Parkes/Bowlby attachment model of bereavement and compare how it is similar to and different from Kübler-Ross's model.
- Compare the dual-process model of bereavement to the Parkes/Bowlby model.

People who develop life-threatening illnesses face the challenge of coping with the knowledge that they are seriously ill and are likely to die. What is it like to be dying, and how does the experience compare to the experience of losing a loved one to death?

Perspectives on Dying

Perhaps no one has done more to focus attention on the emotional needs and reactions of dying patients than psychiatrist Elisabeth Kübler-Ross, whose “stages of dying” are widely known and whose 1969 book *On Death and Dying* revolutionized the care of dying people. In interviews with terminally ill patients, Kübler-Ross (1969, 1974) detected a common set of emotional responses to the knowledge that one has a serious, and probably fatal, illness. She believed that similar reactions might occur in response to any major loss, so bear in mind that the family and friends of the dying person may experience similar emotional reactions during the loved one's illness and after the death.

Kübler Ross's Stages of Dying

Kübler-Ross's five “stages of dying” are as follows:

1. **Denial.** A common first response to dreadful news is to say, “No! It can't be!” **Denial** is a defense mechanism in which anxiety-provoking thoughts are kept out of conscious awareness. A woman who has just been diagnosed as having lung cancer may insist that the diagnosis is wrong—or accept that she is ill but be convinced that she will beat the odds and recover. Denial can be a marvelous coping device: It can get us through a time of acute crisis until we are ready to cope more constructively. Yet even after dying patients face the facts and become ready to talk about dying, care providers and family members often engage in their own denial.
2. **Anger.** As the bad news begins to register, the dying person asks, “Why me?” Feelings of rage or resentment may be directed at anyone who is handy—doctors, nurses, or family members. Kübler-Ross advises those close to the dying person to be sensitive to this reaction so that they will not avoid this irritable person or become angry in return.

Psychiatrist Elisabeth Kübler-Ross called on physicians to emphasize caring rather than curing.

Duane Howell/Denver Post/Getty Images

3. **Bargaining.** When the dying person bargains, he says, “Okay, me, but please. . . .” The bargainer begs for some concession from God, the medical staff, or family members—if not for a cure, perhaps for a little more time, a little less pain, or provision for his children.
4. **Depression.** As the dying person becomes even more aware of the reality of the situation, depression, despair, and a sense of hopelessness become the predominant emotional responses. Grief focuses on the losses that have already occurred (for example, the loss of functional abilities) and the losses to come (separation from loved ones, inability to achieve dreams, and so on).
5. **Acceptance.** If the dying person is able to work through the emotional reactions of the preceding stages, she may accept the inevitability of death in a calm and peaceful manner. Kübler-Ross (1969) described the acceptance stage this way: “It is almost void of feelings. It is as if the pain had gone, the struggle is over, and there comes a time for ‘the final rest before the long journey,’ as one patient phrased it” (p. 100).

In addition to these five stages of dying, Kübler-Ross emphasized a sixth response that runs throughout the stages: *hope*. She believed that it is essential for terminally ill patients to retain some sense of hope, even if it is only the hope that they can die with dignity. Sadly, Kübler-Ross spent her own dying days mostly alone, a prisoner in her armchair with the television for company (O’Rourke, 2010).

Problems with Kübler-Ross’s Stages

Kübler-Ross deserves immense credit for sensitizing our society to the emotional needs of dying people. She convinced medical professionals to emphasize caring rather than curing in working with terminally ill people. At the same time, there are flaws in her account of the dying person’s experience (Kastenbaum, 2012; Walter & McCoyd, 2009). Among the points

critics make are these: Emotional responses to dying are not stagelike; the nature and course of an illness affects reactions to it; individuals differ widely in their responses; and dying people focus on living, not just dying.

The first and most important problem with Kübler-Ross’s stages is that *the dying process is simply not stagelike*. Although many dying patients display symptoms of depression as death nears, the other emotional reactions Kübler-Ross describes seem to affect only minorities of dying people (Schulz & Aderman, 1974). Moreover, when these responses occur, they do not unfold in a standard order. It might have been better if Kübler-Ross had, from the start, described her stages simply as emotional reactions to dying. Unfortunately, some overzealous medical professionals have tried to push dying patients through the “stages” in order, believing incorrectly that their patients would never accept death unless they experienced the “right” emotions at the “right” times (Kastenbaum, 2012).

Edwin Shneidman (1973, 1980) offered an alternate view, arguing that dying patients experience a complex and ever-changing interplay of emotions, alternating between denial and acceptance of death. One day a patient may seem to understand that death is near; the next day she may talk of getting better and going home. Along the way many reactions—disbelief, hope, terror, bewilderment, rage, apathy, calm, anxiety, and others—come and go and are even experienced simultaneously. According to Shneidman, then, dying people experience many unpredictable emotional swings rather than distinct stages. Research tends to support him (Chochinov & Schwartz, 2002).

Second, Kübler-Ross’s theory *does not take into account the disease a person has and its course or trajectory* (Glaser & Strauss, 1968; Kastenbaum, 2012). When a patient is slowly and gradually worsening over time, the patient, family members, and staff can all become accustomed to the death that lies ahead, whereas when the path toward death is more erratic, perhaps involving remissions and relapses and surgeries along the way, emotional ups or downs are likely each time the patient’s condition takes a turn for better or worse.

Third, Kübler-Ross’s approach *overlooks the influence of personality on how a person experiences dying*. People cope with dying much as they have coped with life (Schulz & Schlarb, 1987–1988). For example, cancer patients who previously faced life’s problems directly and effectively, were satisfied with their lives, and maintained good interpersonal relationships before they became ill display less anger and are less depressed and withdrawn during their illnesses than patients who were not so well adjusted before their illnesses (Hinton, 1975). Depending on their predominant personality traits and coping styles, some dying people may deny until the bitter end, some may “rage against the dying of the light,” some may quickly be crushed by despair, and still others may display incredible strength.

Fourth and finally, Kübler-Ross focused on emotional responses to the news that one is dying but *gave little attention to how dying people approach living*. An interesting study by Rinat Nissim and colleagues (2012) identified themes in interviews with Canadian patients who had advanced cancer

and less than 2 years to live. An important discovery was that these patients continued to set and work toward goals. Their goals centered on:

- *controlling dying* (primarily by focusing on their chemotherapy and other treatments but also, for some, by holding in the back of their mind the possibility of suicide if necessary)
- *valuing life in the present* (getting the most out of their remaining time, even if they could no longer make long-range plans)
- *creating a living legacy* (for example, getting their affairs in order, creating good memories in their children, touching others' lives)

In short, these patients were not just coping with difficult emotions and they were certainly not just lying back waiting to die. As the researchers put it, they were “striving to grow in the land of the living/dying” (Nissim et al., 2012, p. 368). In sum, Kübler-Ross highlighted five relevant emotional responses to dying, but we should not think of them as stages, or as applicable to all diseases or all personalities, or as all that is going on in people who are not only coping with dying but trying to live.

Perspectives on Bereavement

Most of us are more familiar with the process of grieving a death than the process of dying. To describe responses to the death of a loved one, we must distinguish among three terms: **Bereavement** is a state of loss, **grief** is an emotional response to loss, and **mourning** is a culturally prescribed way of displaying reactions to death. Thus, we can describe a bereaved person who grieves by experiencing such emotions as sadness, anger, and guilt and who mourns by attending the funeral and laying flowers on the grave each year.

Unless a death is sudden, relatives and friends, like the dying person, will experience many painful and changing emotions before the death, from the initial diagnosis through the last breath (Grbich, Parker, & Maddocks, 2001). They, too, may alternate between acceptance and denial. They also may experience what has been termed **anticipatory grief**—grieving before death occurs for what is happening and for what lies ahead (Rando, 1986). Anticipatory grief occurs but it typically does not reduce grieving after the death (Nielsen et al., 2016). How, then, do we grieve?

The Parkes/Bowlby Attachment Model

Pioneering research on the grieving process was conducted by Colin Murray Parkes and his colleagues in Great Britain (Parkes, 1991, 2006; Parkes & Prigerson, 2010; Parkes & Weiss, 1983). John Bowlby (1980), whose influential theory of attachment was outlined in Chapter 14, and Parkes conceptualized grieving in the context of attachment theory as a reaction to separation from a loved one. As Parkes (2006) notes, “love and loss are two sides of the same coin. We cannot have one without risking the other” (p. 1). The grieving adult is very much like the infant who experiences separation anxiety when her mother disappears from view. As humans, we have evolved not only to form attachments but also to protest their loss.

A family systems perspective is needed to understand the impacts of death on the bereaved—here, the wife and children of a slain police officer.

Peter Casolino/Alamy Stock Photo

The **Parkes/Bowlby attachment model of bereavement** describes four predominant reactions. They overlap considerably and therefore should be viewed as phases, not as sequential stages. These reactions are numbness, yearning, disorganization and despair, and reorganization (see also Jacobs et al., 1987–1988, and see ● **Table 17.2** to view this phase model of bereavement side by side with Kübler-Ross’s stages of dying:

1. **Numbness.** In the first few hours or days after the death, the bereaved person is often in a daze—gripped by a sense of unreality and disbelief and almost empty of feelings. Underneath this state of numbness and shock is a sense of being on the verge of bursting, and, occasionally, painful emotions break through. The bereaved person is struggling to defend himself against the full weight of the loss; the bad news has not fully registered.
2. **Yearning.** As the numbing sense of shock and disbelief diminishes, the bereaved person experiences more agony. This is the time of acute separation anxiety and efforts to reunite with the lost loved one. Grief comes in pangs or waves that typically are most severe from 5 to 14 days after the death. The grieving person has feelings of panic, bouts of uncontrollable

● **Table 17.2** Models of Dying and Bereavement

Kübler-Ross’s Stages of Dying	The Parkes/Bowlby Attachment Model of Bereavement
1. Denial	1. Numbness
2. Anger	2. Yearning (including anger and guilt)
3. Bargaining	
4. Depression	3. Disorganization and despair
5. Acceptance	4. Reorganization

weeping, and physical aches and pains. She is likely to be extremely restless, unable to concentrate or to sleep, and preoccupied with thoughts of the loved one and of the events leading to the death. Most importantly, the bereaved person pines and yearns and searches for the loved one, longing to be reunited.

According to Parkes and Bowlby, it is these signs of separation anxiety—the distress of being parted from the object of attachment—that most clearly make grieving different from other kinds of emotional distress. A widow may think she heard her husband’s voice or saw him in a crowd; she may sense his presence in the house and draw comfort from it; she may be drawn to his favorite chair—or may try to recover him by smelling his bathrobe. Ultimately the quest to be reunited, driven by separation anxiety, fails.

Both anger and guilt are common during these early weeks and months of bereavement. Frustrated in their quest for reunion, bereaved people often feel irritable and sometimes experience intense rage—at the loved one for dying, at the doctors for not doing a better job, at anyone handy. They seem to need to pin blame somewhere. Unfortunately, they often find reason to blame themselves—to feel guilty. A father may moan that he should have spent more time teaching his son gun safety; the friend of a young man who dies of AIDS may feel that he was not a good enough friend. One of the London widows studied by Parkes felt guilty because she never made her husband bread pudding.

3. **Disorganization and despair.** As time passes, pangs of intense grief and yearning become less frequent, although they still occur. As it sinks in that a reunion with the loved one is impossible, depression, despair, and apathy increasingly predominate. During most of the first year after the death, and longer in many cases, bereaved individuals often feel apathetic and may have difficulty managing and taking interest in their lives.
4. **Reorganization.** Gradually, bereaved people begin to pull themselves together again as their pangs of grief and periods of apathy become less frequent. They invest less emotional energy in their attachment to the deceased and more in their attachments to the living. If they have lost a spouse, they begin to make the transition from being a wife or husband to being a widow or widower, revising their identities. They begin to feel readier for new activities and possibly for new relationships or attachments.

In **Figure 17.2**, you can see the changing mix of overlapping reactions predicted by this attachment model of grief (Jacobs et al., 1987–1988). To test the Parkes/Bowlby model, Paul Maciejewski and his colleagues (2007) assessed disbelief, yearning, anger, depression, and acceptance in 233 bereaved individuals from 1 to 24 months after their loss of a loved one to death from natural causes. The different emotional reactions peaked in the predicted order (disbelief, yearning, anger, and despair/depression), while acceptance steadily gained strength over time. Although the worst of the grieving process for widows and widowers is during the first 6 months after the loss,

Figure 17.2 The overlapping phases of grief in the Parkes/Bowlby attachment model of bereavement. Numbness and disbelief quickly give way to yearning and pining (signs of separation anxiety) and then to despair or depression (and, although not shown here, growing acceptance and reorganization).

the process typically takes a year or more and can take much longer (Parkes & Prigerson, 2010).

The Dual-Process Model of Bereavement

Like responses to dying, responses to bereavement have proven to be messy—messier than the Parkes/Bowlby attachment model suggests (Röcke & Cherry, 2002). Margaret Stroebe and Henk Schut have put forth a **dual-process model of bereavement** in which the bereaved oscillate, often unpredictably, between coping with the emotional blow of the loss and coping with the practical challenges of living, as illustrated in **Figure 17.3** (Stroebe & Schut, 1999; and see Hansson & Stroebe, 2007; Stroebe & Schut, 2010). **Loss-oriented coping** involves dealing with one’s emotions and reconciling oneself to the loss, whereas **restoration-oriented coping** is focused on managing daily living, rethinking one’s life, and mastering new roles and challenges that come in the wake of the loss. The bereaved need to grieve, but they also need to figure out their finances, take over household tasks that the loved one used to do, get reinvolved in life, revise their identities, and manage other challenges.

Both loss- and restoration-oriented issues need to be confronted, but they also need to be avoided at times or they would exhaust us. We therefore have to strike a balance between confrontation and avoidance of coping challenges and between loss-oriented and restoration-oriented coping. So, for example, working on practical tasks like preparing taxes—or just watching a movie—may give a widow relief from dealing with painful emotions so that she can reenergize for a while before shifting back to a focus on her loss. Bereaved people ideally oscillate

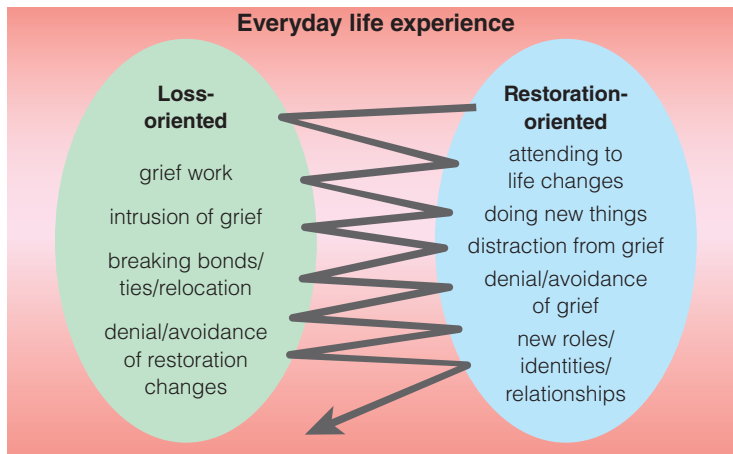

Figure 17.3 The dual-process model of coping with bereavement. The bereaved oscillate between loss-oriented and restoration-oriented coping, both of which involve both positive and negative emotions and thoughts.

Source: From Stroebe, M. S., & Schut, H. A. W. (1999). The dual process model of coping with bereavement: Rationale and description. *Death Studies*, 23, 197–224, Figure 1. Reprinted by permission of Taylor & Francis Group.

flexibly between the two types of coping rather than focusing on only one; otherwise, they would either fail to deal with their loss or fail to take steps toward recovery. Over time, emphasis shifts from loss-oriented to restoration-oriented coping and from more negative to more positive thoughts and emotions.

More recently, Stroebe and Schut (2015) have extended their model to consider how the family as a whole deals with its loss. Family dynamics affect how individual family members cope, and individual family members affect overall family coping as well. For example, after a child's death, a father may try to avoid talking about the loss or expressing grief to protect his wife from pain. As it turns out, this strategy may backfire, leading both he and his wife to experience more intense grief later on (Stroebe et al., 2013). At the family level too, there is oscillation between loss-oriented coping (for example, shared mourning activities) and restoration-oriented coping (for example, reconfiguring family roles). In the end, some families prove to be more resilient than others (Bonanno, Romero, & Klein, 2015).

Most researchers agree that bereavement is a complex and not-very-stagelike process that involves many ever-shifting emotions (like Shneidman's description of the emotional responses of dying people), varies greatly from person to person, and can take a long time. Meanwhile, the rest of us are sympathetic toward the bereaved immediately after a death—eager to help in any way we can—but we quickly grow weary of someone who is depressed, irritable, or preoccupied. We begin to think, sometimes after only a few days or weeks, that it is time for the bereaved person to cheer up and get on with life. We are wrong. To be of help to bereaved people, we must understand that their reactions of numbness and disbelief, yearning, and despair, and their needs to engage in both loss-oriented and restoration-oriented coping, may last a long time.

We have now considered some major perspectives on how people experience dying and bereavement. However, these perspectives have been based primarily on the responses of adults. How do infants, children, and adolescents respond to death? What does death even mean to infants and young children? A life-span perspective on death and dying is needed.

● Checking Mastery

1. What are three of the four main criticisms of Kübler-Ross's stage theory of dying?
2. How does attachment theory inform the Parkes/Bowlby model of bereavement?
3. What oscillates in the dual-process model of bereavement?

● Making Connections

1. Look carefully at the five stages of dying that Elisabeth Kübler-Ross believes terminally ill patients experience and at the four phases of adjustment bereaved people experience according to Colin Murray Parkes and John Bowlby (see Table 17.2). What common themes do you see? How do these models differ?
2. If you worked in a hospital wing with terminally ill adults, how might you use Kübler-Ross's perspective to improve care? And how might you avoid misusing it?

17.3

The Infant

LEARNING OBJECTIVES

- Explain how infants might first come to understand death.
- Describe how John Bowlby characterized infants' responses to separation from an attachment figure and how these responses resemble grief.

Looking at bereavement from an attachment theory perspective makes us wonder how infants understand and cope with the death of an attachment figure. Infants surely do not comprehend death as the cessation of life, but they do gain an understanding of concepts that pave the way for an understanding of death (Corr, 2010).

Infants may, for example, come to grasp the concepts of being and nonbeing, here and “all gone,” from such experiences as watching objects and people appear and disappear, playing peekaboo, and even going to sleep and “coming alive” again in the morning (Maurer, 1961). Possibly, infants first form a global category of

Games of peekaboo help infants understand the concept of “all gone” and pave the way for an understanding of death.

Tony Freeman/PhotoEdit

things that are “all gone” and later divide it into subcategories, one of which is “dead” (Kastenbaum, 2000). Infants lack the concept of death as permanent separation and loss, however. And, although they may notice changes in the emotional climate in their home when their companions are grieving or may miss a no longer present caregiver (Corr, 2010), they lack the cognitive capacity to interpret what has happened when someone in the family dies.

The experience most directly relevant to the infant’s emerging concept of death is separation from a loved one, and it is here that Bowlby’s theory of attachment and research are helpful. Only after infants form their first attachments around 6 or 7 months do they begin to display separation anxiety when their beloved caregivers leave them. According to Bowlby, they are biologically programmed to protest separations by crying, searching for their loved one, and attempting to follow, thereby increasing the chances that they will be reunited with the caregiver and protected from harm.

Bowlby (1980) observed that infants separated from their attachment figures first engage in vigorous *protest*—yearning and searching for the loved one and expressing outrage when they fail. One 17-month-old girl said only, “Mum, Mum, Mum” for 3 days after her mother died. She was willing to sit on a nurse’s lap but would turn her back, as if she did not want to see that the nurse was not “Mum” (Freud & Burlingham, cited in Bowlby, 1980).

If, after some hours or days of protest, an infant has not succeeded in finding the loved one, he begins to *despair*, displaying depression-like symptoms. The baby loses hope, ends the search, and becomes apathetic and sad. Grief may be reflected in a poor appetite, a change in sleeping patterns, excessive clinginess, or regression to less mature behavior (Furman, 1984; Walter & McCoy, 2009; and see the description of depressed infants in Chapter 16). After some days—longer in some cases—the bereaved infant may enter a *detachment* phase, in which he takes renewed interest in toys and companions. Infants will recover from their protest, despair, and detachment most completely if they can rely on an existing attachment figure (for example, the surviving parent) or can attach themselves to someone else who will be sensitive and responsive to them (Walter & McCoy, 2009). Notice the similarities between these reactions and the yearning, disorganization and despair, and reorganization phases of the Parkes/Bowlby attachment model of adult bereavement.

● Checking Mastery

1. What kinds of experiences in infancy may pave the way for an understanding of the concept of death?
2. When in infancy would you expect an infant to show grief reactions if a parent were to die?

● Making Connections

1. Baby Seth was a year old when his mother died in a car accident. How would you expect him to react, and how would his reactions compare to those of a bereaved adult, as described by the Parkes/Bowlby attachment model of bereavement?

17.4

The Child

LEARNING OBJECTIVES

- Summarize the four key components of an understanding of biological death and when they develop in childhood.
- Characterize the reactions of terminally ill children to their situation.
- Describe children’s common reactions to bereavement and what is most critical in helping them to adjust.

Much as parents would like to shelter their children from unpleasant life experiences, children encounter death in their early years, whether only of bugs and birds or, in the case of Sandy Hook Elementary School students, of their siblings, classmates, and teachers. How do they come to understand and cope with their experiences of death?

Grasping the Concept of Death

Contrary to what many adults assume, young children are highly curious about death, think about it with some frequency, build it into their play, and talk about it (Kastenbaum, 2012). Yet their beliefs about death often differ considerably from

those of adults. In Western societies, a “mature” understanding of death has several components (Brent et al., 1996; Hoffman & Strauss, 1985; Slaughter, Jaakkola, & Carey, 1999). We see death as characterized by the following:

- **Finality.** It is the cessation of life and of all life processes, such as movement, sensation, and thought.
- **Irreversibility.** It cannot be undone.
- **Universality.** It is inevitable and happens to all living beings.
- **Biological causality.** It is the result of natural processes internal to the organism, even if external causes set off these internal changes.

Researchers have studied children’s conceptions of death by asking them the sorts of questions contained in • **Table 17.3.** Children between age 3 and age 5 have some understanding of death, especially of its universality (Brent et al., 1996). Rather than viewing death as a final cessation of life functions, however, many of them picture the dead as living under altered circumstances and retaining at least some of their capacities (Slaughter et al., 1999). According to these preschoolers, the dead may have hunger pangs, wishes, and beliefs and may continue to love their moms (Bering & Bjorklund, 2004).

Some preschool-age children also view death as reversible rather than irreversible. They may liken it to sleep (from which a person can awaken) or to a trip (from which a person can return). With the right medical care, the right chicken soup, or a bit of magic, a dead person might be brought back to life (Speece & Brent, 1984). Finally, young children think death is caused by one external agent or another; one may say that people die because they eat aluminum foil; another may say the cause is eating a dirty bug or a Styrofoam cup (Koocher, 1974). They do not grasp the ultimate biological cause of death.

Children ages 5–7 (the age range of the classmates of the children slain at Sandy Hook Elementary School) make considerable progress in acquiring a mature concept of death. Most children this age understand that death is characterized by finality (cessation of life functions), irreversibility, and

• **Table 17.3** Western Children’s Concepts of Death and Questions Pertaining to Them

Concept	Questions
Finality/Cessation of functions	Can a dead person move? Get hungry? Speak? Think? Dream? Do dead people know that they are dead?
Irreversibility	Can a dead person become a live person again? Is there anything that could make a dead animal come back to life?
Universality	Does everyone die at some time? Will your parents die someday? Your friends? Will you die?
Biological causality	What makes a person die? Why do animals die?

Even preschool children understand some aspects of death.

Bernhard Classen/Alamy Stock Photo

universality (Rosengren, Gutiérrez, & Schein, 2014; Speece & Brent, 1992). Understanding the biological causality of death is the hardest concept of death for children to master, although 6-year-olds show some basic understandings (Rosengren et al., 2014). Paula, age 12, had clearly mastered the concept that all deaths are ultimately caused by a failure of internal biological processes: “When the heart stops, blood stops circulating, you stop breathing and that’s it. . . . there’s lots of ways it can get started, but that’s what really happens” (Koocher, 1974, pp. 407–408).

Children’s understandings of death are influenced in part by their level of cognitive development. Major breakthroughs in the understanding of death occur in the 5–7 age range—when, according to Piaget’s theory, children progress from the preoperational stage of cognitive development to the concrete-operational stage. However, Piaget’s theory underestimates how much even 3- and 4-year-olds grasp (Rosengren et al., 2014).

In addition, children’s concepts of death are influenced by the cultural context in which they live and the cultural and religious beliefs to which they are exposed (Sagara-Rosemeyer & Davies, 2007; Stambrook & Parker, 1987). For example, Jewish and Christian children in Israel, who are taught our Western concept of death, provide more “mature” answers to questions about death than Druze children, who are taught to believe in reincarnation (Florian & Kravetz, 1985). Understandably, a child who is taught that dead people are reincarnated may not view death as an irreversible cessation of life processes.

Another good example of the influence of cultural beliefs comes from a comparison of European American and Mexican American immigrant children in a Midwestern city (Gutiérrez, Rosengren, & Miller, 2014). European American parents typically believed that they should protect their children from death, whereas Mexican American parents believed that they had a responsibility to educate their children about it and included them in the community’s yearly *Día de los Muertos*, or Day of the Dead, ceremonies. Among the differences detected between

children in the two groups were these: Mexican American children asked more questions about death and dying, were better able to answer a question about what parents should say to a child after the child's relative died, and more often saw the dead as continuing to function biologically and psychologically after death, probably because they had been taught that the dead come back to the world of the living on *Día de los Muertos* to eat their favorite foods.

Finally, within any society or cultural group, children's unique life experiences also affect their understanding of death. Children who have had personal experience with a death in their immediate or extended family often have more mature understandings of death than similar children who have not yet experienced the loss of a family member (Bonoti, Leondari, & Mastora, 2013). How children's parents communicate with them about death can also make a difference. How is a young child to overcome the belief that death is temporary, for example, if parents and other adults claim that relatives who have died are "asleep"? And if a child is told that "Grandma has gone away," is it not logical to ask why she cannot hop a bus and return?

Experts on death insist that adults only make death more confusing and frightening to young children when they use such euphemisms. They point out that children often understand more than we think, as illustrated by some of the research described above—and by the 3-year-old who, after her father explained that her deceased grandfather had "gone to live on a star in the sky," looked at him quizzically and said, "You mean he is dead?" (Silverman, 2000, pp. 2–3). Experts recommend that parents give children simple but honest answers to the many questions they naturally ask about death and capitalize on events such as the death of a pet to teach children about death and help them understand and express their emotions (Kastenbaum, 2012; Silverman, 2000). In sum, through a combination of cognitive development, cultural learning, and individual experiences, children typically master the concept of death as final, irreversible, universal, and biologically caused.

The Dying Child

Parents and doctors often assume that terminally ill children are unaware that they will die and are better off remaining so. Yet research shows that dying children are far more aware of what is happening to them than adults realize (Essa & Murray, 1994; Stevens et al., 2010). Consider what Myra Bluebond-Langner (1977) found when she observed children ranging in age from 2 to 14 who had leukemia. Even many preschool children arrived, over time, at an understanding that they were going to die and that death is irreversible. Despite the secretiveness of adults, these children noticed changes in their treatments and subtle changes in the way adults interacted with them, and they paid close attention to what happened to other children who had the same disease and were receiving the same treatments. Over time, many of these ill children stopped talking about

the long-term future and wanted to celebrate holidays such as Christmas early. A doctor trying to get one boy to cooperate with a procedure said, "I thought you would understand, Sandy. You told me once you wanted to be a doctor." Sandy threw an empty syringe at the doctor and screamed, "I'm not going to be anything!" (p. 59). Some dying children even start thinking about giving away their toys or planning their funerals (Jalmsell et al., 2015).

How do terminally ill children cope with the knowledge that they are dying? They experience many of the emotions that dying adults experience (Waechter, 1984). Preschool children may not talk about dying, but they may reveal their anxiety by throwing temper tantrums or portraying violent acts in their pretend play. School-age children understand more about their situation and can talk about their feelings if given an opportunity to do so. They want to participate in normal school and sports activities so that they will not feel inadequate compared with their peers, and they want to maintain a sense of control or mastery, even if the best they can do is take charge of deciding which finger should be pricked for a blood sample.

Children with terminal illnesses need the love and support of parents, siblings, and other significant individuals in their lives. Most of all they need a strong sense that their parents are there to care for them (Worchel, Copeland, & Barker, 1987). In one study of Swedish families (Kreicbergs et al., 2004), about a third of parents of terminally ill children talked to their children about dying, and none regretted it. By comparison, about a fourth of the parents who did not talk with their children regretted not having done so, especially if they sensed their child was aware of dying (as over half the parents did). A study of Dutch parents found that the two-thirds of parents who did not discuss death with their terminally ill children offered a variety of good reasons for their decision, mainly centered on their desire to protect their

Lilly Williams paints with Marie the Penguin at the children's hospital where she is being treated for cancer.

Kayte Deiyoma/Alamy Stock Photo

child (van der Geest et al., 2015). In short, this is a difficult call for parents; their best path is often to follow the child's lead, enabling children to talk about their feelings if they wish and answering their questions simply and directly (Faulkner, 1997; Jalmsell et al., 2015).

The Bereaved Child

Children's coping capacities are also tested when a parent, sibling, pet, or other loved one dies. Four major messages have emerged from studies of bereaved children: Children grieve, they express their grief differently than adults do, they lack some of the coping resources that adults command, and some are vulnerable to long-term negative effects of bereavement (Lieberman et al., 2003; Osterweis, Solomon, & Green, 1984; Silverman, 2000).

Consider first some of the reactions that have been observed in young children whose parents have died (Christ, 2010; Lewis & Lippman, 2004; Lieberman et al., 2003; Silverman, 2000). These children often misbehave or strike out in rage at their surviving parent; they can become unglued when favorite routines are not honored (Lieberman et al., 2003). They ask endless questions: Where is Daddy? When is he coming back? Will I get a new Daddy? Anxiety about attachment and separation is common; many bereaved children report being scared that other family members might die (Sanchez et al., 1994). Yet at other times bereaved children go about their activities as if nothing had happened, denying the loss or distracting themselves from it by immersing themselves in play. You can see how caregivers might be disturbed by some of these behaviors. As you may also have noticed, they are not unlike the emotional swings and oscillations that bereaved adults experience.

Because they lack the cognitive abilities and coping skills that older individuals command, young children may have trouble grasping what has happened and attempt to deny and avoid emotions too overwhelming to face. Young children also have mainly behavioral or action coping strategies at their disposal (Skinner & Zimmer-Gembeck, 2007). So, for example, 2-year-old Reed found comfort by taking out a picture of his mother and putting it on his pillow at night, then returning it carefully to the photo album in the morning (Lieberman et al., 2003). Older children are able to use cognitive coping strategies such as conjuring up mental representations of their lost parents (Compas et al., 2001; Skinner & Zimmer-Gembeck, 2007). It is very important to children to have their grief recognized and to be included in the family's mourning rituals (Søfting, Dyregrov, & Dyregrov, 2016).

Grief reactions differ greatly from child to child, but the preschooler's grief is likely to manifest itself in problems with sleeping, eating, toileting, and other daily routines (Oltjenbruns, 2001; Osterweis et al., 1984). Negative moods, dependency, and temper tantrums are also common. Older children express their sadness, anger, and fear more directly, although somatic symptoms such as headaches and other physical ailments are also common (Worden & Silverman, 1996).

Well beyond the first months after the death, some bereaved children continue to display problems such as unhappiness, low self-esteem, social withdrawal, difficulty in school, and problem behavior (Osterweis et al., 1984; Rostila et al., 2016; Worden & Silverman, 1996). In a longitudinal study of school-age children, one in five children who had lost a parent had serious adjustment problems 2 years after the death (Worden & Silverman, 1996; see also Dowdney, 2000). A minority of children develop psychological problems that carry into adulthood—for example, overreactivity to stress, stress-related health problems, depression and other psychological disorders, and insecurity in later attachment relationships (Harris & Bifulco, 1991; Luecken, 2008; Mireault, Bearor, & Thomas, 2001–2002).

However, most bereaved children are resilient and adapt quite well. By 2 to 5 years after their loss, children who have experienced the death of a parent typically look much like similar nonbereaved children in both socioemotional and academic functioning (Williams & Aber, 2016). A child is especially likely to fare well if her caregiver maintains her own mental health, has a secure relationship with the child, and provides good parenting (Little et al., 2011).

Supportive friends can also help a child who has lost a parent adjust (Dopp & Cain, 2012; LaFreniere & Cain, 2015). Yet relationships with peers can become strained if the child develops behavior problems or withdraws socially. Peers can also do damage through insensitive remarks. Some bereaved children are told by other kids that they are making up the death (Dopp & Cain, 2012). Others are taunted by peers (Cain & LaFreniere, 2015). One 7-year-old girl was distraught when told, "You can't go to the father-daughter dance because your daddy is dead," and was calmed only when her mother assured her that her uncles very much wanted to take her (Christ, 2010, p. 172).

● Checking Mastery

1. What are two factors that might lead Jared to develop a fuller understanding of death concepts than Jeremy at age 5?
2. What three concepts of death are children likely to master by ages 5–7 and what concept might still be incomplete?
3. What reactions on the part of bereaved children might irritate their caregivers?

● Making Connections

1. How might you as a parent help or hinder your child's development of a mature concept of death?
2. If your child had untreatable cancer, would you talk to her about dying? Why or why not? Would the child's age affect your decision? How?

17.5

The Adolescent

LEARNING OBJECTIVES

- Explain how understandings of death change in adolescence.
- Analyze how features of the adolescent period are reflected in the dying and bereavement experiences of adolescents.

Adolescents expand their understandings of death and show some of the characteristics we associate with the adolescent period when they encounter death.

Advanced Understandings of Death

Adolescents typically understand death as the irreversible cessation of biological processes. They also are able to think in more abstract ways about death, consistent with the shift from Piaget's concrete-operational stage to his formal-operational stage (Corr, 1995; Koocher, 1973). They use their new cognitive capacities to ponder the meaning of death (Balk, 2014; McCarthy, 2009). Yet many adolescents (and adults too) share with young children a belief that psychological functions such as knowing, believing, and feeling continue even after bodily functions have ceased (Bering & Bjorklund, 2004; Bonoti et al., 2013). Do they regress to childish beliefs?

Not really. By adolescence, children have often acquired a belief in an afterlife—a belief that is common across cultures (Bering & Bjorklund, 2004; Park & Pyszczynski, 2016). Many people end up, then, with both a biological concept of death and a supernatural or religious view of it. Developing a belief that the soul or spirit lives on after death does not mean giving up a biological understanding of death as a cessation of bodily functions, nor does learning about biology undo beliefs about the supernatural based on cultural and religious teachings. Rather, the two sets of beliefs live side by side in adolescents' thinking and can be called upon as needed, depending on the situation and what they are trying to explain (Legare et al., 2012).

Experiences with Death

Themes of the adolescent period are reflected in how adolescents deal with having a terminal illness, losing a parent, and losing a friend.

Dying

Just as children's reactions to death and dying reflect their developmental capacities and needs, adolescents' reactions to becoming terminally ill reflect the themes of adolescence (Balk & Corr, 2009; Knapp et al., 2010). Concerned about their body images as they experience physical and sexual maturation, adolescents may be acutely disturbed if their illness brings hair loss, weight gain, amputation, loss of sexual attractiveness and responsiveness, or other such physical changes. Wanting to be accepted by peers, they may feel like "freaks" or become upset when friends who do not know what to say or do avoid them. Eager to become more autonomous, they may be distressed by having to depend on parents and medical personnel and may struggle to assert their will and maintain a sense of control. Wanting to establish their own

identities and chart future goals, adolescents may be angry and bitter at having their dreams snatched from them.

Losing a Parent

"When my mother died I thought my heart would break," recalled Geoffrey, age 14. "Yet I couldn't cry. It was locked inside. It was private and tender and sensitive like the way I loved her. They said to me, 'You're cool man, real cool, the way you've taken it,' but I wasn't cool at all. I was hot—hot and raging. All my anger, all my sadness was building up inside me. But I just didn't know any way to let it out." (Raphael, 1983, p. 176)

The reactions of adolescents to the deaths of family members also reflect the themes of the adolescent period (Balk, 2014; Tyson-Rawson, 1996). As in Geoffrey's case, adolescents are sometimes reluctant to express their grief for fear of seeming abnormal, losing control, or seeming overdependent; they may express their anguish instead through delinquent behavior and somatic ailments (Osterweis et al., 1984; Walter & McCoyd, 2009). Still being dependent on their parents for emotional support and guidance, adolescents who lose a parent to death may carry on an internal dialogue with the dead parent for years (Silverman & Worden, 1993). They may weave the death of the parent into their emerging identity and life story (Christ, 2010).

As is true of children, some adolescents experience mental health problems and have difficulty functioning after a loss. Children's and adolescents' responses to the sudden loss of a parent through suicide, accident, or sudden natural causes like heart attacks were studied by David Brent and his colleagues (Brent et al., 2009, 2012; Dietz et al., 2013; Melhem et al., 2011). Participants ranged from age 7 to age 18 at the time of the death and were assessed periodically until 5 years after the death. Among the important findings were these:

- About 30% experienced significant grief reactions in the first year that then gradually diminished, while another 10% continued to experience significant grief reactions even 3 years later (Melhem et al., 2011). The remainder (almost 60%) had milder grief reactions.
- Bereaved youth were more likely than nonbereaved comparison youth to suffer from major depression, alcohol and substance abuse, and, in the first year, posttraumatic stress disorder, or PTSD (Brent et al., 2009).
- Cortisol measurements suggested that the stress response systems of bereaved youth were affected; their cortisol levels were higher than those of nonbereaved youth and showed a different pattern of response to a social stress task (Dietz et al., 2013).

- Bereavement also disrupted the completion of key developmental tasks of adolescence. Compared to nonbereaved youth, bereaved youth had less close attachments to peers, more difficulties at work, lower educational aspirations, and less well-developed career plans (Brent et al., 2012).
- Overall, outcomes were poorest for those who lost their mothers, blamed others for the death, had low self-esteem, used negative coping strategies, had earlier bouts of depression, and had a surviving parent or caregiver who was suffering from severe grief reactions or depression (Brent et al., 2009; Melhem et al., 2011).

Losing a Friend

Given the importance of peers in adolescence, it is not surprising that some adolescents also experience psychological problems after a close friend dies (Balk, 2014; Servaty-Seib, 2009). As Table 17.1 revealed, the leading causes of death in adolescence are unintentional injuries (especially car accidents), suicides, and homicides, so a friend's death is often sudden, violent, and potentially traumatic. A national survey of adolescents revealed that one in five adolescents ages 12–17 experienced the death of a close friend in the past year (Rheingold et al., 2004). Moreover, experiencing such a death was associated with higher rates of substance abuse. In another study, 32% of teenagers who lost a friend to suicide experienced clinical levels of depression after the suicide (Bridge et al., 2003).

The death of a friend can be a deeply affecting and transformational experience for adolescents.

Mike Brown/ZUMA Press/Alamy Stock Photo

So, the death of a friend can have serious implications for the mental health of some teens. Yet grief over the loss of a friend is often not taken as seriously as grief over the loss of a family member. Parents, teachers, and friends may not appreciate how much the bereaved adolescent is hurting and provide needed support (Balk, 2014).

● Checking Mastery

1. Why might someone conclude that adolescents “regress” to a less mature concept of death, and why would this be incorrect?
2. In David Brent’s study of bereavement after a parent’s death, what were two differences between bereaved and nonbereaved youth?
3. Why might some bereaved adolescents have difficulty expressing their grief?

● Making Connections

1. Miki (age 3), Rosario (age 9), and Jasmine (age 16) have all been diagnosed with cancer. They have been given chemotherapy and radiation treatments for several months but seem to be getting worse rather than better. Write a short monologue for each child conveying how she understands death.
2. Think about Miki (3), Rosario (9), and Jasmine (16) again but this time write about each girl’s major concerns and wishes based on what you have learned about typical development at each age.

17.6

The Adult

LEARNING OBJECTIVES

- Summarize what research tells us about the effects of widowhood on adults, including the different trajectories of grief uncovered by George Bonanno and others.
- Compare the impacts of the death of a child and the death of a parent.
- Outline and critique the grief work perspective on bereavement, citing relevant evidence.
- Analyze key factors that can contribute to complicated or prolonged grief after a death—or to posttraumatic growth.

For adults, dealing with the loss of a spouse or partner and accepting their own mortality can be considered normal developmental tasks (Röcke & Cherry, 2002). We have already introduced models describing adults’ experiences of dying and bereavement.

Here we will elaborate by examining bereavement from a family systems perspective, trying to define the line between normal and abnormal grief reactions, and identifying factors that make coping easier or harder.

Death in the Family Context

To better understand bereavement, it is useful to adopt a family systems perspective and examine how a death alters relationships, roles, and patterns of interaction within the family, as well as interactions between the family and its social environment (Kisane et al., 2013; Silverman, 2000; Walsh & McGoldrick, 2013). Recall the concept of “linked lives” from Chapter 15 and you can appreciate how the death of a family member affects other family members and alters the relationships among them. The death of a child, for example, changes parents, siblings, grandparents, and other relatives and their interactions with one another and the rest of the world. Adjustment can depend on where the family is in the family life cycle (Is it a young couple or an elderly couple?) and on the sociocultural context, so we need to blend developmental, family systems, and contextual perspectives to fully appreciate the ripple effects of a death (Walsh & McGoldrick, 2013). Consider the challenges associated with three kinds of death in the family: the loss of a spouse or partner, the loss of a child, and the loss of a parent.

Loss of a Spouse or Partner

How odd to smile during Richard’s funeral. He was dead and I was smiling to myself. Grief does that. Laughter lies close in with despair, numbness nearby acuity, and memory with forgetfulness. I would have to get used to it, but I didn’t know this at the time. All I knew, as I sat in Thomas Jefferson’s church next to Richard’s coffin, was that memory had given pleasure first, and then cracking pain. (Jamison, 2009, pp. 126–127)

Most of what we know about bereavement is based on studies of widows and widowers. Experiencing the death of a spouse or partner becomes increasingly likely as we age. In heterosexual relationships, it is something most women can expect to endure because women tend both to live longer than men and to marry men who are older than they are. The marital relationship is a central one for most adults, and the loss of a spouse or other romantic partner can mean the loss of a great deal. Moreover, the death of a partner often precipitates a cascade of other stressors—the need to move, enter the labor force or change jobs, assume responsibilities that the partner formerly performed, parent single-handedly, cope with less money, and so on. Finally, bereaved partners must often redefine their identities and assumptions about life in fundamental ways (Lopata, 1996; Parkes & Prigerson, 2010). Consider Rachel after her husband died of a heart attack: “I was Frank’s wife, that was it mostly. He’s gone. And I am basically, I am, now—I am nobody” (Bonanno, 2009, p. 97).

Colin Murray Parkes, co-developer of the *Parkes/Bowlby attachment model of bereavement*, concluded based on his extensive studies of widows and widowers younger than age 45 that bereaved adults progress through overlapping phases of numbness, yearning, disorganization and despair, and reorganization. What tolls does this grieving process take on physical, emotional, and cognitive functioning? Parkes (2006) found that widows and widowers are at risk for illness and physical symptoms such as loss of appetite and sleep disruption, and they tend to overindulge in

alcohol, tranquilizers, and cigarettes. Cognitive functions such as memory and decision making are often impaired, and emotional problems such as loneliness and anxiety are common. Most bereaved partners do not become clinically depressed, but many feel lonely and experience symptoms of depression in the year after the death (Fried et al., 2015; Wilcox et al., 2003). Widows and widowers as a group even have a higher-than-average risk of death (Shah et al., 2013). For those who served as caregivers for their loved ones, a deterioration in health appears to begin before the death (Vable et al., 2015).

Modest disruptions in physical, cognitive, emotional, and social functioning are common, usually lasting for a year; less severe, recurring grief reactions may then continue for several years (Bonanno & Kaltman, 2000). Although not captured in the Parkes/Bowlby attachment model, positive thoughts about the deceased, expressions of love, and feelings of gaining from the loss are also part of the typical picture, as in the quote at the beginning of this section.

Importantly, though, George Bonanno and his colleagues have found much diversity in patterns of response to loss by looking for subgroups of bereaved adults rather than just describing the average response (Boerner, Mancini, & Bonanno, 2013; Bonanno, Boerner, & Wortman, 2008). Bonanno studied adults who lost a partner from an average of 3 years before the death to 6 and 18 months afterward (Boerner, Wortman, & Bonanno, 2005; Bonanno, Wortman, & Nesse, 2004; Bonanno et al., 2002; and see Galatzer-Levy & Bonanno, 2012). The sample was assessed again 4 years after their loss to examine the long-term implications of different patterns of grieving.

■ **Figure 17.4** shows the average depression symptom scores over time associated with five distinct patterns of adjustment shown by widows and widowers:

- A resilient pattern in which distress is at low levels all along
- Common grief, a recovery pattern with heightened and then diminishing distress after the loss
- Chronic grief in which loss brings distress and the distress lingers
- Chronic depression in which individuals were depressed before the loss and remained so after it
- A depressed–improved pattern in which individuals who were depressed before the loss become less depressed after the death

Resilience. The biggest surprise in this study was that the resilient pattern of adjustment involving low levels of distress all along turned out to be the most common pattern of response, characterizing almost half the sample. The resilient grievers were not just cold, unfeeling people who did not really love their partners. Rather, before the death they seemed to be well-adjusted and happily married people with good coping resources (Bonanno et al., 2002). They experienced emotional pangs in the first months after the death, but they were more comforted than most by positive thoughts of their partners and simply coped effectively with their loss.

Patterns of Depression. This study also helps us understand that some bereaved people who display symptoms of depression after a loss were depressed even before the death, whereas others become depressed in response to their loss. Those who become

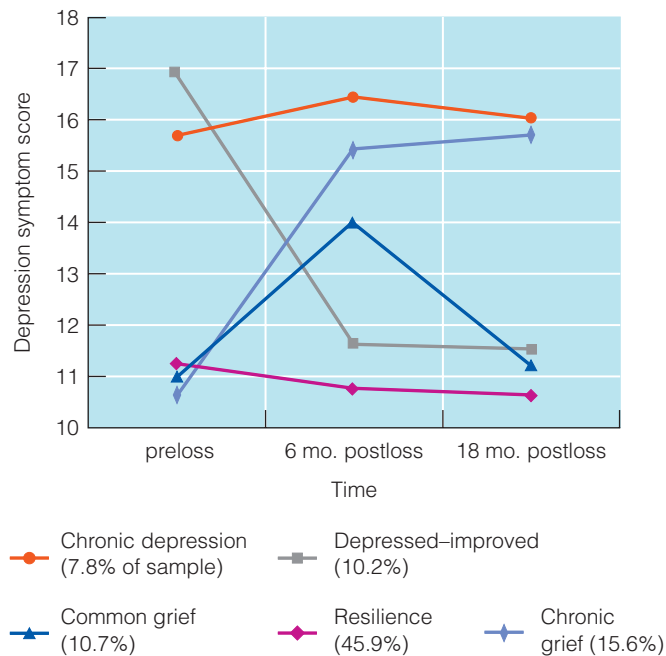

Figure 17.4 Depression symptom scores of five subgroups of elderly widows and widowers an average of 3 years before, 6 months after, and 18 months after the death of their spouse. In parentheses are the percentages of the sample showing each pattern. Notice that resilience—a low level of depression all along—is the most common response, characterizing almost half. This result runs counter to our belief that all bereaved people must go through a period of significant distress.

depressed in response to the loss often recover from their depression within a year or so; they show the “common grief” or recovery pattern of adjustment (Boerner et al., 2005; Bonanno et al., 2004). Yet this group was small in Bonanno’s study (see also Maccallum, Galatzer-Levy, & Bonanno, 2015). Another 15%, the chronic grief group, become depressed after the loss and stay depressed for a year or two before they show signs of recovery.

Some of the ones who were depressed before the loss were chronically depressed and remained so even 4 years later (Galatzer-Levy & Bonanno, 2012). The “depressed-improved” individuals who were depressed before the death but recovered quickly afterward are intriguing. Most likely many were experiencing caregiver burden (see Chapter 15) before the death and were relieved of stress after it. It is common among those who bear the burden of caring for a family member with Alzheimer’s disease or another form of dementia to experience more depression before their partner’s death than after (Schulz et al., 2003). More than 70% admit that the death came as a relief to both themselves and their loved one.

But What Is Resilience? Could Bonanno’s study have overestimated the percentage of widows and widowers who are resilient? Bonanno focused only on depression symptoms in defining resilience. What if other indicators were examined? Frank Infurna and Suniya Luthar (2016) studied 421 Australian adults who had lost a spouse. The participants completed five measures of adjustment from as many as 5 years before to as many as 5 years after their loss: life satisfaction, negative affect, positive affect, self-perceived health, and physical functioning (ability to carry out activities of daily living).

Only 8% of the participants were resilient in the sense of showing good adjustment over the years on all five measures of adjustment. The percentage of people judged to be resilient varied considerably depending on which indicator was used, as shown in **Figure 17.5**. For example, 66% were judged to be resilient in the sense of maintaining high life satisfaction before, during, and after their loss but only 19% consistently registered low scores on a measure of negative emotions. Many adults in the study showed a recovery pattern in which their adjustment suffered after their loss but rebounded; another 20% showed consistently poor adjustment across the five measures.

Overall, then, it is difficult to pin down what percentage of bereaved adults show resilience: It depends on what measures of adjustment and methods of analysis the researchers use. On this much bereavement researchers can agree, though: *There is no one standard response to bereavement; different people follow different grief trajectories.* Some adults who lose spouses or partners are resilient, showing low levels of distress and disruption all along; others experience a decline in well-being and functioning for somewhere between about 6 months and 2 years and then recover, and others show still other trajectories.

Complicated Grief. For a minority of bereaved individuals, up to about 15%, significant grieving and psychological distress continue for many months or even years (Bonanno, 2009; Neimeyer & Holland, 2015). In such cases psychologists speak of **complicated grief** to refer to grief that is unusually prolonged or intense and that impairs functioning. People who have difficulty coping with loss are sometimes diagnosed as having a

Figure 17.5 Percentages of Australian widows and widowers judged to be “resilient” on five measures. Resilient adults were able to maintain their pre-loss level of adjustment steady for up to 5 years after their spouse’s death. The proportion of adults judged to be resilient varied widely across measures.

depressive disorder or, if the death was traumatic, PTSD. However, some experts have concluded that complicated grief, also called prolonged grief disorder, has unique symptoms, is distinct from these other conditions, and should be considered a distinct psychological disorder (Boelen & Prigerson, 2013; Prigerson, Vanderwerker, & Maciejewski, 2008). Complicated grief persists for 6 months or longer and involves intense distress over separation from the deceased, as well as a sense of meaninglessness, bitterness over the loss, difficulty getting past the loss, and difficulty functioning.

The 2013 *Diagnostic and Statistical Manual of Mental Disorders*, DSM-5, recognizes complicated grief (which it calls “persistent complex bereavement-related disorder”) as worthy of further study as a distinct disorder (American Psychiatric Association, 2013). Meanwhile, critics warn that what is viewed as complicated grief will vary from society to society (Rosenblatt, 2013) or question the whole idea of treating certain responses to the normal human experience of bereavement as psychological disorders (Wakefield, 2013).

In sum, the loss of a spouse or partner is a painful and sometimes damaging experience that carries risks of developing physical or mental health problems or even dying. Yet possibly as many as half of those who lose spouses or romantic partners, depending on how one counts, show resilience and manage to cope without becoming highly distressed or incapacitated. **Exploration 17.1** looks more closely at some of the challenges faced by the partners and spouses of adults with HIV/AIDS.

Loss of a Child

My child has died! My heart is torn to shreds. My body is screaming. My mind is crazed. The question is always present on my mind. Why? How could this possibly have happened? The anger is ever so deep, so strong, so frightening.

Bertman, 1991, p. 323

As the parents whose children were killed in the Sandy Hook school shooting know too well, no loss seems more difficult for an adult than the death of a child (Murphy, 2008; Parkes, 2006). Even when there is forewarning, the loss of a child seems unexpected, untimely, and unfair and can make parents feel guilty even when they bear no blame—reactions that can complicate their recovery (Duncan & Cacciatore, 2015). In one study, only 12% of parents whose adolescent or young adult child died of an accident, suicide, or homicide said they had found meaning in the death 1 year later, and only 57% had found it 5 years later (Murphy, Johnson, & Lohan, 2003b). Even 10 years after their loss, bereaved parents tend to be less happy than adults who have not lost a child (Moor & Graaf, 2016). Yet researchers find the same diversity of grief trajectories among parents who have lost children as among adults who have lost spouses—for example, many who show resilience, a minority who show prolonged or complicated grief (Maccallum et al., 2015).

The age of the child who dies has little relation to the severity of the grief. True, in some societies with high infant mortality,

● EXPLORATION 17.1

Bereavement among the Partners of Gay Men with HIV/AIDS

The AIDS epidemic continues to take a heavy toll on the gay community in the United States and around the world. George Bonanno and his colleagues (Bonanno, Moskowitz, et al., 2005) wondered whether the resilience he had observed in many heterosexual widows and widowers would also be evident among the partners of gay men who die of AIDS. Many of these men not only experienced the burden of caring for their dying partners but were also HIV infected themselves and therefore stressed by their own illness and likely death. They also had to contend with the stigma surrounding both AIDS and homosexuality. As it turned out, about half of the HIV-positive caregiver partners of gay men who died of AIDS studied by Bonanno showed resilience when compared to nonbereaved, HIV-positive individuals—the same proportion as when heterosexual widows

and widowers were compared to nonbereaved married people. A lower percentage, 27%, showed resilience when the criterion was a low level of depression symptoms all along, from before to after their partner’s death. Many others became depressed but returned to their low levels of depression after a year or two.

The finding of considerable resilience in this group is all the more surprising because gay and lesbian partners often experience what Kenneth Doka (1989, 2016) calls **disenfranchised grief**, grief that is not fully recognized or appreciated by other people and therefore may not receive much sympathy and support. Losses of ex-spouses, extramarital lovers, foster children, pets, and fetuses can also result in disenfranchised grief, which is likely to be harder to cope with than socially supported grief.

Gay widowers report that they are indeed disenfranchised before and after their losses (Piatczany, Bennett, & Soulsby, 2016). James, for example, watched his partner’s brother and sister move in with him and his dying partner, apparently not trusting him to be the caregiver. Adrian, whose partner’s mother took over making funeral arrangements, said this: “We were in a partnership that wasn’t recognized by anyone else” (Piatczany et al., 2016, p. 176). And Steve, in love for three years with a co-worker who had not come out of the closet, had little choice but to grieve alone after his loved one died because his co-workers knew nothing of the relationship (Doka, 2016). Given disenfranchised grief, stigma, and other challenges, gay partners of victims of HIV/AIDS cope surprisingly well with their losses.

parents may not mourn the loss of fetuses or very young infants (Papadatou, 2015). Yet in many societies, including our own, parents, especially mothers, can experience severe grief reactions after a miscarriage, the loss of a premature baby, or the loss of a young infant to sudden infant death syndrome (Buchi et al., 2007; Kulathilaka, Hanwella, & de Silva, 2016). And parents grieve for an adult child as much as for a younger child or adolescent (Walter & McCoyd, 2009).

The death of a child rattles the whole family system, affecting the marital relationship, parenting, and the well-being of surviving siblings, grandparents, and other relatives. The marital relationship is likely to be strained because each partner is grieving and is not always able to provide emotional support for the other. Listen to this father: “When my wife talks about the day our daughter died, I know she is only trying to make sense out of it. But it literally makes me nauseated and I have to leave the room” (Barlé et al., 2015, p. xxx). This powerful life event pushes some couples on a path toward marital distress and even divorce but strengthens the relationship of other couples (Albuquerque, Pereira, & Narciso, 2016). Outcomes are likely to be poor if the marriage was shaky before the death, better if the relationship was close.

Meanwhile, the brothers and sisters of a child who dies have their own challenges. While their sibling is dying, they often feel shut out; they want information about what is going on and what to expect and they want a meaningful role in their sibling’s care but they don’t always get either (Lövgren et al., 2016). After the death, some feel guilty about some of the unsavory feelings of rivalry they have had or feel pressure to be perfect or to replace the lost child in their parents’ eyes (Koehler, 2010). In the year or so after the death, they are often deeply affected and may develop mental health problems (Rosenberg et al., 2015). However, their grief is often not fully appreciated, and their distraught parents are not always able to support them effectively (Koehler, 2010; Lohan & Murphy, 2001–2002). One 12-year-old boy whose brother died described his experience this way: “My dad can’t talk about it, and my mom cries a lot. It’s really hard on them. I pretend I’m O.K. I usually just stay in my room” (Wass, 1991, p. 29). How well brothers and sisters adjust to a sibling’s death often hinges on whether their parents can maintain their mental health and continue to be supportive parents (Morris et al., 2016).

Finally, grandparents also grieve after the death of a child, both for their grandchild and for their child, the bereaved parent. As one grandparent said, “It’s like a double whammy!” (DeFrain, Jakub, & Mendoza, 1991–1992, p. 178). The grandmother of a boy killed in the Sandy Hook mass shooting put it this way:

It’s hard to cope with your own pain when your child is so shattered. My daughter is my flesh and blood, but there is nothing I can say that can help her feel better . . . I don’t think any of us will get over this. When my daughter visits us now, I hear only three car doors open instead of four. When they leave, I have a good hard cry (Goodwin, 2013–2014, p. 48).

So grandparents may feel quite helpless (Fry, 1997). They may also experience disenfranchised grief, ignored while everyone focuses their support on the parents (Hayslip & White, 2008). Clearly the whole family suffers when a child dies.

The death of a child can be devastating for parents.

Oleg Popov OP/DL/REUTERS

Loss of a Parent

Even if we escape the death of a child or spouse, the death of a parent is a normative life transition that most of us will experience. As noted already, some children experience long-lasting problems after the death of a parent. Fortunately, most of us do not have to face this event until we are in middle age. We are typically less dependent on our parents by then. Moreover, we expect that our parents will die someday and have prepared ourselves, at least to some degree.

Perhaps for these reasons, adjusting to the death of a parent is usually not as difficult as adjusting to the death of a romantic partner or child (Parkes, 2006). Yet it can be a turning point in an adult’s life, with effects on his identity and his relationships with his partner, children (who are grieving the loss of their grandparent), surviving parent, and siblings (Umberson, 2003). Adult children may feel vulnerable and alone in the world when their parents no longer stand between them and death (Walter & McCoyd, 2009). Guilt about not doing enough for the deceased parent is also common (Moss et al., 1993). Daughters who lose their mothers tend to show the largest decreases in life satisfaction, especially if the death is off-time and they are young adults when it happens (Leopold & Lechner, 2015; Hayslip, Pruet, & Caballero, 2015).

The Grief Work Perspective and Challenges to It

It’s time to step back and reflect. The view that has guided much research on bereavement has come to be called the **grief work perspective**—the view that to cope adaptively with death, bereaved people must:

- confront their loss
- experience painful emotions and work through those emotions
- detach psychologically from the deceased

In Mexico, the Day of the Dead (*Día de los Muertos*) on November 2 is a time to remember deceased loved ones and to encourage their souls to visit (Bonanno, 2009). Costumes are worn, skulls and skeletons are everywhere, and the festivities are lighthearted, making this yearly event somewhat like American's Halloween. Altars in the home with sugar skulls, marigolds, and the deceased's favorite foods are assembled, and gifts are taken to the grave. "Grief work" takes different forms in different cultures.

Judy Bellah/Alamy Stock Photo

This view, which grew out of Freudian psychoanalytic theory, is widely held in our society, not only among therapists but among the general public, and it influences what we view as an "abnormal" reaction to death (Stroebe, 2001; Wortman & Silver, 2001). From the grief work perspective, either complicated, prolonged grief that lasts longer and is more intense than usual, or an absence, inhibition, or delay of grief, in which the bereaved never seems to confront and express painful feelings, is viewed as pathological.

This grief work perspective has come under attack, however. Questions have been raised about its assumptions that there is a right way to grieve, that bereaved people must experience and work through intense grief to recover, and that they must sever their bonds with the deceased to move on with their lives (Bonanno, 2004; Doka, 2016; Wortman & Boerner, 2007). Let us look at some of the misconceptions built into the grief work perspective.

One Right Way?

Cross-cultural studies reveal that there are many ways to grieve and suggest that the grief work model of bereavement may be culturally biased (Rosenblatt, 2013). An Egyptian mother may be conforming to her culture's norms of mourning if she sits alone, withdrawn and mute, for months or even years after a child's death. Likewise, a Balinese mother is following the rules of her culture if she is calm, composed, and even seemingly cheerful soon after a child's death; by her culture's rules, she would be vulnerable to illness and sorcery if she expressed her emotional pain (Wikan, 1988, 1991). We would be wrong to

conclude, based on our own society's norms, that the Egyptian mother is suffering from prolonged grief or the Balinese mother from absent or inhibited grief. As you have also seen, different individuals in our society or any other society experience different trajectories of grief.

Working Through Grief?

There is also surprisingly little support for the grief work perspective's assumption that bereaved individuals must confront their loss and experience painful emotions to cope successfully (Boerner et al., 2013; Wortman & Silver, 2001). The many bereaved individuals who are resilient and do not show much emotional distress during the early months after the loss do not seem to pay for their lack of grief with delayed grief later, as the grief work model says they should. Delayed grief is extremely rare, and the individuals who adjust best to bereavement are those resilient individuals who display little severe distress at any point in their bereavement, experience many positive emotions and thoughts, and manage to carry on with life despite their loss (Boerner et al., 2013). In fact, there is growing evidence that too much "grief work," like ruminative coping that involves overanalyzing one's problems, may backfire and *prolong* psychological distress rather than relieve it (Bonanno et al., 2005).

Breaking Bonds?

Finally, the grief work view that we must break our attachment bonds to the deceased to overcome our grief is flawed. Freud believed that bereaved people had to let go in order to invest their psychic energy elsewhere. However, John Bowlby (1980) noticed that many bereaved individuals revise their internal working models of self and others and continue their relationships with their deceased loved ones on new terms (Bonanno & Kaltman, 1999). Recent research supports Bowlby, suggesting

This Vietnamese woman maintains a continuing bond with her deceased relatives through ancestor worship. Such practices are common in East Asian countries.

robertharding/Alamy Stock Photo

that many bereaved individuals maintain their attachments to the deceased indefinitely through **continuing bonds** (Klass, 2001; Neimeyer & Holland, 2015). They reminisce and share memories of the deceased, derive comfort from the deceased's possessions, consult with the deceased and feel his or her presence, seek to make the deceased proud of them, and so on. Bereavement rituals in some cultures (in Japan, China, and other East Asian societies, for instance) are actually designed to ensure a continued bond between the living and the dead (Klass, 2001).

Individuals who continue their bonds rather than severing them sometimes suffer from doing so but sometimes benefit (Field et al., 1999; Hayes & Leudar, 2016; Neimeyer & Holland, 2015; Stroebe, Schut, & Boerner, 2010). Nigel Field and his colleagues (1999) tried to determine why this is by investigating whether a continuing attachment to a deceased spouse was positively or negatively related to grief symptoms among widows and widowers at 6 months, 14 months, and 25 months after their loss. Those who expressed their continuing attachment by having and sharing fond memories of the deceased and by sensing that their loved one was watching over and guiding them experienced relatively low levels of distress. By contrast, those who used their spouse's possessions to comfort themselves at the 6-month mark showed high levels of distress and little decrease in grief over the coming months. Researchers have concluded that internal approaches to continuing the bond, such as carrying a mental image of the loved one that provides comfort, tend to aid adjustment, but that externalized approaches, such as seeking comfort from the loved one's possessions or visiting the grave every day, may reflect continued efforts to reunite and difficulty coping (Field, 2008; Field & Filanosky, 2010; Scholtes & Browne, 2015).

Cultural context can also make a difference in whether continuing bonds are adaptive. In a study comparing bereaved adults in China and the United States (Lalande & Bonanno, 2006), maintaining continuing bonds was associated with distress soon after the death among bereaved adults in both societies. By 18 months after the death, though, it was related to better adjustment in China but to poorer adjustment in the United States. Why? Most likely because continuing a relationship with the deceased is viewed as more appropriate in Chinese culture. In sum, maintaining continuing bonds is adaptive for some people, especially those who do so through an internal approach in a culture that encourages continuing bonds, but can be a sign of continued yearning and prolonged or complicated grief for others.

Overall, then, research does not support the traditional grief work model that many people assume is correct:

- Ways of expressing grief vary widely across cultures and across individuals, so there is no one “right” way to grieve.
- There is little evidence that bereaved people must do intense “grief work” to adapt or that those who do not do it will pay later with a delayed grief reaction.
- People do not need to sever their attachment to the deceased to adjust to a loss; indeed, they can benefit from internal continuing bonds.

Who Copes and Who Succumbs?

What risk and protective factors distinguish people who cope well with loss from people who cope poorly? Coping with bereavement is influenced by the individual's personal resources, the nature of the loss, and the surrounding context of support and stressors (Burke & Neimeyer, 2013; Dyregrov & Dyregrov, 2013; Piper et al., 2011).

Personal Resources

Just as some individuals are better able to cope with their own dying than others are, some are better equipped to handle the stresses of bereavement due to their *personal resources*. Start with *personality and coping style*. For example, individuals who are emotionally stable cope well, whereas those who have difficulty coping tend to score high on the Big Five personality dimension of neuroticism (Robinson & Marwit, 2006; Wijngaards-de Meij et al., 2007). Some who have difficulty coping have also had chronic psychological problems such as depression before they were bereaved (Bonanno et al., 2004; Piper et al., 2011). Many also rely on ineffective coping strategies such as denial or avoidance, escape through alcohol and drugs, or unproductive rumination about their loss rather than active coping strategies (Morina, 2011; Murphy, Johnson, & Lohan, 2003a; Riley et al., 2007). By contrast, people who are optimistic, look for and find positive ways of interpreting their loss, and use active coping strategies experience less intense grief reactions and are more likely to report personal growth after their losses than other bereaved adults.

Attachment style is another important resource (or liability). Bowlby's attachment theory emphasizes that early experiences in attachment relationships, along with later experiences, shape the internal working models we have of self and others. If infants and young children receive loving and responsive care, they form internal working models of self and others that tell them that they are lovable and that other people can be trusted, and they develop a secure attachment style (see Chapter 14). Otherwise, they may develop one of the insecure attachment styles.

Attachment styles are systematically related to reactions to death (Beverung & Jacobvitz, 2016; Fraley et al., 2006; Kho et al., 2015; Mikulincer & Shaver, 2013; Parkes, 2006):

- A secure attachment style is associated with coping relatively well with the death of a loved one.
- A resistant (or preoccupied) style of attachment, which involves being highly anxious about being abandoned, is linked to being overly dependent and displaying extreme and prolonged grief and anxiety after a loss, ruminating about the death, and clinging to the lost loved one.
- An avoidant (or dismissing) attachment style is associated with difficulty expressing emotions or seeking comfort; such individuals may do little visible grieving, may minimize how much they miss their loved one, and may disengage from or even devalue this person.
- A disorganized (or fearful) attachment style, which is rooted in unpredictable and anxiety-arousing parenting, is associated

with being especially unequipped to cope with loss; these individuals may turn inward, harm themselves, or abuse alcohol or drugs.

In the language of the dual-process model of bereavement, anxious or resistant/preoccupied individuals focus on their loss and dwell on their negative thoughts and emotions, whereas avoidant/dismissing individuals focus on restoration and avoid dealing with their emotions (Delespau et al., 2013; Stroebe et al., 2010). By contrast, securely attached individuals are able to oscillate flexibly between loss-oriented and restoration-oriented coping and tend to emphasize positive memories of the deceased.

Nature of the Loss

Bereavement outcomes are also influenced by the nature of the loss. The closeness of the person's relationship to the deceased is a key factor. For example, we grieve more for members of our immediate family than for distant relatives (Armstrong & Shakespeare-Finch, 2011), and spouses grieve especially hard if their relationship to the deceased was very close and if they were highly dependent on their partners (Mancini, Sinan, & Bonanno, 2015; Piper et al., 2011).

The cause of death can also matter in bereavement outcomes. Surprisingly, sudden deaths are not necessarily harder to cope with in the long run than expected deaths from illnesses, although the initial grief reaction may be more intense (Piper et al., 2011). Any advantages of being forewarned of death may be offset by the strains of caregiver burden during a long illness (Schulz, Boerner, & Hebert, 2008). However, sudden deaths that are violent or traumatic, such as suicides, homicides, car crashes, and terrorist attacks appear to be especially difficult to bear (Barlé, Wortman, & Latack, 2015; Boelen et al., 2016; Piper et al., 2011). In a study of African American parents whose children had been murdered, for example, around 40% showed the signs of complicated grief—and many of them symptoms of PTSD and depression as well—even more than 2 years after the murder (McDevitt-Murphy et al., 2012). Traumatic deaths may be especially difficult to bear because they require coping with both bereavement and trauma (Barlé et al., 2015).

Supports and Stressors

Finally, grief reactions are influenced positively by the presence of social support and negatively by additional life stressors (Hansson & Stroebe, 2007; Parkes, 2006). Social support is crucial at all ages. It is especially important for the child or adolescent whose parent dies to have good parenting (Haine et al., 2006). Brothers and sisters can help each other cope (Hurd, 2002). Adult children can ease the adjustment of their widowed parents (Ha, 2010). Indeed, family members of all ages recover best when the family is cohesive and family members can share their feelings and support one another (Walsh & McGoldrick, 2013).

Many of us are clueless about what to say or do that will be helpful. This can make us avoid the bereaved or say pretty

Sensitive social support can make all the difference to the bereaved.

Monkey Business Images/Shutterstock.com

unhelpful things—for example, trying to talk people out of their grief with cheery messages, claiming to know how they feel, offering advice on how to grieve. Yet there are also simple things we can do to be supportive. Bereaved individuals report that they are helped most by family and friends who say they are sorry to hear of the loss, make themselves available to serve as confidants, ask how things are going, and allow bereaved individuals to express painful feelings freely if and when they choose rather than trying to cheer them up and talk them out of their grief (Dyregrov, 2003–2004; Lehman, Ellard, & Wortman, 1986).

Just as social support helps the bereaved, additional stressors hurt. For example, outcomes tend to be poor for widows and widowers who must cope with financial problems after bereavement, manage household tasks they are not used to managing, single-handedly raise young children, find new jobs, or move (Lopata, 1996; Parkes, 1996; Worden & Silverman, 1993). In some cultures, a widow may be tossed out of her home and thrown into poverty, whereas in others she may find herself with more resources and freedom than she had before her husband died (Rosenblatt, 2015a).

By taking into account the person who has experienced a death, the nature of the death, and the context of supports and stressors surrounding it, we can put together a profile of the individuals who are most likely to have long-term problems after bereavement. These individuals have had an unfortunate history of interpersonal relationships, perhaps suffering the death of a parent when they were young or experiencing insecurity in their early attachments. They have had previous psychological problems and generally have difficulty coping effectively with adversity. The person who died is someone whom they loved deeply and on whom they depended greatly, and the death was untimely and traumatic. Finally, these

high-risk individuals lack the kinds of social support that can aid them in overcoming their loss, and they are burdened by multiple stressors.

Posttraumatic Growth

The grief work perspective on bereavement put the focus on the negative side of bereavement, but psychologists have come to appreciate that bereavement and other life crises also have positive consequences and sometimes foster personal growth (Joseph, 2012; Tedeschi & Calhoun, 2004). Granted, it can be a painful way to grow, and we could hardly recommend it as a plan for optimizing human development. Still, the literature on death and dying is filled with testimonials about the lessons that can be learned. We invite you to consider the statements in **Engagement 17.2** and whether they apply to you.

Posttraumatic growth refers to positive psychological change resulting from highly challenging experiences such as being diagnosed with a life-threatening illness or losing a loved one (Tedeschi & Calhoun, 1995). Posttraumatic stress and posttraumatic growth seem to go hand in hand. Growth is unlikely where there is little psychological distress and it is unlikely where the distress is overwhelming. Instead, growth seems most likely when distress is significant but not crushing (Armstrong & Shakespeare-Finch, 2011; Currier, Holland, & Neimeyer, 2012; Joseph, 2012).

Many bereaved individuals, young and old, believe that they have become stronger, wiser, more loving, or more spiritual people with a greater appreciation of life (Kilmer et al., 2014; Tedeschi & Calhoun, 2004). Many widows master new skills, become more independent, and emerge with new identities and higher self-esteem (Carr, 2004; Lopata, 1996). A

mother whose infant died said it all: “Now I can survive anything” (DeFrain, Taylor, & Ernst, 1982, p. 57). So perhaps by encountering tragedy we learn to cope with tragedy, and perhaps by struggling to find meaning in death we come to find meaning in life.

● Checking Mastery

1. What appears to be the most common pattern of adjustment observed in studies of widows and widowers?
2. What are two elements of the grief work perspective that are not well supported by evidence?
3. How would individuals with a resistant (preoccupied) attachment style or orientation and those with an avoidant (or dismissing) style be expected to differ in their grief reactions?

● Making Connections

1. Using the section “Who Copes and Who Succumbs,” analyze your capacity to cope with death. If you have experienced a significant loss, analyze your actual success in coping and the factors that may have influenced it; if you have not experienced a significant loss, predict how you will respond to your first significant loss and why you think so.
2. Many people have misconceptions about what is normal or abnormal when it comes to grieving, as this chapter has illustrated. Identify two such misconceptions and, using relevant research, show why they are just that—misconceptions.

● ENGAGEMENT 17.2

The Bright Side of Bereavement: Posttraumatic Growth

Think about your greatest loss, crisis, or trauma, whether a death or another difficult experience. Now respond to the following items on a scale from 0 to 5, where 0 means “I did not experience this change as a result of my crisis,” and 5 means, “I experienced this change to a very great degree as a result of my crisis.”

- _____ 1. I changed my priorities about what is important in life.
- _____ 2. I have a greater appreciation for the value of my own life.
- _____ 3. I am able to do better things with my life.
- _____ 4. I have a better understanding of spiritual matters.
- _____ 5. I have a greater sense of closeness with others.

- _____ 6. I established a new path for my life.
- _____ 7. I know better that I can handle difficulties.
- _____ 8. I have a stronger religious faith.
- _____ 9. I discovered that I’m stronger than I thought I was.
- _____ 10. I learned a great deal about how wonderful people are.

To the extent that you agreed with these statements, you show signs of posttraumatic growth.

17.7

Taking the Sting Out of Death

LEARNING OBJECTIVES

- Assess how the hospice/palliative care approach differs from the standard medical approach to dying patients and how it affects patients and their families.
- Illustrate how individual therapy, family interventions, and mutual support groups can benefit bereaved individuals.

What can be done to help children and adults who are dying or who are bereaved grapple with death and their feelings about it? Here is a sampling of strategies.

For the Dying

Dramatic changes in the care of dying people have occurred in the past few decades, thanks in part to the efforts of Elisabeth Kübler-Ross and others. The hospice movement is a prime example. A **hospice** is a program that supports dying people and their families through a philosophy of “caring” rather than “curing” (Connor, 2000; Knee, 2010; Saunders, 2002). The hospice concept spread quickly from St. Christopher’s Hospice in London, where it originated, to North America, leading to the establishment of hospice facilities in many communities to serve individuals with cancer, AIDS, and other life-threatening diseases. Participants typically must be judged to be within 6 months of death. In many hospice programs today, however, dying patients stay at home and are visited by hospice workers. Hospice care is part of a larger movement to provide **palliative care**, care aimed at bringing comfort to and meeting the physical, psychological, and spiritual needs of people with serious illnesses even if their illnesses are still being treated (Shannon, 2006; Van den Block et al., 2015).

What makes hospice care different from hospital care? Whether hospice care is provided in a facility or at home, it entails these key features (Connor, 2000; Corr & Corr, 1992; Siebold, 1992):

- The dying person and his family—not the “experts”—decide what support they need and want.
- Attempts to cure the patient or prolong his life are deemphasized (but death is not hastened either).
- Pain control is emphasized.
- The setting for care is as normal as possible (preferably the patient’s own home or a homelike facility that does not have the sterile atmosphere of many hospital wards).
- Bereavement counseling is provided to the family before and after the death.

Do dying patients and their families fare better when they receive hospice care? They seem to. Patients have less interest in physician-assisted suicide because their pain is better controlled (Foley & Hendin, 2002); they feel more emotionally supported (Teno et al., 2004); and they spend more of their last days without pain, undergoing fewer medical interventions and operations (Seale, 1991). Meanwhile, the relatives of dying people rate the quality of the death experience more positively (Hales et al., 2014) and display fewer symptoms of grief and have a greater sense of

St. Christopher's Hospice in London started what is now a worldwide hospice movement.

BH Generic Stock Images/Alamy Stock Photo

well-being 1 to 2 years after the death than similar family members who did not receive hospice care (Ragow-O’Brien, Hayslip, & Guarnaccia, 2000).

In sum, the hospice and palliative care approach can mean an opportunity to die with dignity, free of pain and surrounded by loved ones. The next challenge may be to extend this philosophy of caring rather than curing to more children (Davies et al., 2007; Orloff & Huff, 2010). Many children who die of cancer and other terminal illnesses die in hospitals, rather than at home with palliative care, possibly because their doctors and parents cannot accept that the child is dying. Parents of dying children who do participate in palliative care are highly satisfied with it (Sheetz & Bowman, 2013).

In some cultures, uneasiness in talking about death—even with adult patients—may be a barrier to the development of hospice and palliative care. In China, for example, it has been taboo for health professionals to talk to dying patients about cancer, because cancer is viewed as a death sentence, and it is believed that open talk about death may undermine hope and bring bad luck or an earlier death (Dong et al., 2016). Family members, wanting to protect their loved one, also avoid talk of death. In this cultural context, it has taken a while for the hospice concept to take root. Meanwhile, in our own society, some ethnic groups (African Americans and Asian Americans) have been more reluctant than others (European and Hispanic Americans) to embrace hospice services (LoPresti, Dement, & Gold, 2016).

For the Bereaved

Most bereaved individuals deal with this normal life transition on their own, with support from family and friends (Mancini, Griffin, & Bonanno, 2012). What is available for bereaved children, adolescents, and adults who are experiencing or are likely to experience complicated grief? Bereaved individuals at risk for complicated grief can benefit from individual psychotherapy aimed at preventing or treating debilitating grief (Boelen, van den Hout, & van den Bout, 2013; Neimeyer & Currier, 2009; Rosner, Kruse, & Hagl, 2010). Because death takes place in a family context, family therapy often makes even better sense (Kissane et al., 2013). Interventions designed for the whole family can help bereaved parents and children communicate more openly and support one another. Family interventions can also help parents deal with their own emotional issues so that they can provide the warm and supportive parenting that can be so critical to their children's adjustment. This is well illustrated by research on the Family Bereavement Program, described in **Application 17.1**.

Mutual support or self-help groups are another option (Lieberman & Videka-Sherman, 1986; Murphy et al., 2003a). These days, of course, bereavement self-help groups are available online (Hartig & Viola, 2016; Wagner, 2013). Examples of well-established self-help organizations with local chapters around the country are: The Compassionate Friends for parents whose children have died; the Widowed Persons Service for widows and widowers; and the National Alliance for Grieving Children. Support groups offer everything from practical advice to emotional support and friendship. Sometimes other bereaved people are in the best position to understand what a bereaved person is going

through and to offer effective social support. One widow summed it up this way: "What's helpful? Why, people who are in the 'same boat'" (Bankoff, 1983, p. 230).

Taking Our Leave

We have reached the end not only of the life span but of this book and want to leave you with a few parting words. Notice that the book's inside back cover provides a chart summarizing key developments in different periods of the life span; it will help you put the "whole person" back together again and see relationships among the domains of physical, cognitive, personal, and social development. Also notice the Appendix on Careers in Human Development—a resource for those of you who think you may want to make a life of studying development or intervening to optimize it.

Finally, we leave you with a reminder of some of the themes echoed throughout this book, many of them part of the life-span perspective on development formulated by Paul Baltes (1987; see Chapter 1). We hope you can now think of many illustrations of each:

1. **Nature and Nurture Truly Interact in Development:** It's clear that both biology and environment, reciprocally influencing each other all the way, steer development.
2. **We Are Whole People throughout the Life Span:** Advances in one area of development have implications for other areas of development (for example, motor development advances cognitive development through exploration); we must understand interrelationships among domains of development to understand whole human beings.

● APPLICATION 17.1

The Family Bereavement Program

The Family Bereavement Program is a successful intervention for families in which a parent has died (Ayers et al., 2014; Sandler et al., 2003; Sandler, Ayers, et al., 2010; Sandler, Ma, et al., 2010; Schoenfelder et al., 2015). Children and adolescents who were ages 8 to 16 and had lost a parent, along with the surviving parent or caregiver in the family, were randomly assigned to either the program or a control condition that involved self-study of books about grief. Program participants, 244 in all, met for 14 sessions. The aims of the sessions for children and adolescents included helping them interpret stressful events, use positive coping strategies, and find adaptive ways to express their grief. The aims for surviving parents were to help them deal with their mental health problems and maintain close parent-child relationships and

effective discipline at home. A behavioral approach involving modeling and role-playing of target skills and homework assignments to apply skills was used. The developers of the program based it on research on bereavement and on evidence that the parenting bereaved children receive after their loss is critical in their adjustment.

Outcomes were assessed immediately after, 11 months after, and 6 years after the program ended. Were there lasting effects? Six years after the program ended, child participants showed fewer problematic grief symptoms than control youth did (Sandler, Ma, et al., 2010). Some subgroups of children and adolescents in the program also showed fewer internalizing problems (depression, anxiety) and externalizing problems (acting out, aggression) and improved self-esteem

(Sandler, Ayers, et al., 2010). The program even had positive effects on students' stress response systems, as measured by their cortisol levels (Luecken et al., 2013). And, for some students, participating in the program was associated with higher academic expectations and grade point averages (Schoenfelder et al., 2015).

The Family Bereavement Program was effective, in part, because it focused on the whole family. It reduced surviving parents' depression symptoms (Sandler, Ayers, et al., 2010). Moreover, it increased their warmth toward their children and use of effective discipline techniques (Hagan et al., 2012). Overall, then, the program enabled surviving parents to do a better job of helping their children cope with their loss while strengthening the ability of children and adolescents to help themselves.

3. **Development Proceeds in Multiple Directions:** We experience gains and losses, along with changes that simply make us different than we were, at every age. We must reject the view that childhood is only gain—and old age only loss.
4. **There Is Both Continuity and Discontinuity in Development:** Each of us is at once “the same old person” and a new person, qualitatively different from the person who came before; development is also both gradual and stagelike.
5. **There Is Much Plasticity in Development:** We can change in response to experience at any age, getting off one developmental pathway and onto another. Plasticity, both neural and behavioral, is greatest among infants and young children, but it continues through life.
6. **We Are Individuals, Becoming Even More Diverse with Age:** Developing humans are diverse from the start—and become even more diverse with age.
7. **We Develop in a Cultural and Historical Context:** Human development takes different forms in different times and cultures, in different socioeconomic and racial/ethnic groups, and in different social niches.
8. **We Are Active in Our Own Development:** We help create our environments, influence those around us, and, by doing so, help shape our own development.
9. **Development Is a Lifelong Process:** We never stop developing, and our development during any one phase of life is best understood in relation to what came before and what is to come.
10. **Development Is Best Viewed from Multiple Perspectives:** Many disciplines have something to contribute to a comprehensive understanding of human development—and we need them all.
We hope that you are intrigued enough by the mysteries of life-span human development to observe more closely your own development and that of those around you—or even to seek further course work and practical experience in the field. And we sincerely hope that you will use what you learn to steer your own and others’ development in positive directions.

● Checking Mastery

1. What are three of the key features of hospice care?
2. What are two approaches used to help bereaved individuals cope?

● Making Connections

1. If you were in charge of developing policies and programs to help families deal with death and dying, what would you propose and why?
2. Which of the life-span development themes illustrated throughout this book can you detect in this chapter on death and dying?

Chapter Summary

17.1 Matters of Life and Death

- In defining death as a biological process, the definition of total brain death has been influential. Many controversies surround issues of active and passive euthanasia and assisted suicide, complicated by findings of higher brain functioning in some people who are supposedly in “vegetative states”; meanwhile, the social meanings of death vary widely.
- The average life expectancy for a newborn in the United States has risen to almost 79 years; life expectancy varies across nations from the 50s to the 80s; it also differs by gender, race/ethnicity, and socioeconomic status. Death rates decline after infancy but rise in adulthood as accidents give way to chronic diseases as the primary causes of death.

17.2 The Experience of Death

- Elisabeth Kübler-Ross stimulated much concern for dying patients by describing five stages of dying, but, as Edwin Shneidman emphasized, dying people experience ever-changing emotions; their reactions also depend on the course of their disease and on their personality, and they include setting goals for living rather than just coping with dying.

- Bereavement precipitates grief and mourning; grief is expressed, according to the Parkes/Bowlby attachment model, in overlapping phases of numbness, yearning, disorganization and despair, and reorganization.
- The dual-process model describes oscillation between loss-oriented coping and restoration-oriented coping.

17.3 The Infant

- Infants may not comprehend death except as a form of “all gone,” but, as John Bowlby noticed, they clearly grieve—protesting, despairing, and detaching after separations from attachment figures.

17.4 The Child

- Children are curious about death and usually understand by age 5 to 7 or even earlier that it is a final cessation of life functions that is irreversible and universal, later realizing that it is ultimately caused by internal biological changes.
- Terminally ill children often become very aware of their plight, and bereaved children may experience somatic symptoms, academic difficulties, and behavioral problems, especially if they lack a secure attachment and good parenting.

17.5 The Adolescent

- Adolescents understand death more abstractly than children do and typically develop a supernatural view of death that includes an afterlife but do not abandon their understanding of death's biological finality.
- They cope with dying and bereavement in ways that reflect the developmental themes of adolescence, and some display adjustment difficulties and even psychological disorders after a significant loss.

17.6 The Adult

- Widows and widowers experience diverse trajectories of grief, many showing great resilience; yet on average widows and widowers experience physical, emotional, and cognitive symptoms for a year or more and are at increased risk of dying.
- The death of a child is often especially difficult for an adult to bear, whereas the death of a parent may be easier because it is more expected.
- The grief work perspective has been challenged. What is normal depends on the cultural context and individual; many

people display resilience, never doing “grief work” or paying with delayed grief because they did not; and many people benefit from continuing rather than severing their attachment bonds.

- Complicated grief is especially likely among individuals who have neurotic personalities, ineffective coping skills, and insecure attachment styles; who had close and dependent relationships with individuals who died traumatically; and who lack social support or face additional stressors.
- When grief is significant but not crushing, bereaved individuals often report posttraumatic growth.

17.7 Taking the Sting Out of Death

- Successful efforts to take the sting out of death have included hospices and other forms of palliative care for dying patients and their families and individual therapy, family therapy, and mutual support groups for the bereaved.
- Themes of this book include many that are part of the life-span perspective on development formulated by Paul Baltes and introduced in Chapter 1.

• Appendix: Careers in Human Development

What career possibilities lie ahead for students interested in understanding or optimizing human development? We would argue that anyone who works with people can benefit from an understanding of life-span human development. We are not alone in our belief: Preparation for many “people” professions—teaching, counseling, and nursing and other allied health professions—includes coursework in human development. Indeed, some of you are taking this course because it is required for your chosen career.

If you think you are interested in a career in human development, you might first ask yourself some basic questions:

- What *level of education* do you seek—bachelor’s, master’s, or doctoral?
- Are you interested in a particular *age group*—infants, children, adolescents, adults, elderly people?
- Are you interested in a particular *aspect of development*—physical, cognitive, or social development, typical or atypical development?
- Are you most interested in *research, teaching, or practice* (work as a helping professional of some kind)?

We will sketch out some career possibilities within the broad areas of research, teaching, and professional practice, illustrating as we go how the level of education you seek and the age groups and aspects of development of interest to you come into play. Some of this information is drawn from the U.S. Bureau of Labor Statistics’s *Occupational Outlook Handbook* (see Resources list at end of this appendix), available online; you may want to consult it to learn more about the employment outlook and average salaries in some of the professions discussed.

Research

Depending on what level of authority and responsibility you seek, you can conduct research on human development with a bachelor’s degree, master’s degree (typically 2 years of coursework and either a comprehensive examination or completion of a thesis), or doctoral degree (typically 5–7 years of work, including courses, a qualifying or comprehensive exam, and completion of a doctoral dissertation research project). Research on human development and aging and influences on them is conducted in a variety of settings:

- colleges and universities
- medical schools, hospitals, and other healthcare facilities
- government institutes and agencies (for example, the National Institutes of Health, including the National Institute of Child Health and Human Development and the National Institute on Aging, and state and local health and human services agencies)

- social research organizations (some of the larger ones that conduct research on children, families, aging, and social policy are Abt Associates, SRI International, Mathematica, MDRC, RAND, and Westat)
- other for-profit and nonprofit organizations

How can you get a start on a career in human development research now? Ask your professors or advisor about graduate programs and job opportunities in areas of development that interest you. Seek as much research experience as you can get, too:

- Ask your professors whether they need help with their research and be on the lookout for notices about research projects that need student assistants on either a voluntary or paid basis.
- Sign up for an independent study course that would allow you to conduct a literature review or do a research project with guidance from a professor.
- Seek undergraduate research fellowships that might allow you to do a research project with financial support, possibly a summer living stipend; some colleges and universities offer such research fellowships not only to their own students but also to students from other universities (for example, through the National Science Foundation’s Research Experiences for Undergraduates program).
- Do a senior thesis or capstone research project if it is an option in your major.
- Take extra research methods, statistics, and laboratory courses if possible.
- If you are seeking an internship or job, look for ones that involve research, program evaluation, or policy analysis; even if the research is not directly related to human development, you may learn useful research skills.
- Attend lectures and professional conferences to gain exposure to researchers in your area of interest and hear about the latest research they are conducting.
- Use PsycInfo and other online databases to find out who is doing good research of interest to you and at what universities.

These sorts of activities will help you find out whether or not you like research and what aspects of it you prefer. They will also help you acquire research skills, get to know professors who can write reference letters for you and otherwise help you pursue your career plans, and demonstrate to graduate programs or employers that you are interested in research and have research experience. Increasingly, admission to doctoral programs requires experience assisting with research, presenting papers at professional conferences, or even publishing articles with professors.

With a bachelor’s degree, you could be hired as a research assistant, interviewer, or other member of a research team and might work on research tasks such as reviewing literature,

Getting research experience as an undergraduate student is great preparation for graduate school.

Bob Daemmrich/PhotoEdit

conducting telephone surveys, testing children, observing and coding behavior, analyzing physiological data, and compiling tables and graphs. With additional work experience—or with a master’s degree in a relevant field such as developmental psychology, including coursework in research methods and statistics—you would become eligible for positions of greater responsibility. For example, you might be hired as the project coordinator for an investigator’s study, responsible for implementing the data collection plan and supervising the work of research assistants, or you might become a specialist in testing infants, administering tasks to elderly adults, or analyzing data.

Some students seek paid research staff positions after completing their bachelor’s degree, do well, and work their way up to more responsible positions or decide to go on for an advanced degree so that they can move up the career ladder. Some enter a master’s program after graduation, possibly gaining hands-on experience by serving as research assistants for professors while they are taking courses and then drawing on this apprenticeship experience in designing and conducting a master’s thesis.

Still others, certain they want a research career, apply directly to doctoral programs as college seniors. With a doctor of philosophy (PhD) degree in developmental psychology, clinical psychology, or a related field, you would qualify to be a principal investigator and head a research team—to be the one who designs research projects, submits research proposals to the federal government or foundations to obtain funding, guides implementation of

the study, supervises the research staff, analyzes data, writes up findings, and submits papers for publication in professional journals (publications that are then cited in textbooks like this one). Career options as a PhD include becoming a college or university professor who combines teaching and research or working as a research scientist at a university, hospital, government agency, or research organization. The topics you can study are as wide ranging as those in this book.

If you are considering applying to doctoral programs, we strongly recommend that you do the hard work required to identify programs that are a good fit to your interests and qualifications. Doctoral-level training in human development can be found in a bewildering array of departments, schools, centers, and institutes within universities. The American Psychological Association’s yearly publication *Graduate Study in Psychology* is a good resource for students seeking a graduate program in developmental psychology (typically located in a psychology department), human development (typically an interdisciplinary program located in its own department or even its own school), family studies (also interdisciplinary, sometimes part of a larger “human development and family studies” or “family and consumer sciences” program), educational psychology (in either schools of education or psychology departments), or gerontology (also often interdisciplinary and sometimes based in a center or institute).

Most doctoral-level researchers who conduct research on human development or aging did their doctoral work in either psychology or education, but some departments of sociology and anthropology around the country also have strength in the study of families or aging. Moreover, graduate programs in biology often have faculty who specialize in developmental biology, and neuroscience and cognitive neuroscience programs often have specialists in developmental neuroscience, developmental disabilities, dementia, and other topics relevant to development and aging. The more you know about your own research interests, the better; you will then be able to seek programs that are a good fit to your interests and that have scholars whose work excites you. Doctoral programs are highly competitive, but if you’re selected, you may have your studies supported by fellowships and teaching and research assistantships.

Teaching

Teachers clearly need to understand the developmental characteristics and learning capacities of their students to teach effectively and make a difference in their students’ lives. As a result, coursework in human development is a required part of teacher training at the bachelor’s and master’s levels. Colleges of education offer teacher preparation programs in preschool or early childhood, kindergarten, elementary school, middle school, secondary school, and adult education; in the teaching of specific subjects such as English or science; and in special education (the teaching of students with developmental disabilities, behavior disorders, and other special learning needs). Teachers normally need to complete a teacher education program leading to a bachelor’s or master’s degree and then obtain certification from the state in which they will teach by demonstrating that they have taken the required coursework and have passed a standardized teacher exam (see teach.com).

Teachers need to understand their children's cognitive, emotional, and social competencies.

Blend Images/Alamy Stock Photo

To teach at the college or university level, a doctor of philosophy (PhD) degree is normally required. In schools of education, either a PhD or an EdD (doctor of education) is acceptable. The PsyD degree, discussed later, prepares people to be practicing psychologists and is not the best choice for those interested primarily in research and teaching positions in higher education.

Much of what we said earlier about doctoral education for researchers applies to doctoral education for professors. Most PhD programs are highly research-oriented and involve learning the field (through coursework) and how to contribute to the field (through research and scholarship). Teaching responsibilities are heavy and research responsibilities are light at a community college, whereas research may be the first and foremost responsibility of a professor at a large research university.

Professional Practice

By *professional practice* we mean the use of knowledge of human development to optimize development and functioning. Opportunities for professional practice are even more varied than those for research and teaching.

Pre-Bachelor's- or Bachelor's-Level Positions

If you decide you want to enter one of the many helping professions, it makes sense to seek applied experience while you are completing your bachelor's degree or afterward—for example, through unpaid or paid internships or jobs in counseling centers, hospitals, human services agencies, treatment facilities for children or adolescents, or senior centers or nursing homes, depending on your interests (Landrum, 2009). This is a great way to gauge your interests and abilities and develop skills. Jobs available to individuals with a bachelor's degree or less include:

- **Child care worker** The pay is not good, but individuals who love working with children can, with a bachelor's degree or less, work

in day care and preschool facilities, before- and after-school programs, camps and recreation programs, and residential programs for disturbed children (U.S. Bureau of Labor Statistics, 2015).

- **Social and human service assistant** Countless entry-level positions in human services, mental health, and health care are available, carrying diverse titles such as case management aide, community outreach worker, residential counselor, life skills counselor, and gerontology aide. Social and human service assistants assist psychologists, nurses, social workers, and other professionals in hospitals, mental health centers and facilities, and government agencies, performing such tasks as assessing client needs, conducting intake interviews, keeping case records, processing paperwork, teaching life skills, supervising clients in residential facilities, and leading group or family sessions.
- **Social and community service manager** A bachelor's degree, especially if combined with work experience, may qualify an individual to manage a social service program or community outreach organization, setting policies and practices, overseeing the budget, supervising staff, and so on (U.S. Bureau of Labor Statistics, 2015). Fundraising is often part of the job description in nonprofit organizations that depend on grants and donations for their survival.

Some human service workers organize and lead activities at senior day care centers and residential facilities for elderly adults. Here an aide helps an elderly woman at the On Lok Senior Health Service in San Francisco.

Ronnie Kaufman/Getty Images

Most of the following career options require graduate training in areas such as assessment and treatment approaches; supervised practicum and internship experiences in which learning is put to practice; and the passing of an examination after completion of studies in order to be licensed or certified by a state to practice.

Applied Developmental Psychologist

If you want to be squarely in the field of human development and have a positive impact on development but do not want to become a therapist or a counselor, you might look into master's or doctoral programs in applied developmental psychology. Although many graduate programs in developmental psychology, human development, and family studies engage in real-world, policy-relevant research, applied developmental psychology programs make a point of it. Applied developmental psychologists may be trained to conduct research on practical problems such as improving early childhood education, supporting at-risk families, or reducing childhood injuries; assess the developmental status of infants and children; design, implement, and evaluate interventions aimed at preventing or treating problems such as alcohol and drug abuse, aggression, or abusive parenting; and consult or serve as expert witnesses in juvenile court proceedings, custody hearings, and the like. After earning a doctorate, applied developmental psychologists may seek a license to practice psychology as a scientist-practitioner; they must obtain the required supervised field experience and pass a licensure examination (Kuther & Morgan, 2013).

Counselor, Psychologist, or Therapist

Now consider some options if you want to provide counseling or psychotherapy to individuals or families as a state-licensed or certified psychologist. Wearing the title “psychologist” generally requires doctoral-level training in the United States. Individuals with master's degrees in fields such as clinical or counseling psychology are needed in mental health centers and facilities, but they are hired as “psychological assistants” or “psychological associates” and must be supervised by doctoral-level psychologists or psychiatrists (see U.S. Bureau of Labor Statistics, 2015). There are three main types of doctoral-level, practicing psychologists.

Clinical Psychologist

Clinical psychologists are trained to diagnose and treat individuals with psychological disorders. Child clinical psychologists focus their practice and research on infants, children, and adolescents. Pediatric psychologists, who may obtain their degree in clinical psychology, health psychology, or pediatric psychology programs, focus their practice and research on child and adolescent illnesses and health care, often working in medical schools, hospitals, and other pediatric care settings. Clinical geropsychologists specialize in treatment of elderly adults.

Becoming a clinical psychologist normally requires earning either a PhD or a PsyD (the doctor of psychology degree, a more practice-oriented and less research-oriented degree than the

PhD). You should decide whether you want to be primarily a scientist, primarily a practitioner, or a scientist-practitioner who integrates the two roles and then look closely at the extent to which a program of interest is practice-oriented versus research-oriented. You should also understand that clinical psychology programs are extremely selective, requiring high grades, high scores on the Graduate Record Examinations (GREs), relevant experience, and excellent recommendations.

Counseling Psychologist

Counseling psychologists may earn a PhD, EdD, or PsyD. Like clinical psychologists they qualify to be licensed as psychologists. Compared with clinical psychologists, though, they tend to emphasize optimizing mental health and more often work with everyday problems of adjustment (for example, as a counselor in a college or university, company, or community mental health center).

School Psychologist

After completing either an education specialist (EdS) degree (which requires about 3 years of study and a yearlong internship) or a PhD, EdD, or PsyD in school psychology, a school psychologist is prepared to use IQ tests and other assessment instruments to evaluate students believed to have learning disabilities or other special educational needs, consult with teachers and parents on how best to educate them, and provide other supportive psychological services in schools.

Psychiatrist

Becoming a psychiatrist involves earning a doctor of medicine (MD) degree and choosing psychiatry as one's specialty; job descriptions and employment opportunities are much like those of clinical psychologists, but psychiatrists can prescribe medications for psychological disorders.

Now consider some additional possibilities for careers in the helping professions, some of which do not require doctoral-level education.

Counselor

A wide range of counseling programs exist in psychology departments, schools of education, and human development and family studies programs. Many provide opportunities for independent practice after earning a master's degree and passing a state licensing examination. Subareas of counseling include school counseling (which may involve helping students who have academic or personal problems or, at the secondary school level, helping high school students plan their futures), career counseling, rehabilitation counseling (work in the vocational rehabilitation field helping adults with disabilities adapt to their disabilities and find appropriate jobs), substance abuse or addiction counseling, mental health or community counseling, marriage and family therapy, genetic counseling, gerontological counseling, and more (see U.S. Bureau of Labor Statistics, 2015, on Counselors).

Family therapy may be provided by clinical or counseling psychologists or by clinical social workers.

Lisa F. Young/Alamy Stock Photo

Social Worker

Careers in social work normally require at least a master's degree in social work (MSW). Specialties include child, family, and school social work; medical and public health social work; and mental health or clinical social work (U.S. Bureau of Labor Statistics, 2015). Some social workers are employed by human services agencies as caseworkers who work with families on welfare, neglected or abused children and their families, or aging adults and their families; medical social workers are based in healthcare facilities and support patients and their families. Clinical social workers are trained in diagnosing personal and family problems and in providing counseling and therapy. Clinical social workers with an MSW can practice independently, whereas psychologists must have a doctoral degree to do so.

Given the steady growth of the aging population, career opportunities for psychologists, counselors, and social workers with training in gerontology are likely to expand. A number of universities offer certificates or minors in gerontology that students can combine with any number of academic majors to position themselves to work with elderly people; other universities offer bachelor's, master's, and even doctoral programs in gerontology (see Association for Gerontology in Higher Education under Resources). Services for older adults are varied and are expanding, providing plenty of opportunities for individuals with bachelor's and master's degrees. Our society clearly needs more individuals in a variety of disciplines and professions who care about and have expertise in aging.

Health and Allied Health Professionals

Let's briefly note that a wide range of careers in medicine and allied health professions offer opportunities to apply knowledge of human development and aging to practice. Physicians can focus

their careers on newborns, children, adolescents, or elderly adults, as they choose, selecting specialties such as pediatrics or geriatrics in medical school and seeking positions that allow them to work with the age groups and health problems of greatest interest to them. Similarly, nurses can become hospice or palliative care nurses who work with terminally ill patients, developmental disabilities nurses, or psychiatric nurses—or can specialize in the care of a particular age group. Schools of public health offer opportunities for training for roles studying the epidemiology of health problems, providing health education, and delivering community health services to various populations. Other allied health professions such as speech therapy, physical therapy, and occupational therapy also allow for specialization in particular age groups and type of problems.

Other Options

Finally, we need an “Other” category to say that individuals with training in developmental psychology and other human development fields land in surprising places. Many people who enter the occupations we have discussed here advance to become administrators; for example, a teacher may become a principal; a psychologist, counselor, or social worker may become the director of a treatment facility or human service agency. Some of these helping professionals seek further education relevant to their administrative roles (for example, a master's degree in business administration, public administration, or health care management); others simply take on higher administrative roles and learn on the job.

Many people with training in human development also find their way into business and industry. One may become a book editor in a company that publishes books on psychology; another may test toys or other products for children or conduct market research on them; another may design computer products for older adults; still another may advise a company's employees on retirement issues. Many also work as self-employed consultants, offering help to agencies, organizations, and businesses in areas in which they have expertise. • **Table A.1** summarizes some of the career options we have discussed.

We hope this is enough to get you thinking and dreaming—and, better yet, taking concrete steps now to gain the knowledge, skills, and experience that will help you formulate and realize your dream. We are confident that the need for individuals who understand the complexities and marvels of life-span human development and can steer it in healthy directions will remain strong as long as humans develop and age.

Resources

American Psychological Association The APA website, www.apa.org/careers/index.aspx, has information and publications about careers in psychology. Find a short overview of the different types of jobs psychologists hold at: www.apa.org/careers/resources/guides/careers.aspx

● **Table A.1** Some Career Options in Human Development

Degree Required	Research	Teaching	Professional Practice
Bachelor's or master's degree	Research assistant Research staff member Project coordinator	Teacher's aide Teacher in preschool, elementary, secondary, or adult education	Child care worker Social and human services worker Psychological assistant or associate Social worker* School psychologist*
Doctoral degree	Professor or research professor Principal investigator in university, hospital, health or mental health facility, research organization	Professor (e.g., of developmental psychology, human development, family studies, clinical or counseling psychology, or social work)	Applied developmental psychologist Clinical psychologist Counseling psychologist Psychiatrist Counselor Health professional (medicine, allied health)

U.S. Bureau of Labor Statistics. (2015). *Occupational outlook handbook* A huge but wonderful government resource describing, for all major occupational fields, the nature of the work involved, working conditions, training and other qualifications, employment data, job prospects, and average earnings. It includes sections on psychologists and counselors, is updated yearly, and is available free at www.bls.gov/ooh.

Wegenek, A. R., & Buskist, W. (2010). *The insider's guide to the psychology major: Everything you need to know about the degree and profession*. Washington, DC: American Psychological Association This guide aims to help psychology majors get the most out of their education and position themselves for careers in psychology.

• Glossary

A-not-B error The tendency of 8- to 12-month-old infants to search for a hidden object in the place they last found it (A) rather than in its new hiding place (B).

acceptance–responsiveness A dimension of parenting capturing the extent to which parents are supportive, sensitive to their children’s needs, and willing to provide affection and praise when their children meet their expectations.

accommodation In Piaget’s cognitive developmental theory, the process of modifying existing schemes to incorporate or adapt to new experiences. Contrast with *assimilation*. In vision, a change in the shape of the eye’s lens to bring objects at differing distances into focus.

acquired immunodeficiency syndrome (AIDS) The life-threatening disease in which the human immunodeficiency virus (HIV) destroys the immune system and makes victims susceptible to rare, so-called opportunistic, infections that eventually kill them. AIDS is transmitted through sexual activity, drug needle sharing, and from mother to child before or during birth.

active gene–environment correlation Phenomenon in which children’s genotypes influence the kinds of environments they seek out and therefore experience. Contrast with *evocative gene–environment correlation* and *passive gene–environment correlation*.

activity–passivity issue The issue in developmental theory centering on whether humans are active contributors to their own development or are passively shaped by forces beyond their control.

adaptation In Piaget’s cognitive developmental theory, a person’s inborn tendency to adjust to the demands of the environment, consisting of the complementary processes of *assimilation* and *accommodation*.

adolescence The transitional period between childhood and adulthood that begins with puberty and ends when the individual has acquired adult competencies and responsibilities; roughly ages 10 to 18 or later.

adolescent egocentrism A characteristic of adolescent thought that involves difficulty differentiating between the person’s own thoughts and feelings and those of other

people; evident in the *personal fable* and *imaginary audience* phenomena.

adolescent growth spurt The rapid increase in physical growth that occurs during adolescence.

adoption study Method of studying genetic and environmental influence that involves determining whether adopted children are more similar to their biological parents (whose genes they share) or adoptive parents (who shaped their environment).

adrenarche A period of increased production of adrenal hormones, starting around 6–8 years of age, that normally precedes increased production of gonadal hormones associated with puberty.

affordances In Eleanor and James Gibson’s ecological theory of perception, characteristics of an object that reveal what it has to offer humans and how it might be used by them.

age effects In developmental research, the effects of getting older or of developing. Contrast with *cohort effects* and *time of measurement effects*.

age grades Socially defined age groups or strata, each with different statuses, roles, privileges, and responsibilities in society.

age norms Expectations about what people should be doing or how they should behave at different points in the life span.

age of viability A point (around the 24th prenatal week) when a fetus may survive outside the uterus if the brain and respiratory system are well enough developed and if excellent medical care is available.

ageism Prejudice and discrimination against elderly people.

agency An orientation toward individual action and achievement that emphasizes traits of dominance, independence, assertiveness, and competitiveness; considered masculine.

age-related macular degeneration (AMD) Damage to cells in the retina responsible for central vision.

aging To most developmentalists, positive, negative, and neutral changes in the mature organism; different from *biological aging*.

alphabetic principle The idea that the letters in printed words represent the sounds in spoken words.

Alzheimer’s disease A pathological condition of the nervous system that results in an irreversible loss of cognitive capacities; the leading cause of dementia, or neurocognitive disorder, in later life.

amniocentesis A method of extracting amniotic fluid from a pregnant woman so that fetal body cells within the fluid can be tested for chromosomal abnormalities and other genetic defects.

amnion A watertight membrane that surrounds the developing embryo, regulating its temperature and cushioning it against injuries.

amoral Lacking any sense of morality; without standards of right and wrong.

analytic component In Sternberg’s triarchic theory of intelligence, the information-processing skills such as thinking critically and analytically.

androgenized female A genetic female who was exposed to male sex hormones during the prenatal period and therefore developed malelike external genitals and some masculine behaviors.

androgens Male hormones that help trigger the adolescent growth spurt and the development of the male sex organs, secondary sex characteristics, and sexual motivation.

androgyny A gender-role orientation in which the person blends both positive masculine-stereotyped and positive feminine-stereotyped personality traits.

androgyny shift A psychological change that begins in midlife, when parenting responsibilities are over, in which both men and women retain their gender-typed qualities but add to them qualities traditionally associated with the other sex, thus becoming more androgynous.

andropause The slower and less-dramatic male counterpart of *menopause*, characterized by decreasing levels of testosterone and symptoms that include low libido, fatigue and lack of energy, erection problems, memory problems, and loss of pubic hair.

anencephaly Condition in which the top of the neural tube fails to close and the main

portion of the brain above the brain stem fails to develop properly.

anorexia nervosa A life-threatening eating disorder characterized by failure to maintain a normal weight, a strong fear of weight gain, and a distorted body image; literally, “nervous lack of appetite.”

anoxia A lack of sufficient oxygen to the brain that may result in neurological damage or death.

anterograde amnesia The inability to form new memories of recent experiences. Contrast with *retrograde amnesia*.

anticipatory grief Grieving before death for what is happening and for what lies ahead.

antioxidant Vitamins C, E, and similar substances that may increase longevity, although not for long, by inhibiting the free radical activity associated with oxidation and in turn preventing age-related diseases.

antisocial behavior Behavior that violates social norms, rules, or laws and harms others or society (for example, lying, stealing, behaving aggressively).

Apgar test A test routinely used to assess a newborn’s heart rate, respiration, color, muscle tone, and reflexes immediately after birth and 5 minutes later; used to identify high-risk babies.

aphasia A language disorder.

applied behavior analysis (ABA) The application of reinforcement principles to teach skills and change behavior, for example to shape social and language skills in children with autism.

artificial insemination A method of conception that involves injecting sperm from a woman’s partner or from a donor into the uterus.

Asperger syndrome A form of autistic spectrum disorder in which the individual has normal or above-average intelligence, has good verbal skills, and wants to establish social relationships but has seriously deficient mindreading and social skills. No longer a separate diagnosis in DSM-5.

assimilation Piaget’s term for the process by which children interpret new experiences in terms of their existing schemata. Contrast with *accommodation*.

assisted suicide Making available to individuals who wish to commit suicide the means by which they may do so, such as when a physician provides a terminally ill patient who wants to die with enough medication to overdose.

at risk Children who have a higher than normal chance of either short-term or long-term problems because of genetic defects, prenatal hazards, or perinatal damage.

attachment A strong affectional tie that binds a person to an intimate companion and is characterized by affection and a desire to maintain proximity.

attachment theory The theory of close relationships developed by Bowlby and Ainsworth and grounded in ethological theory (with psychoanalytic theory and cognitive theory); it says that close emotional bonds such as parent-child attachments are biologically based and contribute to species survival.

attention Focusing perception and cognition on something in particular.

attention deficit hyperactivity disorder (ADHD) A disorder characterized by attentional difficulties, or overactive and impulsive behavior, or both.

authoritarian parenting A restrictive style of parenting combining high demandingness–control and low acceptance–responsiveness in which adults impose many rules, expect strict obedience, and often rely on power tactics rather than explanations to elicit compliance.

authoritative parenting A flexible style of parenting combining high demandingness–control and high acceptance–responsiveness in which adults lay down clear rules but also take their children’s views into account and explain the rationale for their restrictions.

autism See *autism spectrum disorder*.

autism spectrum disorder (ASD) A category of pervasive developmental disorders that includes what was previously called autism, Asperger syndrome, and related conditions and that involves (1) social and communication problems and (2) restricted interests and repetitive behavior.

autobiographical memory Memory of everyday events that the individual has experienced.

automatization The process by which information processing becomes effortless and highly efficient as a result of continued practice or increased expertise.

autonomy The capacity to make decisions independently, serve as one’s own source of emotional strength, and otherwise manage life tasks without being overdependent on other people; an important developmental task of adolescence.

autonomy versus shame and doubt The psychosocial conflict in which toddlers attempt to demonstrate their independence from and control over other people; second of Erikson’s stages.

avoidant attachment An insecure infant caregiver bond or other intimate relationship characterized by little separation anxiety and

a tendency to avoid or ignore the attachment object upon reunion.

babbling An early form of vocalization that appears between 4 and 6 months of age and involves repeating consonant–vowel combinations such as “baba” or “dadada.”

baby biographies Carefully recorded observations of the growth and development of children by their parents over a period; the first scientific investigations of development.

baby boom generation The huge generation of people born between 1946 (the close of World War II) and 1964.

Bayley Scales of Infant Development (BSID) Standardized test to measure the mental, motor, and behavioral progress of infants and young children.

behavioral genetics The scientific study of the extent to which genetic and environmental differences among individuals are responsible for differences among them in traits such as intelligence and personality.

behavioral inhibition A temperamental characteristic reflecting a person’s tendency to withdraw from unfamiliar people and situations.

behaviorism A school of thinking in psychology that holds that conclusions about human development should be based on controlled observations of overt behavior rather than on speculation about unconscious motives or other unobservable phenomena; the philosophical underpinning of early theories of learning.

belief–desire psychology The theory of mind reflecting an understanding that people’s desires and beliefs guide their behavior and that their beliefs are not always an accurate reflection of reality; evident by age 4. Contrast with *desire psychology*.

bereavement A state of loss that provides the occasion for grief and mourning.

beta-amyloid A toxic protein that injures neurons and is located in the senile plaques outside neural cells that are associated with Alzheimer’s disease.

Big Five The five major dimensions used to characterize people’s personalities: neuroticism, extraversion, openness to experience, agreeableness, and conscientiousness.

bilingual Knowing two or more languages.

binge eating disorder Eating disorder that, like bulimia, involves binge eating but, unlike bulimia, does not involve purging.

bioecological model Bronfenbrenner’s model of development that emphasizes the roles of

both nature and nurture as the developing person interacts with a series of environmental systems (microsystem, mesosystem, exosystem, and macrosystem) over time (chronosystem).

biological aging The deterioration of organisms that leads inevitably to their death.

biological sex The physical characteristics that define male and female.

biosocial theory Money and Ehrhardt's theory of gender-role development that focuses on how biological events influence the development of boys and girls and how early biological developments influence how society reacts to children.

blastocyst A hollow sphere of about 100 to 150 cells that the zygote forms by rapid cell division as it moves through the fallopian tube.

body mass index (BMI) An indicator of body fat calculated from a person's height and weight.

bonding As distinguished from attachment, a more biologically-based process in which parent and infant form a connection through contact in the first hours after birth when both are highly alert.

breech presentation A delivery in which the fetus emerges feet first or buttocks first rather than head first.

bulimia nervosa A life-threatening eating disorder characterized by recurrent eating binges followed by purging activities such as vomiting.

bullying Repeatedly inflicting harm through words or actions on weaker peers who cannot or do not defend themselves.

caloric restriction A technique demonstrated to extend the life span of laboratory animals involving a highly nutritious but severely calorie-restricted diet.

caregiver burden The psychological distress associated with providing care for someone with physical, cognitive, or both types of impairment.

carrier In genetics, individuals who possess a recessive gene associated with a disease and who, although they do not have the disease, can transmit the gene for it to offspring.

cascade model of substance use Transactional, multifactor model of substance use that envisions a chain of influences starting with a child with a difficult temperament born into troubled family and ending with involvement in a deviant adolescent peer group.

case study An in-depth examination of an individual (or a small number of individuals),

typically carried out by compiling and analyzing information from a variety of sources such as observing, testing, and interviewing the person or people who know the individual.

cataract A pathologic condition of the eye involving opacification (clouding) of the lens that can impair vision or cause blindness.

catch-up growth A phenomenon in which children who have experienced growth deficits will grow rapidly and catch up to the growth trajectory they are genetically programmed to follow.

categorical self A person's classification of the self along socially significant dimensions such as age and sex.

celiac disease An inherited digestive problem in which gluten (the proteins found in all wheat products) triggers an immune response that damages a person's small intestine.

centenarian An individual who lives to be 100 years of age.

central executive Mechanism that directs attention and controls the flow of information in the working memory system.

centration In Piaget's theory, the tendency to focus on only one aspect of a problem when two or more aspects are relevant.

cephalocaudal principle The principle that growth proceeds from the head (cephalic region) to the tail (caudal region).

cerebral palsy A neurological disability caused by anoxia that is associated with difficulty controlling muscle movements.

cesarean section A surgical procedure in which an incision is made in the mother's abdomen and uterus so that the baby can be removed through the abdomen.

characteristic adaptations Compared to traits, more situation-specific and changeable aspects of personality; ways in which people adapt to their roles and environments, including motives, goals, plans, schemas, self-conceptions, stage-specific concerns, and coping mechanisms.

child abuse Mistreating or harming a child physically, emotionally, or sexually, as distinguished from another form of child maltreatment, neglect of the child's basic needs.

child effects model A model of family influence in which children are believed to influence their parents rather than vice versa.

child maltreatment A broad term for inadequate care or harmful treatment of a child; encompasses both child abuse and child neglect.

child poverty A household climate that includes low income along with low levels of response to children's basic needs.

child-directed speech Speech used by adults speaking with young children; it involves short, simple sentences spoken slowly and in a high-pitched voice, often with much repetition and with exaggerated emphasis on key words.

childhood amnesia A lack of memory for the early years of a person's life.

childhood gender nonconformity (CGN) Lack of adherence as a child to the typical gender-role norms for members of one's assigned gender group.

chorion A membrane that surrounds the amnion and becomes attached to the uterine lining to gather nourishment for the embryo.

chorionic villus sampling (CVS) An alternative to amniocentesis in which a catheter is inserted through the cervix to withdraw fetal cells from the chorion for prenatal testing to detect genetic defects.

chromosome A threadlike structure made up of genes; in humans, there are 46 chromosomes in the nucleus of each cell.

chromosome abnormalities Conditions in which a child has too few, too many, or incomplete chromosomes because of errors in the formation of sperm or ova.

chronic traumatic encephalopathy (CTE) A degenerative brain disease with symptoms of memory loss, poor impulse control, depression, and eventually dementia; a risk for football players and participants in other contact sports.

chronosystem In Bronfenbrenner's bioecological approach, the system that captures the way changes in environmental systems, such as social trends and life events, are patterned over a person's lifetime.

chumship According to neo-Freudian Harry Stack Sullivan, a close friendship in childhood that provides emotional support and teaches children how to participate in intimate relationships.

class inclusion The logical understanding that parts or subclasses are included in the whole class and that the whole is therefore greater than any of its parts.

classical conditioning A type of learning in which a stimulus that initially had no effect on the individual comes to elicit a response because of its association with a stimulus that already elicits the response.

clinical method An unstandardized interviewing procedure used by Piaget in which a child's response to each successive

question (or problem) determines what the investigator will ask next.

clique A small friendship group that interacts frequently. See *crowd*.

cochlear implant A surgically implanted amplification device that stimulates the auditory nerve to provide the sensation of hearing to a deaf individual.

coercive family environment A home in which family members are locked in power struggles, each trying to control the other through aggressive tactics such as threatening, yelling, and hitting.

cognition The activity of knowing and the processes through which knowledge is acquired (for example, attending, perceiving, remembering, and thinking).

cognitive behavioral therapy Well-established psychotherapy approach that involves identifying and changing distorted thinking and maladaptive emotions and behavior associated with it.

cognitive reserve The extra brain power or cognitive capacity that some people can fall back on as aging and diseases such as Alzheimer's begin to take a toll on brain functioning.

cohabitation The living together of two single adults as an unmarried couple.

cohort A group of people born at the same time; a particular generation of people.

cohort effects In cross-sectional research, the effects on findings that the different age groups (cohorts) being compared were born at different times and had different formative experiences. Contrast with *age effects* and *time-of-measurement effects*.

collectivist culture A culture in which people define themselves in terms of group memberships, give group goals higher priority than personal goals, and socialize children to seek group harmony. Contrast with *individualistic culture*.

communality An orientation that emphasizes the well-being of others and includes traits of emotionality and sensitivity to others; considered feminine.

comorbid Co-occurring, as when two or more psychiatric conditions affect the same individual.

companionate love In Sternberg's triangular theory of love, affectionate love characterized by high intimacy and commitment but low passion.

complementarity Basis for mate selection in which people choose partners who are different from them but have strengths that

compensate for their weaknesses or otherwise complement their own characteristics.

Contrast with *homogamy*.

complicated grief An emotional response to a death that is unusually prolonged or intense and that impairs functioning; pathological grief.

conception The moment of fertilization, when a sperm penetrates an ovum, forming a zygote.

concordance rate The percentage of cases in which a particular attribute is present for both members of a pair of people (for example, twins) if it is present for one member.

concrete operations stage Piaget's third stage of cognitive development, lasting from about age 7 to age 11, when children are acquiring logical operations and can reason effectively about real objects and experiences.

concussion A brain injury involving a brief loss of brain function in response to a hit or blow to the head; immediate symptoms include headache, sensitivity to light and sound, feeling dizzy or foggy, and slowed reaction time.

conduct disorder A persistent pattern of behavior in which a child or adolescent violates the rights of others or age-appropriate societal norms, as through fighting, bullying, and cruelty.

confidant A spouse, relative, or friend to whom a person feels emotionally close and with whom that person can share thoughts and feelings.

congenital malformations Defects that are present at birth and are caused by genetic factors, prenatal events, or both.

conservation The recognition that certain properties of an object or substance do not change when its appearance is altered in some superficial way.

consolidation In information processing, the processing and organizing of information into a form suitable for long-term storage.

constraint-seeking questions In the Twenty Questions task and similar hypothesis-testing tasks, questions that rule out more than one answer to narrow the field of possible choices rather than asking about only one hypothesis at a time.

constructivist A proponent of constructivism, the position taken by Piaget and others that humans actively create their own understandings of the world from their experiences, as opposed to being born with innate ideas or being programmed by the environment.

consummate love In Sternberg's triangular theory of love, love with high levels of all three

components of love: passion, intimacy, and decision/commitment.

contact comfort The pleasurable tactile sensations provided by a parent or a soft, terry cloth mother substitute; believed to foster attachments in infant monkeys and possibly humans.

continuing bond Maintenance of attachment to a loved one after the person's death through reminiscence, use of the person's possessions, consultation with the deceased, and the like.

continuity–discontinuity issue The debate among theorists about whether human development is best characterized as gradual and continuous or abrupt and stagelike.

contour The amount of light-dark transition or boundary area in a visual stimulus.

conventional morality Kohlberg's term for the third and fourth stages of moral reasoning in which societal values are internalized and judgments are based on a desire to gain approval or uphold law and social order.

convergent thinking Thinking that involves "converging" on the one best answer to a problem; what IQ tests measure. Contrast with *divergent thinking*.

cooing An early form of vocalization that involves repeating vowel-like sounds.

coordination of secondary schemes During Piaget's sensorimotor period, the infant's combining of actions to solve problems, using one scheme as a means to an end, as in batting aside a barrier in order to grasp a toy.

coparenting The extent and manner in which the two parents coordinate their parenting and function as a team in relation to their children.

copy number variations Instances in which a person receives too many or too few copies of a stretch of DNA; like gene mutations, they can either be inherited from a parent or arise spontaneously and can contribute to diseases and disorders.

correlation coefficient A measure, ranging from +1.00 to -1.00, of the extent to which two variables or attributes are systematically related to each other in either a positive or a negative way.

correlational method A research technique that involves determining whether two or more variables are related. It cannot indicate that one thing caused another, but it can suggest that a causal relationship exists or allow us to predict one characteristic from our knowledge of another.

co-rumination Excessive discussion and analysis of personal problems with a close friend.

couvade Sympathetic pregnancy, or the experiencing by fathers of some of the same physiological symptoms their pregnant partners experience (for example, bloating, weight gain, fatigue, insomnia, and nausea).

creative component In Sternberg's triarchic theory of intelligence, the aspect of intelligence that varies with experience on a task.

creativity The ability to produce novel responses or works; see also *divergent thinking*.

critical period A defined period in the development of an organism when it is particularly sensitive to certain environmental influences; outside this period, the same influences will have far less effect.

crossing over A process in which genetic material is exchanged between pairs of chromosomes during meiosis.

cross-modal perception The ability to use one sensory modality to identify a stimulus or a pattern of stimuli already familiar through another modality.

cross-sectional design A developmental research design in which different age groups are studied at the same point in time and compared.

crowd A network of heterosexual cliques that forms during adolescence and facilitates mixed-sex social activities. See *clique*.

crystallized intelligence Those aspects of intellectual functioning that involve using knowledge acquired through experience. Contrast with *fluid intelligence*.

cued recall memory Recollecting objects, events, or experiences in response to a hint or cue. Contrast with pure *recall memory* and *recognition memory*.

cultural evolution Change in a species achieved not through biological evolution but through learning and passing on from one generation to the next new ways of adapting to the environment.

culture A system of meanings shared by a population of people and transmitted from one generation to the next.

culture bias The situation that arises in testing when one cultural or subcultural group is more familiar with test items than another group and therefore has an unfair advantage.

cumulative-deficit hypothesis The notion that impoverished environments inhibit intellectual growth and that these inhibiting effects accumulate over time.

decentration The ability to focus on two or more dimensions of a problem at one time.

decontextualize To separate the demands of a task at hand from prior beliefs and knowledge.

defense mechanisms Mechanisms used by the ego to defend itself against anxiety caused by conflict between the id's impulses and social demands.

deferred imitation The ability to imitate a novel act after a delay.

delay of gratification The willingness to give up a reward now for a more desirable reward later; related to *self-control*.

delirium A clouding of consciousness characterized by alternating periods of disorientation and coherence.

demandingness–control A dimension of parenting reflecting the extent to which parents as opposed to children exert control over decisions and set and enforce rules; also called permissiveness–restrictiveness.

dementia A progressive loss of cognitive capacities such as memory and judgment that affects some aging individuals and that has a variety of causes; now called neurocognitive disorder.

denial A defense mechanism in which anxiety-provoking thoughts are kept out of, or isolated from, conscious awareness.

dependent variable The aspect of behavior measured in an experiment and assumed to be under the control of, or dependent on, the *independent variable*.

depression See *major depressive disorder*.

desire psychology The earliest theory of mind: An understanding that desires guide behavior (for example, that people seek things they like and avoid things they hate). Contrast with *belief–desire psychology*.

development Systematic changes in the individual occurring between conception and death; such changes can be positive, negative, or neutral.

developmental norm The age at which half of a large group of infants or children master a skill or display a behavior; the average age for achieving a milestone in development.

developmental psychopathology A field of study concerned with the origins and course of maladaptive or psychopathological behavior.

developmental quotient (DQ) A numerical measure of an infant's performance on a developmental test relative to the performance of other infants the same age.

developmental range In Fischer's dynamic skill framework, the concept that people's abilities vary depending on the context, from optimal levels in highly supportive contexts to lower levels in unsupportive situations.

developmental stage A distinct phase within a larger sequence of development; a period characterized by a particular set of abilities, motives, behaviors, or emotions that occur together and form a coherent pattern.

diabetes A metabolic disorder characterized by high levels of glucose or sugar in the blood leading to symptoms of thirst, excessive urination, fatigue, and problems involving eyes, kidneys, and other organs.

dialectical thinking An advanced form of thought that involves detecting paradoxes and inconsistencies among ideas and trying to reconcile them.

diathesis–stress model The view that psychopathology results from the interaction of a person's predisposition to psychological problems and the experience of stressful events.

differential susceptibility hypothesis The concept that some people's genetic makeup makes them more reactive than other people to both good and bad environmental influences.

differentiation In brain development, the progressive diversification of cells that results in their taking on different characteristics and functions.

difficult temperament Characteristic mode of response in which the individual is irregular in habits and adapts slowly, often with vigorous protest, to changes in routine or new experiences. Contrast with *easy temperament* and *slow-to-warm-up temperament*.

diffusion status Identity status characterizing individuals who have not questioned who they are and have not committed themselves to an identity.

directionality problem The problem in correlational studies of determining whether a presumed causal variable is the cause or the effect. See also *third variable problem*.

disenfranchised grief Grief that is not fully recognized or appreciated by other people and therefore may not receive much sympathy and support, as in the loss of a gay partner.

disorganized–disoriented attachment An insecure infant–caregiver bond, common among abused children, that combines features of the resistant and avoidant attachment styles and is characterized by the infant's dazed response to reunion and confusion about whether to approach or avoid the caregiver.

dispositional traits Relatively enduring dimensions or qualities of personality along which people differ (for example, extraversion, aloofness).

divergent thinking Thinking that requires coming up with a variety of ideas or solutions to a problem when there is no one right answer. Contrast with *convergent thinking*.

DNA Deoxyribonucleic acid, the double helix molecule whose chemical code makes up chromosomes and serves as our genetic endowment; it is made up of sequences of the chemicals A (adenine), C (cytosine), G (guanine), and T (thymine).

dominant gene A relatively powerful gene that is expressed phenotypically and masks the effect of a less-powerful *recessive gene*.

double standard The view that sexual behavior appropriate for members of one gender is inappropriate for members of the other.

Down syndrome A chromosomal abnormality in which the child has inherited an extra 21st chromosome and is, as a result, intellectually disabled; also called trisomy 21.

DSM-5 The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* published by the American Psychiatric Association, which spells out defining features and symptoms for the range of psychological disorders.

dual-process model of bereavement A theory of coping with bereavement in which the bereaved oscillate between loss-oriented coping in which they deal with their emotions, restoration-oriented coping in which they try to manage practical tasks and reorganize their lives, and periods of respite from coping.

dual-process model of morality The view that *both* deliberate thought and more automatic emotion-based intuitions can inform decisions about moral issues and motivate behavior.

dynamic In Fischer's dynamic skill framework, the idea that human performance changes in response to changes in context.

dynamic systems theory A perspective on development which, when applied to motor development, proposes that more sophisticated patterns of motor behavior emerge over time through a "self-organizing" process in which children modify their motor behavior in adaptive ways on the basis of the sensory feedback they receive when they try different movements.

dyslexia Serious difficulties learning to read in children who have normal intellectual ability and no sensory impairments or emotional difficulties that could account for their learning problems.

dysrationalia A term coined by Keith Stanovich for a quite common inability to think and behave rationally despite having adequate intelligence.

easy temperament Characteristic mode of response in which the individual is even-tempered, content, and open and adaptable to new experiences. Contrast with *difficult temperament* and *slow-to-warm-up temperament*.

eclectic In the context of science, an individual who recognizes that no single theory can explain everything but that each has something to contribute to our understanding.

effortful control Dimension of temperament pertaining to being able to sustain attention, control one's behavior, and regulate one's emotions (as opposed to unable to regulate one's arousal and stay calm and focused). See also *negative affectivity* and *surgency/extraversion*.

ego Psychoanalytic term for the rational component of the personality.

egocentrism The tendency to view the world from the person's own perspective and fail to recognize that others may have different points of view.

elaboration A strategy for remembering that involves adding something to or creating meaningful links between the bits of information the person is trying to retain.

Electra complex Female version of the *Oedipus complex*, in which a 4- to 6-year-old girl is said to envy her father for possessing a penis and would choose him as a sex object in the hope of sharing this valuable organ that she lacks.

embryologist Scientist who studies early growth and development during the prenatal period.

embryonic period Second phase of prenatal development, lasting from the third through the eighth prenatal week, during which the major organs and anatomical structures begin to develop.

emergent literacy The developmental precursors of reading skills in young children, including knowledge, skills, and attributes that will facilitate the acquisition of reading competence.

emerging adulthood Newly identified period of the life span extending from about age 18 to age 25 or even later, when young people are neither adolescents nor adults and are exploring their identities, careers, and relationships.

emotion regulation The processes involved in initiating, maintaining, and altering emotional responses.

emotional competence Mastery of emotions in terms of appropriate expression of emotions, understanding of emotions and what triggers them, and ability to regulate emotions.

emotional display rules Cultural rules specifying what emotions should and should not be expressed under what circumstances (for example, "look pleased when you receive a lousy gift").

empathy The vicarious experiencing of another person's feelings.

emotionally focused therapy Psychotherapy approach based on attachment theory that helps partners understand their attachment-related emotions, communicate their emotions, and collaborate to better meet one another's emotional needs.

empty nest The term used to describe the family after the last child departs the household.

encoding The first step in learning and remembering something, it is the process of getting information into the information-processing system, or learning it.

endocrine gland A type of gland that secretes chemicals called hormones directly into the bloodstream. Endocrine glands play critical roles in stimulating growth and regulating bodily functions.

endometriosis A condition arising when bits of tissue lining the uterus grow outside the uterus; a cause of infertility.

environment Events or conditions outside the person that are presumed to influence and be influenced by the individual.

epigenesis The process through which nature and nurture, genes and environment, jointly bring forth development in ways that are difficult to predict at the outset.

epigenetic effects Ways in which environmental influences alter the expression of genes (whether genes are turned on or off) and therefore the influence of genes on traits.

episodic memory A type of explicit memory consisting of specific episodes that one has experienced.

equilibration In Piaget's theory, the process of seeking a state of mental stability in which our thoughts (schemes) are consistent with the information we receive from the external world.

erectile dysfunction A man's inability to achieve or sustain an erection for intercourse, despite having sufficient levels of testosterone.

error (damage) theories of aging Theories of aging that call attention to haphazard processes that cause damage or errors in cells to accumulate and organ systems to deteriorate. Contrast with *programmed theories of aging*.

estrogen The female hormone responsible for the development of the breasts, the female sex organs, and secondary sex characteristics and for the beginning of menstrual cycles.

ethnic identity A sense of personal identification with the individual's ethnic group and its values and cultural traditions.

ethnicity A person's classification in or affiliation with a group based on common heritage or traditions.

ethnocentrism The belief that one's own cultural or ethnic group is superior to others.

ethology A discipline and theoretical perspective that focuses on the evolved behavior of different species in their natural environments.

euthanasia Literally, "good death"; specifically, hastening, either actively or passively, the death of someone suffering from an incurable illness or injury.

evidence-based practice Grounding what professionals do in research and ensuring that the curricula and treatments provided to students or clients have been demonstrated to be effective.

evocative gene–environment correlation Phenomenon in which children's genotypes *evoke* certain kinds of reactions from other people so that their genetic makeup and experiences are correlated. Contrast with *active gene–environment correlation* and *passive gene–environment correlation*.

evoked potentials Electrical activity in the brain, as measured through electrodes attached to the surface of the skull, in response to various stimuli; used to study infant perception.

evolutionary psychology The application of evolutionary theory and its concept of natural selection to understanding why humans think and behave as they do.

executive control processes Processes that direct and monitor the selection, organization, manipulation, and interpretation of information in the information-processing system, including executive functions.

executive functions The planning, organizational, and inhibitory functions carried out in the prefrontal cortex of the brain.

exosystem In Bronfenbrenner's bioecological approach, settings not experienced directly by individuals that still influence their development (for example, effects of events at a parent's workplace on children's development).

expansion A conversational tactic used by adults in speaking to young children in which they respond to a child's utterance with a more grammatically complete expression of the same thought.

experiment A research strategy in which the investigator manipulates or alters some aspect of a person's environment to measure its effect on the individual's behavior or development.

experimental control The holding of all other factors besides the independent variable in an experiment constant so that any changes in the dependent variable can be said to be caused by the manipulation of the independent variable.

explicit memory Memory that involves consciously recollecting the past. Contrast with *implicit memory*.

extended family household A family unit composed of parents and children living with other kin such as grandparents, aunts and uncles, cousins, or a combination of these. Compare with *nuclear family*.

externalizing problem Childhood behavioral problem that involves "undercontrolled" behavior such as aggression or acting out difficulties that disturb other people. Contrast with *internalizing problem*.

extinction The gradual weakening and disappearance of a learned response when it is no longer reinforced.

eyewitness memory Remembering and reporting events the person has witnessed or experienced.

factor analysis Statistical technique to identify meaningful groupings of personality scale or intelligence test items that are correlated with each other but not with other groupings of items.

false belief task A research paradigm used to assess an important aspect of a theory of mind, mainly the understanding that people can hold incorrect beliefs and be influenced by them.

family life cycle The sequence of changes in family composition, roles, and relationships that occurs from the time people marry until they die.

family stress model Model of the effects of economic hardship in families that centers on the negative effects of financial stresses on parent mental health, parenting, and, in turn, child development.

family study Method of studying genetic and environmental influence that examines similarities in traits between pairs of siblings who have different degrees of genetic similarity—for example, identical twins, full biological siblings, half siblings, and unrelated stepsiblings who live together in stepfamilies.

family systems theory The conceptualization of the family as a whole consisting of interrelated parts, each of which affects and is affected by every other part, and each of which contributes to the functioning of the whole.

fast mapping The capacity of young language learners to readily determine the object or other referent of a word and then remember this for future encounters with the word.

fetal alcohol syndrome (FAS) A group of symptoms commonly observed in the offspring of mothers who use alcohol heavily during pregnancy, including a small head, widely spaced eyes, and mental retardation.

fetal period The third phase of prenatal development, lasting from the ninth prenatal week until birth; during this period, the major organ systems begin to function effectively and the fetus grows rapidly.

fetal programming Processes through which the prenatal environment affects the genetic unfolding of the embryo/fetus and its physiologic functions in ways that can influence health and mental health much later in life.

fine motor skills Skills that involve precise movements of the hands and fingers or feet and toes. Contrast with *gross motor skills*.

fixation In psychoanalytic theory, a defense mechanism in which development is arrested and part of the libido remains tied to an early stage of development.

fixed mindset The belief that intelligence and other traits are fixed or static; associated with the tendency to want to prove rather than improve one's ability. Contrast with *growth mindset*.

fluid intelligence Aspects of intelligence that involve actively thinking and reasoning to solve novel problems. Contrast with *crystallized intelligence*.

Flynn effect The rise in average IQ scores over the 20th century.

focusing system Attentional system that deliberately seeks out and maintains attention to events. Contrast with *orienting system*, which is captured by stimuli.

foreclosure status An identity status characterizing individuals who appear to have committed themselves to a life direction but who have adopted an identity prematurely, without much thought.

form perception In visual perception, recognition of the patterns that constitute an object.

formal operations stage Piaget's fourth and final stage of cognitive development (from age 11 or 12), when the individual begins to think more rationally and systematically about abstract concepts and hypothetical ideas.

fragile X syndrome A chromosome abnormality in which one arm of the X chromosome is only barely connected to the rest of the chromosome; the most common hereditary cause of mental retardation.

fraternal twins Twins who are not identical and who result when a mother releases two ova at roughly the same time and each is fertilized by a different sperm.

free radicals Chemically unstable byproducts of metabolism that have an unpaired electron and react with other molecules to produce toxic substances that damage cells and contribute to aging.

functional grammar An analysis of the semantic relations (meanings such as naming and locating) that children express in their earliest sentences.

functional magnetic resonance imaging (fMRI) A brain-scanning technique that uses magnetic forces to measure the increase in blood flow to an area of the brain that occurs when that brain area is active. By having children and adults perform cognitive tasks while lying very still in an fMRI scanner, researchers can determine which parts of the brain are involved in particular cognitive activities.

fuzzy-trace theory The view that verbatim and general or gistlike accounts of an event are stored separately in memory.

gender A combination of all those features that a society associates with or considers appropriate for being a man and woman.

gender consistency The stage of gender typing in which children realize that their sex is stable across situations or despite changes in activities or appearance.

gender constancy A solid understanding of oneself as male–female, man–woman, over time and across situations.

gender identity Individuals' basic awareness that they are either a male or a female.

gender intensification A magnification of differences between males and females during adolescence associated with increased pressure to conform to traditional gender roles.

gender role A pattern of behaviors and traits that defines how to act the part of a female or a male in a particular society.

gender schema (plural: *schemata*) Organized sets of beliefs and expectations about males and females that guide information processing.

gender segregation The formation of separate boys' and girls' peer groups during childhood.

gender similarities hypothesis The hypothesis that males and females are similar on most, but not all, psychological variables.

gender stability The stage of gender typing in which children realize that their sex remains the same over time.

gender stereotypes Overgeneralized and largely inaccurate beliefs about what males and females are like.

gender typing The process by which children become aware of their gender and acquire

the motives, values, and behaviors considered appropriate for members of their biological sex.

gene A functional unit of heredity made up of DNA and transmitted from generation to generation.

gene expression The activation of particular genes in particular cells of the body at particular times in life.

gene therapy Interventions that involve substituting normal genes for the genes associated with a disease or disorder; otherwise altering a person's genetic makeup.

gene–environment correlation A systematic interrelationship between an individual's genes and that individual's environment; ways in which genes influence the kind of home environment provided by parents (*passive gene–environment correlation*), the social reactions to the individual (*evocative gene–environment correlation*), and the types of experiences the individual seeks (*active gene–environment correlation*).

gene–environment interaction The phenomenon in which the effects of people's genes depend on the kind of environment they experience and in which the effects of the environment depend on their genetic endowment.

General Adaptive Composite (GAC) An overall score on the *Bayley Scales of Infant Development* reflecting the cognitive, language, motor, and social–emotional development of an infant in comparison with a large norm group of infants or toddlers the same age.

general event representation (GER) Representations that people create over time of the typical sequence of actions related to an event; also called “scripts.”

generativity versus stagnation The psychosocial conflict in which middle-aged adults must gain the sense that they have produced something that will outlive them and genuinely care for younger generations to avoid self-preoccupation; seventh of Erikson's stages.

genetic counseling A service designed to inform people about genetic conditions they or their unborn children are at risk of inheriting.

genetically informed study A study designed to determine whether there are genetic explanations for apparent environmental effects and establish more firmly whether environment matters (for example, by seeing whether the influence of a parenting behavior is as powerful for adopted children as for biological children).

genotype The genetic endowment that an individual inherits. Contrast with *phenotype*.

germinal period First phase of prenatal development, lasting about 2 weeks from conception until the developing organism becomes attached to the wall of the uterus.

gerontology The study of aging and old age.

giftedness The possession of unusually high general intellectual potential or of special abilities in such areas as creativity, mathematics, or the arts.

glaucoma A condition in which increased fluid pressure in the eye damages the optic nerve and causes progressive loss of peripheral vision and ultimately blindness.

goal-corrected partnership In Bowlby's attachment theory, the most mature phase of attachment in which parent and child accommodate to each other's needs and the child becomes more independent.

goodness of fit The extent to which the child's temperament and the demands of the child's social environment are compatible or mesh, according to Thomas and Chess; more generally, a good match between person and environment.

grief The emotional response to loss. Contrast with *mourning*.

grief work perspective The view commonly held, but now challenged, that to cope adaptively with death bereaved people must confront their loss, experience painful emotions, work through these emotions, and move toward a detachment from the deceased.

gross motor skills Skills that involve large muscles and whole body or limb movements (for example, kicking the legs or drawing large circles). Contrast with *fine motor skills*.

growth The physical changes that occur from conception to maturity.

growth hormone Hormone produced by the pituitary gland that stimulates childhood physical growth and the adolescent growth spurt.

growth mindset The belief that intelligence is not fixed but malleable and can therefore be improved through hard work and effort. Contrast with *fixed mindset*.

guided participation A process in which children learn by actively participating in culturally relevant activities with the aid and support of their parents and other knowledgeable individuals.

habituation A simple form of learning that involves learning not to respond to a repeated stimulus; learning to be bored by the familiar.

Hayflick limit The estimate that human cells can double only 50 times, plus or minus 10, and then will die.

helicopter parenting Also called overparenting, parenting characterized by developmentally inappropriate levels of control of and assistance to late adolescent and emerging adult children.

hemophilia A deficiency in the blood's ability to clot. It is more common among males than females because it is associated with a sex-linked gene on the X chromosome.

heritability The amount of variability in a population on some trait dimension that is attributable to genetic differences among those individuals.

hippocampus Structure in the medial temporal lobe of the brain centrally involved in the formation of memories.

holophrase A single-word utterance used by an infant that represents an entire sentence's worth of meaning.

Home Observation for Measurement of the Environment (HOME) inventory A widely used instrument that allows an observer to determine how intellectually stimulating or impoverished a home environment is.

homogamy Basis for mate selection centered on similarity between partners in demographic and personal characteristics. Contrast with *complementarity*.

hookup A sexual encounter between two people who have often just met and have little expectation of forming a romantic relationship.

hormone replacement therapy (HRT) Taking estrogen and progestin to compensate for hormone loss because of menopause in women.

hospice A program that supports dying persons and their families through a philosophy of caring rather than curing, either in a facility or at home.

hostile attribution bias The tendency of aggressive individuals to attribute hostile intentions to others, assuming that any harm to them was deliberate rather than accidental.

hot flash A sudden experience of warmth and sweating, often followed by a cold shiver, that occurs in a menopausal woman.

Human Genome Project The massive, government-sponsored effort to decipher the human genetic code.

Huntington's disease A genetic disease caused by a single, dominant gene that strikes in middle age to produce a deterioration of physical and mental abilities and premature death.

hyperactivity See *attention deficit hyperactivity disorder (ADHD)*.

hypothesis A theory-based prediction about what will hold true if we observe a phenomenon.

hypothetical-deductive reasoning A form of problem solving in which a person starts with general or abstract ideas and deduces or traces their specific implications; "if-then" thinking.

id A psychoanalytic term for the inborn component of the personality that is driven by the instincts or selfish urges.

ideal self Idealized expectations of what one's attributes and personality should be like.

ideational fluency The sheer number of different (including novel) ideas that a person can generate; a measure of *creativity* or *divergent thinking*.

identical twins Monozygotic twins who develop from a single zygote that later divides to form two genetically identical individuals.

identification Freud's term for the individual's tendency to emulate, or adopt the attitudes and behaviors of, another person, particularly the same-sex parent.

identity A self-definition or sense of who one is, where one is going, and how one fits into society.

identity achievement status An identity status characterizing individuals who have carefully thought through identity issues and made commitments or resolved their identity issues.

identity versus role confusion The psychosocial conflict in which adolescents must form a coherent self-definition or remain confused about their life directions; fifth of Erikson's stages.

imaginary audience A form of adolescent egocentrism that involves confusing one's own thoughts with the thoughts of a hypothesized audience for behavior and concluding that others share these preoccupations.

imaginary companion A play companion invented by a child in the preoperational stage who has developed the capacity for symbolic thought.

implicit memory Memory that occurs unintentionally and without consciousness or awareness. Contrast with *explicit memory*.

imprinting An innate form of learning in which the young of certain species will follow and become attached to moving objects (usually their mothers) during a critical period early in life.

independent variable The aspect of the environment that a researcher deliberately changes or manipulates in an experiment to see its effect on behavior; a causal variable. Contrast with *dependent variable*.

indirect effect The instance in which the relationship between two individuals in a family is modified by the behavior or attitudes of a third family member.

individualistic culture A culture in which individuals define themselves as individuals and put their own goals ahead of their group's goals and in which children are socialized to be independent and self-reliant. Contrast with *collectivist culture*.

induction A form of discipline that involves explaining why a child's behavior is wrong and should be changed by emphasizing its effects on other people.

industry versus inferiority The psychosocial conflict in which school-aged children must master important cognitive and social skills or feel incompetent; fourth of Erikson's stages.

infertility A couple's inability to get pregnant after a year of trying to do so.

information-processing approach An approach to cognition that emphasizes the fundamental mental processes involved in attention, perception, memory, and decision making.

initiative versus guilt The psychosocial conflict in which preschool children must learn to initiate new activities and pursue bold plans or become self-critical; third of Erikson's stages.

instinct An inborn biological force assumed to motivate a particular response or class of responses.

integrity versus despair The psychosocial conflict in which elderly adults attempt to find a sense of meaning in their lives and to accept the inevitability of death; eighth of Erikson's stages.

intellectual disability Significantly below-average intellectual functioning with limitations in areas of adaptive behavior such as self-care and social skills, originating before age 18 (previously known as *mental retardation*).

intelligence quotient (IQ) A numerical measure of a person's performance on an intelligence test relative to the performance of other examinees of the same age, typically with a score of 100 defined as average.

interactional model A model of family influence in which it is the combination of a particular kind of child with a particular kind of parent that determines developmental outcomes.

intergenerational transmission of parenting The passing down from generation to generation of parenting styles, abusive or otherwise.

internal working model In attachment theory, cognitive representation of self and

other that children construct from their interactions with caregivers and that shape their expectations about relationships.

internalizing problem Childhood behavioral problem that represents an “overcontrolled” pattern of coping with difficulties and is expressed in anxiety, depression, and other forms of inner distress. Contrast with *externalizing problem*.

intimacy versus isolation The psychosocial conflict in which young adults must commit themselves to a shared identity with another person or remain aloof and unconnected to others; sixth of Erikson’s stages.

intuitive theories Organized systems of knowledge, believed to be innate, that allow children to make sense of the world in areas such as physics and psychology.

investment theory Sternberg’s view that creativity emerges from a confluence, or coming together, of several ingredients, each in the right amounts and at the right times: intellectual abilities, knowledge, cognitive style, personality, motivation, and a supportive environment.

in vitro fertilization (IVF) Procedure in which several eggs are removed from a woman’s ovary, fertilized by sperm in a petri dish in the laboratory, then transferred to the woman’s uterus in hopes that one will implant on the wall of the uterus.

joint attention The act of looking at the same object at the same time with someone else; a way in which infants share perceptual experiences with their caregivers.

juvenile delinquency Lawbreaking by a minor.

kanaroo care Holding a young infant skin-to-skin on a parent’s chest; often used with premature babies to help maintain body temperature, heart rate, and oxygen levels in the blood.

karyotype A chromosomal portrait created by staining chromosomes, photographing them under a high-power microscope, and arranging them into a predetermined pattern.

kinkeeper An individual, typically a woman, who keeps family members in touch with each other and handles family problems when they arise.

knowledge base A person’s existing information about a content area, significant for its influence on how well that individual can learn and remember.

Lamaze method Prepared childbirth in which parents attend classes and learn mental exercises and relaxation techniques to ease delivery.

language A symbolic system in which a limited number of signals can be combined according to rules to produce an infinite number of messages.

language acquisition device (LAD) A set of linguistic processing skills that nativists believe to be innate; presumably the LAD enables a child to infer the rules governing others’ speech and then use these rules to produce language.

latent learning Learning occurs but is not evident in behavior; children can learn from observation even though they do not imitate (perform) the learned responses.

lateralization The specialization of the two hemispheres of the cerebral cortex of the brain.

learning A relatively permanent change in behavior (or behavioral potential) that results from a person’s experiences or practice.

learning goal A goal adopted by learners in which they seek to learn new things so that they can improve their abilities. Contrast with *performance goal*.

Lewy body dementia Considered the second or third most common neurocognitive disorder after Alzheimer’s disease, a condition associated with protein deposits in neurons called Lewy bodies that cause changes in cognitive functioning, visual hallucinations, and often motor and balance problems.

libido Freud’s term for the biological energy of the sex instinct.

life expectancy The average number of years a newborn baby can be expected to live; now about 78 years in the United States.

life review Process in which elderly adults reflect on unresolved conflicts of the past and evaluate their lives; it may contribute to a sense of integrity and readiness for death.

life script The story a person constructs about his or her life story and tells over and over again.

life-span perspective A perspective that views development as a lifelong, multidirectional process that involves gain and loss, is characterized by considerable plasticity, is shaped by its historical–cultural context, has many causes, and is best viewed from a multidisciplinary perspective.

linked lives The concept that the development of the individual is intertwined with the development of other family members.

literacy The ability to use printed information to function in society, achieve goals, and develop potential.

living will A document, also called an advance directive, in which people state

in advance that they do not wish to have extraordinary medical procedures applied if they are hopelessly ill.

locomotion The process of moving from one location to another.

longitudinal design A developmental research design in which one group of subjects is studied repeatedly over months or years.

long-term memory Memory store in which information that has been examined and interpreted is stored relatively permanently.

loss-oriented coping In the dual-process model of bereavement, coping focused on dealing with one’s emotions and reconciling oneself to the loss. Contrast with *restoration-oriented coping*.

love withdrawal A form of discipline that involves withholding attention, affection, or approval after a child misbehaves.

low birth weight (LBW) A weight at birth of less than 2500 grams, or 5½ pounds, associated with increased risk of developmental problems.

macrosystem In Bronfenbrenner’s bioecological approach, the larger cultural or subcultural context of development.

major depressive disorder An affective or mood disorder characterized by at least one episode of feeling profoundly sad and hopeless, losing interest in almost all activities, or both.

mastery (learning) goal In achievement situations, aiming to learn new things in order to learn or improve ability; contrast with *performance goal*.

mastery motivation An intrinsic motive to master and control the environment evident early in infancy.

maternal blood sampling A noninvasive method of prenatal diagnosis involving testing for substances in maternal blood; more recently, analysis of fetal cells that have slipped through the placenta into the mother’s blood.

maturation Developmental changes that are biologically programmed by genes rather than caused primarily by learning, injury, illness, or some other life experience.

maturity principle A shift toward greater emotional stability, agreeableness, and conscientiousness in personality from adolescence to middle adulthood.

maximum life span A ceiling on the number of years that any member of a species lives; 120 years for humans.

mediation deficiency The initial stage of mastery of memory strategies in which children cannot spontaneously use or benefit from strategies even if they are taught to use them.

meiosis The process in which a germ cell divides, producing sperm or ova, each containing half of the parent cell's original complement of chromosomes; in humans, the products of meiosis normally contain 23 chromosomes.

memory The ability to store and later retrieve information about past events.

menarche A female's first menstrual period.

menopause The ending of a woman's menstrual periods and reproductive capacity around age 51.

mental age (MA) A measure of intellectual development that reflects the level of age-graded problems that a child is able to solve; the age at which a child functions intellectually.

mental retardation See *intellectual disability*.

mesosystem In Bronfenbrenner's bioecological approach, interrelationships between microsystems or immediate environments (for example, ways in which events in the family affect a child's interactions at a day care center).

meta-analysis A research method in which the results of multiple studies addressing the same question are synthesized to produce overall conclusions.

metabolic syndrome (MeTS) A combination of risk factors that can lead to heart disease; notably obesity, high blood pressure, unhealthy cholesterol levels, and insulin resistance (which can lead to diabetes).

metacognition Knowledge of the human mind and of the range of cognitive processes, including thinking about personal thought processes.

metalinguistic awareness Knowledge of language as a system.

metamemory A person's knowledge about memory and about monitoring and regulating memory processes.

microsystem In Bronfenbrenner's bioecological approach, the immediate settings in which the person functions (for example, the family).

middle generation squeeze The phenomenon in which middle-aged adults sometimes experience heavy responsibilities for both the younger and the older generations in the family.

midlife crisis A period of major questioning, inner struggle, and re-evaluation hypothesized to occur in an adult's early 40s.

migration Process in early brain development in which neurons move from their place of origin in the center of the brain to particular locations throughout the brain

where they will become part of specialized functioning units.

mild cognitive impairment A level of memory loss between normal loss with age and pathological loss from disease.

millennials Also called Generation Y or the "baby boomlet" generation, the American generation born from 1982 to 2004.

mind-mindedness The tendency to think and talk in elaborated ways about mental states; parents' mind-mindedness contributes to the development of children's theory-of-mind and other social cognitive skills.

mirror neurons Neural cells in several brain areas that are activated not only when we perform an action but also when we observe someone else performing it. Implicated in imitation, theory of mind skills, empathy, and language.

miscarriage Loss of a pregnancy before survival of the baby outside the womb is possible.

mitosis The process in which a cell duplicates its chromosomes and then divides into two genetically identical daughter cells.

molecular genetics The analysis of particular genes and their effects, including the identification of specific genes that influence particular traits and the comparison of animals or humans who have these specific genes and those who do not.

moral disengagement According to Bandura, the ability to avoid self-condemnation when engaged in immoral behavior by justifying, minimizing, or blaming others for one's actions.

moral identity Viewing being caring, fair, honest, and otherwise moral as a central aspect of who you are.

moral reasoning The cognitive component of morality; the thinking that occurs when people decide whether acts are right or wrong.

moral rules Standards of conduct that focus on the basic rights and privileges of individuals. Contrast with *social-conventional rules*.

morality The ability to distinguish right from wrong, to act on this distinction, and to experience pride when doing something right and to experience guilt or shame when doing something wrong. Morality has emotional, cognitive, and behavioral components.

moratorium period A period of time in high school or college when young adults are relatively free of responsibilities and can experiment with different roles to find their identities.

moratorium status Identity status characterizing individuals who are experiencing an identity crisis or actively exploring identity issues but who have not yet achieved an identity.

morphemes The basic units of meaning that exist in a word.

mourning Culturally prescribed ways of displaying reactions to a loss. Contrast with *grief*.

multitasking Attending to and performing two or more tasks at the same time.

mutation A change in the structure or arrangement of one or more genes that produces a new phenotype.

mutually responsive orientation A close, affectively positive, and cooperative relationship in which child and parent are attached to each other and are sensitive to each other's needs; a contributor to moral development.

myelin A fatty sheath that insulates neural axons and thereby speeds the transmission of neural impulses.

myelination The depositing of a fatty sheath around neural axons that insulates them and thereby speeds the transmission of neural impulses.

narrative identities Unique and integrative "life stories" that we construct about our pasts and futures to give ourselves an identity and our lives meaning; an aspect of personality.

nativist An individual whose approach to human development emphasizes the contribution of genetic factors; specifically, a person who believes that infants enter the world equipped with knowledge that allows them to perceive a meaningful world from the start.

natural selection The evolutionary principle that individuals who have characteristics advantageous for survival in a particular environment are most likely to survive and reproduce. Over many generations, this process of "survival of the fittest" will lead to changes in a species and the development of new species.

naturalistic observation A research method in which the scientist observes people as they engage in common everyday activities in their natural habitats. Contrast with *structured observation*.

nature-nurture issue The debate over the relative roles of biological predispositions (nature) and environmental influences (nurture) as determinants of human development.

negative affectivity Dimension of temperament that concerns the tendency to be sad, fearful, easily frustrated, and irritable (as opposed to laid back and adaptable). See also *effortful control* and *surgency/extraversion*.

negative punishment The process in operant conditioning in which a response is weakened or made less probable when its consequence is the removal of a pleasant stimulus from the situation.

negative reinforcement The process in operant conditioning in which a response is strengthened or made more probable when its consequence is the removal of an unpleasant stimulus from the situation.

neglectful parenting A parenting style low in demandingness—control and low in acceptance—responsiveness; uninvolved parenting.

neonatal Pertaining to events or developments in the first month after birth.

neuro-constructivism theory Approach that explains the construction of new knowledge by the child in terms of changes in neural structures in response to experience.

neurogenesis The process of generating new neurons across the life span.

neuron The basic unit of the nervous system; a nerve cell.

neuroplasticity The brain's remarkable ability to change in response to experience throughout the life span, as when it recovers from injury or benefits from stimulating learning experiences.

nonshared environmental

influences Experiences unique to the individual that are not shared by other members of the family and that tend to make members of the same family different. Contrast with *shared environmental influences*.

normal distribution A symmetrical (bell-shaped) curve that describes the variability of a characteristic within a population. Most people fall at or near the average score; there are relatively few high or low scores.

nuclear family A family unit consisting of husband—father, wife—mother, and at least one child. Compare with *extended family household*.

obesity Condition of being overweight; specifically, being 20% or more above the “ideal” weight for one's height, age, and sex.

object permanence The understanding that objects continue to exist when they are no longer visible or otherwise detectable to the senses; fully mastered by the end of infancy.

observational learning Learning that results from observing the behavior of other people; emphasized in Bandura's social cognitive theory.

Oedipus complex Freud's term for the conflict that 4- to 6-year-old boys experience when they develop an incestuous desire for their mothers and a jealous and hostile rivalry with their fathers.

olfaction The sense of smell, made possible by sensory receptors in the nasal passage that react to chemical molecules in the air.

operant conditioning Also called instrumental conditioning, a form of learning in which freely emitted acts (or operants) become more or less probable depending on the consequences they produce.

oral sex Sexual activity involving contact between the mouth and genitals.

organization In Piaget's cognitive developmental theory, a person's inborn tendency to combine and integrate available schemes into more coherent and complex systems or bodies of knowledge; as a memory strategy, a technique that involves grouping or classifying stimuli into meaningful clusters.

organogenesis The process, occurring during the period of the embryo, in which major organs take shape.

orienting system An attentional system that reacts to events in the environment; contrast with a *focusing system* that deliberately seeks out and maintains attention to events.

orthogenetic principle Werner's principle that development proceeds from global and undifferentiated states toward more differentiated and integrated patterns of response.

osteoarthritis A joint problem among older adults resulting from a gradual deterioration of the cartilage that cushions the bones and keeps them from rubbing together.

osteoporosis A disease affecting older adults in which bone tissue is lost, leaving bones fragile and easily fractured.

overextension The young child's tendency to use a word to refer to a wider set of objects, actions, or events than adults do (for example, using the word *car* to refer to all motor vehicles). Contrast with *underextension*.

overimitation An adaptive and apparently universal tendency of children to imitate every detail of what they see a model do, even actions that are not directly useful in achieving a goal.

overlapping waves theory Siegler's view that the development of problem-solving skills is not a matter of moving from one problem-solving approach to a better one with age but of knowing and using a variety of strategies at each age, becoming increasingly selective with experience about which strategies to use in particular situations, and adding new strategies to one's collection.

overregularization The overgeneralization of observed grammatical rules to irregular cases to which the rules do not apply (for example, saying *mouses* rather than *mice*).

oxytocin A hormone that plays important roles in facilitating parent-infant attachment as well as reducing anxiety and encouraging affiliation in other social relationships.

palliative care Care aimed not at curing but at meeting the physical, psychological, and spiritual needs of dying patients.

parallel processing Carrying out multiple cognitive operations simultaneously rather than in a sequence.

parent-child interaction therapy (PCIT) A therapy approach to treat young children with behavioral or psychological problems that centers on modifying the parent-child relationship and building more effective parenting skills.

parent effects model A model of family influence in which parents are believed to influence their children rather than vice versa.

parental imperative The notion that the demands of parenthood cause men and women to adopt distinct roles and psychological traits.

Parkes/Bowlby attachment model of bereavement Model of grieving describing four predominant reactions to loss of an attachment figure: numbness, yearning, disorganization and despair, and reorganization.

passive gene-environment correlation Phenomenon in which, because parents provide children with both their genes and a home environment compatible with those genes, the home environments to which children are exposed are correlated with (and typically reinforce) their genotypes. Contrast with *active gene-environment correlation* and *evocative gene-environment correlation*.

peer A social equal; a person who functions at a level of behavioral complexity similar to that of the self, often someone of similar age.

peer selection/socialization issue Issue in the study of peer influence asking whether adolescents resemble their peers because they select similar others as friends or because their friends socialize them in certain directions.

perception The interpretation of sensory input.

perceptual salience Phenomenon in which the most obvious features of an object or situation have disproportionate influence on the perceptions and thoughts of young children.

perceived popularity Perceived status, power, and visibility in the peer group, as distinct from likeability. Contrast with *sociometric popularity*.

performance goal A goal adopted by learners in which they attempt to prove their ability rather than to improve it. Contrast with *learning (or mastery) goal*.

perinatal environment The environment surrounding birth.

perinatologist A maternal-fetal specialist who focuses on high-risk pregnancies.

permissive parenting A lax style of parenting combining low demandingness–control and high acceptance–responsiveness in which adults love their children but make few demands on them and rarely attempt to control their behavior.

perseveration error Mistake made when an information processor continues to use the same strategy that was successful in the past over and over despite the strategy's lack of success in the current situation.

person–environment fit The match between the individual's personality and environment (for example, work environment); similar to *goodness of fit* between temperament and environment.

personal fable A form of adolescent egocentrism that involves thinking that oneself and one's thoughts and feelings are unique or special.

personality The organized combination of attributes, motives, values, and behaviors that is unique to each individual.

perspective-taking skills The ability to assume other people's perspectives and understand their thoughts, feelings, and behaviors; role-taking skills.

phenotype The way in which a person's genotype is expressed in observable or measurable characteristics.

phenylketonuria (PKU) A genetic disease in which the child is unable to metabolize phenylalanine; if left untreated, it soon causes hyperactivity and mental retardation.

phoneme One of the basic units of sound used in a particular spoken language.

phonological awareness The understanding that spoken words can be decomposed into some number of basic sound units, or phonemes; an important skill in learning to read.

pincer grasp A grasp in which the thumb is used in opposition to the fingers, enabling an infant to become more dexterous at lifting and manipulating objects.

pituitary gland The “master gland” located at the base of the brain that regulates the other endocrine glands and produces growth hormone.

placenta An organ, formed from the chorion and the lining of the uterus, that provides for the nourishment of the unborn child and the elimination of its metabolic wastes.

plasticity An openness of brain cells or of the organism as a whole to positive and negative environmental influence; a capacity to change in response to experience.

polygenic inheritance Mechanism of inheritance in which multiple gene pairs interact with environmental factors to influence a trait.

polygenic trait A characteristic influenced by the action of many gene pairs rather than a single pair.

population A well-defined group that a researcher who studies a sample of individuals is interested in drawing conclusions about.

positive punishment The process in operant conditioning whereby a response is weakened when its consequence is an unpleasant event.

positive reinforcement The process in operant conditioning whereby a response is strengthened when its consequence is a pleasant event.

positive youth development (PYD) An approach that emphasizes developing the strengths of youth rather than reducing their problem behaviors.

positivity effect The tendency of older adults to pay more attention to, better remember, and put more priority on positive information than on negative information; see also *socioemotional selectivity theory*.

postconventional morality Kohlberg's term for the fifth and sixth stages of moral reasoning, in which moral judgments are based on a more abstract understanding of democratic social contracts or on universal principles of justice that have validity apart from the views of particular authority figures.

postformal thought Proposed stages of cognitive development that lie beyond formal operations.

postpartum depression An episode of severe, clinical depression lasting for months in a woman who has just given birth; to be contrasted with milder cases of the “baby blues,” in which a new mother is tearful and moody in the first days after birth.

posttraumatic growth Positive psychological change resulting from highly challenging experiences such as being diagnosed with a life-threatening illness or losing a loved one.

posttraumatic stress disorder A psychological disorder involving flashbacks to traumatizing events, nightmares, and feelings of helplessness and anxiety in the face of danger experienced by victims of extreme trauma such as soldiers in combat and sexually abused children.

poverty of the stimulus (POTS) Term for the notion that the language input to young children is so impoverished or limited that they could not possibly acquire language (without a powerful, innate *language acquisition device*).

power assertion A form of discipline that involves the use of superior power to administer spankings, withhold privileges, and so on.

PPCT model In Bronfenbrenner's bioecological theory, a call for doing more than comparing children who live at different social addresses by examining development as a function of four factors: process, person, context, and time.

practical component In Sternberg's triarchic theory of intelligence, the aspect of intelligence that varies from one sociocultural context to another.

pragmatics Rules specifying how language is to be used appropriately in different social contexts to achieve goals.

preconventional morality Kohlberg's term for the first two stages of moral reasoning, in which society's rules are not yet internalized and judgments are based on the punishing or rewarding consequences of an act.

preimplantation genetic diagnosis Prenatal diagnostic procedure in which a mother's eggs are fertilized in the laboratory using in vitro fertilization techniques, DNA tests are conducted on the first cells that result from mitosis of each fertilized egg, and only eggs that do not have chromosome abnormalities or genes associated with disorders are implanted in the uterus.

premenstrual dysphoric disorder (PDD) Severe form of premenstrual syndrome that includes affective symptoms in addition to physical symptoms associated with the menstrual cycle and that can be disabling or disruptive to work and relationships.

premenstrual syndrome (PMS) Several symptoms experienced shortly before each menstrual period that include having tender breasts, feeling bloated, and being irritable and moody.

prenatal environment The physical environment of the womb during the 9 months of pregnancy.

preoperational stage Piaget's second stage of cognitive development, lasting from about age

2 to age 7, when children think at a symbolic level but have not yet mastered logical operations.

presbycusis Problems of the aging ear, which commonly involve loss of sensitivity to high-frequency or high-pitched sounds.

presbyopia Problems of the aging eye, especially loss of near vision related to a decreased ability of the lens to accommodate to objects close to the eye.

pretend play Symbolic play in which one actor, object, or action symbolizes or stands for another.

primary circular reaction During Piaget's sensorimotor period, the infant's repetition of interacting acts centered on his or her own body (for example, repeatedly kicking).

primary emotion One of the distinct basic emotions that emerges within the first six months of life universally (joy, surprise, sadness, disgust, anger, fear).

private speech Nonsocial speech, or speech for the self, commonly used by preschoolers to guide their activities and believed by Vygotsky to be the forerunner of inner speech, or silent thinking in words.

proactive parenting strategies Parenting tactics that prevent misbehavior and therefore reduce the need for discipline (for example, teaching values, removing temptations).

problem solving The use of the information-processing system to achieve a goal or arrive at a decision.

prodigies Individuals, especially children, endowed with one or more extraordinary ability.

production deficiency A phase in the mastery of memory strategies in which children can use strategies they are taught but cannot produce them on their own.

programmed theories of aging Theories that emphasize the systematic genetic control of aging processes. Contrast with *random error theories of aging*.

proliferation Process in early brain development in which neurons multiply at a staggering rate throughout the prenatal period

prosocial behavior Positive actions toward other people such as helping and cooperating.

prosody The melody or sound pattern of speech, including intonation, stress, and timing with which something is said.

protective factors Influences that prevent the damaging effects of risk factors or help children overcome disadvantages.

proximal processes In Bronfenbrenner's bioecological theory, the important recurring,

reciprocal interactions between the individual and other people, objects, or symbols that move development forward (for example, parent and child reading bedtime stories together nightly).

proximodistal principle In development, the principle that growth proceeds from the center of the body (or the proximal region) to the extremities (or the distal regions).

psychoanalytic theory The theoretical perspective associated with Freud and his followers that emphasizes unconscious motivations for behavior, conflicts within the personality, and stages of psychosexual development.

psychometric approach The research tradition that spawned standardized tests of intelligence and that views intelligence (or personality) as a set of traits that can be measured and that varies from person to person.

psychosexual stages Freud's five stages of development, associated with biological maturation and shifts in the libido: oral, anal, phallic, latency, and genital.

psychosocial stages Erikson's eight stages of development (trust, autonomy, initiative, industry, identity, intimacy, generativity, and integrity), emphasizing social influences more and biological urges less than Freud's psychosexual stages.

puberty The processes of biological change that result in an individual's attaining sexual maturity and becoming capable of producing a child.

random assignment A technique in which research participants are placed in experimental conditions in an unbiased or random way so that the resulting groups are not systematically different.

random sample A sample formed by identifying all members of the larger population of interest and then selecting a portion of them in an unbiased or random way to participate in the study; a technique to ensure that the sample studied is representative or typical of the larger population of interest.

reaction time The interval between the presentation of a stimulus and a response to it.

recall memory Recollecting or actively retrieving objects, events, and experiences when examples or cues are not provided. Contrast with *cued recall memory* and *recognition memory*.

recessive gene A less powerful gene that is not expressed phenotypically when paired with a *dominant gene*.

reciprocal determinism The notion in social cognitive theory that the flow of influence between people and their environments is a

two-way street; the environment may affect the person, but the person's characteristics and behavior will also influence the environment.

reciprocity The mutual give and take by both parties in a human relationship that forms an important basis for morality.

recognition memory Identifying an object or event as one that has been experienced before, such as when a person must select the correct answer from several options. Contrast with *cued recall memory* and *recall memory*.

reconstituted family A new family that forms after the remarriage of a single parent, sometimes involving the blending of two families into a new one.

reflex An unlearned and automatic response to a stimulus.

regression A defense mechanism that involves retreating to an earlier, less traumatic stage of development.

rehearsal A strategy for remembering that involves repeating the items the person is trying to retain.

relational aggression Subtle and indirect aggression that involves gossiping about and ignoring or excluding others.

relativistic thinking A form of postformal operational thought in which it is understood that there are multiple ways of viewing a problem and that the solutions people arrive at will depend on their starting assumptions and perspective.

religiousness Sharing the beliefs and participating in the practices of an organized religion. Contrast with *spirituality*.

REM sleep A state of active, irregular sleep associated with dreaming; named for the rapid eye movements associated with it.

repression Removing unacceptable thoughts or traumatic memories from consciousness, as when a young woman who was raped has no memory at all of having been raped (or less drastically, engages in denial, knowing deep down that she was raped but not accepting the reality of it).

research ethics Standards of conduct that investigators are ethically bound to honor to protect their research participants from physical or psychological harm.

reserve capacity The ability of many organ systems to respond to demands for extraordinary output, such as when the heart and lungs work at maximal capacity.

resilience The ability to function well despite exposure to risk factors for maladaptive development or to overcome early developmental problems to become well adjusted.

resistant attachment An insecure infant–caregiver bond or other intimate relationship characterized by strong separation anxiety and a tendency to show ambivalent reactions to the attachment object upon reunion, seeking and yet resisting contact and not being comforted.

restoration-oriented coping In the dual-process model of bereavement, coping focused on managing daily living, rethinking one’s life, and mastering new roles and challenges. Contrast with *loss-oriented coping*.

retinitis pigmentosa (RP) A group of hereditary disorders that involve gradual deterioration of the light-sensitive cells of the retina.

retrieval The process of retrieving information from long-term memory when it is needed.

retrograde amnesia Loss of memory for information and events occurring prior to the incident that caused the amnesia. Contrast with *anterograde amnesia*.

reversibility In Piaget’s theory, the ability to reverse or negate an action by mentally performing the opposite action.

reversible dementia Significant cognitive decline that, unlike most dementia, can be cured or reversed; causes include alcoholism, toxic reactions to medication, infections, metabolic disorders, vitamin deficiencies, and malnutrition.

rhythmic stereotypies Repetitive movements observed in infants shortly before a new motor skill emerges.

rite of passage A ritual that marks a person’s “passage” from one status to another, usually in reference to rituals marking the transition from childhood to adulthood.

role reversal Phenomenon in which the aging parent becomes the child and the child becomes the caregiver, not typical of most aging parent–child relationships.

role-taking skills The ability to assume other people’s perspectives and understand their thoughts, feelings, and behaviors. See *perspective-taking skills*.

rubella A disease that has little effect on a pregnant woman but may cause several serious birth defects, such as blindness, deafness, and mental retardation, in unborn children exposed in the first 3 to 4 months of gestation; German measles.

rule assessment approach Siegler’s approach to studying the development of problem solving that determines what information about a problem children take in and what rules they then formulate to account for this information.

ruminative coping Way of managing stress that involves dwelling on problems and attempting to analyze them; may help explain higher rates of depression in females than in males.

safe haven A point of safety, represented by an infant’s attachment figure, to which the infant can return for comfort if frightened.

sample The group of individuals chosen to be the subjects of a study.

savant syndrome The phenomenon in which extraordinary talent in a particular area is displayed by a person who is otherwise mentally retarded.

scaffolding Jerome Bruner’s term for providing structure to a less skilled learner to encourage advancement.

scheme (or **schema**; plural: **schemes** or **schemata**) A cognitive structure or organized pattern of action or thought used to deal with experiences.

schizophrenia A serious form of mental illness characterized by disturbances in logical thinking, emotional expression, and interpersonal behavior.

scientific method An attitude or value about the pursuit of knowledge that dictates that investigators must be objective and must allow their data to decide the merits of their theorizing.

script A mental representation of a typical sequence of actions related to an event that is created in memory and that then guides future behaviors in similar settings.

secondary circular reaction During Piaget’s sensorimotor period, the infant’s repetition of interesting actions on objects (for example, repeatedly shaking a rattle to make a noise).

secular trend A trend in industrialized societies toward earlier maturation and greater body size.

secure attachment An infant–caregiver bond or intimate relationship in which the individual welcomes close contact, uses the attachment object as a source of comfort, and dislikes but can manage separations.

secure base A point of safety, represented by an infant’s attachment figure, that permits exploration of the environment.

selective attention Deliberately concentrating on one thing and ignoring something else.

selective optimization with compensation (SOC) The concept that older people cope with aging through a strategy that involves focusing on the skills most needed, practicing those skills, and developing ways to avoid the need for declining skills.

self-concept People’s perceptions of their unique attributes or traits.

self-conscious emotion A “secondary emotion” such as embarrassment or pride that requires an awareness of self; unlikely to emerge until about 18 months of age.

self-control The ability to control or regulate one’s desires, impulses, and behavior.

self-efficacy The belief that one can effectively produce desired outcomes in a particular area of life.

self-esteem People’s overall evaluation of their worth as based on an assessment of the qualities that make up the self-concept.

self-recognition The ability to recognize oneself in a mirror or photograph, which occurs in most infants by 18 to 24 months of age.

self-stereotyping Applying stereotypes of one’s group (for example, negative stereotypes of older adults) to oneself.

semantic memory A type of explicit memory consisting of general facts.

semantics The aspect of language centering on meanings.

semenarche A boy’s first ejaculation.

sensation The process by which information is detected by the sensory receptors and transmitted to the brain; the starting point in perception.

sensitive period As compared to a critical period, a period of life during which the developing individual is especially susceptible to the effects of experience or has an especially high level of plasticity.

sensorimotor stage Piaget’s first stage of cognitive development, spanning the first 2 years of life, in which infants rely on their senses and motor behaviors in adapting to the world around them.

sensory register The first memory store in information processing in which stimuli are noticed and are briefly available for further processing.

sensory threshold The point at which low levels of stimulation can be detected.

separation anxiety A wary or fretful reaction that infants display when separated from their attachment objects.

sequential design A developmental research design that combines the cross-sectional approach and the longitudinal approach in a single study to compensate for the weaknesses of each.

seriation A logical operation that allows a person to mentally order a set of stimuli along a quantifiable dimension such as height or weight.

sex chromosome abnormality A chromosome abnormality in which a child receives too many or too few sex chromosomes (X or Y).

sex-linked characteristic An attribute determined by a gene that appears on one of the two types of sex chromosomes, usually the X chromosome.

sex-linked inheritance Mechanism of inheritance in which a characteristic is influenced by single genes located on the sex chromosomes (usually the X chromosome).

sexual assault Unwanted and nonconsensual sexual contact or behavior ranging from unwanted touching to rape.

sexual orientation A person's preference for sexual partners of the same or other sex, often characterized as primarily heterosexual, homosexual, or bisexual.

shared environmental influences Experiences that individuals living in the same home environment share and that work to make them similar. Contrast with *nonshared environmental influences*.

short-term memory The memory store in which limited amounts of information are temporarily held; called *working memory* when its active quality is being emphasized.

sibling rivalry A spirit of competition, jealousy, or resentment that may arise between two or more brothers or sisters.

sickle-cell disease A genetic blood disease in which red blood cells assume an unusual sickle shape and become inefficient at distributing oxygen throughout the body.

single gene-pair inheritance The genetic mechanism through which a characteristic is influenced by only one pair of genes, one gene from the mother and its partner from the father.

size constancy The tendency to perceive an object as the same size despite changes in its distance from the eyes.

skill In Fischer's dynamic skill framework, a person's ability to perform a particular task in a specific context.

sleepier effect The delayed effect of an earlier experience, for example, the effect of early deprivation of visual stimulation.

slow-to-warm-up temperament A characteristic mode of response in which the individual is relatively inactive and moody and displays mild resistance to new routines and experiences but gradually adapts. Contrast with *easy temperament* and *difficult temperament*.

social clock A personal sense of when things should be done in life and when the individual is ahead of or behind the schedule dictated by age norms.

social cognition Thinking about the thoughts, feelings, motives, and behavior of the self and other people.

social cognitive theory Bandura's social learning theory, which holds that children and adults can learn novel responses merely by observing the behavior of a model, making mental notes on what they have seen, and then using these mental representations to reproduce the model's behavior; more broadly, a theory emphasizing the importance of cognitive processing of social experiences.

social comparison The process of defining and evaluating the self through comparisons with other people.

social learning theory See *social cognitive theory*.

social norm A socially defined expectation about how people should behave in particular social contexts.

social pretend play A form of play that involves both cooperation with playmates and pretend or symbolic activity.

social referencing Infants' monitoring of companions' emotional reactions in ambiguous situations and use of this information to decide how they should feel and behave.

social-conventional rules Standards of conduct determined by social consensus that indicate what is appropriate within a particular social setting. Contrast with *moral rules*.

social-role theory Eagly's view that gender-role stereotypes are created and maintained by differences in the roles that men and women play in society rather than being inherent in males and females.

sociocultural perspective Vygotsky's theory of development, which maintains that cognitive development is shaped by the sociocultural context in which it occurs and grows out of children's social interactions with members of their culture.

socioeconomic status (SES) The position people hold in society based on such factors as income, education, occupational status, and the prestige of their neighborhoods.

socioemotional selectivity theory Carstensen's notion that our needs change as we grow older and that we actively choose to narrow our range of social partners to those who can best meet our emotional needs.

sociometric popularity Being liked by many peers and disliked by few. Contrast with *perceived popularity*.

sociometric techniques Methods for determining who is well liked and popular and who is disliked or neglected in a group.

somaesthetic senses Body senses, including the senses of touch, temperature, and pain, as well as the *kinesthetic sense* of where one's body parts are in relation to other body parts and to the environment.

somatic symptoms Physical or bodily signs of emotional distress such as loss of appetite or disruption of normal sleep patterns.

species heredity The genetic endowment that members of a particular species have in common; a contributor to universal species traits and patterns of maturation.

spillover effects Instances in which events at work affect home life, and events at home carry over into the work place.

spina bifida Condition in which the bottom of the neural tube fails to fully close during prenatal development and part of the spinal cord is not fully encased in the protective covering of the spinal column.

spirituality A search for ultimate meaning in life that may or may not be carried out in the context of religion. Contrast with *religiousness*.

standard deviation A measure of the dispersion or spread around the mean of a distribution of scores; in the case of IQ tests with a mean score of 100, the standard deviation is 15, meaning that about two-thirds of people taking the test have scores between 85 and 115.

Stanford-Binet Intelligence Scale One of the most widely used, individually administered intelligence tests, which yields an IQ score.

static thought In Piaget's theory, the thought characteristic of the preoperational period that is fixed on end states rather than on the changes that transform one state into another. Contrast with *transformational thought*.

stem cell Undifferentiated, primitive cells that have the ability both to multiply and to differentiate into a variety of specific cells.

stereotype threat An individual's fear of being judged to have the qualities associated with negative stereotypes of his or her social group.

Sternberg's Triarchic Abilities Tests (STAT) An intelligence test based on Sternberg's triarchic theory that uses a variety of question formats to assess practical, creative, and analytical components of intelligence.

stillbirth Fetal death that occurs late in pregnancy when survival outside womb would normally have been possible.

storage In information processing, the holding of information in the long-term memory store.

storm and stress G. Stanley Hall's term for the emotional ups and downs and rapid changes that he believed characterize adolescence.

Strange Situation A series of mildly stressful experiences involving the departure of the parent and exposure to a stranger to which infants are exposed to determine the quality of their attachments; developed by Ainsworth.

stranger anxiety A wary or fretful reaction that infants often display when approached by an unfamiliar person.

structured observation A research method in which scientists create special conditions designed to elicit the behavior of interest to achieve greater control over the conditions under which they gather behavioral data. Contrast with *naturalistic observation*.

substance use disorders Diagnostic term for continued use of alcohol or psychoactive drugs despite adverse consequences for health, performance, and/or interpersonal relations.

successful intelligence Sternberg's concept that people are intelligent to the extent that they are able to succeed in life in their sociocultural context.

sudden infant death syndrome (SIDS) The death of a sleeping baby because of a failure of the respiratory system; linked to maternal smoking.

superego The psychoanalytic term for the component of the personality that consists of the individual's internalized moral standards.

surfactant A substance that aids breathing by preventing the air sacs of the lungs from sticking together.

surgency/extraversion Dimension of temperament that involves the tendency to actively and energetically approach new experiences in an emotionally positive way (rather than to be inhibited and withdrawn). See *negative affectivity* and *effortful control*.

symbolic capacity The capacity to use symbols such as words, images, or actions to represent or stand for objects and experiences; representational thought.

synapse The point at which the axon or dendrite of one neuron makes a connection with another neuron.

synaptic pruning The removal of unnecessary synapses between neurons in response to experience.

synaptogenesis The growth of synapses, or connections between neurons.

synchronized routine Harmonious, dancelike interaction between infant and caregiver in which each adjusts behavior in response to that of the other.

syntactic bootstrapping Using the syntax of a sentence—that is, where a word is placed in a sentence—to determine the meaning of the word.

syntax Rules specifying how words can be combined to form meaningful sentences in a language.

sypphilis A common sexually transmitted disease that may cross the placental barrier in the middle and later stages of pregnancy, causing miscarriage or serious birth defects.

systemize To analyze things and explore how they work; male brains (and the brains of autistic individuals) are hypothesized by Baron-Cohen to excel at systemizing, whereas females excel at empathizing.

systems theories Theories of development holding that changes over the life span arise from the ongoing interrelationships between a changing organism and a changing environment, both of which are part of a larger, dynamic system.

tabula rasa The idea that the mind of an infant is a “blank slate” and that all knowledge, abilities, behaviors, and motives are acquired through experience.

tau Protein in the neurofibrillary tangles in the bodies of neural cells of individuals with Alzheimer's disease.

telegraphic speech Early sentences that consist primarily of content words and omit the less meaningful parts of speech such as articles, prepositions, pronouns, and auxiliary verbs.

telomere A stretch of DNA that forms the tip of a chromosome and that shortens after each cell division, serving as an aging clock and timing the death of cells.

temperament A genetically based pattern of tendencies to respond in predictable ways; building blocks of personality.

teratogen Any disease, drug, or other environmental agent that can harm a developing fetus.

terminal drop A rapid decline in intellectual abilities that people within a few years of dying often experience.

tertiary circular reaction During Piaget's sensorimotor period, the infant's experimenting with actions to find new ways to solve problems or produce interesting effects.

test norms Standards of normal performance on psychometric instruments based on the average scores and range of scores obtained by a large, representative sample of test takers.

testosterone The most important of the male hormones, or androgens; essential for normal sexual development during the prenatal period and at puberty.

thalidomide A mild tranquilizer that, taken early in pregnancy, can produce a variety of malformations of the limbs, eyes, ears, and heart.

theory A set of concepts and propositions designed to organize, describe, and explain a set of observations.

theory of mind The understanding that people have mental states (feelings, desires, beliefs, intentions) and that these states underlie and help explain their behavior.

thin ideal The cultural message that associates being thin with being attractive and teaches young girls to fear being fat, wish to be thinner, and diet at young ages.

third variable problem In correlation studies, the problem posed by the fact that the association between the two variables of interest may be caused by some third variable; see also *directionality problem*.

time-of-measurement effects In developmental research, the effects on findings of historical events occurring when the data for a study are being collected (for example, psychological changes brought about by an economic depression rather than as a function of aging). Contrast with *age effects* and *cohort effects*.

tinnitus Condition caused by exposure to high noise levels that involves ringing sounds in one or both ears and that can last for days, weeks, or indefinitely.

total brain death An irreversible loss of functioning in the entire brain, both the higher centers of the cerebral cortex that are involved in thought and the lower centers of the brain that control basic life processes such as breathing.

transactional model A model of family influence in which parent and child are believed to influence each other reciprocally over time, and development is influenced by how their relationship evolves.

transformational grammar Rules of syntax that allow a person to transform statements into questions, negatives, imperatives, and other kinds of sentences.

transformational thought In Piaget's theory, the ability to conceptualize transformations, or processes of change from one state to another, which appears in the stage of concrete operations. Contrast with *static thought*.

transgender Pertaining to individuals who identify with a gender other than their biological one.

transitivity The ability to recognize the necessary or logical relations among elements in a serial order (for example, that if A is taller than B, and B is taller than C, then A must be taller than C).

triangular theory of love Robert Sternberg's model describing types of love in terms of three components: passion, intimacy, and commitment.

triarchic theory of intelligence Sternberg's information-processing theory of intelligence that emphasizes three aspects of intelligent behavior: a practical component emphasizing the effect of context on what is intelligent; a creative component centering on coping with both novel and familiar problems; and an analytic component focused on the cognitive processes used to solve a problem.

trust versus mistrust The psychosocial conflict of infancy in which infants must learn to trust others to meet their needs in order to trust themselves; first stage in Erikson's theory.

twin study Method of studying genetic and environmental influence in which the similarity of identical twins is compared to that of (less genetically similar) fraternal twins, often in studies involving both twins reared together and twins reared apart.

ulnar grasp Holding objects by clamping them between the palm of hand and the fingers.

ultrasound Method of examining physical organs by scanning them with sound waves—for example, scanning the womb and thereby producing a visual outline of the fetus to detect gross abnormalities.

unconscious motivation Freud's term for feelings, experiences, and conflicts that influence a person's thinking and behavior even though they cannot be recalled.

underextension The young child's tendency to use general words to refer to a smaller set of objects, actions, or events than adults do (for example, using *candy* to refer only to mints). Contrast with *overextension*.

universal grammar A system of common rules and properties of language that may allow infants to grow up learning any of the world's languages.

universality–context specificity issue The debate over the extent to which developmental changes are common to everyone (universal, as in most stage theories) or different from person to person (particularistic).

utilization deficiency The third phase in mastery of memory strategies in which children fail to benefit from a memory strategy they are able to produce.

vascular dementia The deterioration of functioning and cognitive capacities caused by a series of minor strokes that cut off the blood supply to areas of the brain; also called multi-infarct dementia, it is one of the leading causes of neurocognitive disorder.

vicarious reinforcement In observational learning, the consequences experienced by models, because of their behavior, that affect the learner's likelihood of imitating the behavior.

video deficit The difficulty infants have learning from video presentations as compared with live interactions with social partners.

visual accommodation The ability of the lens of the eye to change shape to bring objects at different distances into focus.

visual acuity The ability to perceive detail in a visual stimulus.

visual cliff An elevated glass platform that creates an illusion of depth and is used to test the depth perception of infants.

vocabulary spurt A phenomenon occurring around 18 months of age when the pace of word learning quickens dramatically.

Wechsler Scales A set of widely used, individually administered intelligence tests that yield verbal, performance, and overall IQ scores.

WEIRD people An acronym referring to people living in societies that are Western, Educated, Industrialized, Rich, and Democratic. The field of psychology has been characterized as the study of WEIRD people (for example, American college students).

wisdom A combination of rich factual knowledge about life and procedural knowledge such as strategies for giving advice and handling conflicts.

word segmentation In language development, the ability to break the stream of speech sounds into distinct words.

working memory A memory store, often referred to as a mental “scratch pad,” that temporarily holds information when it is being actively operated upon or in one's consciousness.

X chromosome The longer of the two sex chromosomes; normal females have two X chromosomes, whereas normal males have only one.

Y chromosome The shorter of the two sex chromosomes; normal males have one Y chromosome, whereas females have none.

zone of proximal development Vygotsky's term for the difference between what a learner can accomplish independently and what a learner can accomplish with the guidance and encouragement of a more skilled partner.

zygote A single cell formed at conception from the union of a sperm and an ovum.

Adolescent egocentrism, 224
Adolescent growth spurt, 143
Adolescents, 142–151
 abstract thought in, 220–222
 achievement motivation in, 321–323, 325
 adolescent growth spurt, 143
 antisocial behavior, 420–424
 attention, 185–186
 autonomy, 482–483
 basic processing capacities, 251
 beliefs about sexuality, 387–388
 brain development, 142–143
 cognition, 220–225
 cross-national educational outcomes, 323–325
 crowds, implications of, 455–456
 cultural variation in sensory capacities, 187, 188–189
 dating, 456–457
 depression, 522–524
 diabetes in, 149
 eating disorders, 518–520
 emotional development, 438
 experiences with death, 548
 in family, 481–483
 formal operations, progress towards mastery of, 222–224
 formal thought, implications of, 224–225
 friendships, 454–455
 gender differences, 384–392
 gender roles, 384–385
 health and wellness, 148–151
 hearing, 186
 identity, 344–348
 intelligence, 277–279
 language development, 321–326
 math skills, 323–324
 memory, 250–252
 metabolic syndrome in, 149
 moral development, 419–424
 moral identity, 419
 parent–child relationship, 454, 481–482
 peer influence, 456
 personality, 343–348
 problem behaviors, 518
 psychological disorders, 517–524
 self-concept, 343–344
 self-esteem, 344
 sensory and perceptual capacities, 185–189
 sexual assaults on campus, 390
 sexual behavior, 388–389, 390–392
 sexual maturation, 143, 145–148
 sexual maturity, 385–392
 sexual orientation, 386–387
 sleep, 150–151
 smell, 187
 social media and, 13
 social networks, 455–456

 substance use disorders, 520–522
 taste, 187, 188
 understandings of death, 548
 weight, 149–150
Adoption study, 73
Adrenaline, 109
Adrenarche, 143, 145
Adults, 151–161. *See also* Aging adults
 achievement motivation in, 327–328
 attachment styles, 460–461, 462
 brain development, 151–153
 career, establishing, 358–359
 child-rearing, 485–486
 cognitive performance, limitations on, 226–227
 continuing education, 328–329
 culture and morality, 425–426
 death in family context, 550–553
 death of spouse or partner, 550–552
 depression, 525–526
 emotions, 438–439
 empty nest, 486
 expertise, developing, 253–254
 in family, 483–490
 formal operations, growth beyond, 227–228
 gender differences, 392–396
 gender roles, 392–394
 grandparenthood, 486–487
 health and wellness, 155–157
 intelligence, 279–286
 intimacy, 356
 language development, 327–329
 literacy, 328
 marriage, 483–484
 memory, 253–261
 midlife crisis, 357–358
 midlife generativity, 356–356
 moral action, 428
 moral development, 425–429
 moral emotion, 426, 427–428
 moral intuition, 426, 427–428
 moral reasoning, 425
 new parenthood, 484–485
 path to, 355–356
 personality, 349–361
 psychological disorders, 525–526
 psychosocial development, 355–357
 relationships and adult
 development, 461, 462–463
 religion and spirituality, 428–429
 reproductive system, 153–155
 romantic relationships, 458–460
 self-concept, 349–352
 self-esteem, 349–352
 sexuality, 394–396
 social cognition in, 405–406
 social networks, 458
 stress, 525
Affection phase of dating, 456
Affordances, 167
Age-associated hypogonadism. *See* Andropause
Age differences
 depression and, 525–526
 self-esteem and, 349–350
Age effects, 22
Age grade, 6
Ageism, 350
Agency, 367
Age norms, 7, 504
Age of viability, 96
Age-related macular degeneration (AMD), 191–192
Aggressive behavior, genetics and, 78
Aging. *See also* Older adults
 brain and, changes in, 151–153
 cognitive skills and, 228–229
 damage or error theories of, 159–160
 defined, 5
 dementia and, 526–530
 emotions and, 438–439
 health and wellness, 155–157
 memory and, 255–260
 nature–nurture issue, 160
 parents, caring for, 489–490
 problem solving and, 260–261
 programmed theories of, 157, 158–159
 reproductive system and, changes in, 153–155
 successful, 158, 160–161, 361
Agreeableness, 335, 336
AIDS dementia complex (ADC), 529
Alcohol abuse. *See* Substance abuse
Alcohol consumption, prenatal
 exposure to, 101–103
Alcohol-related dementia, 529
Alphabetic principle, 318
Altruistic motivations, in infants, 413
Alzheimer's disease, 527–528
 causes and contributors, 527–528
 genetics and, 68, 78
 prevention and treatment, 528
American family of today, characteristics of, 469
Amnesia
 anterograde, 236
 retrograde, 234
Amniocentesis, 71
Amnion, 93
Amoral, 412
Anal stage, 37
Analytic component, 271

- Androgenized female, 376
 Androgens, 130
 Androgyny, 393–394
 Andropause, 155
 Anencephaly, 94
 Anger, data collection methods for measuring, 17
 Anorexia nervosa, 518–519
 A-not-B error, 214
 Anoxia, 113
 Anterograde amnesia, 236
 Anticipatory grief, 541
 Antidepressant drugs, prenatal exposure to, 103
 Antiepileptic drugs, prenatal exposure to, 103
 Anti-Müllerian hormone, 154
 Antioxidant, 159–160
 Antisocial behavior
 adolescents, 420–424
 bullying, 423, 424
 coercive family environments, 421, 422
 conduct disorder, 420
 defined, 408
 Dodge's social information-processing model, 421

Summary of Physical, Cognitive, Personal, and Social Development Across the Life

• Period

• Physical Development

• Cognitive Development

Infant (Birth to 2 years)

Physical growth is rapid; neuronal connections in the brain rapidly expand and undergo pruning. Reflexes are followed by more voluntary motor control; walking occurs at 1 year. Functioning senses are available at birth; early ability to understand sensory information is impressive.

Sensorimotor period: Through senses and actions, infants acquire symbolic capacity and object-permanence concept. Cooing and babbling are followed by one-word and two-word sentences. Learning capacity and recognition memory are present from birth; recall improves with age.

Preschool child (2 to 5 years)

Rapid brain development continues. Coordination and fine motor skills improve. Perceptual abilities are good; attention span is short.

Preoperational stage: Thought is guided by perceptions rather than logic. Symbolic capacity (language acquisition and pretend play) blossoms. There are some limits in information-processing capacity, use of memory strategies, and reasoning.

School-age child (6 to 10 years)

Physical growth is slow; motor skills gradually improve. Children have increased ability to control attention and use the senses intelligently.

Concrete operations stage: Logical actions are carried out in the head; children master conservation. They also master fine points of language; memory strategies and problem-solving with concrete objects improve. IQs begin to stabilize.

Adolescent (10 to 18 years)

Adolescents experience a brain spurt, a growth spurt, and attainment of sexual maturity. Physical functioning improves. Concern with body image is common.

Formal operations stage: Hypothetical and abstract thought emerge; scientific problem-solving improves. Attention and information-processing skills continue to improve, linked to brain growth spurt.

Emerging and young adult (18 to 39 years)

This is the time of peak functioning, but a gradual decline in physical and perceptual capacities begins.

Brain development is completed, improving executive control; intellectual functioning is at a peak and mostly stable.

Middle-aged adult (40 to 64 years)

Physical declines become noticeable (e.g., some loss of endurance, need for reading glasses). Chronic illness increases. Menopause and male andropause occur.

Sophisticated cognitive skills develop, especially in areas of expertise. There is the possibility of growth beyond formal thought and gains in knowledge. Fluid intelligence may begin to decline, but crystallized knowledge is maintained well. Often a peak time for creative achievement.

Older adult (65 years and older)

Physical decline continues; more chronic disease, disability, and sensory impairment are common; and reaction time slows. But there is also continued plasticity and reorganization of the brain in response to intellectual stimulation.

Declines in cognition are common but not inevitable. Slower learning, memory problems, declines in IQ and problem-solving may occur, especially if skills are rarely exercised, but crystallized intelligence survives longer than fluid.

• Personal Development

Infants acquire a sense of self, self-recognition, and early precursors of theory of mind such as joint attention. They gain awareness of gender identity and experience Erikson's conflict of trust *versus* mistrust. Temperament becomes a basis for later personality.

Concrete, physical self-concept. Understanding of gender and gender-stereotyped behaviors are rapidly acquired. Children master the theory of mind concept that people can have false beliefs; they have a conscience as early as 2 years but also a self-serving morality. They experience Erikson's conflicts of *autonomy versus shame* and *initiative versus guilt*.

Self-concept includes psychological traits. Personality "gels." Strong gender typing occurs. Children have a mostly pre-conventional morality centered on consequences for themselves. Much social comparison occurs during Erikson's conflict of *industry versus inferiority*.

Adolescents have a more abstract, differentiated, and integrated self-concept. They incorporate sexuality into their gender role. Conventional moral reasoning reflects internalization of society's rules. The conflict of *identity versus role confusion* is prominent.

Identity continues to be defined. Some shift from conventional to post-conventional moral reasoning. There is increased confidence. Some adopt more traditional gender roles with new parenthood. Personality matures and becomes fairly stable. The conflict of *intimacy versus isolation* is addressed.

Personality continues to be stable; for some, midlife questioning and a shift toward androgyny may occur. There may be a conflict of *generativity versus stagnation*.

Most maintain their characteristic personality traits, self-esteem, and life satisfaction. Many grow as they resolve conflict of *integrity versus despair*.

• Social Development

Infants are social beings from birth. They become attached to a caregiver at about 7 months; separation and stranger anxiety follow. They increase their social skills by interacting with parents and gain the capacity for simple pretend play. There is a family-centered lifestyle.

The parent-child relationship is still central in the child's social world. Increased social cognitive abilities allow more cooperation with peers; social pretend play blossoms. First exposure to schooling occurs.

Involvement with same-sex peers increases; close friendships form. Role-taking skills advance. Play centers on organized games with rules. School and the media are important socialization agents.

Peak peer involvement and conformity occur. More emotionally intimate friendships are followed by dating relationships. Parent-child relationship becomes more equal; autonomy increases. School and career exploration prepare youth for adult roles.

Social networks continue to expand; committed romantic relationships develop. Most establish families and assume roles as spouses and parents. Careers are launched; job switching is common. This is a period of much life change and stress; there is a high risk of divorce and psychological problems.

The nest empties and the grandparent role is often added to existing roles. Responsibility is taken for younger and older generations. Career is more stable, and peak success is attained. Family and work roles dominate.

Close ties to family and friends are maintained to optimize socioemotional well-being; loneliness is rare. Generally there is a smooth adjustment to retirement and continuity of social activities. For women especially, loss of spouse is normative and requires adjustment.
