To the students who have inspired us

Brief Contents

- 1** Understanding Life-Span Human Development 3
- 2** Theories of Human Development 31
- 3** Genes, Environment, and Development 59
- 4** Prenatal Development and Birth 89
- 5** Body, Brain, and Health 127
- 6** Sensation, Perception, and Action 165
- 7** Cognition 201
- 8** Memory and Information Processing 233
- 9** Intelligence and Creativity 265
- 10** Language and Education 299
- 11** Self and Personality 333
- 12** Gender Roles and Sexuality 365
- 13** Social Cognition and Moral Development 399
- 14** Emotions, Attachment, and Social Relationships 433
- 15** The Family 467
- 16** Developmental Psychopathology 501
- 17** The Final Challenge: Death and Dying 533
- Appendix: Careers in Human Development 562

Contents

1 Understanding Life-Span Human Development 3

- 1.1 How Should We Think about Development?** 4
 - Defining Development 4
 - Conceptualizing the Life Span 5
 - Framing the Nature–Nurture Issue 9
- 1.2 What Is the Science of Life-Span Development?** 10
 - Goals and Uses of Studying Development 11
 - Early Beginnings 11

- The Modern Life-Span Perspective 12
- Exploration 1.1** Growing Up Online 13
- 1.3 How Is Development Studied?** 14
 - The Scientific Method 14
 - Sample Selection 15
 - Data Collection 15
 - The Case Study, Experimental, and Correlational Methods 16
 - Exploration 1.2** Data Collection Methods in Action: Measuring Anger 17
 - Developmental Research Designs 21
 - Exploration 1.3** Millennials and Boomers: Cohort Effects 23
 - Engagement 1.1** Recognizing Research Strategies 25
- 1.4 What Special Challenges Do Developmental Scientists Face?** 26
 - Conducting Culturally Sensitive Research 26
 - Protecting the Rights of Research Participants 27
 - Chapter Summary** 28
 - Key Terms** 29

2 Theories of Human Development 31

- 2.1 Developmental Theories and the Issues They Raise** 32
 - Nature–Nurture 33
 - Engagement 2.1** Where Do You Stand on Major Developmental Issues? 33
 - Activity–Passivity 34
 - Continuity–Discontinuity 34
 - Universality–Context Specificity 35
- 2.2 Psychoanalytic Theory** 35
 - Freud’s Legacy 36
 - Exploration 2.1** Freud and Erikson: Notes on Sexual Risk Behavior 38

Erikson's Psychosocial Theory 38

Strengths and Weaknesses 39

2.3 Learning Theories 40

Watson: Classical Conditioning 41

Skinner: Operant Conditioning 41

Bandura: Social Cognitive Theory 43

Exploration 2.2 Learning Theorists: Notes on Sexual Risk Behavior 45

Strengths and Weaknesses 46

2.4 Piaget: Cognitive Developmental Theory 46

Constructivism 47

Stages of Cognitive Development 47

Strengths and Weaknesses 48

Exploration 2.3 Piaget: Notes on Sexual Risk Behavior 48

Other Perspectives on Cognitive Development 49

2.5 Systems Theories 50

Bronfenbrenner's Bioecological Model 50

Strengths and Weaknesses 52

Exploration 2.4 Bronfenbrenner: Notes on Sexual Risk Behavior 53

2.6 Theories in Perspective 53

Application 2.1 Using Developmental Theories to Reduce Sexual Risk Behavior among Teens 55

Chapter Summary 56

Key Terms 57

3 Genes, Environment, and Development 59

Chromosome Abnormalities 68

Genetic Diseases and their Diagnosis 69

Application 3.1 Prenatal Detection of Abnormalities 71

3.3 Studying Genetic and Environmental Influences 72

Twin, Adoption, and Family Studies 73

Estimating Influences 73

Molecular Genetics 75

3.4 Selected Behavioral Genetics Findings 76

Intellectual Abilities 76

Temperament and Personality 77

Psychological Disorders 78

The Heritability of Different Traits 78

3.5 Gene–Environment Interplay 79

Gene–Environment Interactions 80

Gene–Environment Correlations 80

Exploration 3.1 Differential Susceptibility: Orchids and Dandelions 81

Epigenetic Effects on Gene Expression 83

Controversies Surrounding Genetic Research 85

Chapter Summary 86

Key Terms 87

3.1 Evolution and Species Heredity 60

Engagement 3.1 Genetic Influence: What is Myth, What is Reality? 61

3.2 Individual Heredity 62

The Genetic Code 62

From Genotype to Phenotype 65

Mechanisms of Inheritance 66

Mutations 67

Copy Number Variations 68

4 Prenatal Development and Birth 89

4.1 Prenatal Development 90

Conception 90

Prenatal Stages 92

4.2 The Prenatal Environment and Fetal Programming 98

Teratogens 99

The Mother's State 107

Application 4.1 Growing Healthier Babies 108

The Father's State 110

Engagement 4.1 Understanding Effects of Teratogens 111

4.3 The Perinatal Environment 111

Possible Hazards 113

The Mother's Experience 114

The Father's Experience 117

4.4 The Neonatal Environment 118

Breast or Bottle? 118

Identifying At-Risk Newborns 119

Risk and Resilience 122

Exploration 4.1 Skills for Parenting Tiny Babies 123

Chapter Summary 124

Key Terms 125

5 Body, Brain, and Health 127

5.1 Building Blocks of Growth and Lifelong Health 128

The Endocrine System 129

The Brain and Nervous System 131

Principles of Growth 132

A Life-Span Developmental Model of Health 132

5.2 The Infant 133

Rapid Growth 134

Newborn Capabilities 134

Health and Wellness 137

5.3 The Child 137

Brain Lateralization 138

Physical Behavior 138

Health and Wellness 139

5.4 The Adolescent 142

The Adolescent Brain: What's Going On in There? 142

The Growth Spurt 143

Sexual Maturation 143

Exploration 5.1 Sports and Brain Damage 144

Health and Wellness 148

5.5 The Adult 151

The Changing Brain 151

The Changing Reproductive System 153

Health and Wellness 155

Theories of Aging: Why Do We Age and Die? 157

Exploration 5.2 Want to Live to Be 100? 158

Successful Aging 160

Chapter Summary 162

Key Terms 163

6 Sensation, Perception, and Action 165

6.1 Perspectives on Perception 166

6.2 The Infant 167

Vision 168

Hearing 172

Application 6.1 Aiding Infants and Children with Hearing Impairments 174

The Chemical Senses: Taste and Smell 175

The Somaesthetic Senses 176

Influences on Early Perceptual Development 177

6.3 The Child 179

Locomotion: The Coupling of Perception and Action 179

Exploration 6.1 Grasping and Reaching 182

Integrating Sensory Information 182

Advances in Attention 183

6.4 The Adolescent 185

Attention 185

Hearing 186

Another Look at the Chemical Senses 187

Engagement 6.1 Are You a Supertaster? 188

6.5 The Adult 190

Vision 190

Hearing 193

Exploration 6.2 Aging Drivers 194

Aging of the Chemical Senses 196

Application 6.2 Aiding Adults with Hearing Impairments 196

Changes in the Somaesthetic Senses 197

The Adult in Perspective 197

Chapter Summary 198

Key Terms 199

7 Cognition 201

7.1 Piaget's Constructivist Approach 202

What Is Intelligence? 203

How Does Intelligence Develop? 203

Piaget's Contributions 204

Challenges to Piaget 205

A Modern Take on Constructivism 206

7.2 Vygotsky's Sociocultural Perspective 207

Culture and Thought 207

Social Interaction and Thought 208

Tools of Thought 208

Evaluation of Vygotsky 209

Application 7.1 Improving Cognitive Functioning 210

7.3 Fischer's Dynamic Skill Framework 211

Comparison to Piaget and Vygotsky 212

7.4 The Infant 213

The Development of Object Permanence 213

The Emergence of Symbols 215

7.5 The Child 216

Preschoolers: Symbolic Thinking 216

Exploration 7.1 Can There Really Be a Santa Claus? 217

Elementary-Aged Children: Logical Thinking 219

7.6 The Adolescent 220

Emergence of Abstract Thought 220

Progress Toward Mastery of Formal Operations 222

Engagement 7.1 How Well Do You Understand Piaget's Stages of Cognitive Development? 223

Implications of Formal Thought 224

7.7 The Adult 226

Limitations in Adult Cognitive Performance 226

Growth Beyond Formal Operations? 227

Aging and Cognitive Skills 228

Chapter Summary 229

Key Terms 231

Preface

This book is about the development of human beings—from their start as fertilized eggs to their dying days. It explores regularities as well as differences in development, and it asks fundamental questions about why we humans develop as we do. This ninth edition of *Life-Span Human Development* retains four core features valued by students and instructors over the years: (1) our unique integrated topical-chronological approach, (2) a presentation that is both research-based and relevant to students, (3) an emphasis on ideas—on the different theoretical perspectives that guide thinking about human development and research, and (4) an in-depth exploration of the all-important nature–nurture issue. In addition, we introduce exciting new topics and controversies in life-span human development, update coverage throughout, and offer new pedagogical features and supplements to enhance the teaching-learning process.

Topical and Chronological Approach

The most distinctive feature of this book is its unique integrated topical-chronological approach. Almost all other life-span development textbooks adopt a chronological or “age-stage” approach, carving the life span into age ranges and describing the prominent characteristics of individuals within each age range. In contrast, we adopt a topical approach for the overall organization of the book blended with a chronological approach within chapters. Each chapter focuses on a domain of development, such as cognition, personality, or social relationships, and traces developmental trends and influences in that domain from infancy to old age. At the same time, each chapter highlights the special qualities of different age groups through major sections on infancy, childhood, adolescence, and adulthood.

Why Topical?

Why have we fought the tide? Like many other instructors, we have typically favored topically organized textbooks when teaching child, adolescent, or adult development. As a result, it seemed natural to extend that same topical approach to the whole life span. It also bothered us that chronologically organized texts often have to repeat themselves to remind readers of where development left off in an earlier age period that was covered much earlier in the book.

More important, a topic-by-topic organization conveys the flow of development in each area—the systematic, and often dramatic, transformations we undergo as well as the ways in which we continue to be the same individuals. The topical approach also

helps us emphasize the processes behind development. Finally, a topical approach captures the spirit of a life-span perspective on development: It encourages us—indeed obliges us—to view each period of life in relation to what comes before and what comes after. In chronologically organized textbooks, many topics are taken up only in connection with the age group to which they seem most relevant and are then dropped. A topical organization stimulates us to ask intriguing questions we might otherwise not ask, such as these about close relationships:

- What do infants’ attachments to their parents have in common with, and how do they differ from, attachments between childhood friends or between adult romantic partners?
- Do securely attached infants later have a greater capacity to form and sustain close relationships than infants whose early social experiences are less favorable?
- What are the consequences at different points in the life span of lacking a close relationship?

Attachments are important throughout the life span and evolve over the life span; a topical organization helps make that clear.

Why Chronological?

We also appreciate the strengths of the chronological approach, particularly its ability to portray the whole person in each period of the life span. For this reason, we integrated the age-stage approach with the topical organization, aiming to have the best of both worlds.

Each topical chapter contains major sections on infancy, childhood, adolescence, and adulthood. These age-stage sections call attention to the distinctive qualities of each phase of life and make it easier for students to find material on an age period of particular interest to them. In short, we believe that our integrated topical-chronological approach gives students exactly what they deserve: an understanding of the flow of life-span development in particular areas and the factors influencing it along with an appreciation of the flavor of each developmental period.

Adaptability of the Integrated Topical-Chronological Approach

Even though links across chapters are noted throughout the book, instructors who are teaching condensed courses or who are otherwise pressed for time can omit a chapter without fear of rendering other chapters incomprehensible. For example:

- A cognitively oriented course might omit one or more of the socially oriented chapters (Chapters 11, 12, 14, 15, 16, and 17).

- A socially oriented course might omit one or more of the cognitively oriented chapters (Chapters 6, 7, 8, 9, and 10).

Moreover, this approach gives instructors the flexibility to cover infancy, childhood, and adolescence in the first portion of the course, if they prefer, and to save the material on adulthood for the end.

Research-Oriented and Relevant Coverage

We have worked hard to create a text that is rigorous yet readable—research-oriented yet “real” to students. The ninth edition of *Life-Span Human Development* tackles complex theoretical controversies and presents both classic and contemporary research from multiple disciplines. We aim to make developmental science accessible and relevant to students’ lives and career goals but we do not “dumb it down.”

Students need to understand how we know what we know about development—to appreciate the research process. With that in mind, we describe illustrative studies and present data in graphs and tables, and we cite the authors and dates of publication for a large number of books and articles, all fully referenced in the bibliography at the end of the book. Some students may wonder why they are there. It is because we are committed to the value of systematic research, because we are bound to give credit where credit is due, and because we want students and their professors to have the resources they need to pursue their interest in a topic during and after the course.

We also appreciate that solid scholarship is of little good to students unless they want to read it, can understand it, and see its relevance. To make the material more “real,” we clarify developmental concepts through examples, analogies, and visuals; we connect topics in the text to topics in the news, and highlight the practical implications of research findings. This book contains a wealth of applied material relevant to students’ current and future roles as parents, teachers, psychologists, health professionals, and other human service professionals. It helps students see that major theories of human development do not just guide researchers but can guide them—for example, in raising, educating, or treating infants, children, or adolescents, understanding themselves and making important life decisions, appreciating that their parents and grandparents are also developing persons, and coping with developmental challenges.

Theoretical Grounding

Theories are critical in any science, guiding scientists on what to study, how to study it, and how to interpret their findings. We want students to leave the study of life-span human development with more than facts alone; we want them to appreciate the major issues of interest to developmental scientists and how the leading theories in the field have shaped our thinking about development. Most important, we want students to learn to use

these theoretical perspectives to guide their thinking and action when they encounter a question about human development outside the course.

With this in mind, we have devoted Chapter 2 to laying out in broad strokes the psychoanalytic, learning, cognitive developmental, and systems perspectives on human development. In later chapters, we draw on these and other perspectives as we explore different aspects of development; see, for example, treatment of the dynamic systems view of motor development in Chapter 6; Jean Piaget’s groundbreaking cognitive-developmental theory in comparison to Lev Vygotsky’s sociocultural perspective and Kurt Fischer’s dynamic skill theory in Chapter 7; the information-processing perspective in Chapter 8; alternative views of intelligence in Chapter 9; nativist, learning, and interactionist theories of language development in Chapter 10; alternative theories of personality development in Chapter 11; theories of gender identity in chapter 12; theories of moral development, including evolutionary theory, in Chapter 13; attachment theory in Chapter 14; and family systems theory in Chapter 15.

Nature–Nurture Theme

Finally, we want students to gain a deeper understanding of the nature–nurture issue and of the many interacting forces affecting the developing person. We want students to appreciate that human development is an incredibly complex process that grows out of transactions between a changing person and a changing world and out of dynamic relationships among biological, psychological, and social influences. No contributor to development—a gene, a temperament, a parent, a culture—acts alone and is unaffected by other influences on development.

We introduce the nature–nurture issue in Chapter 1, compare theorists’ stands on the issue in Chapter 2, and give the issue extended treatment in Chapter 3 on genes and environment. Each subsequent chapter includes one or more illustrations of the intertwined contributions of nature and nurture to development and aging, and Chapter 16 looks at their roles in the development of psychological disorders. Along the way, we describe exciting studies that bring home what it means to say that genes and environment interact to influence development—as when genes predisposing an individual to depression combine with stressful life events to produce depression. We also illustrate the many ways in which genes and environment affect one another—for instance, ways in which genetic makeup influences the experiences an individual has, and ways in which experience can affect the activation or expression of genes in ways that alter development.

In this edition, we have tried to convey how much more today’s developmental scientists know about the intricacies of nature and nurture. We have incorporated new discoveries about genes, hormones, neural networks, and other biological forces in development. We have also strengthened coverage of contextual influences on development—ways in which developmental pathways can differ, sometimes dramatically, depending on the individual’s family, school, neighborhood, social class, and subcultural

and cultural contexts. Most important, we illuminate the interplay between biological and environmental influences that is at the heart of the developmental process—and that makes it difficult to leave this course as either an extreme nativist or an extreme environmentalist.

Organization of the Text

Core Concepts: Chapters 1 to 4

The book begins by orienting students to the life-span perspective on human development and to approaches to the scientific study of development (Chapter 1), as well as to the central issues and theoretical perspectives that have dominated the field (Chapter 2). Next it explores developmental processes in some depth, examining genetic and environmental influences on development (Chapter 3) and then focusing on important environmental influences during the critical prenatal and perinatal periods (Chapter 4).

Development of Basic Human Capacities: Chapters 5 to 10

Chapters on the growth and aging of the body and nervous system and on health (Chapter 5) and on the development of sensory, perceptual, and motor capacities (Chapter 6) launch our examination of the development of basic human capacities. Chapter 7 turns to cognitive development, starting with the influential theory of Jean Piaget and then moving on to Vygotsky's and Fischer's perspectives; Chapter 8 views memory and problem solving from an information-processing perspective; Chapter 9 highlights the psychometric approach to cognition, exploring individual differences in intelligence and creativity; and Chapter 10 explores language development and the roles of language, cognition, and motivation in educational achievement.

Development of Self in Society: Chapters 11 to 17

The next three chapters concern the development of the self: changes in self-conceptions and personality and their relationships to vocational identity and development (Chapter 11); in gender roles and sexuality (Chapter 12); and in social cognition, morality, and prosocial and antisocial behavior (Chapter 13). The self is set more squarely in a social context as we trace life-span changes in attachment relationships (Chapter 14) and in roles and relationships within the family (Chapter 15). Finally, we offer a life-span perspective on developmental problems and disorders (Chapter 16) and examine how humans of different ages cope with dying and bereavement (Chapter 17).

Getting the Big Picture

To help students pull together the “big picture” of life-span human development at the end of the course, we remind students of some of the major themes of the book at the end of

Chapter 17 and offer a chart inside the back cover that summarizes major developments in each of seven periods of the life span. Finally, an appendix, *Careers in Human Development*, lays out possibilities for translating an interest in human development into a career in research, teaching, or professional practice.

Engaging Students

The ninth edition provides learning objectives for each major numbered section and continues to use a variety of other strategies to increase students' engagement with the material and, more importantly, their learning.

Learning Objectives

Each major numbered section starts with two to five learning objectives to focus students' reading and give it purpose.

Checking Mastery Questions

To encourage students to actively check their command of the material as they progress through the chapter, we pose two to four Checking Mastery questions at the end of each numbered chapter section. Instructors can find the answers in the *Instructor's Manual* and can decide whether they want to use the questions as assignments or test items or give the answers to students so that they can test their own mastery.

Making Connections Questions

Also at the end of each major section, Making Connections questions invite students to reflect on the material—to weigh in on a debate in the field, evaluate the material's implications for public policy, apply the material to a case example, or explore the material's relevance to their own development. These questions can serve as the basis for writing assignments, essay questions, or class discussions.

Boxes

The topics we address in boxes sprinkled throughout the chapters were chosen because they struck us as both interesting and important; they are not fluff to be skipped! This edition continues to include three kinds of boxes, each with a different purpose:

- **Exploration boxes** allow more in-depth investigation of research or thinking on a topic.
- **Application boxes** examine how knowledge has been applied to optimize development.
- **Engagement boxes** provide opportunities for students to engage personally and actively with the material—to assess their own knowledge, beliefs, traits, and attitudes by completing personality scales, test items, surveys, and short quizzes.

To see the titles of these boxes, scan the table of contents.

Content Updates in This Edition

As always, the book has been thoroughly updated to convey the most recent discoveries and insights developmental scientists have to offer. We have added some exciting new topics and revised and updated coverage of many other topics for this edition. A few examples:

Chapter 1. Understanding Life-Span Human Development

- New illustrations of how the digital age may be affecting development
- Discussion of the criticism that most psychological research is about “WEIRD people” (such as American college students) who are not representative of people around the globe—and a call for understanding development in its cultural context

Chapter 2. Theories of Human Development

- Application of each major theoretical perspective to understanding and changing sexual risk behavior in adolescence
- A deeper dive into Bronfenbrenner’s bioecological systems theory

Chapter 3. Genes, Environment, and Development

- Coverage of the differential susceptibility hypothesis and research suggesting that so-called risk genes that predispose some children to psychological problems in unsupportive environments may also help them benefit from supportive environments
- More on epigenetic effects of the environment on gene expression and examples of key findings and their implications

Chapter 4. Prenatal Development and Birth

- The latest research on fetal programming in response to the prenatal environment and its implications for later health and development
- New studies of the effects of exposure to radiation, pollution, and maternal stress on prenatal development
- A box on parenting tiny, low birth weight babies

Chapter 5. Body, Brain, and Health

- A timely discussion of sports-related concussions and brain development
- The latest on centenarians and why they live so long

Chapter 6. Sensation, Perception, and Action

- New twists in the study of how infants learn to avoid drop-offs
- Discussion of our limited capacity for multitasking
- An updated discussion of driving in later life

Chapter 7. Cognition

- Introduction of the theories of Piaget, Vygotsky, and Fischer and reminders of their themes in the chapter’s survey of milestones in cognitive development
- New attempts to relate theories to classroom learning

Chapter 8. Memory and Information Processing

- Discussion of cases of amnesia to bring home the importance of memory processes in development
- More on the neural bases of memory

Chapter 9. Intelligence and Creativity

- A new report on the implications of socioeconomic status for IQ and changes in intellectual abilities with age
- Research on why even intelligent people sometimes make “dumb” decisions

Chapter 10. Language and Education

- The latest on bilingualism and its implications for cognitive development and aging
- A reworked discussion of nature and nurture in language acquisition, including a discussion of how the quantity and quality of speech to young language learners affects their progress

Chapter 11. Self and Personality

- A new box on culture and personality to supplement the chapter’s contrasts of development in individualistic and collectivist cultures
- Recent multicultural research on changes in self-esteem and personality in adulthood

Chapter 12. Gender Roles and Sexuality

- An updated account of significant similarities and differences between the sexes
- A new section on transgender youth
- An exploration of sexual assaults on college campuses

Chapter 13. Social Cognition and Moral Development

- Exciting research on the roots of morality in infancy and early childhood, as illustrated by a sense of fairness, evaluation of good guys and bad guys, and a motivation to help
- A look at moral thinking in India and the role of religious and spiritual beliefs in moral thinking

Chapter 14. Emotions, Attachment, and Social Relationships

- More on the quality of adolescents' attachments to parents, friends, and romantic partners
- New coverage of dating among LGBT youth
- A box examining loneliness as a public health threat through the life span

Chapter 15. The Family

- More on the family as a system and the importance of supportive coparenting
- Research on the implications of helicopter parenting for the development of college students
- Challenges facing older adults in a rapidly changing China

Chapter 16. Developmental Psychopathology

- Highlights of the Great Smoky Mountains Study of the origin and course of psychological disorders.
- Research on identifying through brain imaging children at risk for depression and treating preschool children suffering from depression
- A new section on how adolescent problem behavior grows out of the normal developmental tasks of adolescence

Chapter 17. The Final Challenge: Death and Dying

- Coverage of the Brittany Maynard right-to-die case
- Recent research questioning findings of widespread resilience among bereaved adults
- An exploration of bereavement among partners of gay men with HIV/AIDS

Chapter Organization

The chapters of this book use a consistent format and contain the following:

- A chapter outline that orients students to what lies ahead
- A chapter opener that engages student interest

- Introductory material that lays out the plan for the chapter and introduces key concepts, theories, and issues relevant to the area of development to be explored
- Learning objectives at the start of each major numbered section
- Developmental sections (in Chapters 5–17) highlighting four developmental periods: infancy, childhood, adolescence, and adulthood
- Checking Mastery and Making Connections questions after each major section
- A Chapter Summary reviewing the chapter's main messages
- A Key Terms section listing new terms introduced in the chapter in the order in which they were introduced and with the page number on which they were introduced. Printed in blue, bold font, **key terms** are defined when they are first presented in a chapter and are included in the glossary at the end of the book.

Supplements

The ninth edition of *Life-Span Human Development* is accompanied by an outstanding array of supplements for both the instructor and the student that are intended to enrich the student's learning experience inside and outside the classroom. All the supplements have been thoroughly revised and updated. We invite instructors and students to examine and take advantage of the teaching and learning tools available.

Online Instructor's Manual

The *Instructor's Manual* contains chapter-specific outlines; a list of print, video, and online resources; and student learning objectives. The manual has a special emphasis on active learning, offering suggested student activities and projects for each chapter.

Cengage Learning Testing, Powered by Cognero®

Cengage Learning Testing Powered by Cognero® is a flexible, online system that allows you to import, edit, and manipulate content from the text's test bank or elsewhere, including your own favorite test questions; create multiple test versions in an instant; and deliver tests from your learning management system, your classroom, or wherever you want.

Online PowerPoint® Lecture Slide Decks

The *Online PowerPoint® Lecture Slides* are designed to facilitate an instructor's use of PowerPoint in lectures. Slides are provided for each chapter; they contain main concepts with figures, graphics, and tables to visually illustrate main points from the text. Slides have been designed to be easily modifiable so instructors are able to customize them with their own materials.

MindTap

MindTap for *Life-Span: Human Development* creates a unique learning path that fosters increased comprehension and efficiency of learning. It engages students and empowers them to produce their best work—consistently. In MindTap, course material is seamlessly integrated with videos, activities, apps, and more.

In MindTap, instructors can:

- Control the content. Instructors select what students see and when they see it.
- Create a unique learning path. In MindTap, your textbook is enhanced with multimedia and activities to encourage and motivate learning and retention, moving students up the learning taxonomy. Materials can be used as is or modified to match an instructor's syllabus exactly.
- Integrate their own content. Instructors can modify the MindTap Reader using their own documents or by pulling from sources like RSS feeds, YouTube videos, websites, Google docs, and more.
- Follow student progress. Powerful analytics and reports provide a snapshot of class progress, the time students spend logging into the course, and information on assignment completion to help instructors assess levels of engagement and identify problem areas.

Acknowledgments

We would like to express our continuing debt to David Shaffer of the University of Georgia for allowing his child development textbook to inform the first and second editions of this book.

Credit for excellent supplementary materials goes to Bradley Caskey, who revised the *Instructor's Manual with Test Bank*.

Producing this book required the joint efforts of Cengage Learning and SPi Global. We thank our product manager, Star Barruto, for her leadership of the project, and Stefanie Chase, our content developer, for her superb efforts to keep the project moving, support us cheerfully throughout, and make this edition the most visually appealing and pedagogically effective edition yet. We thank Phil Scott at SPi Global for outstanding management of the book's production and Padmarekha Madhukannan and Carly Bergey for photo research. We are grateful, as well, for the able assistance of Ruth Sakata Corley, production project manager; Vernon Boes, art director; and Deanna Ettinger, IP analyst. We also appreciate the strong support of James Finlay, marketing manager.

We remain deeply indebted to sponsoring editors past—to C. Deborah Laughton, who insisted that this project be undertaken, and to Vicki Knight, who skillfully shepherded the first edition through its final stages and oversaw the second edition. Finally, Patrick Sheehan deserves thanks for his help with referencing, and Corby Rider deserves appreciation for his support and understanding of his workaholic mother.

Reviewers

We are very grateful to nine “cohorts” of reviewers for the constructive criticism and great suggestions that have helped us make each edition of this book better than the one before:

About the Authors

CAROL K. SIGELMAN is professor and chair of psychology at George Washington University, where she also served as an associate vice president for 13 years. She earned her bachelor's degree from Carleton College and a double-major doctorate in English and psychology from George Peabody College for

Teachers, now part of Vanderbilt University. She has been on the faculty at Texas Tech University, Eastern Kentucky University (where she won her college's outstanding teacher award), and the University of Arizona. She has taught courses in child, adolescent, adult, and life-span development and has published research on such topics as the communication skills of individuals with developmental disabilities, the development of stigmatizing reactions to children and adolescents who are different, and children's emerging understandings of diseases and psychological disorders. She is a Fellow of the Association for Psychological Science. For fun, she enjoys hiking, biking, and discovering good movies.

ELIZABETH A. RIDER is professor of psychology and associate provost at Elizabethtown College in Pennsylvania. She has also been on the faculty at the University of North Carolina at Asheville. She earned her undergraduate degree from Gettysburg College and her doctorate from Vanderbilt

University. She has taught courses on child and life-span development, women and gender issues, applied developmental psychology, and genetic and environmental influences on development. She has published research on children's and adults' spatial perception, orientation, and ability to find their way. Through a grant from the Pennsylvania State System for Higher Education, she studied factors associated with academic success. The second edition of her text on the psychology of women, *Our Voices*, was published by John Wiley & Sons in 2005. When she is not working, her life revolves around her son and a fun-loving springer spaniel.

1.4 What Special Challenges Do Developmental Scientists Face?

Conducting Culturally Sensitive Research
Protecting the Rights of Research Participants

In a middle-class neighborhood in Los Angeles, California, 8-year-old Ben’s father asks him to get his jacket so they can leave the house. Ben ignores him, trying to put his feet into shoes that are already tied. Ben’s father, expressing his annoyance, tells Ben again to get his jacket. Instead, Ben sits down and says, “Seriously, it’s like you’re always a control freak,” then asking his father to untie his shoes and, that accomplished, asking his father to tie them—after getting Ben’s jacket for him. After more resistance from Ben, Ben’s father finally insists, “No, son, *go* get your own jacket and *you* tie your shoes and let’s *go*” (Ochs & Izquierdo, 2009, p. 400). The boy finally goes for his jacket.

This sounds like pretty typical child behavior until we contrast it with the behavior of Matsigenka children in Peru. The Matsigenka live by fishing, hunting, and growing vegetables and children contribute to the work of the family and community from an early age. Thus 6-year-old Yanira, invited to travel down the Amazon with another family from her village, pulls her weight the whole time without ever being asked—stacking and carrying leaves to be used for roofing, sweeping sand off the sleeping mats, fishing for crustaceans and cleaning and boiling them to serve to the group, taking care of her own needs without prompts or help. Like other children in her culture, she probably experimented with heating her own food on the fire as a toddler—expected to learn, even if by burning herself, how to do it well. She was probably told folk stories about characters whose laziness had terrible consequences. By the age of 6 or 7, Matsigenka girls are cooking alongside their mothers while boys are hunting and fishing with their fathers.

Anthropologists Elinor Ochs and Carolina Izquierdo (2009) have been struck by these and other examples of how children in many societies of the world are far more responsible and self-sufficient far earlier in life than children in the United States are. Their observations of family life suggest that American parents, rather than expecting and counting on children to contribute to the family's work, load their children with toys and perform what in other cultures would be viewed as basic self-care tasks such as shoe tying for their children—or at least prod them at every step of the way (see Arnold, Graesch, & Ochs, 2012).

This book is about the development of humans like Ben and Yanira—and yes, you—from conception to death. The lives of Ben and Yanira raise questions: What will be the later effects on them of their very different childhood experiences? Will Yanira grow up to be more responsible and independent as an adult than Ben because she was expected to learn self-care and responsibility to other people from an early age, or will Ben benefit from all the help and guidance his parents are providing him? How much can human development be bent this way or that depending on a person's experiences in his or her family and culture?

We address questions like these and others in this book. We tackle fundamental questions: How in the world does a single fertilized egg cell turn into a unique human being? How do

Life on the Amazon for a Matsigenka family in Peru.

Takahiro Igarashi/Image Source/Getty Images

genetic and environmental forces shape development? What can be done to optimize development? We also ask questions about different periods of the life span—for example, about how infants perceive the world, how preschool children think, how life events such as divorce affect an adolescent's adjustment, why some college students have more trouble than others deciding on a major, whether most adults experience a midlife crisis, and how people typically change as they age.

Do any of these questions intrigue you? Probably so, because we are all developing persons interested in ourselves and the other developing people around us. Most college students want to understand how they and those they know have been affected by their experiences, how they have changed over the years, and where they may be headed. Many students also have practical motivations for learning about human development—for example, a desire to be a good parent or to pursue a career as a psychologist, nurse, teacher, or other human services professional.

This introductory chapter lays the groundwork for the remainder of the book by addressing some basic questions: How should we think about development and the influences on it? What is the science of life-span development? How is development studied? And what are some of the special challenges in studying human development?

1.1

How Should We Think about Development?

LEARNING OBJECTIVES

- Define development, aging, and their relationship to each other.
- Explain and illustrate the role played by age grades, age norms, and the social clock in making human development different in different historical, cultural, and subcultural contexts.
- Summarize the extreme positions one can take on the “nature–nurture” issue and the position most developmental scientists today take.

We begin by asking what it means to say that humans “develop” or “age” over the life span, how we can conceptualize the life span and its cultural and historical diversity, and how we can approach the single biggest issue in the study of development, the nature–nurture issue.

Defining Development

Development can be defined as systematic changes and continuities in the individual that occur between conception and death, or from “womb to tomb.” By describing developmental

changes as systematic, we imply that they are orderly, patterned, and relatively enduring—not fleeting and unpredictable like mood swings. The changes can be gains, losses, or just differences from what we were like before. Development also involves continuities, ways in which we remain the same or continue to reflect our past selves.

The systematic changes and continuities of interest to students of human development fall into three broad domains:

1. **Physical development.** The growth of the body and its organs, the functioning of physiological systems including the brain, physical signs of aging, changes in motor abilities, and so on.

2. **Cognitive development.** Changes and continuities in perception, language, learning, memory, problem solving, and other mental processes.
3. **Psychosocial development.** Changes and carryover in personal and interpersonal aspects of development, such as motives, emotions, personality traits, interpersonal skills and relationships, and roles played in the family and in the larger society.

Even though developmentalists often specialize in one of these three aspects of development, they appreciate that humans are whole beings and that changes in one area affect the others. The baby who develops the ability to crawl, for example, has new opportunities to develop her mind by exploring kitchen cabinets and to hone her social skills by trailing her parents from room to room. And the older adult who joins an exercise group may not only become fitter but sharpen his cognitive skills and strengthen his social network.

How would you portray, as a line on a graph, typical changes from birth to old age? Many people picture tremendous positive gains in capacity from infancy to young adulthood, a flat line reflecting little change during early adulthood and middle age, and a steep decline of capacities in the later years. This stereotyped view of the life span is largely false, but it also has some truth in it, especially with respect to biological development. Traditionally, biologists have defined **growth** as the physical changes that occur from conception to maturity. We indeed become biologically mature and physically competent during the early part of the life span. **Biological aging** is the deterioration of organisms (including humans) that leads inevitably to their death. Biologically, then, development *does* involve growth in early life, stability in early and middle adulthood, and declines associated with now-accumulated effects of aging in later life.

Many aspects of development do not follow this “gain–stability–loss” model, however. Modern developmental scientists have come to appreciate that developmental change at any age involves both gains and losses. For example, although children gain many cognitive abilities as they get older and become more efficient at solving problems, they also become less flexible in their thinking, less open to considering unusual solutions (Gopnik, Griffiths, & Lucas, 2015). They also lose self-esteem and become more prone to depression (Gotlib & Hammen, 2002).

Nor should we associate aging only with loss: Some cognitive abilities do decline over the adult years. However, adults aged 50 and older typically score higher on vocabulary tests and on tests of mental ability that draw on a person’s accumulated knowledge than young adults do (Hartshorne & Germine, 2015; Salthouse, 2012). They also sometimes show more wisdom when given social problems to ponder (Grossmann et al., 2010). Gerontologist Margaret Cruikshank (2009) conveyed the gains associated with aging this way: “Decline is thought to be the main theme of aging, and yet for many old age is a time of ripening, of becoming most ourselves” (p. 207).

In addition, people do not always improve or worsen but instead just become different than they were (as when a child who once feared loud noises comes to fear hairy monsters under the bed instead, or an adult who was worried about career success becomes more concerned about her children’s futures). Development clearly means more than positive growth during infancy,

childhood, and adolescence. And **aging**, as developmental scientists define it, involves more than biological aging; it refers to a range of physical, cognitive, and psychosocial changes, *positive and negative*, in the mature organism (Overton, 2010). In short, development involves gains, losses, neutral changes, and continuities in each phase of the life span, and aging is part of it.

Conceptualizing the Life Span

If you were to divide the human life span into periods, how would you do it? • **Table 1.1** lists the periods that many of today’s developmentalists regard as distinct. You will want to keep them in mind as you read this book, because we will constantly be speaking of infants, preschoolers, school-age children, adolescents, emerging adults, and young, middle-aged, and older adults. Note, however, that the given ages are approximate. Age is only a rough indicator of developmental status. Improvements in standards of living and health, for example, have meant that today’s 65-year-olds are not as “old” physically, cognitively, or psychosocially as 65-year-olds a few decades ago were. There are also huge differences in functioning and personality among individuals of the same age; while some adults are bedridden at age 90, others are swimming laps.

The most recent addition to this list of periods of the life span—the one you may not have heard of—is **emerging adulthood**, a transitional period between adolescence and full-fledged adulthood that extends from about age 18 to age 25 and maybe as late as 29. After World War II, as jobs became more complex and required more education, more adolescents began to attend college in large numbers to prepare for work and postponed marriage and parenthood in the process (Keniston, 1970). As a result, psychologist Jeffrey Arnett and others began to describe emerging adulthood as a distinct phrase of the life span in which college-aged youth spend years getting educated and saving money in order to launch their adult lives (Arnett, 2000, 2011, 2015). Emerging adulthood is a distinct developmental period primarily in developed countries but the phenomenon is

What periods of the life span do these four females, representing four generations of the same family, fall in?

Takahiro Igarashi/Image Source/Getty Images

● **Table 1.1** An Overview of Periods of the Life Span

Period of Life	Age Range
Prenatal period	Conception to birth
Infancy	First 2 years of life (the first month is the neonatal or newborn period)
Preschool period	2–5 (some prefer to describe as <i>toddlers</i> children who have begun to walk and are age 1–3)
Middle childhood	6 to about 10 (or until the onset of puberty)
Adolescence	Approximately 10–18 (or from puberty to when the individual becomes relatively independent)
Emerging adulthood	18–25 or even 29 (transitional period between adolescence and adulthood)
Early adulthood	25–40 years (adult roles are established)
Middle adulthood	40–65 years
Late adulthood	65 years and older (some break out subcategories such as the young-old, old-old, and very old based on differences in functioning)

spreading to developing ones, especially in urban areas (Arnett, 2015). According to Arnett (2004), emerging adults (maybe you?):

- explore their identities;
- lead unstable lives filled with job changes, new relationships, and moves;
- are self-focused, relatively free of obligations to others, and therefore free to focus on their own psychological needs;
- feel in between—adultlike in some ways but not others; and
- believe they have limitless possibilities ahead.

Do you believe you are truly an adult rather than an “emerging” adult? Why or why not? There are many ways to define adulthood, but sociologist Frank Furstenberg and his colleagues (2004) looked at five traditional, objective markers of adulthood: completing an education, being financially independent, leaving home, marrying, and having children. In 1960, 65% of men and 77% of women in the United States had achieved these milestones by age 30. By 2000, only 31% of men and 46% of women had achieved them by age 30.

Not everyone agrees that emerging adulthood is a truly distinct period of development (Epstein, 2013). However, it is clear that adolescents in modern societies are taking longer and longer to enter adult roles. Knowing that many youth do not yet have adult responsibilities and knowing too that brain development is not complete in our 20s, some European countries and some states in the United States are questioning the notion that 18-year-olds should be treated as adults under the law. For example, they are raising legal ages or creating special provisions to protect emerging adults from the adult criminal system (Schiraldi & Western, 2015).

Cultural Differences

● **Table 1.1** represents only one view of the periods of the life span. Age—like gender, race, and other significant human characteristics—means different things in different societies (Fry, 2009). **Culture** is often defined as the shared understandings and way of life of a people (see Mistry & Dutta, 2015; Packer & Cole, 2015). It includes beliefs, values, and practices concerning the nature of humans in different phases of the life span, what children need to be taught to function in

their society, and how people should lead their lives as adults. Different cultures can lead us along different developmental pathways, as we saw in the case of Ben and Yanira, but we all participate in a culture. That culture becomes part of us, influencing how we live and how we experience our lives (Packer & Cole, 2015).

Each culture has its own ways of carving up the life span and of treating the people in different age groups. Each socially defined age group in a society—called an **age grade**—is assigned different statuses, roles, privileges, and responsibilities. Separating children into grades in school based on age is one form of age grading. Just as high schools have “elite” seniors and “lowly” freshmen, whole societies are layered into age grades.

Our society, for example, grants “adults” (18-year-olds by law in the United States) a voting privilege not granted to children. Legal definitions of the boundary between adolescence and adulthood vary, though. In most states in the United States, the legal age for marrying is lower than the legal ages for voting or serving in the military, and the right to drink alcohol is granted last, commonly at age 21 (Settersten, 2005). Similarly, although we seem to define age 65 as the boundary between middle age and old age, in fact the ages at which people become eligible for Medicare, Social Security benefits, and “senior discounts” at restaurants and stores differ.

We define old age as age 65 or older, but the !Kung San of Botswana often don’t know people’s chronological ages and define old age instead in terms of functioning (Rosenberg, 2009). They distinguish between the *na* or “old” (an honorary title meaning big and great granted to all older people starting at around age 50); the “old/dead” (older but still able to function); and the “old to the point of helplessness,” who are ailing and need care. The St. Lawrence Eskimo simply distinguish between boys and men (or between girls and women), whereas the Arusha people of East Africa devised six socially meaningful age grades for males: youths, junior warriors, senior warriors, junior elders, senior elders, and retired elders (Keith, 1985). In certain other cultures, the recognized periods of the life span include a period before birth and an afterlife (Fry, 1985; Kojima, 2003).

Cultures differ not only in the age grades they recognize but in how they mark the transition from one age grade to another. A **rite of passage** is a ritual that marks a person’s “passage” from one status to another, usually in reference to the transition from

Each January 15 in Japan, 20-year-olds are officially pronounced adults in a national celebration and enter a new age grade. Young women receive kimonos, young men receive suits, and all are reminded of their responsibilities to society. Young adults also gain the right to drink, smoke, and vote. The modern ceremony grew out of an ancient one in which young samurai became recognized as warriors (Reid, 1993). The age-grading system in Japanese culture clearly marks the beginning of adulthood with this rite of passage.

AP Photo/Shizuo Kambayashi

childhood to adulthood. Rites of passage can involve such varied practices as body painting, circumcision, beatings, instruction by elders in adult sexual practices, tests of physical prowess, and gala celebrations (see Schlegel & Barry, 2015).

Adolescent rites of passage were more common in traditional societies than they are in modern industrial societies. Yes, Jewish youth experience a clear rite of passage when they have their *bar* or *bat mitzvahs*, and 15-year-old Hispanic American girls in some communities participate in a *quinceañera* (meaning “fifteen years ceremony”) to signify that they have become women. But often coming-of-age ceremonies do not have the broader meaning for the whole society that they used to have. Modern societies are more diverse than traditional societies, are not so clearly organized around distinct male and female roles, and tend to move us from childhood to adolescence and on to adulthood more gradually (Schlegel & Barry, 2015). About the clearest rite of passage to adulthood in our society, unfortunately, is a night of binge drinking at age 21. In one study, four of five college students reported that they drank on their 21st birthday to celebrate—12% of them an extremely dangerous 21 drinks (Rutledge, Park, & Sher, 2008). Perhaps because we lack a clear, society-wide rite of passage, adolescents in our society end up less sure than adolescents in many other societies of when they are adults.

Once a society has established age grades, it defines what people should and should not do at different points in the life span (Elder & Shanahan, 2006). According to pioneering gerontologist Bernice Neugarten and her colleagues (Neugarten, Moore, & Lowe, 1965), these expectations, or **age norms**, are society’s way of telling people how to act their age. In our culture, for example, most people agree that 6-year-olds are too young to date or drink beer but

are old enough to attend school. We also tend to agree that adults should think about marrying around age 25 (although in some segments of society earlier or later is better) and should retire around age 65 (Neugarten et al., 1965; Settersten, 1998). In less industrialized countries, age norms often call for starting work in childhood, marrying and having children in one’s teens and often remaining in the family home, and stopping work earlier than 65 in response to illness and disability (Juárez & Gayer, 2014; Shanahan, 2000).

Why are age norms important? First, they influence people’s decisions about how to lead their lives. They are the basis for what Neugarten (1968) called the **social clock**—a person’s sense of when things should be done and when he or she is ahead of or behind the schedule dictated by age norms. Prompted by the social clock, for example, an unmarried 30-year-old may feel that he should propose to his girlfriend before she gives up on him, or a 70-year-old who loves her job may feel she should start planning for retirement. Second, age norms affect how easily people adjust to life transitions. Normal life events such as having children tend to affect us more negatively when they occur “off time” than when they occur “on time” (McLanahan & Sorensen, 1985). It can be challenging to experience puberty at either age 8 or age 18 or to become a new parent at 13 or 45. However, as Neugarten could see even in the 1960s, age norms in our society have been weakening for some time. It’s less clear now what one should be doing at what age and so people do things like marry and retire at a wide range of ages (Settersten & Trauten, 2009). Witness Madonna adopting a child at 50 or Elton John becoming a first-time father at 62 (Mayer, 2011).

Subcultural Differences

Age grades, age norms, and social clocks differ not only from culture to culture but also from subculture to subculture. Our own society is diverse with respect to race and **ethnicity**, or people’s affiliation with a group based on common heritage or traditions. It is also diverse with respect to **socioeconomic status (SES)**, or standing in society based on such indicators as occupational prestige, education, and income. African American, Hispanic American, Native American, Asian American, and European American individuals, and individuals of high versus low SES, sometimes have very different developmental experiences. Within these broad groups, of course, there are immense variations associated with a host of other factors. We must be careful not to overgeneralize.

To illustrate, age norms tend to differ in higher-SES and lower-SES communities: Youth from lower-income families tend to reach milestones of adulthood such as starting work, marrying, and having children earlier and to feel like adults sooner (Benson & Elder, 2011; Elder & Shanahan, 2006; Mollborn, 2009). When sociologist Linda Burton (1990, 1996, 2007) studied a low-SES African American community, she found it was common for young women to become mothers at about age 16—earlier than in most middle-class communities, white or black. Teenage mothers in this community looked to their own mothers and grandmothers to help them care for their children. Meanwhile, children were asked to grow up fast; they often tended younger siblings and helped their mothers with household tasks. Although age norms in middle-class communities in the United States call for postponing parenthood (Mollborn, 2009), it is common in cultures around the world for females to become mothers in their teens and for grandmothers

and older children to help them with child care responsibilities (Ochs & Izquierdo, 2009; Rogoff, 2003).

Perhaps the most important message about socioeconomic status is that, regardless of race and ethnicity, poverty can be very damaging to human development. About one in five children—and more like one of every three children of color—lives in poverty in the United States today, defined as an income of \$24,250 for a family of four (Children’s Defense Fund, 2014). Parents and children living in poverty experience more stress than higher-SES parents and children owing to noise, crowding, family disruption, hunger, exposure to violence, and other factors (Evans & Kim, 2013). Under these conditions, parents may have difficulty providing a safe, stable, stimulating, and supportive home environment for their children (Duncan, Magnuson, & Votruba-Drzal, 2015; and see Chapter 15). As a result, the developmental experiences and trajectories of children who grow up in poverty and children who grow up in affluence are significantly different. The damaging effects of poverty can be seen in measurable differences in brain development between high- and low-SES children that grow wider over the critical months of infancy and early childhood (Hanson et al., 2013) and that are linked to lower school achievement in adolescence (Mackey et al., 2015). Indeed, the negative impacts of poverty show themselves in a host of ways: not only in lower average academic achievement but in poorer mental health and well-being and even poorer physical health in adulthood (Aber, Morris, & Raver, 2012; Conger & Dogan, 2007; Evans & Kim, 2012).

Historical Changes

The nature and meanings of periods of the life span also change from one historical period to another. In Europe and North America, they have changed along these lines:

- **Childhood as an age of innocence.** Although it is not quite this simple (Stearns, 2015), it has been claimed that not until the 17th century in Western cultures did children come to be viewed as distinctly different from adults, as innocents to be protected and nurtured. In medieval Europe (A.D. 500–1500), for example, 6-year-olds were dressed in miniature versions of adult clothing, treated much like adults under the law, and expected to contribute to the family’s survival as soon as possible (Ariès, 1962). Today the goal in Western families is for children to be happy and self-fulfilled rather than economically useful, as illustrated by the case of Ben at the start of the chapter (Stearns, 2015).
- **Adolescence.** Not until the late 19th century and early 20th century was **adolescence**—the transitional period between childhood and adulthood that begins with puberty and involves significant physical, cognitive, and psychosocial changes—given a name and recognized as a distinctive phase of the life span (Kett, 1977). As farming decreased and industrialization advanced, an educated labor force was needed, so laws were passed restricting child labor, making schooling compulsory, and separating youths attending school from the adult world (Furstenberg, 2000).
- **Emerging adulthood.** As you saw earlier, the transition period from adolescence to adulthood has become so long in modern societies that a new period of the life span, *emerging adulthood*, has been defined in the late 20th and early 21st centuries.

Although medieval children were pressured to abandon their childish ways as soon as possible and were dressed like miniature adults, it is doubtful that they were really viewed as miniature adults. Still, the modern concept of children as innocents to be nurtured and protected did not begin to take hold until the 17th century.

PAINTING/Alamy Stock Photo

- **Middle age as an emptying of the nest.** This distinct life phase emerged in the 20th century as parents began to bear fewer children and live long enough to see their children grow up and leave home (Moen & Wethington, 1999).
- **Old age as retirement.** Not until the 20th century did our society come to define old age as a period of retirement. In earlier eras, adults who survived to old age literally worked until they dropped. Starting in the last half of the 20th century, thanks to Social Security, pensions, Medicare, and other support programs, working adults began to retire in their 60s with many years ahead of them (Schulz & Binstock, 2006).

Projecting the Future

What will the life span look like in the future? In the early 21st century, the average **life expectancy** for a newborn in the United States—the average number of years a newborn who is born now can be expected to live—is almost 79 years, compared with 47 years in 1900 (National Center for Health Statistics, 2015). As **Figure 1.1** shows, that life expectancy is generally greater for females than for males and

Figure 1.1 Life expectancy for non-Hispanic white, African American, and Hispanic males and females at birth in the United States.

Source: National Center for Health Statistics

is highest among Hispanic Americans, lowest among African Americans, and in-between among European Americans. In each group, wealth is associated with longer life than poverty.

To put these numbers in a global context, the average life expectancy of 79 in the United States is quite a bit lower than life expectancies in the longest-lived countries, Japan (84) and Singapore (83), but considerably higher than life expectancies in Central African Republic (51), Chad (52) and other African nations that have been hurt by widespread poverty and disease, including the HIV/AIDS epidemic (World Health Organization, 2015). By 2030, when most members of the baby boom generation will have retired, adults 65 and older will represent not the 13% of the U.S. population they represented in 2010 but over 20% (Ortman, Velkoff, & Hogan, 2014). As a result, an increasingly large group of elderly people will depend on a smaller generation of younger, working adults to support them. Although these elders will be healthier, wealthier, and better educated than the generations that preceded them, they will also need a lot of services—and health and mental health professionals trained in aging to serve them—as more of them reach very old ages (Schaie, 2011; Treas & Hill, 2009). How will policy makers address these issues? Conflict between the generations over resources and resentful attitudes toward aging adults could become problems (North & Fiske, 2012). This “graying of America,” and indeed of the world’s population, along with societal changes we cannot yet anticipate, will make the aging experience by the end of the 21st century different than it is today.

In sum, age—whether it is 7, 17, or 70—has had different meanings in different historical eras and most likely will mean something different in the 21st century than it did in the 20th. The broader message is clear: *We must view development in its historical, cultural, and subcultural context.* We must bear in mind that each

social group settles on its own definitions of the life span, the age grades within it, and the age norms appropriate to each age range, and that each social group experiences development differently. We must also appreciate that in Western cultures it was only in the 17th century that children came to be seen as innocents; in the late 19th century that adolescence emerged as a distinct phase; and in the 20th century that our society recognized emerging adulthood, a middle-aged “empty nest” period, and an old age retirement period. One of the most fascinating challenges in the study of human development is to understand which aspects of development are universal and which differ across social and historical contexts—and why.

Framing the Nature–Nurture Issue

Understanding human development means grappling with the major issue in the study of human development—the **nature–nurture issue**, or the question of how biological forces and environmental forces act and interact to make us what we are (see Goldhaber, 2012). We will highlight this central and always fascinating issue throughout this book.

Nature

On the nature side of the debate are those who emphasize the influence of heredity, universal maturational processes guided by the genes, biologically based or innate predispositions produced by evolution, and biological influences on us every day of hormones, neurotransmitters, and other biochemicals. To those who emphasize nature, some aspects of development are inborn or innate, others are the product of **maturation**, the biological unfolding of the individual as sketched out in the **genes** (the hereditary material passed from parents to child at conception). Just as seeds turn into mature plants through a predictable process, humans “unfold” within the womb (assuming that they receive the necessary nourishment from

Today’s older adults are healthier, wealthier, and more educated than older adults of previous generations. However, as more of them reach advanced ages, they will need more services from people trained in gerontology and geriatrics.

Ariel Skelly/Blend Images/Getty Images

their environment). Their genetic code then makes it likely that they will walk and utter their first words at about 1 year of age, achieve sexual maturity between 10 and 14, and gray in their 40s and 50s. Maturational changes in the brain contribute to cognitive changes such as increased memory and problem-solving skills and to psychosocial changes such as increased understanding of other people's feelings. Genetically influenced maturational processes guide all of us through many of the same developmental changes at about the same points in our lives. Meanwhile, *individual* hereditary endowment is making each person's development unique.

Nurture

On the nurture side of the nature–nurture debate are those who emphasize change in response to **environment**—all the external physical and social conditions, stimuli, and events that can affect us, from crowded living quarters and polluted air, to social interactions with family members, peers, and teachers, to the neighborhood and broader cultural context in which we develop. We know that the physical environment matters—for example, that exposure to lead in the paint in old buildings or in water pipes can stunt children's intellectual development or that living near a noisy airport can interfere with their progress in learning to read (Evans, 2004). And we will see countless examples in this book of how the social environment—the behavior of other people—shapes development. Rather than seeing biological maturation as the process driving development, those on the nurture side of the nature–nurture debate emphasize **learning**—the process through which experience brings about relatively permanent changes in thoughts, feelings, or behavior. A certain degree of maturation is clearly necessary before a child can dribble a basketball, but careful instruction and long, hard hours of practice are just as clearly required if the child is to excel in basketball. In some ways, humans around the world have similar experiences at similar ages but in many ways their experiences differ dramatically, as suggested by the stories of Yanira and Ben at the start of the chapter.

The Interplay of Nature and Nurture

● **Table 1.2** summarizes the terms of the nature–nurture debate. But let's settle the nature–nurture debate right now: Developmental changes are the products of a complex interplay between nature and nurture. It is not nature *or* nurture; it is nature *and* nurture (Plomin et al., 2013). To make matters more complex, it is nature affecting

● **Table 1.2** The Language of Nature and Nurture

Nature	Nurture
Heredity	Environment
Maturation	Learning
Genes	Experience
Innate or biologically based predispositions	Cultural influences

nurture and nurture affecting nature! For example, biology (nature) provides us with the beginnings of a brain that allows us to learn from our experiences (nurture), experiences that in turn change our brains by altering neural connections and that can even change our genes by activating or deactivating them (see Chapter 3). Much of the fascination of studying human development comes from trying to understand more precisely how these two forces combine to make us what we are and become. It is appropriate, then, that we look next at the science of life-span human development and whether it is up to the challenge of answering questions like this.

● Checking Mastery

1. How does the concept of aging differ from the concept of biological aging?
2. What is the difference between an age grade and an age norm?

● Making Connections

1. Many observers, starting with Bernice Neugarten, believe that age norms for transitions in adult development such as marriage, parenthood, peak career achievement, and retirement have weakened in our society. Do you think such age norms could ever disappear entirely? Why or why not?
2. Returning to the chapter opener, how might your life and development be different if you had been born to a Matsigenka family in the rain forest of Peru? Speculate a bit.
3. We know that men are much more likely to commit murder than women are. How might you explain this in terms of “nature” and how might you explain it in terms of “nurture”?

1.2

What Is the Science of Life-Span Development?

LEARNING OBJECTIVES

- Summarize the four goals of the science of life-span development and describe how the study of human development began.
- List and illustrate the seven key assumptions of the modern life-span perspective.

If development consists of systematic changes and continuities from conception to death, the science of development consists of the study of those changes and continuities and their causes.

In this section we consider the goals of the science of life-span development, its origins, and the modern life-span perspective on development.

Goals and Uses of Studying Development

The goals driving the study of life-span development are:

describing,
predicting,
explaining, and
optimizing development (Baltes, Reese, & Lipsitt, 1980).

To achieve the goal of *description*, developmentalists characterize the functioning of humans of different ages and trace how it changes with age. They describe both normal development and individual differences, or variations, in development. Although average trends in human development across the life span can be described, it is clear that no two people (even identical twins) develop along precisely the same pathways.

Description is the starting point in any science, but scientists ultimately strive to achieve their second and third goals, *prediction* and *explanation*. Developmentalists seek to identify factors that predict development and establish that these factors actually cause humans to develop as they typically do or cause some individuals to develop differently than others. To do so, developmentalists often address nature-nurture issues. A first step is often finding a relationship between a possible influence on development and an aspect of development—for example, a relationship between whether or not an adolescent's friends use drugs and whether or not the adolescent does. If there is a relationship, knowing whether an adolescent's friends use drugs allows us to *predict* whether the adolescent uses drugs. But is this a causal relationship? That's what must be established before the goal of *explanation* is achieved. Maybe it's not that friends cause adolescents to use drugs by exposing them to drugs and encouraging them to try them. Maybe it's just that adolescents who use drugs pick friends who also use drugs (see Chapter 16 for evidence that both possibilities may be true).

The fourth goal of developmental science is *optimization* of human development. How can humans be helped to develop in positive directions? How can their capacities be enhanced, how can developmental difficulties be prevented, and how can any developmental problems that emerge be overcome? Pursuing the goal of optimizing development might involve evaluating ways to stimulate intellectual growth in preschool programs, to prevent binge drinking among college students, or to support elderly adults after the death of a spouse.

To those who are or aspire to be teachers, psychologists or counselors, nurses or occupational therapists, or other helping professionals, applied research aimed at optimizing development is especially relevant. Today's educators and human service and health professionals are being asked to engage in **evidence-based practice**, grounding what they do in research and ensuring that the curricula and treatments they provide have been demonstrated to be effective. Too often, these professionals go with what their personal experience tells them works rather than using what scientific research establishes to be the most effective approaches (Baker, McFall, & Shoham, 2009; Williams et al., 2012). We can all probably agree that we would rather have interventions

of proven effectiveness than interventions that are ineffective or even harmful.

Early Beginnings

Just as human development has changed through the ages, attempts to understand it have evolved over time. Although philosophers have long expressed their views on the nature of humans and the proper methods of raising children, it was not until the late 19th century that the first scientific investigations of development were undertaken. Several scholars began to carefully observe the growth and development of their own children and to publish their findings in the form of **baby biographies**. Perhaps the most influential baby biographer was Charles Darwin (1809–1882), who made daily records of his son's development (Darwin, 1877). Darwin's curiosity about child development stemmed from his interest in evolution. He believed that infants share many characteristics with their nonhuman ancestors and that understanding the development of the embryo and child can offer insights into the evolution of the species. Darwin's evolutionary perspective strongly influenced early theories of human development, which emphasized universal, biologically based maturational changes (Cairns & Cairns, 2006; Parke et al., 1994).

Baby biographies left much to be desired as works of science, however. Can you see why? Because different baby biographers emphasized different aspects of their children's behavior, baby biographies were difficult to compare. Moreover, parents are not entirely objective observers of their own children, and early baby biographers may have let their assumptions about evolution bias their observations. Finally, because each baby biography was based on a single child—often the child of a distinguished family—its findings were not necessarily generalizable to other children.

Darwin greatly influenced the man most often cited as the founder of developmental psychology, G. Stanley Hall (1846–1924), the first president of the American Psychological Association (see Lepore, 2011, for an interesting view of the man). Well aware of the shortcomings of baby biographies, Hall attempted to collect more objective data from larger samples of individuals. He developed a now all-too-familiar research tool—the questionnaire—to explore “the contents of children's minds” at different ages (Hall, 1891).

G. Stanley Hall, regarded as the founder of developmental psychology and first president of the American Psychological Association, did pioneering research on childhood, adolescence, and old age. He is perhaps best known for characterizing adolescence as a period of “storm and stress.”

Library of Congress, Prints & Photographs Division,
Reproduction number LC-DIG-ggbain-05209 (digital file
from original neg.)

Hall went on to write an influential book, *Adolescence* (1904). Inspired by Darwin's evolutionary theory, Hall drew parallels between adolescence and the turbulent period in the evolution of human society during which barbarism gave way to modern civilization. Adolescence, then, was a tempestuous period of the life span, a time of emotional ups and downs and rapid changes—a time of what Hall characterized as **storm and stress**. Thus, we have Hall to thank for the idea that most teenagers are emotionally unstable—a largely inaccurate idea, as it turns out (see Chapter 16). Yet as this book will reveal, Hall was right to mark adolescence as a time of dramatic changes.

Hall capped his remarkable career by turning his attention to the end of the life span in *Senescence* (1922), an analysis of how society treats (or, really, mistreats) its older members. Among other things, he recognized that aging involves more than just decline (Thompson, 2009). Clearly G. Stanley Hall deserves much credit for stimulating scientific research on the entire human life span and for raising many important questions about it.

The Modern Life-Span Perspective

Although a few early pioneers of the study of human development like G. Stanley Hall viewed all phases of the life span as worthy of study, the science of human development began to break into age-group specialty areas during the 20th century. Some researchers focused on infant or child development, others specialized in adolescence, and still others formed the specialization of **gerontology**, the study of aging and old age. Development was often viewed as something that happened in infancy, childhood, and adolescence, that proceeded through universal stages, and that led toward one outcome: mature adult functioning.

In the 1960s and 1970s, however, a true **life-span perspective** on human development began to emerge. In an influential paper, Paul Baltes (1939–2006) laid out seven key assumptions of the life-span perspective (Baltes, 1987; also see Baltes, Lindenberger, & Staudinger, 2006). These are important themes that you will see echoed throughout this book. They will also give you a good sense of the challenges facing researchers who study human development.

1. **Development is a lifelong process.** Today's developmentalists appreciate that human development is not just “kid stuff,” that we change throughout the life span. They also believe that development in any period of life is best seen in the context of the whole life span. For instance, our understanding of adolescent career choices is bound to be richer if we concern ourselves with how those choices took shape during childhood and whether and how they affect adult career development and success.
2. **Development is multidirectional.** To many pioneers of its study, development was a universal process leading in one direction—toward more “mature” functioning. Today's developmentalists recognize that different capacities show different patterns of change over time. For example, some intellectual abilities peak in adolescence while others do not peak until a person's 40s or 50s; some decline in late adulthood, some don't change much, and some, such as command

Developmentalist Paul Baltes is credited with encouraging adoption of a life-span perspective on development.

Christine Windbichler

of vocabulary, continue to improve (Hartshorne & Germine, 2015; and see Chapters 7, 8, and 9). Different aspects of human functioning have different trajectories of change.

3. **Development involves both gain and loss.** Building on the theme that development is multidirectional and that it is not all gain in childhood and loss in old age, Baltes maintained that both gain and loss are evident in each phase of the life span. Moreover, he believed that gain inevitably brings with it loss of some kind, and loss brings gain—that gain and loss occur jointly. Examples? As infants become more able to discriminate the sounds of the language they hear spoken around them, they lose their ability to discriminate sounds used in other languages of the world (Werker et al., 2012; and see Chapter 6). Similarly, choosing to hone certain skills in one's education or career often means losing command of other skills (see Chapter 11).
4. **Development is characterized by lifelong plasticity.** **Plasticity** refers to the capacity to change in response to experience, whether positive or negative. Developmental scholars have long appreciated that child development can be damaged by a deprived environment and optimized by an enriched one. It is now understood that this plasticity continues into later life—that the aging process is not fixed but rather can take many forms depending on the individual's environment and experiences. For example, older adults can maintain or regain some of their intellectual abilities and even enhance them with the help of physical exercise, a mentally and socially active lifestyle, or training designed to improve specific cognitive skills (Hertzog et al., 2009; Park et al., 2014; and see Chapter 9). Such cognitive benefits are rooted in **neuroplasticity**, the brain's remarkable ability to change in response to experience throughout the life span (see Chapter 5).
5. **Development is shaped by its historical-cultural context.** This theme was illustrated in Section 1.1 of this chapter and is illustrated beautifully by the pioneering work of Glen Elder and his colleagues. They researched how the Great Depression of the 1930s affected the later life courses and development of the era's children and adolescents (Elder, 1998; Elder, Liker, & Cross, 1984). This work gives us insights into the many effects of the economic crisis called the Great Recession that began in 2008 (see Chapter 15). A few years after the stock market crashed in 1929, one of three workers was unemployed and many families were tossed into poverty. Although many families survived the Great Depression nicely, this economic crisis proved to be especially difficult for children if their

out-of-work and demoralized fathers became less affectionate and less consistent in disciplining them. When this happened, children displayed behavior problems and had low aspirations and poor records in school. They turned into men who had erratic careers and unstable marriages and women who were seen by their own children as ill tempered. Adolescents generally fared better than children did. Less dependent on their parents than children, adolescents were pushed into working to help support their families and developed a strong sense of responsibility from their experience. No question about it: Our development is shaped by how our lives play out over time in the social contexts and historical times in which we develop (see Elder, Shanahan, & Jennings, 2015). See **Exploration 1.1**

for a look at how adolescent development is being changed by today's innovations in digital media and communication technologies.

6. **Development is multiply influenced.** Today's developmental scientists believe that human development is the product of nature and nurture, of many interacting causes both inside and outside the person, and both biological and environmental (see Chapter 3). It is the often-unpredictable outcome of ongoing interactions between a changing person and her changing world.
7. **Development must be studied by multiple disciplines.** Because human development is influenced by everything from biochemical reactions to historical events, it is impossible for one discipline to have all the answers. A full

● EXPLORATION 1.1

Growing Up Online

How is adolescent development affected by the fact that teens today spend many hours a week with media—everything from TV and videos to Facebook, texting, Twitter, and Skype? When baby boomers grew up, there were no cell phones or home computers, much less an Internet. The Internet came into being in the early 1980s, around the time that home computers were becoming common (see, for example, Cotten et al., 2011). Facebook was launched in 2004, Twitter in 2006, Snapchat in 2011.

Media are now a big part of the daily lives of children and teens (Calvert, 2015; Lenhart et al., 2015). In a national survey, it was found that 8- to 18-year-olds spent an average of 7½ hours a day using media—from most to least frequently used, TV, music, computers, video games, print, and movies (Rideout, Foehr, & Roberts, 2010). And the researchers did not even ask about texting! Of teens aged 13 to 17, 88% text with friends and 55% do it daily (Lenhart et al., 2015).

How are these technologies affecting adolescent development? Researchers are beginning to address the question (see Calvert, 2015). For example, early research suggested that heavy Internet use was turning adolescents into social isolates with few friends and low well-being. However, that may have been because the first adolescent users were surfing the web and talking to strangers in chat rooms (Valkenburg & Peter, 2009). Now most adolescents use the Internet and use it primarily to interact with their friends—mainly through Facebook and other social media sites if they are girls, often through video game sites if they

are boys (Lenhart et al., 2015). And now that teens are spending much of their online time interacting with friends, studies seem to be showing more positive correlations between Internet use and social adjustment and well-being (Reich, Subrahmanyam, & Espinoza, 2012; Valkenburg & Peter, 2009). For emerging adults who have gone away to college, for example, social networking sites can be a way to hold on to the social support offered by their high school friends (Manago et al., 2012).

However, questions about the effects of digital media on adolescents are far from resolved. For example, Roy Pea and his colleagues (2012), studying a young sample of girls aged 8 to 12, found that heavy media use—especially spending large amounts of time watching videos, communicating online, and multitasking by using multiple media at once—was negatively associated with feeling good about one's close relationships and social acceptance. By contrast, spending time in face-to-face conversations was positively

The creation of the Internet is an historical change with many implications for the social lives of teens and for human development more generally.

Rawpixel.com/Shutterstock.com

related to these aspects of social well-being. Then there are the negative effects of cyberbullying to consider. Cyberbullying, which has increased in recent years (Jones, Mitchell, & Finkelhor, 2013), is linked to stress, depression, and suicidal thoughts among its victims (Hamm et al., 2015; Kowalski et al., 2014).

We have much to learn about the effects of digital media. It is becoming clear that these effects can be good or bad depending on what adolescents are doing with media, how much time they are spending with it, and whether it is crowding out other more developmentally important activities. In the meantime, there is much to be said for interacting with friends the old-fashioned way: offline.

understanding of human development will come only when many disciplines, each with its own perspectives and tools of study, join forces. Not only psychologists but also biologists, neuroscientists, historians, economists, sociologists, anthropologists, and many others have something to contribute to our understanding. Some universities have established interdisciplinary human development programs that bring members of different disciplines together to forge more integrated perspectives on development.

In sum, Baltes's modern life-span perspective assumes that development occurs throughout the life span, is multidirectional, involves gains and interlinked losses at every age, is characterized by plasticity, is affected by its historical and cultural context, is influenced by multiple, interacting causes, and is best studied by multiple disciplines.

1.3

How Is Development Studied?

LEARNING OBJECTIVES

- Summarize the scientific method and the choices involved in selecting a sample and choosing data collection methods.
- Evaluate the strengths and weaknesses of the case study, experimental, and correlational methods.
- Evaluate the strengths and weaknesses of the cross-sectional, longitudinal, and sequential designs.

How do developmental scholars gain understanding of life-span development? Let us review for you, briefly, some basic concepts of scientific research and then turn to research strategies devised specifically for describing, predicting, explaining, and optimizing development (see Miller, 2013). Even if you have no desire to do developmental research yourself, it is important for you to understand how the knowledge of development represented in this book was generated.

The Scientific Method

There is nothing mysterious about the **scientific method**. It is both a method and an attitude—a belief that investigators should allow their systematic observations (or data) to determine the merits of their thinking. For example, for every “expert” who believes that psychological differences between males and females are largely biological in origin, there is likely to be another expert who just as firmly insists that boys and girls differ because they are raised differently. Whom should we believe? It is in the spirit of the scientific method to believe the data—the findings of research. The scientist is willing to abandon a pet theory if the data contradict it. Ultimately, then, the scientific method can help the scientific community and society at large weed out flawed ideas.

The scientific method involves generating ideas and testing them by making observations. Often, preliminary observations provide ideas for a **theory**—a set of concepts and propositions

Checking Mastery

1. Focusing on the development over childhood of self-esteem, state a research question that illustrates each of four main goals of the study of life-span development.
2. Which three of the seven assumptions in Baltes's life-span perspective concern the nature-nurture issue?

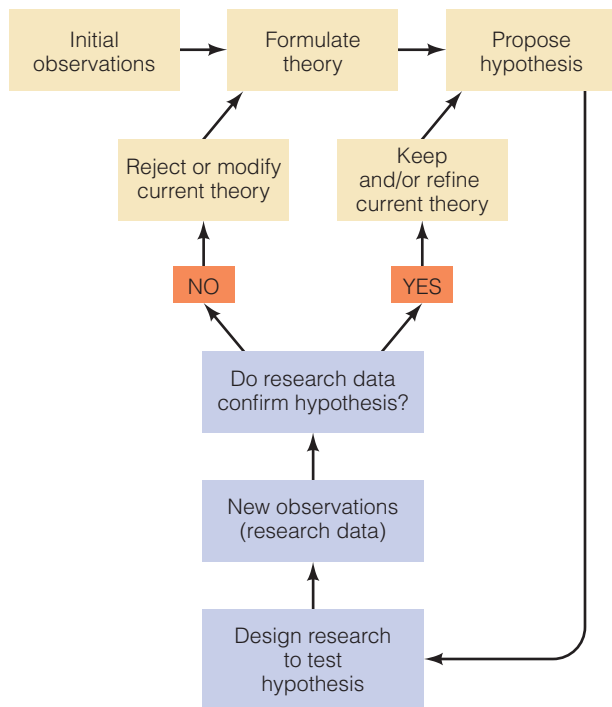

Making Connections

1. How does the developmental psychology of Paul Baltes improve on the developmental psychology of Charles Darwin?
2. Create examples to show how four of the assumptions of the life-span perspective might apply to your development.

intended to describe and explain certain phenomena. Jean Piaget, for instance, formulated his influential theory of cognitive development by closely observing how French children of different ages responded to items on the Binet IQ test when he worked on the test's development, as well as by watching his own children's development (see Chapters 2 and 7).

Theories generate specific predictions, or **hypotheses**, regarding a particular set of observations. Consider, for example, a theory claiming that psychological differences between males and females are largely caused by differences in their experiences in the family. Based on this theory, a researcher might hypothesize that if parents grant boys and girls the same freedoms, the two sexes will be similarly independent, whereas if parents give boys more freedom than girls, boys will be more independent than girls. Suppose that the study designed to test this hypothesis indicates that boys are more independent than girls no matter how their parents treat them. Then the hypothesis would be disconfirmed by the findings, and the researcher would want to rethink this theory of gender differences. If other hypotheses based on this theory were inconsistent with the facts, the theory would have to be significantly revised or abandoned in favor of a better theory.

This, then, is the heart of the scientific method: Theories generate hypotheses, which are tested through observation of behavior, and new observations indicate which theories are worth keeping and which are not (■ **Figure 1.2**). It should be clear that theories are not just speculations, hunches, or unsupported opinions. A good theory should be:

■ **Figure 1.2** The scientific method in action.

- **Internally consistent.** Its different parts and propositions should hang together and should not generate contradictory hypotheses.
- **Falsifiable.** It can be proved wrong; that is, it can generate specific hypotheses that can be tested and either supported or not supported by the data collected. If a theory is vague or does not generate clear hypotheses, it cannot be tested and will not be useful in advancing knowledge.
- **Supported by data.** A good theory should help us better describe, predict, and explain human development; that is, its hypotheses should be confirmed by research results.

Sample Selection

Any study of development focuses on a particular research **sample** (the group of individuals studied) with the intention of generalizing the results to a larger **population**, a well-defined group (such as premature infants, American high school students, or Chinese elders) from which the sample is drawn and about which we want to draw conclusions. Although it is advocated more than it is used, the best approach is to study a **random sample** of the population of interest—a sample formed by identifying all members of the larger population and then, by a random means (such as drawing names blindly), selecting a portion of that population to study. Why do this? Random sampling increases confidence that the sample studied is representative of the larger population of interest and therefore that conclusions based on studying the sample will be true of the whole population.

In practice, developmentalists often draw their samples—sometimes random, sometimes not—from their local communities. Thus, researchers might survey students at a local high school about their drug use but then be unable to draw firm conclusions about American teenagers in general if, for example, the school is in a suburb where drug-use patterns are different than they might be in an inner-city or rural area. They would certainly be unable to generalize about Kenyan or Brazilian high school students. All researchers must therefore be careful to describe the characteristics of the sample they studied and to avoid overgeneralizing their findings to populations that might be socioeconomically or culturally different from their research sample.

Data Collection

No matter what aspect of human development we are interested in, we must find appropriate ways to measure what interests us. The methods used to study human development are varied, depending on the age group and aspect of development of interest (Miller, 2013). Here we will focus on three major methods of data collection used by developmental researchers: verbal reports, behavioral observations, and physiological measurements.

Verbal Reports

Interviews, written questionnaires or surveys, ability and achievement tests, and personality scales all involve asking people questions, either about themselves (self-report measures) or about someone else (for example, child behavior as reported by informants such as parents or teachers). These verbal report measures usually ask the same questions in precisely the same order of everyone so that the responses of different individuals can be directly compared. Increasingly, verbal report measures are administered via websites and smart phones (Wilt, Condon, & Revelle, 2012).

Although self-report and other verbal report methods are widely used to study human development, they have shortcomings. First, self-report measures typically cannot be used with infants, young children, cognitively impaired elders, or other individuals who cannot read or understand speech well. Informant surveys, questionnaires, or interviews are often used in these situations instead. Second, because individuals of different ages may not understand questions in the same way, age differences in responses may reflect age differences in comprehension or interpretation rather than age differences in the quality of interest to the researcher. Finally, respondents may try to present themselves (or those they are providing information about) in a positive or socially desirable light.

Behavioral Observations

Naturalistic observation involves observing people in their everyday (that is, natural) surroundings (Miller, 2013; Pellegrini, 1996). Ongoing behavior is observed in homes, schools, playgrounds, workplaces, nursing homes, or wherever people are going about their

lives. Naturalistic observation has been used to study child development more often than adult development, largely because infants and young children often cannot be studied through self-report techniques that demand verbal skills. It is the only data collection technique that can reveal what children or adults do in everyday life.

However, naturalistic observation has its limitations as well. First, some behaviors (for example, heroic efforts to help in emergencies) occur too infrequently and unexpectedly to be studied through naturalistic observation. Second, it is difficult to pinpoint the causes of the behavior observed, because in a natural setting many events are usually happening at the same time, any of which may affect behavior. Finally, the presence of an observer can sometimes make people behave differently than they otherwise would. Children may “ham it up” when they have an audience; parents may be on their best behavior. Therefore, researchers sometimes videotape the proceedings from a hidden location or spend time in the setting before they collect their “real” data so that the individuals they are observing become used to their presence and behave more naturally.

To achieve greater control over the conditions under which they gather behavioral data, and to capture rarely occurring events, researchers often use **structured observation**; that is, they create special stimuli, tasks, or situations designed to elicit the behavior of interest. To study moral development and cheating among college students, for example, researchers might arrange a situation in which students take a cognitive test after having been led to believe that any cheating on their part could not possibly be detected. By exposing all research participants to the same stimuli, this approach increases the investigator’s ability to compare the effects of these stimuli on different individuals. Concerns about this method center on whether research participants will behave naturally and whether conclusions based on their behavior in specially designed settings will generalize to their behavior in the real world.

Physiological Measurements

Finally, developmental scientists sometimes take physiological measurements to assess variables of interest to them. For example, they use electrodes to measure electrical activity in the brain, chart changes in hormone levels in menopausal women, or measure heart rate and other indicators of arousal to assess emotions.

Today, exciting breakthroughs are being made in understanding relationships between brain and behavior through the use of **functional magnetic resonance imaging (fMRI)**, a brain-scanning technique that uses magnetic forces to measure the increase in blood flow to an area of the brain that occurs when that brain area is active. By having children and adults perform cognitive tasks while lying very still in an fMRI scanner, researchers can determine which parts of the brain are involved in particular cognitive activities. Sometimes fMRI studies reveal that children and adults, or young adults and older adults, rely on different areas of the brain to perform the same tasks, providing new insights into typical and atypical brain development and aging and its implications (see, for example, Goh & Park, 2009; Matthews & Fair, 2015; Wittmann & D’Esposito, 2012; and see Chapter 5).

Physiological measurements have the advantage of being hard to fake; the person who tells you she is not angry may be physiologically aroused, and the adolescent who claims not to take drugs may be given away by a blood test. Physiological measurements are also particularly useful in the study of infants because infants cannot tell us verbally what they are thinking or feeling. The main limitation of physiological measurements is that it is not always clear exactly what they are assessing. For example, physiological arousal can signal other emotions besides anger.

These, then, are the most commonly used techniques of collecting data about human development: verbal report measures (interviews, questionnaires, and tests), behavioral observation (both naturalistic and structured), and physiological measures. **Exploration 1.2** illustrates the use of the three techniques in a study of anger and aggression. Because each method has its limitations, knowledge is advanced the most when *multiple* methods and measures are used to study the same aspect of human development and these different methods lead to similar conclusions.

The Case Study, Experimental, and Correlational Methods

Once developmental scientists have formulated hypotheses, chosen a sample, and figured out what to measure and how to measure it, they can test their hypotheses. As we have seen, developmental science got its start with baby biographies, and on occasion today’s researchers still study the development of particular individuals through case studies. More often they use the experimental and correlational methods to examine relationships between one variable and another—and, where possible,

Functional magnetic resonance imaging is increasingly being used to study which parts of the brain are activated when humans of different ages perform various cognitive tasks. Testing children is challenging, however; they may fear entering the tube of the MRI scanner and, once there, may have difficulty staying still as required.

● EXPLORATION 1.2

Data Collection Methods in Action: Measuring Anger

We can illustrate the primary methods of data collection by considering a study by Julie Hubbard and her colleagues (2002) that used all three approaches. Hubbard was interested in the relationship between anger and two styles of aggression in 8-year-olds, as determined by teachers' responses to questions about children's behavior in the classroom: a "hot" kind of aggression in which children hit, pinch, and otherwise abuse other children when provoked, and a cooler, more calculating style of aggression in which children use aggression to get what they want. The researchers hypothesized that aggressive children of the first type would be more likely than aggressive children of the second type to become angry in a laboratory situation in which another child (a confederate of the researchers) cheated shamelessly in a board game about astronauts and won. The researchers needed a way to measure anger. What would you suggest?

Behavioral observation. Hubbard used *structured observation* by setting up the astronaut game situation, having the

confederate cheat to provoke children's anger, and then observing signs of anger in facial expressions and nonverbal behavior. The confederate was carefully trained to behave the same way with each of the 272 participants in the study. Sessions were videotaped; trained graduate and undergraduate students then coded second by second whether the participants' facial expressions were angry, sad, happy, or neutral and whether they showed any nonverbal signs of anger (for example, slamming game pieces on the table). Two students independently coded a subsample of the videotapes to ensure that their codings agreed.

Verbal report. The researchers also had each participant watch a videotape of the game he or she played with the cheating confederate, stopped the tape at each turn in the game, and asked each child, "How angry did you feel now?" The child responded on a four-point scale ranging from 1 (not at all) to 4 (a lot). The researchers used these ratings to calculate for each child an average degree of self-reported anger during the game.

Physiological measure. The researchers collected data on two physiological indicators of anger by attaching electrodes to children's hands and chests (after convincing the children that astronauts normally wear sensors when they go into space). Emotionally aroused individuals, including angry ones, often have sweaty palms and low electrical resistance of the skin, which can be measured by electrodes attached to their hands. Emotional arousal is also given away by a high heart rate, measured through electrodes on the chest.

Using these measures, Hubbard and her colleagues found that, as hypothesized, children who engaged in "hot" aggression in the classroom showed more anger during the game than "cool" aggressors. Their anger was clearest in the skin resistance and nonverbal behavior measures. Because all data collection methods have their weaknesses, and because different measures often yield different results, as in this study, use of multiple methods in the same study is a wise research strategy.

to establish that one variable causes another. We will illustrate these methods by sampling research on the implications of digital media for human development.

The Case Study

A **case study** is an in-depth examination of an individual (or a small number of individuals), typically carried out by compiling and analyzing information from a variety of sources, such as observation, testing, and interviewing the person or people who know her (see Flyvbjerg, 2011; Miller, 2013). The case study method can provide rich information about the complexities of an individual's development and the influences on it. It is particularly useful in studying people with rare conditions, disorders, and developmental experiences when it is not possible to assemble a large sample of people to study or when an unusual case can say something important about typical development. To illustrate, the case study method was used by Matthew Bowen and Marvin Firestone (2011) to describe four individuals, all European American males, who have what has come to be called "Internet addiction." One of the four men that they studied spent all

afternoon and night until 8 or 9 A.M. online, mostly in chat rooms and at blogs or playing video games. He enjoyed disguising his identity and making other participants in chat rooms think that he knew of their most painful experiences. All four men in the study had psychological problems and difficulties in interpersonal relationships.

The case study method can complement correlational and experimental research (Flyvbjerg, 2011). It can be a good source of hypotheses that can be examined further in larger-scale studies, and it can provide a rich picture of atypical development. However, conclusions based on a single case (or four) may not generalize to other individuals, and inferences about what may have caused a person to develop as he or she did often need further study.

The Experimental Method

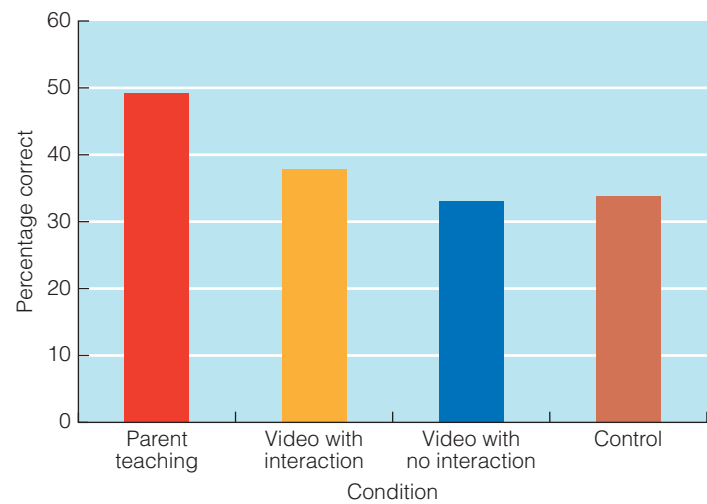

In an **experiment**, an investigator manipulates or alters some aspect of the environment to see how this affects the behavior of the sample of individuals studied. Consider the effects of watching videos or DVDs on infants. Many of today's parents, wanting to

get their children off to a great start, not only set their babies in front of *Sesame Street* and other television programs and let them play with iPhones and iPads but buy them special baby videos that claim they will advance infants' cognitive and language development—products such as Baby Einstein's Baby Wordsworth, Intellectual Baby (which promises to teach babies to read), and many others. Do such infant videos actually speed infant language development?

Judy DeLoache and her colleagues (2010) decided to find out by conducting an experiment with 72 infants ranging in age from 12 to 18 months. The DVD they studied showed scenes of a house and yard while a voice labeled 25 different household objects, each shown three different times. Each family in the study was randomly assigned to one of four experimental groups: (1) *parent teaching* (in this old-fashioned condition, no video was provided; rather, parents were given the 25 words featured in the video and asked to teach as many as possible to their babies however they wished), (2) *video-with-interaction* (child and parent watched the video together five or more times a week for four weeks and interacted as they did), (3) *video-with-no-interaction* (infants watched the video by themselves; their parents were usually nearby but did not interact with them), and (4) a *no-intervention* control (these babies got no video and no parent training; this control group was needed to determine how many words infants might learn naturally, without any training). After the training period, babies took a test of their knowledge of the target words. For example, an infant would be presented with replicas of a table (a target word in the video) and a fan (not a target word) and asked to point to the right object: “Can you show me the table?”

The goal of an experiment is to see whether the different treatments that form the **independent variable**—the variable manipulated so that its causal effects can be assessed—have different effects on the behavior expected to be affected, the **dependent variable** in the experiment. The independent variable in DeLoache's experiment was the type of training babies received, as defined by the four different experimental conditions. The dependent variable of interest was vocabulary learning (the percentage of words taught in the video that were correctly identified by the infant during the vocabulary test). When cause-effect relationships are studied in an experiment, the independent variable is the hypothesized cause and the dependent variable is the effect. For example, if researchers were testing drugs to improve memory function in elderly adults with Alzheimer's disease, the type of drug administered (for example, a new drug versus a placebo with no active ingredients) would be the independent variable, and performance on a memory task would be the dependent variable.

So, in DeLoache's experiment, did vocabulary learning “depend on” the independent variable, the type of training received? Did infants learn from the baby video? The mean or average word learning scores for the four treatment groups are shown in ■ **Figure 1.3**. Babies did no better on the vocabulary learning test if they had seen the video than if they were in the control condition and received no training at all. The only group that did better on the test than what would be expected by chance was the group of babies taught the old-fashioned

■ **Figure 1.3** Infants' mean scores on the vocabulary test after training in the DeLoache et al. (2010) experiment. Only infants taught words by their parents did better than chance on the test; exposure to baby videos that taught the words had no effect.

Source: Adapted from DeLoache, J. S., Chiong, C. S., Sherman, K., Islam, N., Vanderborcht, M., Troseth, G. L., Strouse, G. A., & O'Doherty, K. (2010). “Do babies learn from baby media?” *Psychological Science*, 21, 1570–1574 (Figure 1 on p. 1572).

way—those in the parent teaching group. And it wasn't that babies or mothers were unenthusiastic about the video. As one mother exclaimed, “She loves the blasted thing. It's crack for babies!” (p. 1572).

The DeLoache study has the three critical features shared by any true experiment:

1. **Random assignment.** **Random assignment** of participants to different experimental conditions (for example, by drawing names blindly to determine who gets which treatment) is critical in experiments. It helps ensure that the treatment groups are similar in all respects at the outset (for example, in the baby video study, similar in socioeconomic status, ethnicity, previous level of cognitive and language development, and any other characteristics that could affect infants' performance). Only if experimental groups are similar in all respects initially can researchers be confident that differences among groups at the end of the experiment were caused by differences in which experimental treatment they received. Some studies, such as those evaluating already-started interventions, cannot randomly assign participants to groups; instead they compare the group receiving the intervention to a control group. Such studies are sometimes called “quasi experiments” because uncontrolled differences between the two groups could influence the results.
2. **Manipulation of the independent variable.** Investigators must arrange the experiences that different groups in the experiment have so that the effects of those experiences can be assessed. If investigators merely compare infants who already watch baby videos with infants who do not, they cannot establish whether video watching *causes* an increase in word

knowledge. For example, it could be that more-educated parents buy these videos more often than less-educated parents and also talk and read more to their children.

- 3. Experimental control.** In a true experiment with proper **experimental control**, all factors other than the independent variable are controlled or held constant so that they cannot contribute to differences among the treatment groups. In a laboratory study, for example, all experimental groups may be tested in the same room by the same experimenter reading the same instructions. It is hard in a field experiment like DeLoache's, where the experimental conditions are implemented in children's homes by their parents, to control all extraneous factors. However, DeLoache and her colleagues asked parents to keep a log of their use of the video (or of the time they spent teaching vocabulary words if they were in the parent teaching condition). This allowed the experimenters to check that parents were following instructions and not using other materials or departing from the study plan. They were trying their best to ensure that infants in the four treatment conditions were treated similarly except for the type of training they received.

The greatest strength of the experimental method is its ability to establish unambiguously that one thing causes another—that manipulating the independent variable causes a change in the dependent variable. When experiments are properly conducted, they contribute to our ability to *explain* human development and sometimes to *optimize* it. In the DeLoache study, the results suggest that parent-infant interaction may contribute more to vocabulary growth than baby videos. Does the experimental method have limitations? Absolutely! First, because experiments are often conducted in laboratory settings or under unusual conditions, the results may not always hold true in the real world. Noted developmental psychologist Urie Bronfenbrenner (1979) was critical of the fact that so many developmental studies are contrived experiments. He once charged that developmental psychology had become “the science of the strange behavior of children in strange situations with strange adults” (p. 19). Experiments often show what can cause development but not necessarily what most strongly shapes development in natural settings (McCall, 1977).

A second limitation of the experimental method is that it often cannot be used for ethical reasons. How would you conduct a true experiment to determine how older women are affected by their husbands' deaths, for example? You would need to identify a sample of elderly women, randomly assign them to either the experimental

group or the control group, and then manipulate the independent variable by killing the husbands of all the members of the experimental group! Ethical principles obviously demand that developmentalists use methods other than true experimental ones to study questions about the effect of widowhood—and a host of other significant questions about development.

The Correlational Method

Largely because it is unethical to manipulate people's lives, most developmental research is correlational rather than experimental. The **correlational method** generally involves determining whether two or more variables are related in a systematic way. Researchers do not randomly assign participants to treatment conditions and manipulate the independent variable as in an experiment. Instead, researchers take people as they are and attempt to determine whether there are relationships among their experiences, characteristics, and developmental outcomes.

Like DeLoache and her colleagues, Frederick Zimmerman and his colleagues (2007) were interested in the effects of media viewing on the language development of infants. They conducted a correlational study that involved telephone surveys with 1008 parents of children 8–24 months of age. They asked about infants' exposure to several types of media—not only videos and DVDs especially for babies, but children's educational programs, children's noneducational programs, and grownup TV. They used an established measure of language development in which parents report on their children's understanding of various words, and they correlated frequency of exposure to the different types of media with infants' vocabulary scores. Appreciating that there could be uncontrolled differences between families high and low in media use, they used statistical control techniques to adjust vocabulary scores to make it “as if” families were equal in potentially confounding characteristics such as race/ethnicity, parent education, family income, the presence of two parents in the home, day care participation, and other factors that they believed might be related to both media use and language development. They also asked about and controlled for the amount of time parents spent interacting with their infants by reading books and telling stories.

In correlational studies, researchers often determine the strength of the relationship between two variables of interest by calculating a **correlation coefficient**—an index of the extent to which individuals' scores on one variable are systematically associated with their scores on another variable. A correlation coefficient (symbolized as r) can range in value from -1.00 to $+1.00$. A positive correlation between video viewing time and language development

Is this infant really building her vocabulary as she watches baby videos? Both experimental and correlational research suggest that infants learn more from face-to-face interactions than from videos.

Peopleimages/E+/Getty Images

would indicate that as time spent watching videos increases, so does an infant's language development score. (■ **Figure 1.4**, Panel A). A positive correlation of $r = +.90$ would indicate a stronger, more predictable positive relationship than a smaller positive correlation such as $r = +.30$. A negative correlation would result if the heaviest video viewers consistently had the lowest language development scores and the lightest viewers had the highest language development scores (■ **Figure 1.4**, Panel B). A correlation near 0.00 would be obtained if there was no relationship between the two variables—if one cannot predict how advanced in language development infants are based on knowing how much they watch baby videos (■ **Figure 1.4**, Panel C).

The findings of Zimmerman's study were quite surprising. Among the youngest infants (8–16 months), each hour of viewing baby DVDs or videos per day was associated with *fewer* words known; the correlation was negative. By contrast, parent reading and storytelling were positively correlated with language development scores. Among older infants (ages 17–24 months), baby video viewing was not associated one way or the other with language development scores, as the DeLoache et al. (2010) experimental study also found. However, reading, and to a lesser extent storytelling, continued to be positively correlated with language development.

Should we conclude from the Zimmerman study, then, that reading to infants and toddlers advances their language development but that giving babies under 17 months of age baby videos and DVDs impedes their language development? Not so fast. Because this is a correlational study, we cannot draw firm cause-effect conclusions the way we can in an experiment. Does watching baby videos really delay language development among young infants, or could there be other reasons for the negative relationship between watching baby videos and vocabulary?

One important rival interpretation in most correlational studies is the **directionality problem**: The direction of the cause-effect relationship could be the reverse of what the researcher thinks it is. That is, exposure to baby videos may not

cause infants to be delayed in language development; rather, as Zimmerman et al. (2007) acknowledge, slow language development could cause video viewing. That is, parents who fear that their infant is delayed in language development may buy baby videos in the hope that the videos will speed language development.

A second rival interpretation in correlational studies is the **third variable problem**: The association between the two variables of interest may be caused by some third variable. Zimmerman and his colleagues measured and tried to control for a number of possible third variables. For example, it could be that parents who are not very motivated to interact with their babies rely more on videos to entertain or babysit them and that it is the lack of parent-infant interaction, not increased time watching baby videos, that hurts young infants' language development. To rule out this possibility, Zimmerman and his colleagues showed that babies' video watching was negatively correlated with vocabulary score even when the amount of parent interaction through reading and storytelling, as well as a number of other potential "third variables," such as parent education and income, were controlled. However, as they admit, they did not control for the quality of parent-infant interactions and for additional, unmeasured factors that could explain why some infants both watch more baby videos than other infants and have lower language development scores.

Thus, the correlational method has one major limitation: It cannot unambiguously establish a causal relationship between one variable and another the way an experiment can. Correlational studies can only *suggest* that a causal relationship exists. Although Zimmerman's team used statistical control techniques to make it as if other factors were equal, they could not completely rule out the directionality problem and the third variable problem to establish a cause-effect relationship between baby video viewing and delayed language development. It's a rule every researcher knows by heart: "Correlation is not causation."

Despite this key limitation, the correlational method is extremely valuable. First, as already noted, most important

■ **Figure 1.4** Plots of hypothetical correlations between the time babies spend watching infant videos and their knowledge of vocabulary words. Each dot represents a specific child who watches a certain amount of baby videos and has a certain score on a vocabulary test. Panel A shows a positive correlation between video watching and vocabulary: The more infants watch infant videos, the more vocabulary words they know. Panel B shows a negative correlation: The more infants watch videos, the fewer vocabulary words they know. Finally, Panel C shows zero correlation: The amount of time watching baby videos is unrelated to an infant's knowledge of vocabulary words.

questions about human development can be addressed only through the correlational method because it would be unethical to manipulate people’s experiences in experiments. Second, complex correlational studies and statistical analyses allow researchers to learn about how multiple factors operating in the “real world” may combine to influence development. We just have to be on the lookout for the directionality problem and the third variable problem in interpreting correlational relationships. See • **Table 1.3** for a comparison of experimental and correlational methods.

In the end, understanding of why humans develop as they do is best advanced when the results of different kinds of studies *converge*—when experiments demonstrate a clear cause-effect relationship and correlational studies reveal that the same relationship seems to operate in everyday life. One study’s findings are not enough to go on; indeed, very often in psychology as well as in other sciences the findings of a particular study are not consistently confirmed when other researchers try to replicate the study (Open Science Collaboration, 2015). When we have the results of multiple studies addressing the same question, they can be synthesized to produce overall conclusions through the research method of **meta-analysis** (Glass, McGaw, & Smith, 1981; van IJzendoorn, Bakermans-Kranenburg, & Alink, 2012). In our baby DVDs example, this might involve comparing, across many studies, the language development scores of infants who were exposed to baby videos and infants who were not.

We do not yet have enough studies to say whether baby videos are helpful or worthless as a tool of language development. However, the experimental study and correlational study we have highlighted here, as well as other studies, do not support the claims of the makers of these products. They mostly say that baby DVDs neither help nor hurt infants (see, for example, Ferguson & Donnellan, 2014; Neuman et al., 2014; Richert et al., 2010). It’s still the case that the best way for infants and toddlers to learn language is the old-fashioned way: by conversing with their caregivers as they go about their daily activities (Golinkoff et al., 2015; and see Chapter 7). Researchers are discovering that infants have a **video deficit**, a difficulty learning as much from video presentations as they do from face-to-face presentations (Anderson & Pempek, 2005; Strouse & Troseth, 2014). Interestingly, they seem to need to

perceive an adult on a screen as a real social partner who is talking with them personally in order to learn from that adult (Roseberry, Hirsh-Pasek, & Golinkoff, 2014; Troseth, Saylor, & Archer, 2006). Partly because of findings like these, the American Academy of Pediatrics (2010) recommends that children younger than 2 not watch television or other media on the grounds that they are likely to develop better if they spend that time interacting with adults.

Developmental Research Designs

Along with the experimental and correlational methods they use to study relationships between variables, developmental researchers need specialized research designs to study how people change and remain the same as they get older (Schaie, 2000). To describe development, researchers have relied extensively on two types of research designs: the cross-sectional design and the longitudinal design. A third type of design, the sequential study, has come into use in an attempt to overcome the limitations of the other two techniques.

Cross-Sectional Designs

In a **cross-sectional design**, the performances of people of different age groups, or cohorts, are compared. A **cohort** is a group of individuals born at the same time, either in the same year or within a specified span of years (for example, a generation is a cohort). A researcher interested in the development of vocabulary might gather samples of speech from several 2-, 3-, and 4-year-olds; calculate the mean (or average) number of distinct words used per child for each age group; and compare these means to describe how the vocabulary sizes of children age 2, 3, and 4 differ. The cross-sectional study provides information about *age differences*. By seeing how age groups differ, researchers can attempt to draw conclusions about how performance changes with age.

Suppose we are interested in learning about how people’s use of computers, the Internet, and other communication technologies changes as they get older. Psychologists Patricia Tun and Margie Lachman (2010) conducted a cross-sectional study of computer use and its relationship to cognitive functioning in

• **Table 1.3** A Comparison of the Experimental Method and the Correlational Method

Experimental Method	Correlational Method
Manipulation by the investigator of an independent variable to observe effect on a dependent variable	Study of the relationship between one variable and another (without investigator manipulation and control of people’s experiences)
Random assignment to treatment groups (to ensure similarity of groups except for the experimental manipulation)	No random assignment (so comparison groups may not be similar in all respects)
Experimental control of extraneous variables	Lack of control over extraneous variables
Can establish a cause-effect relationship between independent variable and dependent variable	Can suggest but not firmly establish that one variable causes another owing to directionality and third variable problems
May not be possible for ethical reasons	Can be used to study many important issues that cannot be studied experimentally for ethical reasons
May be artificial (findings from contrived experiments may not generalize to the “real world”)	Can study multiple influences operating in natural settings (findings may generalize better to the “real world”)

adulthood. They surveyed a national sample of adults ranging in age from 32 to 84 about how often they used computers and then compared computer use across age groups. ■ **Figure 1.5** shows the percentage of each age group using computers to some extent. Clearly computer use was more common among younger adults than among elderly adults. But can we conclude that computer use normally declines with age as people get older? Not really.

People who are in their 70s not only are older than people in their 50s and 30s but they also belong to a different cohort or generation and have had different formative experiences. The 70-year-olds in Tun and Lachman's study did not have computers when they were children, whereas the 30-year-olds did. Do 70-year-olds use computers less because people lose interest in computers as they age, or is it that 70-year-olds were never as heavily into computers even when they were younger? Tun and Lachman's study cannot tell us.

In cross-sectional studies, such as Tun and Lachman's, *age effects and cohort effects are confounded, or entangled*. **Age effects** are relationships between age (a rough proxy for changes brought about by nature and nurture) and an aspect of development. **Cohort effects** are the effects of being born as a member of a particular cohort or generation in a particular historical context. Cross-sectional studies tell how people of different ages (cohorts) differ, but they do not necessarily tell how people normally *change* as they get older. In Tun and Lachman's study, for example, what initially looked like a developmental trend toward declining computer use in later life (an age effect) could actually be a cohort effect resulting from differences in the formative experiences of the different generations studied.

Indeed, the Pew Research Center (2014) has found through yearly surveys that Internet use among U.S. adults has in fact been steadily *increasing* from year to year. And this is just as true

■ **Figure 1.5** Percentage of American adults of different ages who used computers in 2005–2006. Do you think that computer use normally declines with age during adulthood? Read about age effects vs. cohort effects in cross-sectional studies.

Source: Adapted from Tun, P. A. & Lachman, M. E. (2010). "The association between computer use and cognition across adulthood: Use it so you won't lose it?" *Psychology and Aging*, 25, 560–568.

among adults age 65 and older as among younger adults. The percentage of adults aged 65 and older who report Internet use climbed from only 14% in 2000 to 59% by 2013. This is quite a different picture than we got from the cross-sectional study shown in **Figure 1.5**, where Internet use seemed to *decrease* with age.

The discovery of cohort effects tells us that it can make a difference whether you are born into one generation or another (see **Exploration 1.3** on the millennial and baby boom generations). However, the presence of cohort effects poses a problem in cross-sectional research whenever the growing-up experiences of the cohorts being compared differ. As you will see in Chapter 9, it was once believed, based on cross-sectional studies of performance on intelligence tests, that people experience significant declines in intellectual functioning starting in middle age. However, later longitudinal studies suggested that intellectual declines were much less steep and came later in life (Schaie, 2000). Why the discrepancy? The elderly adults in cross-sectional studies probably performed less well than younger cohorts not because they experienced steep losses of intellectual abilities during adulthood (a true developmental or age effect) but because they had received less education in their youth (a cohort effect). They probably always had lower intellectual abilities than younger cohorts as a result.

The second major limitation of the cross-sectional design besides the entanglement of age effects and cohorts is this: Because each person is observed at only one point, researchers learn nothing about how individuals change with age. Returning to our computer-use example, researchers cannot see whether different people show similar or different patterns of change in computer use as they get older or whether people's levels of computer use at age 30 predict whether they are heavy or light users at 70. To address issues like these, researchers need to do longitudinal research.

Despite the limitations of the cross-sectional design, it is a very important approach and developmentalists rely heavily on it. It has the great advantage of being quick and easy: Researchers can go out this year, sample individuals of different ages, and be done with it. Moreover, cross-sectional studies should yield valid conclusions about age effects if the cohorts studied are likely to have had similar growing-up experiences—as when 3- and 4-year-olds rather than 30- and 40-year-olds are compared. It is when researchers attempt to make inferences about development over the span of many years that cohort effects in cross-sectional studies can yield a misleading picture of development.

Longitudinal Designs

In a **longitudinal design**, one cohort of individuals is assessed repeatedly over time. A study of the development of vocabulary would be longitudinal rather than cross-sectional if a researcher identified a group of 2-year-olds and measured their vocabulary sizes, then measured their vocabularies again at age 3 and then again at age 4, and compared the children's mean scores at ages 2, 3, and 4. In any longitudinal study, whether it covers only a few months in infancy or 50 years, the same individuals are studied as they develop. Thus, the longitudinal design provides information about *age changes* rather than age differences.

Imagine that we had had the foresight to design a longitudinal study of computer use back in 1970 and had surveyed 30-year-olds about their computer use in 1970, and again every 20 years since,

● EXPLORATION 1.3

Millennials and Boomers: Cohort Effects

For baby boomers growing up in the 1950s, gender roles were more traditional than they are now. Fewer women worked outside the home, and more parents dressed and treated girls and boys differently.

Liu Liqun/Corbis Documentary/Getty Images

Does it make a difference in your development what generation, or cohort, you belong to? Whether you are part of the Silent Generation (the World War II and Korean War generation born between 1925 and 1946), the **baby boom generation** (the huge cohort born after World War II between 1946 and 1964), Generation X (the small generation born between 1964 and 1982), or the **millennials** (also called Generation Y or the “baby boomlet,” the generation born from the early 1980s to the early 2000s)?

until 2010 (when they would have been 70). The study would have shown that very few adults used computers in 1970 but that rates of computer use increased with age as more and more people gained access to computers. ■ **Figure 1.6** compares a cross-sectional and a longitudinal design for studying 30-, 50-, and 70-year-olds.

We seem to believe that different cohorts or generations not only have different formative experiences but also develop different characters. Popular writing on the subject often presents overgeneralized portraits of different generations—call it stereotyping—based on little solid data. The first wave of baby boomers turned 65 in 2011: George W. and Laura Bush, Bill Clinton, Dolly Parton, Donald Trump, and Cher. They were a year old when Howdy Doody first appeared on the first home TVs and 17 when John F. Kennedy was assassinated; they grew up fearing nuclear bombs and Russians and listening to rock and roll; and many of them protested the Vietnam War or fought in it (Adler, 2005). In the 1960s, boomers were stereotyped as antiestablishment, antiwar rebels who were into drugs and sexual freedom.

Millennials (born from the early 1980s to the early 2000s) have also gotten a lot of attention. They grew up in a digital world, are close to their parents, and appear to be less committed to traditional institutions like marriage and organized religion, less trusting, and more liberal on social issues like gay marriage than older generations (Pew Research Center, 2014). They also have been characterized quite uncharitably as a self-absorbed, narcissistic, “pampered, over-praised, relentlessly self-confident generation” (Matchar, 2012,

p. B1; and see Twenge, 2006; Twenge et al., 2008).

Should we believe this profile? There are more psychological differences within than between generations, so this description surely doesn’t apply to all millennials. Some surveys do suggest, though, that the millennials as a group score higher on personality scales measuring narcissism, or self-absorption, than earlier generations (Twenge & Foster, 2010; Twenge et al., 2008).

But are these generational differences (cohort effects) or are they developmental differences (age effects)? Jean Twenge and her colleagues conclude from their studies that these are real generational differences. But what if millennials appear to be more narcissistic than older adults only because they do not yet have spouses, children, jobs, and other adult responsibilities that require thinking beyond their own needs, whereas older generations do? Perhaps we would see signs of self-absorption in emerging and young adults *regardless of the era in which they live*. After finding evidence to support this possibility, Roberts, Edmonds, and Grijalva (2010) concluded that high narcissism in emerging adulthood may be a normal developmental phenomenon, speculating that “every generation is Generation Me. That is, until they grow up” (p. 101). Here, then, is another example of how, in cross-sectional studies comparing different age groups, we cannot easily separate cohort effects and age effects. Understanding how people typically change with age and understanding how they are affected by the historical-cultural context in which they develop are both important goals of the science of life-span development. We must be careful, though, not to stereotype whole generations based on ambiguous findings.

Because the longitudinal design traces changes in individuals as they age, it can tell whether most people change in the same direction or whether different individuals travel different developmental paths. It can indicate whether the characteristics and behaviors measured remain consistent over time—for example,

Figure 1.6 Cross-sectional and longitudinal studies of development from age 30 to age 70. The longitudinal study involves repeated assessment every 20 years starting in 1970, whereas in the cross-sectional study, the three age groups of interest are compared in 2010.

whether people who used computers a lot at age 30 were still among the heaviest users at age 70. And it can tell whether experiences earlier in life predict traits and behaviors later in life. The cross-sectional design can do none of these.

What, then, are the limitations of the longitudinal design? Our hypothetical longitudinal study of computer use centered on *one cohort* of individuals: members of the 1940 birth cohort. These people were raised in an historical context in which computers were scarce and lived through a time when they became a fixture in almost every American home (Cotten, McCullough, & Adams, 2011). Their computer use probably increased over time from 1970 to 2010 as a result—a developmental trend precisely the opposite of the “decline” with age in computer use in Tun and Lachman’s (2010) cross-sectional study (shown in Figure 1.5). However, this does not necessarily mean that computer use *typically* increases with age. The technological advances that occurred from one time of measurement to the next during the time frame of this particular study could be responsible for the observed increase. **Time-of-measurement effects** in developmental research are the effects of historical events and trends occurring when the data are being collected and that can affect anyone alive at the time (for example, effects of an economic recession, a traumatic event like 9/11, advances in health care, or, here, the invention of personal computers and the Internet). In a longitudinal study, then, *age effects and time-of-measurement effects are confounded*.

Because of time-of-measurement effects, we may not know whether the age-related changes observed in a longitudinal study are generalizable to people developing in other sociohistorical contexts. Perhaps we would obtain different “developmental” trends if we were to conduct a longitudinal study about computer use starting today, when computer use is already widespread, rather than in 1970. Our research example was chosen to highlight problems in both cross-sectional studies (where cohort effects

are tangled with age effects) and longitudinal studies (where time-of-measurement effects are tangled with age effects). Moral: It can be challenging to identify true developmental or age effects.

The longitudinal design has other disadvantages (Pulkkinen & Kokko, 2012): It is costly and time-consuming; its methods and measures may seem outdated or incomplete by the end of the study; its participants may drop out because they move, lose interest, or die; and participants may be affected by being tested repeatedly (for example, become more test wise).

Are both the cross-sectional and the longitudinal designs hopelessly flawed, then? Not at all. Cross-sectional studies are very efficient and informative, especially when the cohorts studied are not widely different in age or formative experiences. Longitudinal studies are extremely valuable for what they can reveal about how people change as they get older—even though it must be recognized that we may not be able to generalize to people living during other times in history. Still, in an attempt to overcome the limitations of both cross-sectional and longitudinal designs, developmentalists have devised a more powerful method of describing developmental change: the sequential design.

Sequential Designs: The Best of Both Worlds

A **sequential design** combines the cross-sectional approach and the longitudinal approach in a single study (Schaie, 1994; Schaie & Caskie, 2005). In Chapter 9, you will read about an ambitious and important sequential study of changes in mental abilities during adulthood conducted by psychologist and gerontologist K. Warner Schaie and his colleagues (1996, 2005). Adults ranging in age from 22 to 70 and grouped into age groups (cohorts) were tested on a battery of mental ability tests (in a cross-sectional design), and then they were retested every 7 years (to create a longitudinal design). At each testing point, new cohorts of adults in their 20s–70s were added to the study and those age groups were then retested. Some of the adults in the study were followed for as long as 45 years. This elaborate study has yielded many insights into intellectual aging. Not only were systematic changes with age in mental abilities identified, but cohort and time-of-measurement effects were revealed, suggesting that intellectual functioning is indeed influenced by the times in which people develop.

Sequential designs, by combining the cross-sectional and longitudinal approaches, improve on both. They can tell researchers

1. which age-related trends are truly developmental in nature and reflect how most people, *regardless of cohort*, can be expected to change over time (age effects);
2. which age trends differ from cohort to cohort and suggest that each generation is affected by its distinct growing-up experiences (cohort effects); and
3. which trends suggest that events during a specific period of history affect all cohorts alive at the time (time-of-measurement effects).

In short, sequential designs can begin to untangle the effects of age, cohort, and time of measurement. Yet they are complex and expensive. Generally, the study of life-span human development has progressed from early (and sometimes misleading) cross-sectional

studies to more long-term longitudinal studies and, increasingly, to more complex sequential studies, especially of adult development (Baltes, Lindenberger, & Staudinger, 2006). See ● **Table 1.4** for a summary of the three basic developmental designs.

Now that you have encountered examples of the various data collection methods and research designs used to study development, we challenge you to identify the research examples in **Engagement 1.1**.

● **Table 1.4** Cross-sectional, Longitudinal, and Sequential Developmental Designs

	Cross-Sectional Design	Longitudinal Design	Sequential Design
Procedure	Observe people of different cohorts at one point in time	Observe people of one age group repeatedly over time	Combine cross-sectional and longitudinal approaches; observe different cohorts on multiple occasions
Information Gained	Describes age differences	Describes age changes	Describes age differences and age changes
Advantages	Demonstrates age differences in behavior and hints at developmental trends Takes little time to conduct and is inexpensive	Indicates how individuals are alike and different in the way they change over time Can reveal links between early behavior or experiences and later behavior	Helps separate the effects of age, cohort, and time of measurement Indicates whether developmental changes are similar in different cohorts
Disadvantages	Age trends may reflect cohort effects rather than true developmental change Provides no information about change in individuals over time	Age trends may reflect time of measurement effects during the study rather than true developmental change Relatively time-consuming and expensive Measures may later prove inadequate Participants drop out Participants can be affected by repeated testing	Complex, time-consuming, and expensive Despite being the strongest method, may still leave questions unresolved

● **ENGAGEMENT 1.1**

Recognizing Research Strategies

For each research example, identify the most appropriate descriptive term. Answers are printed upside down below. Testing yourself is a great way to learn!

- To study prejudice, a researcher gives some children red T-shirts and others blue T-shirts to see how children interact with members of the “in-group” and members of the “out-group.”
 - meta-analysis
 - structured observation
 - case study
 - naturalistic observation
- Every 10 years, a researcher assesses the religious participation of a group of adults who were age 20 in 2000, at the start of the study, and does the same with a similar group of adults who were age 20 in 2010.
 - cross-sectional
 - quasi-experimental
 - correlational
 - sequential
- A new program to encourage teenage fathers to support their partners during labor and delivery is compared to a standard childbirth education program to see what effect it has on pain during labor and delivery. The independent variable is:
 - gender of parent
 - type of program
 - pain during labor and delivery
 - support given by fathers
- A researcher finds that adults who were college age when 9/11 occurred in 2001 view the world as a scarier place than adults who were older at that time. This is a(n):
 - time-of-measurement effect
 - age effect
 - cohort effect
 - sequential effect
- A researcher finds a small or modest relationship indicating that the greater a child’s weight, the less he or she is liked by peers. The correlation coefficient calculated is probably around:

a. +.70	b. +.20
c. −.70	d. −.20

Answers: 1. b, 2. d, 3. b, 4. c, 5. d

● Checking Mastery

1. Design an experiment to determine whether listening to music while studying a chapter helps or hurts performance on a test on the chapter material compared to studying the chapter in silence. Make it clear that your experiment has the key features of an experiment and label the independent and dependent variables.
2. You conduct a longitudinal study of the development of self-esteem in college students from age 18 to age 22. What would you be able to learn that you could not learn by conducting a cross-sectional study of the same topic?

● Making Connections

1. Explain how a cross-sectional study of age differences over the adult years in attitudes about gender roles could suggest that attitudes become more traditional with age, but a longitudinal study could suggest that gender attitudes become *less* traditional with age.
2. Professor Feelgood conducts a study that reveals a correlation of $+ .50$ between self-esteem and academic achievement (grade point average) among college students. He then argues, based on this finding, that his college should launch a self-esteem-boosting program if it wants its students to gain more from their college experience. Convince the professor that there are at least two rival explanations for this correlation and suggest how he could do research to try to determine which explanation is most correct.

1.4

What Special Challenges Do Developmental Scientists Face?

LEARNING OBJECTIVES

- Discuss the challenges in conducting culturally sensitive research.
- Explain the four major ethical obligations of investigators to their research participants.

We hope we have convinced you that human development is worthy of study and requires serious and thoughtful research. We conclude this chapter by discussing two additional challenges in the study of human development: being sensitive to cultural and subcultural differences and protecting the rights of research participants.

Conducting Culturally Sensitive Research

Baltes's life-span perspective emphasizes that development is shaped by its cultural context. This implies that we need to study development in a variety of contexts using culturally sensitive research methods and measurements to understand both what is universal and what is culturally specific about human development (Cole & Packer, 2011). Easier said than done!

By one count, two-thirds of the research samples in studies published in American psychology journals were American, yet 95% of the world's population is *not* American (Arnett, 2008). Joseph Henrich and his colleagues have gone so far as to characterize psychology as the study of **WEIRD people**: people living in societies that are Western, Educated, Industrialized, Rich, and Democratic (Henrich, Heine, & Norenzayan, 2010). They go on to suggest that American undergraduate students are especially WEIRD, unrepresentative of the human

species. They give many examples, some of which you will encounter in this book, of psychological differences between WEIRD samples and samples from other types of societies. For example, it has been found that in Western societies, people tend to define themselves as individuals and want to stand out, whereas in Eastern societies, such as Japan, they tend to define themselves in relation to other people and want to fit in (Henrich et al., 2010).

Developmentalists appreciate the importance of studying samples of developing persons from a variety of ecological settings, not just white middle-class America. However, carrying out research in a variety of cultures and subcultures and ensuring that questionnaire, interview, and test questions and testing and observation procedures are meaningful in each culture and allow meaningful comparisons across different subcultural or cultural groups can be extremely challenging (Gardner et al., 2012; Rogoff, 2003). Language differences pose a problem: When one organization translated a survey into 63 languages and then had the questions translated back into English, for example, “married or living with a partner” was translated as “married but have a girlfriend” (Morin, 2003). And when a team of researchers sought to conduct a cross-cultural study of caregiver-infant interactions, they faced a dilemma: Should they observe such interactions when the caregiver and infant were alone (typical in American homes) or when the caregiver and infant were in a group (typical in Micronesia)? They settled on observing in both social contexts

Only cross-cultural research can tell us whether the findings of research conducted in our society hold true in societies very different from ours.

Bettmann/Getty Images

to avoid findings that might be biased toward one cultural group or the other (Sostek et al., 1981). To make their research more culturally sensitive, many researchers involve community members in the planning and design of their studies (Karlawish et al., 2009; Martin & Lantos, 2005).

In addition, researchers who study cultural or racial, ethnic, or socioeconomic differences in development must work hard to keep their own cultural values from biasing their perceptions of other groups and interpretations of their data. Too often, Western researchers have let **ethnocentrism**—the belief that one’s own group and its culture are superior—creep into their research designs, procedures, and measures. And too often, researchers have judged minority group children and adults according to white middle-class standards, have labeled them “deficient” when they would better be described as “different,” and have looked more at their vulnerabilities than at their strengths (Ogbu, 1981; Spencer, 2006). Also too often, researchers have assumed that all African Americans or Asian Americans or Hispanic Americans are alike psychologically, when in fact there is immense diversity within each racial or ethnic group (Helms, Jernigan, & Mascher, 2005). Today’s developmentalists appreciate the importance of understanding human development in its cultural and subcultural context, but actually doing so is a tremendous challenge.

Protecting the Rights of Research Participants

Developmental researchers must also be sensitive to **research ethics**—the standards of conduct that investigators are ethically bound to honor to protect their research participants from physical or psychological harm (see, for example, Buchanan, Fisher, & Gable, 2009; Kodish, 2005; Pimple, 2008).

Many ethical issues arise in developmental research. For example, is it ethical to tell children that they performed poorly on a test to create a temporary sense of failure? Is it an invasion of a family’s privacy to ask adolescents questions about conversations they have had with their parents about sex? If a drug to treat memory loss in elderly adults with Alzheimer’s disease appears to be working, should it be withheld from the control group in the study? Concepts of consent, privacy, and harm also differ from society to society, so researchers must be sensitive to ethical values in the culture they will be studying (Miller, Goyal, & Wice, 2015).

The federal government (through the Office for Human Research Protections) and a variety of professional organizations such as the American Psychological Association have established guidelines for ethical research with humans. Federal regulations require universities and other organizations that conduct research with humans to have institutional review boards (IRBs) that determine whether proposed research projects conform to ethical standards

and to approve projects only if they comply.

Deciding whether a proposed study is on safe ethical ground involves weighing the possible benefits of the research (gains in knowledge and potential benefits to humanity or to the participants) against the potential risks to participants. If the potential benefits greatly outweigh the potential risks, and if there are no other, less risky procedures that could produce these same benefits, the investigation is likely to be viewed as ethical. The investigator’s ethical responsibilities boil down to respecting the rights of research participants by (1) allowing them to freely give their informed consent, (2) debriefing them afterward if they are not told everything in advance or are deceived, (3) protecting them from harm, and (4) treating any information they provide as confidential.

Informed Consent

Researchers generally should inform potential participants of all aspects of the research that might affect their decision to participate so that they can make a voluntary decision based on full knowledge of what the research involves. But are young children or mentally impaired people, such as older adults with Alzheimer’s disease, capable of understanding what they are being asked to do and of giving their *informed* consent? Often they are not or it can be challenging to tell if they are (for example, see Drotar, 2008; Dunn & Misra, 2009; Kodish, 2005; Miller, 2013). Therefore, researchers who study such “vulnerable” populations should obtain at least the “assent” or agreement of the individual (if possible) as well as the informed consent from someone who can decide on the individual’s behalf—for example, the parent or guardian of a child or the legal representative of a cognitively impaired nursing home resident. Investigators also must take care not to pressure anyone to participate and must respect participants’

right to refuse to participate, to drop out during the study, and to refuse to have their data used by the investigator.

Debriefing

Researchers generally tell participants about the purposes of the study in advance, but in some cases doing so would ruin the study. If you told college students in advance that you were studying moral development and then gave them an opportunity to cheat on a test, do you think anyone would cheat? Instead, you might set up a situation in which students believe they can cheat without being detected, see who cheats, and then debrief them afterward, explaining the true purpose of the study. You would also have an obligation to make sure that participants do not leave feeling upset about cheating.

Protection from Harm

Researchers are bound not to harm research participants either physically or psychologically. Infants may cry if they are left in a room with a stranger. Adolescents may become embarrassed if they are asked about their sex lives. Investigators must try to anticipate and prepare to deal with such consequences (for example, by having a counselor on call). If physical or psychological harm to participants seems likely, the researcher may need to find another way of answering the research question. Federal regulations provide extra protection from harm to children (Kodish, 2005).

Confidentiality

Researchers also have an ethical responsibility to keep confidential the information they collect. It would be unacceptable, for example, to tell a child's teacher that the child performed poorly on an intelligence test or to let an adult's employer know that he revealed a drinking problem in an interview. Only if participants give explicit permission to have information about them shared with someone else or, in rare cases, if the law requires disclosure

of information (such as when a researcher learns that a child is being abused) can that information be passed on.

Clearly, developmental researchers have some challenging issues to weigh if they want their research to be well designed, culturally sensitive, and ethically responsible. Understanding life-span human development would be downright impossible, though, if researchers merely conducted study after study without guiding ideas. Theories of human development provide those guiding ideas and are the subject of Chapter 2.

● Checking Mastery

1. How many of the characteristics of WEIRD people do you have?
2. A researcher deceives research participants into thinking they are in a study of learning when the real purpose is to determine whether they are willing to inflict harm on people who make learning errors if told to do so by an authority figure. What ethical responsibilities does this researcher have? (Yes, this is about the famous obedience research conducted by Stanley Milgram, featured in the recent film *The Experimenter*.)

● Making Connections

1. Now that you have earned your PhD in life-span developmental psychology, you want to interview elderly widows in Japan and in the United States about their emotional reactions to widowhood shortly after the deaths of their husbands. What ethical issues should you consider, and what steps should you take to make your study as ethical as possible?
2. What might you do to make this research as culturally sensitive as possible?

Chapter Summary

1.1 How Should We Think about Development?

- Development is systematic changes and continuities over the life span, involving gains, losses, and neutral changes in physical, cognitive, and psychosocial functioning; it is more than growth in childhood and biological aging in adulthood.
- Development takes place in an historical, cultural, and subcultural context and is influenced by age grades, age norms, and social clocks.
- Concepts of the life span and its distinctive periods have changed over history in Europe and North America and differ from culture to culture. Starting in the 17th century, children came to be seen as innocents; in the late 19th century, adolescence emerged as a distinct phase; and only in the 20th century did our society recognize emerging adulthood, a middle-aged "empty nest" period, and an old age characterized by retirement.

- Understanding the nature-nurture issue means understanding the interaction of biology and maturation with environment and learning.

1.2 What Is the Science of Life-Span Development?

- The study of life-span development, guided by the goals of description, prediction, explanation, and optimization, began with the baby biographies written by Charles Darwin and others.
- Through his use of questionnaires and attention to all phases of the life span, including the storm and stress of adolescence, American psychologist G. Stanley Hall came to be regarded as the founder of developmental psychology.
- The modern life-span perspective on human development set forth by Paul Baltes assumes that development (1) occurs throughout the life span, (2) can take many different directions,

(3) involves gains and interlinked losses at every age, (4) is characterized by plasticity, (5) is affected by its historical and cultural context, (6) is influenced by multiple interacting causal factors, and (7) can best be understood if scholars from multiple disciplines join forces to study it.

1.3 How Is Development Studied?

- The scientific method involves formulating theories and testing hypotheses derived from a theory by conducting research with a sample (ideally a random sample) representative of a larger population of interest. Good theories should be internally consistent, falsifiable, and, ultimately, supported by the data.
- Common data collection methods include verbal reports, behavioral observations (naturalistic and structured), and physiological measures.
- The goal of explaining development is best achieved through experiments, which involve random assignments to conditions, manipulation of the independent variable, and experimental control. However, not all developmental issues can be studied with experiments for ethical reasons. Case studies may have limited generalizability, and in correlational studies, one faces

the directionality and third variable problems in attempting to draw cause-effect conclusions. Developmentalists use meta-analyses to synthesize the results of multiple studies of the same issue.

- Developmental research designs seek to describe age effects on development. Cross-sectional studies compare different age groups but confound age effects and cohort effects. Longitudinal studies study age change but confound age effects and time-of-measurement effects. Sequential studies combine the cross-sectional and longitudinal approaches.

1.4 What Special Challenges Do Developmental Scientists Face?

- To understand human development, researchers must study it in a variety of ecological contexts, develop culturally sensitive methods and measures, and keep their own cultural values and ethnocentrism from biasing their conclusions.
- Researchers must adhere to standards of ethical research practice, with attention to ensuring informed consent, debriefing individuals from whom information has been withheld, protecting research participants from harm, and maintaining confidentiality of data.

2.6 Theories in Perspective

For over a year now, Jared, age 15, has been spending a few nights a week out with his new friend Damien, who is two years older and has a driver’s license. Often they drive around town looking for action. Often they find it, hooking up with girls they know from school or town hangouts and taking them back to Damien’s basement for a few beers and sometimes more. Jared has had sex by now with about ten different partners and he has not used a condom every time—or even most times. After he complained to his doctor about genital sores, he was diagnosed with a case of genital herpes. He will not tell his parents if he can avoid it. They have been on his case lately about doing poorly in school and staying out too late.

Having sex at an early age, having many sexual partners, and having unprotected sex—all part of Jared’s developmental story—are common examples of sexual risk behavior. In the United States, 44% of females and 47% of males in the 15–19 age range (18% of those age 15 like Jared) have had sexual intercourse at least once (Martinez & Abma, 2015). Only about 60% of sexually active American teens used a condom during their last experience of intercourse (Kann et al., 2014). Teenagers have higher rates of sexually transmitted infections such as herpes than adults (Abma, Martinez, & Copen, 2010; and see Chapter 12). And, although teenage pregnancy rates

have decreased considerably since a mid-1950s peak, the current pregnancy rate in the United States, 57 of every 1,000 females aged 15–19, is higher than that of most other Western nations (Abma et al., 2010; Sedgh et al., 2015). Why is there so much sexual risk taking among American teens, and what might we do if we want to reduce it?

What is your explanation? What explanations might the leading theories of human development offer? In this chapter we will illustrate that different theories of human development provide different lenses through which to view developmental phenomena, such as teen sexual risk behavior.

2.1

Developmental Theories and the Issues They Raise

LEARNING OBJECTIVES

- Explain why theories are needed in developmental science.
- Outline the four issues addressed by theories of human development.

Teenagers who start having sex early, with multiple partners and little protection, put themselves at risk for sexually transmitted infections and pregnancy.

Hybrid Images/Cultura/Getty Images

As noted in Chapter 1, a theory is a set of ideas proposed to describe and explain certain phenomena—in this book, human development. In science, it is not enough simply to catalog facts without organizing this information around some set of concepts and propositions. Researchers would soon be overwhelmed by trivia and would lack “the big picture.” A theory of human development provides needed organization, offering a lens through which researchers can interpret and explain any number of specific facts or observations. A theory also guides the collection of new facts or observations, making clear

- what is most important to study,
- what can be hypothesized or predicted about it,
- how it should be studied, and
- how findings should be interpreted.

Because different theorists often have different views on these critical matters, what is learned in any science greatly depends on which theoretical perspectives become dominant, which largely depends on how well they account for the facts.

In this chapter, we examine four major theoretical viewpoints, each with important messages about the nature of human development:

1. The *psychoanalytic* viewpoint developed by Sigmund Freud and revised by Erik Erikson and other neo-Freudians
2. The *learning* perspective developed by such pioneers as Ivan Pavlov, John Watson, B. F. Skinner, and Albert Bandura
3. The *cognitive developmental* viewpoint associated with Jean Piaget
4. The *systems theory* approach, exemplified by Urie Bronfenbrenner’s bioecological model

We will be asking as we go whether these theoretical perspectives meet the criteria of good theories introduced in Chapter 1—that is, whether they are internally consistent (coherent), falsifiable (testable), and supported by data (confirmed by research). To further aid you in comparing the theories, we outline four key developmental issues on which theorists—and people in general—often disagree (Miller, 2016; Lerner et al., 2015;

Newman & Newman, 2016): nature–nurture, activity–passivity, continuity–discontinuity, and universality–context specificity. All of us hold some basic beliefs about human development—for example, about the importance of genes versus good parenting in healthy development. Reading this chapter will make you more aware of your own assumptions about human development and how they compare with those of the major theorists. We therefore invite you to clarify your stands on these issues by completing **Engagement 2.1**. • **Table 2.5** at the end of the chapter indicates how the major developmental theorists might answer the questions, so you can compare your assumptions with theirs.

In Exploration boxes throughout this chapter, we imagine some major points each theorist might make about the causes of sexual risk behavior in adolescence. We suggest that you predict what each theorist would say before you read each of these boxes to see whether you can successfully apply each theory. At the end of the chapter (**Application 2.1**), we’ll invite you to apply the different theories to understanding and preventing risky sexual behavior in adolescence. It is our hope that when you master the major theories of human development, you will be able to draw on their concepts and propositions to make better sense of—and perhaps to guide in more positive directions—your own and other people’s development. Now to the four major issues addressed by theories of human development: nature–nurture, activity–passivity, continuity–discontinuity, and universality–context specificity.

Nature–Nurture

Is development primarily the product of nature (biological forces) or nurture (environmental forces)? As you saw in Chapter 1, the nature–nurture issue has been resolved in the sense that the two forces always “co-act” to produce development. However, different theories have taken different positions on the issue and it remains centrally important in the study of human development (Goldhaber, 2012). Strong believers in nature stress the importance of individual genetic makeup, universal maturational processes guided by genes, biologically based predispositions built into genes over the course of evolution, and other biological influences. They are likely to claim that children will typically achieve the same developmental milestones at similar times because of maturational forces, that major changes in functioning associated with aging are largely biologically based, and that differences among individuals are largely because of differences in their genetic makeup and physiology.

By contrast, strong believers in nurture emphasize environment—influences outside the person. Nurture includes influences of the physical environment (crowding, climate, and the like) as well as the social environment (for example, learning experiences, child-rearing methods, peer influence, societal trends, and the cultural context in which the person develops). A strong believer in nurture is likely to argue that human development can take many paths depending on the individual’s experiences over a lifetime.

● ENGAGEMENT 2.1

Where Do You Stand on Major Developmental Issues?

Choose one option for each statement, and write down the corresponding letter or fill it in at the end of the box. See **Table 2.5** to compare your results with how the theorists described in this chapter view development.

- | | | | | | | | | | | | | | | | | | |
|---|--|--|-----------|---|--|--|--|--|---|---|---|---|---------------------------------|---|---|---|---|
| <p>1. Biological influences (heredity and maturational forces) and environmental influences (culture, parenting styles, and learning experiences) are thought to contribute to development. Overall,</p> <ul style="list-style-type: none"> a. biological factors contribute far more than environmental factors. b. biological factors contribute somewhat more than environmental factors. c. biological and environmental factors are equally important. d. environmental factors contribute somewhat more than biological factors. | <p>e. environmental factors contribute far more than biological factors.</p> <p>2. People are basically</p> <ul style="list-style-type: none"> a. active beings who are the prime determiners of their own abilities and traits. b. passive beings whose characteristics are molded either by social influences (parents, other significant people, experiences) or by biological changes beyond their control. <p>3. Activity–Passivity

The **activity–passivity issue** focuses on the extent to which human beings are active in creating and influencing their own environments and, in the process, in producing their own development, or are passively shaped by forces beyond their control. Some theorists believe that humans are curious, active creatures who orchestrate their own development by exploring the world around them and shaping their environments. The girl who asks for dolls at the toy store and the boy who clamors instead for a toy machine gun are actively contributing to their own gender-role development. Both the budding scientist who experiments with chemicals in the basement and the sociable adolescent who spends hours text messaging are seeking out and creating a niche that suits their emerging traits and abilities—and that further develops those traits in the process (Plomin et al., 2013).

Other theorists view humans as passively shaped by forces beyond their control—usually environmental influences but possibly strong biological forces. From this vantage point, children’s academic failings might be blamed on the failure of their parents and teachers to provide them with appropriate learning experiences, and the problems of socially isolated older adults might be attributed to societal neglect of the elderly.

Continuity–Discontinuity

Do you believe that humans change gradually, in ways that leave them not so different from the way they were before, or do you believe humans change abruptly and dramatically? The **continuity–discontinuity issue** focuses in part on whether the changes people undergo over the life span are gradual or abrupt. Continuity theorists view human development as a process that occurs in small steps, without sudden changes, as when grade school children gradually gain weight from year to year. In contrast, discontinuity theorists tend to picture the course of development as more like a series of stair steps, each of which elevates the individual to a new (and often more advanced) level of functioning. When an adolescent boy rapidly shoots up 6 inches in height, gains a bass voice, and grows a beard, the change seems discontinuous.

The continuity–discontinuity issue also concerns whether changes are quantitative or qualitative in nature. Quantitative changes are changes in *degree* and indicate continuity: a person grows taller, knows more vocabulary words, gains more wrinkles, or interacts with friends less frequently. Or there is continuity when people stay much the same. By contrast, qualitative changes are changes in *kind* and suggest discontinuity. They are changes that make the individual fundamentally different in some way (■ **Figure 2.1**). The transformations of a caterpillar into a butterfly rather than just a bigger caterpillar, of a nonverbal infant into a toddler who uses language, or of a prepubertal

■ **Figure 2.1** Is development continuous (A) or discontinuous (B)? That is, do people change quantitatively, becoming different in degree (as shown in Panel A with a size increase), or do they change qualitatively, becoming different in kind (as shown in Panel B, where a tadpole becomes a frog)?

child into a sexually mature adolescent are examples of qualitative changes.

So continuity theorists typically hold that developmental changes are gradual and quantitative, whereas discontinuity theorists hold that changes are more abrupt and qualitative. Discontinuity theorists often propose that people progress through **developmental stages**. A stage is a distinct phase of development characterized by a particular set of abilities, motives, emotions, or behaviors that form a coherent pattern. Development is said to involve transitions from one stage to another, each stage being qualitatively different from the stage before or the stage after. Thus, the adolescent may be able to grasp abstract concepts like human rights and justice in a way that the school-aged child cannot, or the middle-aged adult may be said to be concerned with fundamentally different life issues or conflicts than the young adult or older adult.

To what extent is human development universal and to what extent is it culture specific? Only cross-cultural research can tell us.

Imagno/Hulton Archive/Getty Images

● **Table 2.1** Issues in Human Development

Issue	Description
1. Nature–Nurture	Is development primarily the product of genes, biology, and maturation—or of experience, learning, and social influences?
2. Activity–Passivity	Do humans actively shape their own environments and contribute to their own development—or are they passively shaped by forces beyond their control?
3. Continuity–Discontinuity	Do humans change gradually and in quantitative ways—or do they progress through qualitatively different stages and develop very different competencies and characteristics?
4. Universality–Context Specificity	Is development similar from person to person and from culture to culture—or do pathways of development vary considerably depending on the social context?

Universality–Context Specificity

Finally, developmental theorists often disagree on the **universality–context specificity issue**—or the extent to which developmental changes are common to all humans (universal) or are different across cultures, subcultures, task contexts, and individuals (context specific). Stage theorists typically believe that the stages they propose are universal. For example, a stage theorist might claim that virtually all children enter a new stage in their intellectual development as they enter adolescence or that most adults, sometime around age 40, experience a midlife crisis in which they raise major questions about their lives. From this perspective, development proceeds in certain universal directions.

But other theorists believe that human development is far more varied because it is so influenced by contextual factors. Paths of development followed in one culture may be quite different from paths followed in another culture (or subculture, neighborhood, or even situational context). For example, preschool children in the United States sometimes believe that dreams are real but give up this belief as they get older. By contrast, children raised in the Atayal culture of Taiwan have been observed to become more and more convinced as they get older that dreams are real, most likely because that is what adults in their culture believe (Kohlberg, 1966b). Within a particular culture, developmental change may also differ from subcultural group to

subcultural group, from family to family, and from individual to individual. The issue is this: How alike—or how diverse—are the developmental pathways we travel?

As we survey the major theories of human development, starting with Freud’s well-known psychoanalytic perspective, look to see what stands each theory takes on these four key issues (● **Table 2.1**).

● Checking Mastery

1. What are the two meanings of discontinuity in development?
2. Stage theorists can disagree about a lot, but they are all likely to take certain stands on the issues of nature–nurture, continuity–discontinuity, and universality–context specificity. What stands?

● Making Connections

1. See if you can apply the four main issues in human development to aging and issues in old age. What questions would be raised about nature and nurture, continuity and discontinuity, and so on?

2.2

Psychoanalytic Theory

LEARNING OBJECTIVES

- Summarize the three parts of the personality and the five psychosexual stages in Freud’s psychoanalytic theory.
- Analyze how Erikson’s psychosocial theory differs from and expands on Freud’s theory.
- Explain the conflicts humans face as they move through Erikson’s eight psychosocial stages.
- Evaluate the strengths and weaknesses of Freud’s and Erikson’s theories.

It is difficult to think of a theorist who has had a greater effect on Western thought than Sigmund Freud, the Viennese physician who lived from 1856 to 1939. This revolutionary thinker’s **psychoanalytic theory**, which focused on the development and dynamics of the personality, revolutionized thinking about

human nature and human development. It proposed that people are driven by motives and emotional conflicts of which they are largely unaware and that they are shaped by their earliest experiences in the family (Hall, 1954; Newman & Newman, 2016; Westen, Gabbard, & Ortigo, 2008). Freud’s ideas continue to

influence thinking about human development, even though they are far less influential today than they once were. We introduce this historically important theorist briefly to set the stage for one of his most influential followers, neo-Freudian Erik Erikson.

Freud's Legacy

Freud's hugely influential theory emphasized biological instincts and unconscious motivation, the dynamics of three parts of the personality, and five stages of psychosexual development.

Instincts and Unconscious Motivation

Central to Freudian psychoanalytic theory is the notion that humans have basic biological urges or drives that must be satisfied. Freud viewed the newborn as an inherently selfish and aggressive creature driven by **instincts**—inborn biological forces that motivate behavior. These biological instincts are the source of the psychic (or mental) energy that fuels human behavior and that is channeled in new directions over the course of human development.

Freud strongly believed in **unconscious motivation**—the power of instincts and other inner forces to influence our behavior without our awareness. A preadolescent girl, for example, may not realize that she is acting in babyish ways in order to regain the security of her mother's love; a teenage boy may not realize that his devotion to body building is a way of channeling his sexual and aggressive urges. You immediately see that Freud's theory tilts toward the nature side of the nature–nurture issue: Development is shaped by biological forces that provide an unconscious motivation for behavior. Nevertheless, his theory also includes environmental influences on development, mostly in the form of experiences in the family during the first 5 years of life.

Sigmund Freud's psychoanalytic theory was one of the first, and one of the most influential, theories of how the personality develops from childhood to adulthood. Here, Freud poses with his grandsons, Heinz and Ernst (and a lighted cigar).

Imagno/Hulton Archive/Getty Images

Id, Ego, and Superego

According to Freud (1933), the child's psychic energy is divided among three components of the personality as she develops: the id, the ego, and the superego. At birth, there is only the **id**—the impulsive, irrational, and selfish part of the personality whose mission is to satisfy the instincts. The id seeks immediate gratification, even when biological needs cannot be realistically or appropriately met. If you think about it, young infants do seem to be “all id” in many ways. When they are hungry or wet, they fuss and cry until their needs are met. They are not known for their patience.

The second component of the personality is the **ego**, the rational side of the individual that tries to find realistic ways of gratifying the instincts. According to Freud (1933), the ego begins to emerge during infancy and takes the form of cognitive processes such as perception, learning, and problem solving. The hungry toddler may be able to do more than merely cry when she is hungry; she may be able to draw on the resources of the ego to hunt down Dad, lead him to the kitchen, and say “cookie.” As the ego matures further, children become more capable of postponing pleasures until a more appropriate time and of devising logical and realistic strategies for meeting their needs.

The third part of the Freudian personality is the **superego**, the individual's internalized moral standards. The superego develops from the ego as 3- to 6-year-old children internalize (take on as their own) the moral standards and values of their parents. Once the superego emerges, children have a parental voice in their heads that keeps them from violating society's rules and makes them feel guilty or ashamed if they do. The superego insists that people find socially acceptable or ethical outlets for the id's undesirable impulses.

Conflict among the id, ego, and superego is inevitable, Freud said. In the mature, healthy personality, a dynamic balance operates: The id communicates its basic needs, the ego restrains the impulsive id long enough to find realistic ways to satisfy these needs, and the superego decides whether the ego's problem-solving strategies are morally acceptable (Freud, 1940/1964). The ego has to balance the opposing demands of id and superego while taking into account the realities of the person's environment. Psychological problems often arise if there is imbalance among the three parts of the personality. For example, a salesman with an antisocial personality who routinely lies and cheats may have a strong id but a weak superego, whereas a married woman who cannot undress in front of her husband may have an overly strong superego that makes it difficult for her to fulfill her sexual needs. Through analysis of the dynamics operating among the id, ego, and superego, Freud and his followers attempted to describe and understand individual differences in personality and the origins of psychological disorders.

Psychosexual Stages

Freud (1940/1964) maintained that as the child matures biologically, the psychic energy of the sex instinct, which he called **libido**, shifts from one part of the body to another, seeking to gratify different biological needs. In the process, as outlined in

- **Table 2.2**, the child moves through five **psychosexual stages**: oral, anal, phallic, latency, and genital. Harsh child-rearing

● **Table 2.2** The Stage Theories of Freud and Erikson

Freud's Psychosexual Theory		Erikson's Psychosocial Theory	
Stage (Age Range)	Description	Stage (Age Range)	Description
Oral stage (birth–1 year)	Libido is focused on the mouth as a source of pleasure. Obtaining oral gratification from a mother figure is critical to later development.	Trust vs. mistrust (birth–1 year)	Infants must learn to trust their caregivers to meet their needs. Responsive parenting is critical.
Anal stage (1–3 years)	Libido is focused on the anus, and toilet training creates conflicts between the child's biological urges and the society's demands.	Autonomy vs. shame and doubt (1–3 years)	Children must learn to be autonomous—to assert their wills and do things for themselves—or they will doubt their abilities.
Phallic stage (3–6 years)	Libido centers on the genitals. Resolution of the Oedipus or the Electra complex, which involves desire for the other-sex parent, results in identification with the same-sex parent and development of the superego.	Initiative vs. guilt (3–6 years)	Preschoolers develop initiative by devising and carrying out bold plans, but they must learn not to impinge on the rights of others.
Latent period (6–12 years)	Libido is quiet; psychic energy is invested in schoolwork and play with same-sex friends.	Industry vs. inferiority (6–12 years)	Children must master important social and academic skills and keep up with their peers; otherwise, they will feel inferior.
Genital stage (12 years and older)	Puberty reawakens the sexual instincts as youths seek to establish mature sexual relationships and pursue the biological goal of reproduction.	Identity vs. role confusion (12–20 years)	Adolescents ask who they are and must establish social and vocational identities; otherwise, they will remain confused about the roles they should play as adults.
		Intimacy vs. isolation (20–40 years)	Young adults seek to form a shared identity with another person, but may fear intimacy and experience loneliness and isolation.
		Generativity vs. stagnation (40–65 years)	Middle-aged adults must feel that they are producing something that will outlive them, either as parents or as workers; otherwise, they will become stagnant and self-centered.
		Integrity vs. despair (65 years and older)	Older adults must come to view their lives as meaningful to face death without worries and regrets.

methods—punishing babies for mouthing paychecks and other interesting objects around the house, or toddlers for their toileting accidents, or preschoolers for taking interest in their genitals—can heighten these biologically based psychic conflicts—and the child's anxiety.

The baby in the *oral stage* of psychosexual development focuses on the mouth as a source of sexual pleasure and can, according to Freud, experience anxiety and need to defend against it if denied oral gratification—for example, by being weaned too early. Through **fixation**, arrested development in which part of the libido remains tied to an earlier stage of development, an infant deprived of oral gratification might become “stuck” in the oral stage. He might become a chronic thumb sucker and then an adult who chain smokes and is overdependent on other people. How the child copes with the challenges of a stage and what parents do to help or hurt can leave a lasting imprint on the personality.

Similarly, the toddler in the *anal stage* must cope with new demands when toilet training begins. Parents who are impatient and punitive as their children learn to delay the gratification of relieving themselves can create high levels of anxiety and a personality that resists demands from authority figures. The parent's goal should be to allow some (but not too much) gratification of impulses while helping the child achieve reasonable (but not too much) control over these impulses.

The *phallic* stage from age 3 to age 6 is an especially treacherous time. Children, Freud claimed, develop an incestuous desire for the parent of the other sex and must defend against it. A boy experiencing an “Oedipus complex” loves his mother, fears that his father will retaliate against him, and resolves this conflict through **identification** with his father—by taking on his father's attitudes and behaviors. Meanwhile, a girl experiencing an “Electra complex” is said to desire her father, view her mother as a rival, and ultimately resolve her conflict by identifying with her

● EXPLORATION 2.1

Freud and Erikson: Notes on Sexual Risk Behavior

(We suggest you read this and subsequent boxes on sexual risk behavior in adolescence after you read about each theory; it will make more sense and you'll be able to test your ability to apply the theory.)

I, Freud, believe teenagers engage in sexual risk-taking because they experience intense emotional conflicts during the genital stage of psychosexual development. Their new sexual urges are anxiety-provoking. From a psychoanalytic perspective, teenagers who engage in risky sex may not have developed strong enough egos and superegos to keep their ids in check. Psychological conflicts stemming from early childhood—for example, conflicts rooted

in a boy's unresolved and unconscious Oedipal desire to possess his mother—can contribute to an adolescent's premature and promiscuous sex (Harris, 2011; Schofield, Bierman, & Heinrichs, 2008). Perhaps Jared is unconsciously acting out his sexual fantasies. His behavior may also be a sign of underlying mental health problems such as depression or conduct disorder (Parkes et al., 2014; Pilgrim & Blum, 2012).

I, Erikson, agree with Dr. Freud that unresolved conflicts from earlier stages of development could contribute to Jared's behavior. If he never developed a sense of trust as an infant, for example, he could fear abandonment and drop one girl for the next so that

he won't be dumped first. But let's focus on my adolescent psychosocial conflict: identity versus role confusion (Erikson, 1968). Adolescents seek a sense of identity by experimenting with different roles and behaviors to see what suits them. They try drugs, dye their hair orange, join radical groups, change majors every semester, and yes, have sex, sometimes with multiple partners. Like Freud, I would also look into the parent-child relationship, but I would recognize that other relationships count too. Something may be going on in Jared's relationships with his friends or teachers, or even in the wider culture, that is influencing him.

mother. When boys and girls resolve their emotional conflicts by identifying with the same-sex parent, they incorporate their same-sex parent's values into their superego and also adopt their gender role, so Freud viewed the preschool period as important in both moral development and gender-role development.

During the *latency period*, sexual urges are tame and 6-to 12-year-olds invest psychic energy in schoolwork and play. However, adolescents experience new psychic conflicts as they reach puberty and enter the final stage of psychosexual development, the *genital stage*. Adolescents may have difficulty accepting their new sexuality, may reexperience the conflicting feelings toward their parents that they felt during the preschool phallic stage, and may distance themselves from their parents to defend themselves against these anxiety-provoking feelings. Freud believed that psychosexual development stops with adolescence and that the individual remains in the genital stage throughout adulthood.

To defend itself against all the anxiety that can arise as these psychic conflicts play out, the ego adopts unconscious coping devices called **defense mechanisms** (Freud, 1940/1964). One well-known example (besides identification, which we already discussed) is **repression**, or removing unacceptable thoughts or traumatic memories from consciousness. Through repression, a young woman who was raped may have no memory at all of it. Or through the defense mechanism of **regression**, or retreating to an earlier, less traumatic stage of development, a preschool girl, threatened by her new baby brother, may revert to infantile behavior and want to be rocked.

We learn these and other defense mechanisms to cope with inner conflicts of which we are largely unaware, deceiving ourselves in order to save ourselves. Defense mechanisms can be

healthy in that they allow us to function despite anxiety, but they can also spell trouble if they involve too much distortion of reality.

Erikson's Psychosocial Theory

A sign of Freud's immense influence is that he inspired so many disciples and descendants to make their own contributions to the understanding of human development (Bergen, 2008). Among these well-known neo-Freudians were Alfred Adler, who suggested that siblings (and rivalries among siblings) are significant in development; Carl Jung, a pioneer in the study of adult development who claimed that adults experience a midlife crisis and then become freer to express both the "masculine" and the "feminine" sides of their personalities; Karen Horney, who challenged Freud's ideas about gender differences; Harry Stack Sullivan, who argued that close friendships in childhood set the stage for romantic relationships later in life; and Freud's daughter Anna, who developed techniques of psychoanalysis appropriate for children.

But the neo-Freudian psychoanalytic theorist who most influenced thinking about life-span development was Erik Erikson (1902–1994), whom we will revisit in more detail in Chapter 11. Erikson studied with Anna Freud and emigrated from Germany to the United States when Hitler rose to power (Friedman, 1999). Like Sigmund Freud, Erikson (1963, 1968, 1982) concerned himself with the inner dynamics of personality and proposed that the personality evolves through systematic stages. However, compared with Freud, Erikson:

- Placed less emphasis on sexual urges as the drivers of development and more emphasis on social influences—not just parents but peers, teachers, schools, and the broader culture—claiming that nature and nurture are equally important.

Erik Erikson built on Freudian theory and proposed that people experience eight psychosexual crises over their life span.

Bettmann/Getty Images

- Placed less emphasis on the unconscious, irrational, and selfish id and more on the rational ego and its adaptive powers.
- Held a more positive view of human nature, seeing people as active in their development, largely rational, and able to overcome the effects of harmful early experiences.
- Put more emphasis on development after adolescence.

Eight Psychosocial Stages

Erikson believed that humans everywhere experience eight major **psychosocial stages**, or conflicts, during their lives. (Erikson's psychosocial stages are matched up with Freud's psychosexual stages in **Table 2.2**.) Whether the conflict of a particular stage is successfully resolved or not, the individual is pushed by both biological maturation and social demands into the next stage. However, the unsuccessful resolution of a conflict will affect how later stages play out.

For example, the first conflict, *trust versus mistrust*, revolves around whether or not infants become able to rely on other people to be responsive to their needs. To develop a sense of trust, infants must be able to count on their primary caregivers not only to feed them (Freud's emphasis) but to relieve their discomfort, come when beckoned, and return their smiles and babbles—to be responsive to all their needs. If caregivers neglect, reject, or respond inconsistently to infants, infants will mistrust others. A healthy balance between the terms of the conflict must be struck for development to proceed optimally. Trust should outweigh mistrust, but an element of skepticism is also needed: an over-indulged infant may become too trusting (a gullible “sucker”).

So it goes for the remaining stages of childhood. If all goes well as children confront and resolve each conflict, they will gain a sense of self and develop *autonomy* (rather than shame and doubt) about their ability to act independently, develop the *initiative* (as opposed to guilt) that allows them to plan and tackle big projects, and acquire the sense of *industry* (rather than inferiority) that will enable them to master important academic and social skills in school.

This growth will position adolescents to successfully resolve the conflict for which Erikson (1968) is best known, *identity versus role confusion*. Erikson characterized adolescence as a time of “identity crisis” in which youth attempt to define who they are (in terms of career, religion, sexual identity, and so on), where they are heading, and how they fit into society. As part of their search, they often change their minds and experiment with new looks, new career plans, and new relationships. Erikson should know: He was the tall, blond stepson of a Jewish doctor and wandered all over Europe after high school, trying out a career as an artist and other possibilities before he ended up studying child psychoanalysis under Anna Freud and finally found his calling in his mid-20s (Friedman, 1999).

Whereas Freud's stages stopped with adolescence, Erikson believed that psychosocial growth continues during the adult years. Successfully resolving the adolescent conflict of identity versus role confusion paves the way for resolving the early adulthood conflict of *intimacy versus isolation* and for becoming ready to form a shared identity with someone else in a committed, long-term relationship. Successful resolution of the middle-age conflict of *generativity versus stagnation* involves adults gaining a sense that they have produced something that will outlive them, whether by successfully raising children or by contributing something meaningful to the world through work or volunteer activities. Finally, elderly adults who resolve the psychosocial conflict of *integrity versus despair* find a sense of meaning in their lives that will help them face death.

Erikson clearly did not agree with Freud that the personality is essentially “set in stone” during the first 5 years of life. Yet he, like Freud and other psychoanalytic theorists, believed that people progress through systematic stages of development, undergoing similar personality changes at similar ages. Individual differences in personality reflect the different experiences individuals have, not only in the family but beyond, as they struggle to cope with the challenges of each life stage. Both biological maturation and demands of the social and cultural environment influence the individual's progress through Erikson's sequence of psychosocial stages. As an illustration, in **Exploration 2.1**, we imagine the notes that Freud and Erikson might have scribbled down to explain Jared's sexual behavior, as described at the start of the chapter. What might you say if you were Freud and Erikson?

Strengths and Weaknesses

Sigmund Freud is a giant in the history of psychology. Many of his general insights have stood up well and have profoundly influenced theories of human development, personality, and psychotherapy (Fonagy & Target, 2000; Newman & Newman, 2016; Westen et al., 2008). Consider these three major contributions:

- Freud called attention to *unconscious processes* underlying human behavior, a fundamental insight supported by modern psychological and neuropsychological research (Bargh & Morsella, 2008; Westen et al., 2008).
- Freud was one of the first to stress the importance for later development of *early experiences* in the family, which, as we will see throughout this book, can be tremendously important.

- Freud emphasized the importance of *emotions* and emotional conflicts in development and the inner workings of personality; most other developmental theories have been more interested in observable behavior or rational thought.

Erikson too has made important contributions. Many people find Erikson's emphasis on our rational, adaptive nature and his interactionist position emphasizing both biological and social influences easier to accept than Freud's emphasis on unconscious, irrational motivations based in biological needs. Erikson also captured important developmental issues in his eight stages. He has had an especially great impact on research on adolescence and adulthood (see Berzoff, 2008; Newman & Newman, 2016; and Chapter 11).

What are the limitations of psychoanalytic theories? Developmentalists fault Freud for proposing a theory that is ambiguous, internally inconsistent, difficult to pin down and test, and therefore not easily falsifiable (Fonagy & Target, 2000; Newman & Newman, 2016). Testing hypotheses that require studying unconscious motivations and the workings of the unseen id, ego, and superego has been challenging. Moreover, when the theory has been tested, many of its specific ideas—for example, ideas about the lasting importance of early feeding practices or the preschool child's Oedipus and Electra conflicts—have not been well supported (Crews, 1996; Fisher & Greenberg, 1977).

Erikson's theory has some of the same shortcomings as Freud's. It is sometimes vague and difficult to test. And although it provides a useful *description* of human personality development, it does not provide an adequate *explanation* of how this development comes about. Important psychoanalytic theorists such

as Erikson continue to shape understanding of human development, but many developmentalists have left psychoanalytic theory behind in favor of theories that are more precise and testable.

● Checking Mastery

1. Jaime believes that people have both a moral side and a selfish side that work against each other. According to Freud's psychoanalytic theory, what are these "sides" called and when do they arise in development?
2. What are three major ways in which Erikson's ideas differ from Freud's?
3. Wanda, at age 40, is depressed. She seems to doubt her ability to assert herself and take charge of situations at work, and she always fears other people will let her down. What Eriksonian stages might have been problematic for her in childhood, and how might her parents have contributed to her current problems?

● Making Connections

1. When Brenda was only 12, her stepfather started sexually abusing her and continued doing so for the next two years. What might Freud hypothesize about Brenda's personality development? What might Erikson hypothesize?
2. Thinking about yourself, your parents, and your grandparents, can you see any evidence that Erikson's conflicts of adolescence and adulthood are relevant in your family?

2.3

Learning Theories

LEARNING OBJECTIVES

- Explain how the learning theory perspective on development differs from stage theory perspectives like Freud's and Erikson's.
- Using examples, differentiate between Watson's classical conditioning, Skinner's operant conditioning, and Bandura's observational learning with regard to what learning involves and what can be learned.
- Evaluate the strengths and weaknesses of learning theories in general and discuss how Bandura overcame some of the weaknesses of earlier learning theories.

Give me a dozen healthy infants, well formed, and my own specified world to bring them up in, and I'll guarantee to take any one at random and train him to become any type of specialist I might select—doctor, lawyer, artist, merchant, chief, and yes, even beggar-man and thief, regardless of his talents, penchants, tendencies, abilities, vocations, and race of his ancestors. (Watson, 1925, p. 82)

This bold statement—that nurture is everything and that nature, or genetic endowment, counts for nothing—was made by John B. Watson, a pioneer of learning theory perspectives on human development. Watson and other early learning theorists believed that children have no inborn tendencies; how they turn out

depends entirely on the environment in which they grow up and the ways in which their parents and other people in their lives treat them.

Early learning theorists such as Watson (1878–1958) and B. F. Skinner (1905–1990) emphasized that human behavior changes in direct response to environmental stimuli. Later learning theorists such as Albert Bandura (born in 1925) grant humans a more active and cognitive role in their own development but still believe that their development can take very different directions depending on their learning experiences. All these learning theorists have provided us with important and practical tools for understanding how human behavior changes through learning and how learning principles can be

applied to optimize development. We will lay out the basics of learning theory here and illustrate its significance throughout this book.

Watson: Classical Conditioning

Watson's (1913) **behaviorism** rested on his belief that conclusions about human development and functioning should be based on observations of overt behavior rather than on speculations about unobservable cognitive and emotional processes. Watson rejected psychoanalytic theory and demonstrated that some of Freud's fascinating discoveries about human behavior could be explained as learned associations between stimuli and responses (Rilling, 2000).

In his most famous study, Watson and colleague Rosalie Raynor (1920) set out to demonstrate that fears can be learned—that fears are not necessarily inborn, as was commonly thought. They used the principles of **classical conditioning**, a simple form of learning in which a stimulus that initially had no effect on the individual comes to elicit a response through its association with a stimulus that already elicits the response. The Russian physiologist Ivan Pavlov first discovered classical conditioning quite accidentally while studying the digestive systems of dogs. In a famous experiment, Pavlov demonstrated how dogs, who have an innate (unlearned) tendency to salivate at the sight of food, could learn to salivate at the sound of a tone if, during a training period, the tone was sounded each time a dog was given meat powder.

In their demonstration of classical conditioning, Watson and Raynor presented a gentle white rat to a now-famous infant named Albert, who showed no fear of it. However, every time the rat was presented, Watson would slip behind Albert and bang a steel rod with a hammer. Babies are naturally scared by loud noises and, through conditioning—through the pairing of the white rat and the loud noise—Albert learned to whimper and cry in response to the white rat alone. Through learning, an initially neutral stimulus, the white rat, had become a stimulus for fear. This conditioned or learned fear response generalized to other furry items such as a rabbit and a Santa Claus mask. By today's standards, Watson's experiment would be viewed as unethical. However, he had made his point: *emotional responses can be learned*. Fortunately, fears learned through classical conditioning can be unlearned if the feared stimulus is paired with a stimulus for happy emotions (Jones, 1924).

Many emotional associations and attitudes, both positive and negative, are acquired through classical conditioning. Classical conditioning is undoubtedly involved when infants learn to love their parents, who become associated with the positive sensations of drinking milk, being rocked, and being comforted. And classical conditioning helps explain why adults find that certain songs, scents, or articles of clothing “turn them on.” It also explains why so many of us have odd phobias (in the case of one of the authors, an aversion to antiseptic cotton, which arose as a learned association between cotton and having a skinned knee daubed with cotton soaked with iodine, a disinfectant that burns when it hits a fresh wound). When a humor columnist polled his colleagues about their phobias, he found one who, like the author, cannot stand the tearing of cotton balls, another whose arm hair stands up if he touches peach fuzz, and another who feels “daggers shooting up my spine” when someone rubs pieces of Styrofoam together

(Weingarten, 2011, p. 29). If you have your own unusual phobia, perhaps you can trace it to classical conditioning.

According to the learning theory perspective, it is a mistake to assume that children advance through a series of distinct stages guided by biological maturation, as Freud, Erikson, and other stage theorists have argued. Instead, learning theorists view development as nothing more than learning. For them, development is a continuous process of behavior change that is context specific and can differ enormously from person to person. Watson's basic view was further advanced by B. F. Skinner.

Skinner: Operant Conditioning

B. F. Skinner, probably the most famous American psychologist, had a long, distinguished career at Harvard University and a huge impact on approaches to behavior change (Rutherford, 2009). Through his research with animals, Skinner (1953) gained

B. F. Skinner's operant conditioning theory emphasized the role of environment in controlling behavior. Here he delivers food pellets (reinforcers) to a rat each time the rat presses a bar in what we now know as a “Skinner box.”

Nina Leen/Time Life Pictures/Getty Images

understanding of another important form of learning, **operant conditioning**, in which a learner's behavior becomes either more or less probable depending on the consequences it produces. In operant conditioning, a learner first behaves in some way (rather than reacting automatically to a stimulus, as in classical conditioning) and then comes to associate this behavior with the positive or negative consequences that follow it. The basic principle behind operant conditioning makes sense: People tend to repeat behaviors that have desirable consequences and cut down on behaviors that have undesirable consequences. Through operant conditioning, individuals can learn new skills and all kinds of habits, good and bad.

In the language of operant conditioning, *reinforcement* occurs when a consequence strengthens a response, or makes it more likely to occur. If a preschool child cleans his room, receives a hug, and then cleans his room more frequently thereafter, the hug provided **positive reinforcement** for room cleaning. *Positive* here means that something pleasant or desirable has been added to the situation, and *reinforcement* means that the behavior is strengthened. Thus, a positive reinforcer is a desirable event that, when introduced following a behavior, makes that behavior more probable. (Note that the effect on the child's behavior, not the parent's belief about what might be reinforcing, defines what is reinforcing.)

Negative reinforcement (which is *not*, we repeat *not*, a fancy term for punishment, as so many people wrongly believe) occurs when a behavior is strengthened because something unpleasant or undesirable is removed from the situation or is escaped or avoided after the behavior occurs. Consider the annoying sound that goes off in the car until you fasten your seat belt. The idea is that your buckling-up behavior will become a habit through negative reinforcement: Buckling your seat belt allows you to escape the unpleasant sound.

Bad habits can also develop because they allow people to avoid or escape unpleasant consequences. Teenagers may learn to lie to avoid lectures from their parents about their misdeeds or to drink alcohol because it allows them to escape their feelings of social anxiety at parties. In each case, a behavior is strengthened through negative reinforcement—because it results in the removal or elimination of something undesirable like a lecture or social anxiety.

Contrast reinforcement, whether it is positive or negative, with punishment: Whereas reinforcement increases the strength of the behavior that preceded it, *punishment* decreases the strength of the behavior or weakens it. Two forms of punishment parallel the two forms of reinforcement. **Positive punishment** occurs when an unpleasant stimulus is the consequence of a behavior (for example, a child is spanked for misbehaving, or a cashier is criticized for coming up short of cash at the end of the day). **Negative punishment** occurs when a desirable stimulus is removed following the behavior (a misbehaving child loses the privilege of watching TV, or the amount the cashier was short is deducted from her pay). By definition, both

positive and negative punishments decrease the likelihood that the punished behavior will be repeated.

The four possible consequences of a behavior are summarized in ■ **Figure 2.2**. In addition, some behavior has no consequence. Behavior that is ignored, or no longer reinforced, tends to become less frequent through the process of **extinction**. Indeed, a good alternative to punishing a child's misbehavior is ignoring it and instead reinforcing desirable behavior that is incompatible with it. Too often, the well-behaved child is ignored and the misbehaving child gets the attention—attention that can backfire because it serves as positive reinforcement for the misbehavior.

Leading learning theorists emphasize the importance of setting up conditions that will prompt desired behaviors and reinforcing that behavior rather than telling kids what not to do all the time, as so many parents do (Kazdin & Rotella, 2013). Their child-rearing advice is, "Catch them being good," and they generally discourage the use of physical punishment. Yet, despite trends suggesting less acceptance of physical punishment today than in the past, most parents of young children in the United States believe that physical punishment of bad behavior is sometimes necessary and spank their children on occasion (Gershoff, 2008; Reeves & Cuddy, 2014). What does research tell us about the effects of physical punishment?

It is generally best to use more positive approaches instead of or before resorting to punishment. Mild physical punishment can be effective in changing behavior if it (1) is administered immediately after the act (not hours later, when the child is being an angel), (2) is administered consistently after each offense, (3) is not overly harsh, (4) is accompanied by explanations, (5) is administered by an otherwise affectionate person, and (6) is used sparingly and combined with efforts to reinforce more acceptable behavior (Benjet & Kazdin, 2003; Domjan, 1993; Gershoff, 2002).

	PLEASANT STIMULUS	UNPLEASANT STIMULUS
ADMINISTERED	<p>Positive reinforcement, adding a pleasant stimulus (strengthens the behavior)</p> <p>Dad gives in to the whining and lets Moosie play Nintendo, making whining more likely in the future.</p>	<p>Positive punishment, adding an unpleasant stimulus (weakens the behavior)</p> <p>Dad calls Moosie a "baby." Moosie does not like this at all and is less likely to whine in the future.</p>
WITHDRAWN	<p>Negative punishment, withdrawing a pleasant stimulus (weakens the behavior)</p> <p>Dad confiscates Moosie's favorite Nintendo game to discourage whining in the future.</p>	<p>Negative reinforcement, withdrawing an unpleasant stimulus (strengthens the behavior)</p> <p>Dad stops joking with Lulu. Moosie gets very jealous when Dad pays attention to Lulu, so his whining enables him to bring this unpleasant state of affairs to an end.</p>

■ **Figure 2.2** Possible consequences of whining behavior. Moosie comes into the TV room and sees his father talking and joking with his sister, Lulu, as the two watch a football game. Soon Moosie begins to whine, louder and louder, that he wants them to turn off the television so he can play Nintendo. If you were Moosie's father, how would you react? Above are four possible consequences of Moosie's behavior. Consider both the type of consequence—whether it is a pleasant or aversive stimulus—and whether it is administered ("added to" the situation) or withdrawn (taken away). Notice that reinforcement, by definition, always strengthens whining behavior, or makes it more likely in the future, whereas punishment weakens it.

However, research is clear: Physical punishment, especially if it is harsh, can have a number of undesirable effects. It has been shown repeatedly to be linked to increased aggression, and in some studies it is also associated with mental health problems such as anxiety, depression, and substance use, and with poorer intellectual and moral functioning (Durrant & Ensom, 2012; Gershoff, 2008; Österman, Björkqvist, & Wahlbeck, 2014). For example, Lisa Berlin and her colleagues (2009) studied low-income African-American, Mexican-American, and Euro-American toddlers longitudinally when they were ages 1, 2, and 3. Spanking, but not verbal punishment, at age 1 was associated with more aggressive behavior at age 2 and lower mental development scores at age 3. Moreover, the researchers showed that physical punishment led to later aggressive behavior and intellectual delay even with early behavior and mental development controlled (see also Lee, Altschul, & Gershoff, 2015; Maguire-Jack, Gromoske, & Berger, 2012).

Especially worrisome is evidence that episodes of physical punishment sometimes turn into child abuse (Benjet & Kazdin, 2003; Gershoff, 2002). Especially encouraging is evidence that training in positive parenting based on Skinnerian principles of reinforcement can have long-lasting, positive effects on both child behavior and parent adjustment (Patterson, Forgatch, & DeGarmo, 2010; Reed et al., 2013). Perhaps this is why more and more countries are banning spanking and other forms of physical punishment, not only in schools and child care settings but in homes (Durrant & Ensom, 2012; Reeves & Cuddy, 2014). In Finland, for example, physical punishment, even by parents, was outlawed in 1983. Numbers of adults reporting being slapped or beaten with objects have declined since, as have numbers of children murdered, and adults who had not been punished as children report fewer mental health problems than those who had (Österman et al., 2014).

In sum, Skinner, like Watson, believed that the course of human development depends on the individual's learning experiences. One boy's aggressive behavior may be reinforced over time because he gets his way with other children or because his parents reinforce his "tough" behavior. Another boy may quickly learn that aggression is prohibited and punished. The two may develop in different directions based on their different histories of reinforcement and punishment.

Skinner's operant conditioning principles can help explain many aspects of human development and behavior. And they are still widely applied in educational and psychotherapeutic settings. Indeed, there are now smart-phone apps based on Skinnerian principles to help people lose weight, exercise more, overcome addictions, and otherwise improve their health and well-being (Freedman, 2012). Yet many developmentalists fault Skinner for not examining the role of cognitive processes in learning. Therefore, today's developmental scholars are more attracted to Albert Bandura's cognitive brand of learning theory than to Skinner's operant conditioning approach.

Bandura: Social Cognitive Theory

In his **social cognitive theory** (also called **social learning theory**), Stanford psychologist Albert Bandura (1977, 1986, 1989, 2000, 2006) claims that humans are cognitive beings

Albert Bandura's social cognitive theory highlighted the role of cognition in human learning. He is on the faculty at Stanford University. Behind him is a film shot from his famous "Bobo doll" study, in which children learned aggressive behaviors through observational learning.

Jon Brenneis/Life Magazine/The Life Images Collection/Getty Images

whose active processing of information plays a critical role in their learning, behavior, and development. Bandura argues that human learning is very different from rat learning because humans have far more sophisticated cognitive capabilities. He agrees with Skinner that operant conditioning is an important type of learning, but he notes that people think about the connections between their behavior and its consequences, anticipate the consequences likely to follow from their behavior, and often are more affected by what they believe will happen than by the consequences they actually encounter. Individuals also reinforce or punish themselves with mental pats on the back and self-criticism, and these cognitions also affect behavior. Bandura prefers to call his position social cognitive theory rather than social learning theory for a reason: to distance himself from behavioral learning theories like Watson's and Skinner's and to emphasize that his theory is about the motivating and self-regulating role of cognition in human behavior (Bandura, 1986).

Observational Learning

By highlighting observational learning as the most important mechanism through which human behavior changes, Bandura made his cognitive emphasis clear. **Observational learning** is simply learning by observing the behavior of other people (called *models*). By learning from and imitating other people, children can master computer skills and math problems, as well as how to swear, sing, or smoke. Observational learning is regarded as a more cognitive form of learning than conditioning because learners must pay attention, construct and remember mental representations (images and verbal summaries) of what they saw, retrieve these representations from memory later, and use them to guide behavior.

In his classic “Bobo doll” experiment, Bandura (1965) set out to demonstrate that children could learn a response neither elicited by a conditioned stimulus (as in classical conditioning) nor performed and then strengthened by a reinforcer (as in operant conditioning). He had nursery school children watch a short film in which an adult model attacked an inflatable “Bobo” doll: hitting the doll with a mallet while shouting “Sockeroo,” throwing rubber balls at the doll while shouting “Bang, bang, bang,” and so on. Some children saw the model praised, others saw the model punished, and still others saw no consequences follow the model’s violent attack. After the film ended, children were observed in a playroom with the Bobo doll and many of the props the model had used to work Bobo over.

What did the children learn? The children who saw the model rewarded and the children in the no-consequences condition imitated more of the model’s aggressive acts than did the children who had seen the model punished. But interestingly, when the children who had seen the model punished were asked to reproduce all of the model’s behavior they could remember, it turned out that they had learned just as much as the other children about how to treat a Bobo doll. Apparently, then, through a process termed **latent learning** in which learning occurs but is not evident in behavior, children can learn from observation even though they do not imitate (perform) the learned responses. Whether they will perform what they learn depends partly on **vicarious reinforcement** (or punishment), a process in which learners become more or less likely to perform a behavior based on whether consequences experienced by the model they observe are reinforcing or punishing. You are more likely to imitate someone who is rewarded for their behavior than someone who is punished.

Research since Bandura’s demonstrations has revealed just how important observational learning is in making us human. Consider the discovery that, across cultures, children display **overimitation**, a tendency to imitate every detail of what they see a model do, even actions that are useless in achieving a goal. In an interesting demonstration of this by Mark Nielsen and Keyan Tomaselli (2010), children in both urban Australia and the Kalahari bush of Africa watched an adult demonstrate how to open a box. Children in both cultures—and both younger and older children within the 2-to-13 age range studied—readily imitated the adult model’s action of pushing a stick down on a knob on the front of the box, even though a more direct and effective way to open the box was to simply pull the knob with one’s hand. More surprisingly, children also faithfully copied completely irrelevant actions such as waving the stick three times over the box like a magic wand before opening the box. Such overimitation is not as evident among chimpanzees, who tend to imitate only the actions that are actually required to open the box (Horner & Whiten, 2005).

Humans can learn almost anything through observational learning.

Hello Lovely/Blend Images/Getty Images

Why do humans overimitate when it makes us look pretty dumb compared to chimps? Possibly because overimitation has proven adaptive for our species, helping us learn “how we do things” in our culture—helping us acquire the many, often arbitrary, skills, rituals, and rules important in our culture, including new ways of solving problems (Nielsen et al., 2014; Nielsen & Tomaselli, 2010; Whiten, 2013). Overimitation also helps us fit in. Thus, after 2-year-olds had learned on their own a perfectly good method of getting rewards by dropping balls in one of three boxes, about half switched to dropping balls in a different box after seeing a peer do so (Haun, Rekers, & Tomasello, 2014). Almost none of the chimpanzees and orangutans tested switched methods. And if you let 3-year-old children learn their own methods of opening a puzzle box to get a reward and then put them all in the same room with the box, the children will soon converge on the same method of opening the box after observing one another for a while (Flynn & Whiten, 2010). Our human tendency to imitate members of our group remains strong later in life and appears to be a critical means of transmitting cultural ways from one person to another and from one generation to the next.

Human Agency

In his later work, Bandura (2000, 2006) moved beyond the study of observational learning to emphasize ways in which people deliberately and actively exercise cognitive control over themselves, their environments, and their lives. From the time they are infants discovering that they can make things happen in their worlds, people form intentions, foresee what will happen, evaluate and regulate their actions as they pursue plans, and reflect on their functioning. These cognitions play a real causal role in influencing their behavior. For example, individuals develop a high or low sense of **self-efficacy**, or belief that they can effectively produce a particular desired outcome. Whether you are trying to lose 10 pounds or get an A on a test, Bandura and colleagues have shown, your success depends greatly on whether you have a sense of self-efficacy concerning your ability to achieve your goal.

Watson and Skinner may have believed that people are passively shaped by parents and other socialization agents, but Bandura does not. Because he views humans as active, cognitive beings, he holds that human development occurs through a continuous reciprocal interaction among the person (the individual’s biological and psychological characteristics and cognitions), his or her behavior, and his or her environment—a perspective he calls **reciprocal determinism** (■ Figure 2.3). As Bandura sees it, environment does not rule, as it did in Skinner’s thinking: People choose, build, and change their environments;

■ **Figure 2.3** Bandura’s reciprocal determinism involves mutual influence of the person, the person’s behavior, and the environment.

they are not just shaped by them. And people’s personal characteristics and behaviors affect the people around them, just as other people are influencing their personal characteristics and future behaviors.

Like Watson and Skinner, however, Bandura doubts that there are universal stages of human development. Indeed, he did research to demonstrate that young children could pass some of Piaget’s cognitive development tasks if they were trained to do so (Bandura, 1986). Like other learning theorists, Bandura maintains that development is context specific and can proceed along many paths. It is also continuous, occurring gradually through a lifetime of learning. Bandura acknowledges that children’s cognitive capacities mature, so they can remember more about what they have seen and can imitate a greater variety of novel behaviors. Yet he also believes that children of the same age will be dissimilar if their learning experiences have differed considerably.

Obviously there is a fundamental disagreement between stage theorists such as Freud and Erikson and learning theorists such as Watson, Skinner, and Bandura (see ● **Table 2.3** for a summary of the three men’s distinct contributions to the learning perspective on development). We imagine what Watson, Skinner, and Bandura would say about sexual risk behavior in **Exploration 2.2**.

● **Table 2.3** A Summary of the Three Major Types of Learning

Learning Theorist	Type of Learning	What It Involves	What Is Learned
John Watson	Classical conditioning	A stimulus comes to elicit a response through its association with an unconditioned stimulus.	Emotional reactions (e.g., pleasant associations, phobias)
B. F. Skinner	Operant conditioning	Learning involves reacting to the consequences of one’s behavior (reinforcement and punishment).	Skills; good and bad habits
Albert Bandura	Observational learning	Learning involves watching a model and, through vicarious reinforcement or punishment, the consequences of the model’s behavior.	Skills, cognitions, and behaviors, including ones that the learner has not been directly reinforced for displaying

● **EXPLORATION 2.2**

Learning Theorists: Notes on Sexual Risk Behavior

We would all agree that patterns of sexual behavior are learned—and can be learned in a variety of ways:

I, John Watson, would argue that, through classical conditioning, a teenager may learn to associate the very presence of potential sexual partners with the pleasurable sensations associated with sexual activity. These learned emotional reactions are part of the picture in Jared’s case.

I, B. F. Skinner, maintain that teenagers probably have unprotected sex because having sex is reinforcing, whereas using contraceptives

may not be. Jared’s friend Damien may also be reinforcing Jared for joining him in his attempts to hook up with girls. Through simple operant conditioning, then, Jared’s sexual risk taking increases.

I, Albert Bandura, think observational learning is at work here. Jared may be imitating the behavior of his older friend Damien, especially if, through what I call vicarious reinforcement, he sees Damien reinforced by other kids when he tells them of his sexual exploits. Consider observational learning

from the media too. Teens who are exposed to lots of sexually explicit material through the media begin having sex earlier in life and engage in more risky sexual behavior than other teens (Bleakley, Hennessy, & Fishbein, 2011; Brown et al., 2006; Chandra et al., 2008; O’Hara et al., 2012). Finally, I want to know more about how Jared perceives the consequences of his behavior, as perceptions of the likelihood of positive or negative consequences are often more important than their actual likelihood.

Strengths and Weaknesses

Pavlov's and Watson's demonstrations of classical conditioning, Skinner's work on operant conditioning, and Bandura's modern social cognitive theory with its highlighting of observational learning have contributed immensely to our understanding of development and continue to be influential. Learning theories are precise and testable. Carefully controlled experiments have shown how people might learn everything from altruism to alcoholism. Moreover, learning principles operate across the life span and can be used to understand behavior at any age. Finally, learning theories have incredibly important applications; principles of classical conditioning, operant conditioning, and observational learning have been the basis for many highly effective techniques for optimizing development and treating developmental problems (Newman & Newman, 2016).

Still, behavioral learning theories, and even Bandura's more recent social cognitive theory, leave something to be desired as theories of human development. First, they do not provide a clear description of the typical course of human development; they have been more focused on describing mechanisms of learning. Second, although they offer a rich account of the mechanisms through which behavior can change, they do not show that learning is responsible for the changes we normally see in developing humans. For instance, Skinnerians have shown that reinforcing 3-month-old infants whenever they happen to make babbling sounds, such as "bababa," causes them to babble more often than infants who are not reinforced (Weisberg, 1963). But does this mean that infants normally begin to babble *because* babbling is reinforced by their caregivers? Probably not. All normal infants, even deaf ones, even infants whose parents do not reinforce their babbling, babble around 4 months of age, probably because that is when they have the neural and muscular control required for babbling.

Third and finally, learning theorists, even Bandura, probably put too little emphasis on biological influences on development, such as

genetic endowment and maturational processes. We may well learn to fear snakes, for example. However, probably because snakes were a threat to our ancestors, we have evolved so that we are biologically prepared to be wary of these critters. Thus, we learn to fear snakes far more easily than we learn to fear bunnies or flowers (Ohman & Mineka, 2003). Today's learning theorists appreciate more than Watson and Skinner did that factors such as genetic endowment, personality, and social context affect how humans react to learning experiences (Mineka & Zinbarg, 2006).

● Checking Mastery

1. The Foxes try to control their teenage daughter's behavior by (a) giving her an allowance only if she does her weekly chores, (b) setting her weekend curfew earlier if she stayed out later than she was supposed to the weekend before, and (c) allowing her to get out of the distasteful task of cleaning the bathroom if she spends time with her grandmother. What specific consequences, using operant conditioning language, are illustrated by these three parenting tactics, and in each case, what effect do the parents hope to have on their daughter's behavior?
2. What are two main criticisms Albert Bandura might make of earlier behavioral learning theories?

● Making Connections

1. Marge, age 78, fell and broke her hip a year ago and has become overly dependent on her daughter for help ever since she left the rehabilitation hospital, even though she can get around quite well now. How might Skinner and Bandura explain her old-age dependency?

2.4

Piaget: Cognitive Developmental Theory

LEARNING OBJECTIVES

- Explain the concept of constructivism and the differences in modes of thinking captured in the four stages in Piaget's cognitive developmental theory.
- Evaluate the strengths and weaknesses of Piaget's theory, noting how the sociocultural and information-processing approaches have attempted to correct for its limitations.

After behavioral learning theories dominated the study of development in the 1950s and 1960s, many developmentalists began to look for a theory that was both more cognitive and more clearly developmental. They found what they wanted in the groundbreaking work of Jean Piaget. No theorist has contributed more to the understanding of children's minds than Piaget (1896–1980), a Swiss scholar who began to study children's intellectual development during the 1920s. This remarkable man developed quickly himself, publishing his first scientific work (a letter to the editor

about an albino sparrow) at age 11. Eventually, Piaget blended his interest in zoology and animals' adaptation to their environments with his interest in philosophy. He then devoted his career to the study of how humans acquire knowledge and use it to adapt to their world. His big insight was that children think in a qualitatively different way than adults do. His stage theory describes the development of thought from infancy to adolescence; we will explore it more thoroughly in Chapter 7 but introduce some basic concepts here.

Constructivism

Influenced by his background in biology, Piaget (1950) viewed intelligence as a process that helps an organism adapt to its environment. The infant who grasps a cookie and brings it to her mouth is behaving adaptively, as is the adolescent who solves algebra problems or the mechanic who fixes cars. As humans mature, they acquire ever more complex cognitive structures, or organized patterns of thought or action, that aid them in adapting to their environments.

Piaget insisted that children are not born with innate ideas about reality, as some philosophers have claimed. Nor did he think children are simply filled with information by adults, as learning theorists believe. Piaget’s position, called **constructivism**, was that children actively construct their own understandings of the world based on their interactions with it. Thus preschool children may invent ideas that were not taught to them by adults, saying that the sun is alive because it moves across the sky, that children get diseases if they tell lies, or that babies are bought at the baby store and then put in their mommies’ tummies. If you’ve ever marveled over what comes out of the mouths of preschool children, you can appreciate constructivism!

How do children construct more accurate understandings of the world? By being curious and active explorers: watching what is going on around them, seeing what happens when they experiment on the objects they encounter, and recognizing instances in which their current understandings are inadequate to explain events. Children use their current understandings of the world to help them solve problems, but they also revise their understandings to make them better fit reality (Piaget, 1952). Piaget was an interactionist: The interaction between biological maturation (most importantly, a developing brain) and experience (especially discrepancies between the child’s current understanding and new experiences) is responsible for the child’s progress from one stage of cognitive development to a new, qualitatively different stage.

Stages of Cognitive Development

Piaget proposed four major periods of cognitive development: the sensorimotor stage (birth to age 2), the preoperational stage (ages 2–7), the concrete operations stage (ages 7–11), and the formal

Swiss psychologist Jean Piaget revolutionized the field of human development with his cognitive developmental theory of intellectual growth.

Bettmann/Getty Images

operations stage (ages 11–12 or older). These stages form what Piaget called an *invariant sequence*; that is, all children everywhere progress through the stages in the order they are listed without skipping stages or regressing to earlier stages (Inhelder & Piaget, 1958). The ages given are only average ages; different children progress at different rates. The key features of each stage are summarized in ● **Table 2.4**.

Infants in the **sensorimotor stage** deal with the world directly through their perceptions (senses) and actions (motor skills). They

● **Table 2.4** Jean Piaget’s Four Stages of Cognitive Development

Stage (Age Range)	Description
Sensorimotor (birth–2 years)	Infants use their senses and motor actions to explore and understand the world. At the start, they have only innate reflexes, but they develop increasingly “intelligent” actions. By the end, they are capable of symbolic thought using images or words and can therefore plan solutions to problems mentally.
Preoperational (2–7 years)	Preschoolers use their capacity for symbolic thought to develop language, engage in pretend play, and solve problems. But their thinking is not yet logical; they are egocentric (unable to take others’ perspectives) and are easily fooled by perceptions, failing conservation problems because they cannot rely on logical operations.
Concrete operations (7–11 years)	School-age children acquire concrete logical operations that allow them to mentally classify, add, and otherwise act on concrete objects in their heads. They can solve practical, real-world problems through a trial-and-error approach but have difficulty with hypothetical and abstract problems.
Formal operations (11–12 years and older)	Adolescents can think about abstract concepts and purely hypothetical possibilities. With age and experience, they can trace the long-range consequences of possible actions, and they can form hypotheses and systematically test them using the scientific method.

Note: Piaget’s theory is elaborated upon in Chapter 7.

are unable to use symbols (gestures, images, or words representing real objects and events) to help them solve problems mentally. However, they learn a great deal about the world by exploring it, and they acquire tools for solving problems through their sensory and motor experiences.

The preschooler who has entered the **preoperational stage** of cognitive development has now developed the capacity for symbolic thought but is not yet capable of logical problem solving. The 4- or 5-year-old can use words as symbols to talk about a problem and can mentally imagine doing something before actually doing it. However, according to Piaget, preschool children are egocentric thinkers who have difficulty adopting perspectives other than their own and who may cling to incorrect ideas simply because they want them to be true. Lacking the tools of logical thought, preoperational children must also rely on their perceptions and as a result are easily fooled by appearances. Piaget demonstrated this with his famous conservation of liquid quantity task, in which preschool children believe that water poured before their eyes from a short, wide glass into a tall, narrow glass has become “more” water because it looks like more (see Chapter 7).

School-age children who have advanced to the **concrete operations stage** are more logical than preschoolers. They use a trial-and-error approach to problem solving and do well on problems that involve thinking about concrete objects. These children can perform many important logical actions, or operations, on concrete objects in their heads (hence, the term *concrete operations*, and Piaget’s description of the preschool child as preoperational). For example, they can mentally categorize or mentally add and subtract objects, and they can mentally coordinate the height and width of glasses in order to solve conservation problems correctly and appreciate that there is not more water in the tall glass. They can also draw sound, general conclusions based on their concrete or specific observations. However, they have difficulty dealing with abstract and hypothetical problems.

Adolescents who reach the **formal operations stage** are able to think more abstractly and hypothetically than school-age children. They can define *justice* abstractly, in terms of fairness, rather than concretely, in terms of the cop on the corner or the judge in the courtroom. They can formulate hypotheses or predictions in their heads, plan how to systematically test their ideas in experiments, and imagine the results of their experiments. It often takes

Cognitive growth occurs when there is a discrepancy between a child’s current understanding of the world and a new experience—here, a butterfly.

Denmro/Shutterstock.com

some years beyond age 11 or 12 before adolescents fully master formal operations and can adopt a thoroughly scientific method of solving problems or think logically about the implications of purely hypothetical ideas. Then they may be able to devise grand theories about what is wrong with their parents or the federal government or analyze the long-term consequences of choosing a particular career or trying drugs.

Obviously, children’s cognitive capacities change dramatically between infancy and adolescence as they progress through Piaget’s four stages of cognitive development. Infants, young children, school-age children, and adolescents and adults simply do not think the same way. What, then, do you suppose Piaget would have said about sexual risk behavior in adolescence? **Exploration 2.3** sketches his possible thoughts.

Strengths and Weaknesses

Like Freud, Piaget was a true pioneer whose work has left a deep and lasting imprint on thinking about human development. You will see his influence throughout this text, for the mind that

● EXPLORATION 2.3

Piaget: Notes on Sexual Risk Behavior

Cognition is an important influence on behavior. I agree with Bandura that we need to understand how Jared is thinking about things, but I would go at this by interviewing him and assessing his stage of cognitive development. Cognitive limitations, failure to anticipate consequences, and lack of

knowledge all influence adolescents’ sexual decision making.

Teens who are slow to develop cognitively and are not yet solidly into the stage of formal operations may not be able to plan out how to acquire and make use of condoms and may not think through the long-range consequences of

unprotected sex (Holmbeck et al., 1994). And misconceptions (pun intended!) about sex and contraception are rampant among teens (Aarons & Jenkins, 2002; Cohn & Richters, 2013). In one study of 13- to 15-year-olds, more than 60% did not know that urinating after sex will not prevent pregnancy (Carrera et al., 2000).

“constructs” understanding of the physical world also comes, with age, to understand gender, moral values, emotions, death, and a range of other important aspects of the human experience. Piaget’s cognitive developmental perspective dominated the study of child development for about three decades, until the 1980s.

Most developmentalists today continue to accept and to build on Piaget’s basic beliefs that children construct their own understandings of the world and that their thinking changes in fundamental and qualitative ways as they get older (see, for example, Carey, Zaitchik, & Bascandziew, 2015). Developmentalists simply assume that children are active in their own development and that development occurs through an interaction of nature and nurture. Piaget’s description of intellectual development has been tested and has been largely, although not wholly, supported. Finally, Piaget’s ideas have influenced education and child rearing by encouraging teachers and parents to pitch their educational programs to children’s levels of understanding and to stimulate children to discover new concepts through their own direct grappling with problems.

Still, Piaget has had his share of criticism (Lourenco & Machado, 1996; Newman & Newman, 2016; and see Chapter 7). For example, critics question whether Piaget’s stages really hang together as general modes of thinking that are applied to a variety of types of problems. Research suggests that cognitive development proceeds at different rates for different types of problems. Critics also conclude that Piaget underestimated the cognitive abilities of infants and young children; if tasks are simplified, they are often mastered earlier than Piaget believed (Desrochers, 2008). Piaget is also charged with putting too little emphasis on social and cultural influences on cognitive development. He said little about the role of parents and other more knowledgeable people in nurturing cognitive development and did not appreciate enough that it can go differently in different cultures (see Chapter 7). As a result, developmentalists began to seek theoretical perspectives that allowed more diversity in the pathways that cognitive development could take.

Other Perspectives on Cognitive Development

Two important approaches to cognitive development that challenged some of Piaget’s thinking are Vygotsky’s *sociocultural perspective* (discussed in Chapter 7) and the *information-processing approach* (discussed in Chapter 8). We will briefly mention them here to elaborate on limitation of Piaget’s cognitive developmental theory.

The **sociocultural perspective** on cognitive development offered by a contemporary of Piaget, Russian psychologist Lev Vygotsky (1896–1934), has become quite influential in recent years.

Disagreeing with Piaget’s notion of universal stages of cognitive development, Vygotsky maintained that cognitive development is shaped by the sociocultural context in which it occurs and grows out of children’s interactions with members of their culture (Vygotsky, 1962, 1978). Each culture provides its members with certain tools of thought—most notably a language, but also tools such as pencils, art media, mathematical systems, and computers. The ways in which people in a particular culture approach and solve problems are passed from generation to generation through oral and written communication. Hence culture, especially as it is embodied in language, shapes thought. As a result, cognitive development is not the same universally. Whereas Piaget tended to see children as independent explorers, Vygotsky saw them as social beings who develop their minds through their interactions with more knowledgeable members of their culture.

Other challenges to Piaget came from scholars who saw a need to look more closely than Piaget did at the processes involved in thinking and factors affecting those processes. Factors like failing to notice or pay attention to key aspects of the problem or being unable, because of working memory limitations, to keep in mind two dimensions at once (like the height *and* width of a glass) can help explain why young children fail Piagetian problems like conservation tasks. The **information-processing approach** to cognitive development, which became the dominant perspective starting in the 1980s, likens the human mind to a computer with hardware and software and examines the fundamental mental processes, such as attention, memory, decision making, and the like, involved in performing cognitive tasks. Development involves changes in the capacity and speed of the information-processing machine we call the brain, in the strategies used to process information, and in the information stored in memory.

This Oglala Lakota girl in South Dakota is learning a traditional skill of her Native American culture with the help of an adult mentor. As Vygotsky emphasized, development is shaped by the cultural environment in which it occurs.

AARON HUEY/National Geographic Creative

● Checking Mastery

1. Distinguish between concrete operational thinking and formal operational thinking in terms of what is operated upon mentally, using specific examples if you can.
2. What one major criticism would advocates of (a) the sociocultural perspective on cognitive development and (b) the information-processing approach to cognition make of Piaget's cognitive developmental theory?

● Making Connections

1. Although we will look at the implications of Piaget's theory for education more closely in Chapter 7, based on what you know so far, what recommendations might Piaget make to teachers of (a) 4-year-olds, (b) 9-year-olds, and (c) 14-year-olds to help them recognize the strengths and limitations of children of these ages?

2.5

Systems Theories

LEARNING OBJECTIVES

- Explain how systems theorists such as Urie Bronfenbrenner have changed the way developmentalists think about the roles of biological and environmental forces in development.
- Define and give an example of each of the four main environmental systems in Bronfenbrenner's bioecological theory.
- Explain what the PPCT model says are the four ingredients of good research on human development.
- Evaluate the strengths and weaknesses of Bronfenbrenner's theory.

Systems theories of development, sometimes called contextual theories, claim that changes over the life span arise from ongoing transactions in which a changing organism and a changing environment affect one another (see, for example, Lerner, 2006; Newman & Newman, 2016; Overton & Molenaar, 2015). The individual and the physical and social contexts with which he interacts are inseparable parts of a larger system in which everything affects everything else. Development can take a variety of paths, and some surprising turns, depending on the complex interplay of multiple influences. Nature and nurture cannot be separated easily because they are part of a dynamic system, continually influencing one another, “co-acting” to produce development.

Bronfenbrenner's Bioecological Model

To help you think about a changing person in a changing environment, consider an influential conceptual model formulated by Russian-born American psychologist Urie Bronfenbrenner (1917–2005). Bronfenbrenner became disturbed that many early developmental scientists were studying human development out of context, expecting it to be universal and failing to appreciate how much it could vary from culture to culture, from neighborhood to neighborhood, and from home to home. He charged that developmental psychology had become the study of “. . . the strange behavior of children in strange situations with strange adults for the briefest possible periods of time” (Bronfenbrenner, 1977, p. 519) and called for more research in natural settings. Bronfenbrenner formulated an ecological model to describe how the environment is organized and how it affects development. He later renamed his framework a **bioecological model** of development to get the “person” back into the picture and to convey how it is really

the transactions between person and environment that produce development (Bronfenbrenner, 1979, 1989; Bronfenbrenner & Morris, 2006; Rosa & Tudge, 2013; Wachs, 2015).

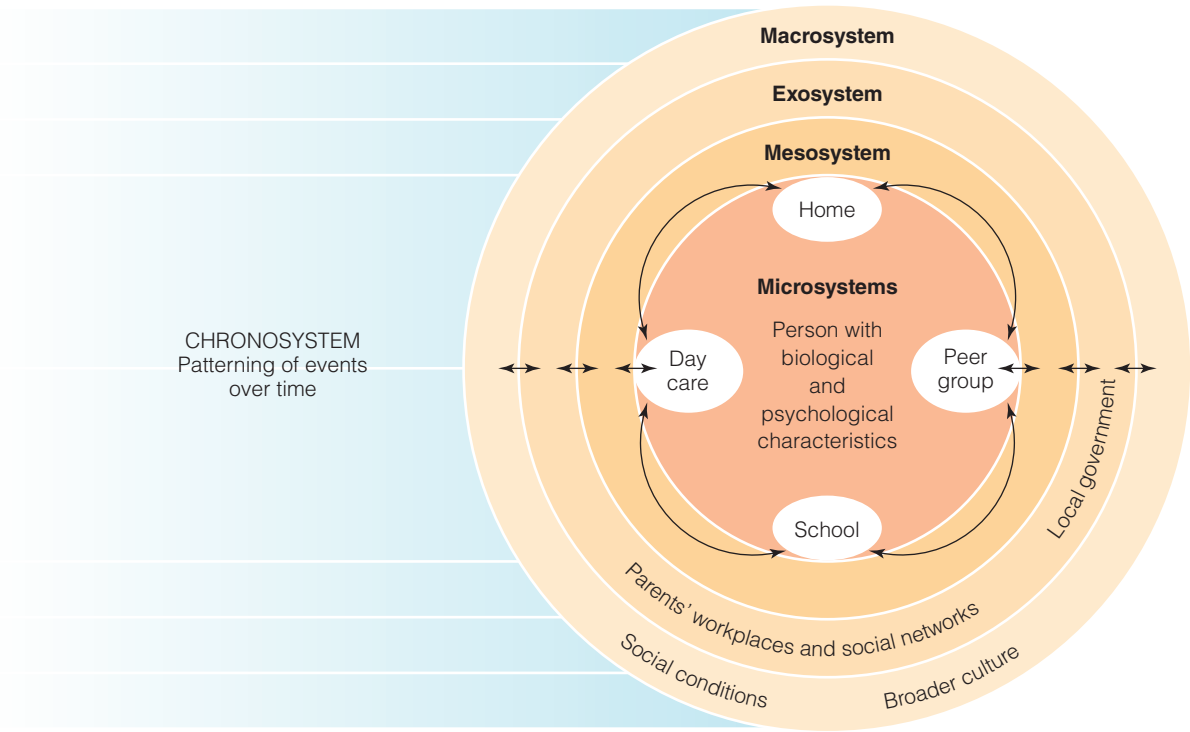

In Bronfenbrenner's view, the developing person, with his or her genetic makeup and biological and psychological characteristics, is embedded in a series of environmental systems. These nested systems interact with one another and with the individual over time to influence development. There are many bidirectional or reciprocal influences at work. The four environmental systems that influence and are influenced by the developing person are shown in ■ **Figure 2.4**.

1. A **microsystem** is an immediate physical and social environment in which the person interacts face-to-face with other people and influences and is affected by them. The

Urie Bronfenbrenner sought to understand how a person and the environmental systems in which the person is embedded interact over time to produce development.

AP Images

■ **Figure 2.4** Urie Bronfenbrenner's bioecological model of development pictures environment as a series of nested structures in which the person is embedded. A microsystem is an immediate environment, such as the family, in which the person interacts. The mesosystem is connections among microsystems, the exosystem is settings that affect but do not contain the individual, and the macrosystem is the broader cultural context of development. The chronosystem is the patterning over time of historical and life events taking place in these systems. All the systems influence and are influenced by the developing person. Source: Adapted from Kopp & Krakow (1982)

primary microsystem for a firstborn infant is likely to be the family—perhaps infant, mother, and father, all reciprocally influencing one another. The developing child may also experience other microsystems, such as a day care center or peer group. We have much evidence that the family environment is an important influence on child development and have also come to appreciate the importance of other microsystems such as peer groups, schools, workplaces, and the like.

2. The **mesosystem** consists of the interrelationships between two or more microsystems. For example, teenagers from Mexican, Chinese, and European American backgrounds who experience stressful events such as arguments in the family, one microsystem, show increased problems of poor attendance and difficulty learning at school, a second microsystem (Flook & Fuligni, 2008). Similarly, problems at school can spill over to the family if adolescents take their bad moods home with them. For any developing person, what happens in one microsystem can have implications, good or bad, for what happens in another microsystem—and for development.
3. The **exosystem** involves social settings that individuals do not experience directly but that can still influence their development. For example, children can be affected by their parents' experiences of stress at work, by how strong their parents' social support network is, or by what kind of neighborhood

they live in. They can also be affected by a decision by the local school board to eliminate health education from the curriculum or a decision by the police department to enforce underage drinking laws more aggressively.

4. The **macrosystem** is the larger cultural or societal context in which the microsystem, mesosystem, and exosystem are embedded. It includes a society's cultural values, laws, political and economic systems, and institutions. To illustrate, although the United States has a high standard of living, it is not a very family-friendly cultural environment in many ways, as Bronfenbrenner himself often lamented (Bronfenbrenner & Morris, 2006). For example, modern nations typically offer paid leave from work to new parents, whereas the United States is among only three countries in the world out of 185 countries reporting that do not; the others are Oman and Papua New Guinea (International Labor Organization, 2014). Policies regarding paid family leave to care for sick children or ailing parents, affordable child care, and flexible work hours are also far behind those of other countries and have negative implications for American families and their children (Schulte, 2014).

In addition to the microsystem, mesosystem, exosystem, and macrosystem levels, Bronfenbrenner introduced the concept of the **chronosystem** (“chrono” means time) to capture the idea that people and their environments and the relations between the two

change over time and unfold in particular patterns or sequences. This time dimension captures minute-by-minute changes (while learning a new skill, for example), changes during a person's life, and historical changes that may span generations. We cannot study development by taking still photos; we need video to understand how one event leads to another and how societal changes intertwine with changes in people's lives. Thus an economic crisis may precipitate a chain of events: a husband's job loss, marital conflict, divorce, and multiple changes in family relationships and children's lives and development. Each of us functions in particular microsystems linked through the mesosystem and embedded in the larger contexts of the exosystem and the macrosystem, all in continual flux.

Bronfenbrenner's bioecological model suggests that answers to questions about how child abuse, marriage, retirement, or other life experiences affect development will often be complex because outcomes depend on so many factors. Contextual effects on development can occur at any of the levels. To illustrate, Ann Crouter and her colleagues (2007) conducted a longitudinal study of changes in gender-role attitudes from age 7 to age 19 during a period of major changes in women's roles in society. They found that most children adopted less traditional attitudes as they got older. However, the attitudes of boys (but not girls) who grew up with traditional parents and brothers became more traditional over the years. In other words, both the child's personal characteristics (here, the child's gender) and the child's social context (parent and sibling characteristics) made for differences in developmental paths.

As Bronfenbrenner continued to think about environmental influences, he became disenchanted with contextual studies that merely compared the development of children who lived at different "social addresses"—in different cultures, in low versus high SES neighborhoods, in different ethnic or racial groups, and so on (Bronfenbrenner, 1979). He wanted to know what was going on at these social addresses. He began to call for the study of what he called **proximal processes**: recurring, reciprocal interactions between the individual and other people, objects, or symbols that move development forward toward more effective functioning (Bronfenbrenner & Ceci, 1994). A proximal process in the family microsystem might be reading bedtime stories together, an activity that is likely to become more complex as the child gets older and helps the child master language skills. Playing with other children as a preschool child or interacting with peers as an adolescent are other examples of proximal processes that happen often, become more complex over time, and build social competence.

According to Bronfenbrenner and Morris (2006), researchers who want to understand development need to do research guided by a **PPCT model**, in which, rather than simply comparing children at different social addresses, they examine development as a function of four factors: *process, person, context, and time*. Thus a researcher interested in parent influences on the development of language skills might examine how parents converse with their children in everyday life (*process*), compare this important proximal process for hearing impaired and hearing children (a *person* factor), examine whether conversations differ for families in the United States and families in China (different

contexts), and use a longitudinal design to examine changes in language skills over *time*.

More and more developmental scientists are adopting a systems or contextual perspective on development (Overton & Molenaar, 2015). In Chapter 3, you will learn that modern developmental psychobiologists maintain that genes do not dictate how development will go. Rather, both over the course of evolution and during the individual's development, genes and environment influence one another and "co-act" to make certain developmental outcomes more or less probable. In Chapter 5, you will encounter Esther Thelen's dynamic systems theory of motor development, in which a process of self-organization of motor skills occurs as infant try to get where they want to go. In Chapter 7, you will become acquainted with Vygotsky's sociocultural or contextual perspective on cognitive development, and in Chapter 15 you will come to appreciate the value of a family systems perspective on parenting and family life.

In **Exploration 2.4**, we imagine what Bronfenbrenner might have thought about contributors to sexual risk behavior in adolescence.

Strengths and Weaknesses

Systems theories of development are complex, but that is one of their great strengths: They capture the complexity of life-span human development. We can applaud Bronfenbrenner and like-minded theorists for conceptualizing development as the product of many biological and environmental forces interacting within a complex system and for challenging us to look closely at ongoing transactions, including proximal processes, involving person and environment (Newman & Newman, 2016).

Yet systems theories can be faulted for not yet providing a clear picture of the course of human development and for being only partially formulated and tested at this point (Newman & Newman, 2016). Indeed, an even more serious criticism can be made: Systems perspectives may never provide a coherent picture of development. Why? If we take seriously the idea that development can take any number of paths depending on a range of interacting influences both within and outside the person, how can we ever state generalizations about development that will hold up for most people? If change over a lifetime depends on the ongoing transactions between a unique person and a unique environment, does each life require its own theory? The problem is this: "For the contextual or systems theorist, often the only generalization that holds is, 'It depends'" (Goldhaber, 2000, p. 33).

Human development may be more predictable than Bronfenbrenner's bioecological model implies, though. When children with typical human biological endowments grow up in typical human environments, they may change in similar directions at similar ages, much as stage theorists like Piaget and Erikson maintain (Hoare, 2009; Lerner & Kauffman, 1985). Perhaps it is still possible to see humans as moving in orderly and similar directions in many aspects of their development while also appreciating the tremendous diversity of human development and the many contextual influences on it (Goldhaber, 2012).

● EXPLORATION 2.4

Bronfenbrenner: Notes on Sexual Risk Behavior

I, Urie Bronfenbrenner, would look for multiple, interacting causes of adolescent sexual risk behavior, analyzing the ongoing interactions between developing adolescents and the environmental systems in which they are developing.

Although I'm best known for describing the ecology of human development, I also look at biological and psychological characteristics of the person who interacts with the environment. We know, for example, that puberty and the hormonal changes associated with it activate certain genes. Among them are genes that contribute to some teens having stronger sensation-seeking tendencies than others; like Jared, they seek new and exciting experiences (Harden & Mann, 2015). Sensation seeking, in turn, contributes to a number of adolescent problem behaviors, including sexual risk behavior (Harden & Mann, 2015; Voisin et al., 2013).

I would definitely assess Jared's environment. I would analyze important adolescent

microsystems such as the family, peer group, and school and the processes that go on in them. Stressful relationships with parents, involvement with peers who are having sex, and lack of connectedness to school can all increase the likelihood of risky sexual behavior (Henrich et al., 2006; James et al., 2012; Lansford et al., 2010; Pilgrim & Blum, 2012).

I would suspect influences of key microsystems on one another—that is, the *mesosystem*—may be important. For example, Jared may be coping with tensions with his parents by becoming more dependent on his older friend Damien; in turn, that friendship may be aggravating problems in Jared's relationship with his parents.

I would consider the *exosystem*—for example, the possibility that Jared comes from a disadvantaged neighborhood in which early sex and sex with multiple partners are common (Carlson et al., 2014), or the possibility that a shortage of job training programs for youth and

jobs in the area could be contributing to a sense that it is pointless to postpone a sex life in order to pursue an education (Cowan, 2011).

I would also wonder whether the broader cultural environment—the *macrosystem*—is one that views teenage sexual behavior a normal developmental milestone or a social problem. In some cultures of the world, and in some low-SES subcultures in the United States, early sexual initiation and parenthood are viewed as adaptive (Davies et al., 2003). The fact is that some teens view having sex at an early age as an important step in becoming a “man” or becoming a parent as a desired goal (Abma et al., 2010; Pilgrim & Blum, 2012).

Mainly, I believe that there is not *one* cause of teenage sexual risk behavior; there is a whole system of interacting causes. Moreover, there are changes in these interactions between person and environment over time (in the *chronosystem*).

● Checking Mastery

1. Describe how being given a big raise at work might affect a mother's parenting and which of Bronfenbrenner's systems would be involved if it did.
2. Describe the relationship between nature and nurture in Bronfenbrenner's bioecological model.

● Making Connections

1. Applying Bronfenbrenner's bioecological model to yourself, give an example of how each of Bronfenbrenner's four environmental systems may have affected you and your development within the past year.
2. How might Bronfenbrenner explain the high prevalence of binge drinking on college campuses today? (Give examples of how each of his four different environmental systems might contribute.)

2.6

Theories in Perspective

LEARNING OBJECTIVES

- Compare and contrast the major theories in this chapter in terms of their stands on the four major issues in human development.

Just as developmental scientists need theories such as the ones we have surveyed in this chapter to guide their work, every parent, teacher, human services professional, and observer of humans is guided by some set of basic assumptions about how humans develop and why they develop as they do. We hope that you will think about your own assumptions about human development by comparing the answers you gave to the questions in **Engagement 2.1** at the start of the chapter with the summary information in ● **Table 2.5** and seeing which theorists' views are most compatible with your own.

Theories of human development can be grouped into categories based on the broad assumptions they make (P. H. Miller, 2016; Pepper, 1942; Reese & Overton, 1970). Stage theorists such as Freud, Erikson, and Piaget form one broad group. They believe that development is guided in certain universal directions by biological-maturational forces, assuming the child also experiences a reasonably nurturing environment. Humans everywhere progress through distinct or discontinuous stages that are universal and lead to the same final state of maturity.

● **Table 2.5** Compare Yourself with the Theorists

In **Engagement 2.1**, you were asked to indicate your position on basic issues in human development by answering four questions. If you transcribe your answers (a, b, c, d, or e) in the appropriate boxes at the bottom of the table below, you can compare your stands with those of the major theorists described in this chapter—and review the theories. With whom do you seem to agree the most?

Theory/Theorist	Message	Nature–Nurture	Activity–Passivity	Continuity–Discontinuity	Universality–Context Specificity
Psychoanalytic Theory: Freud's Psychosexual Theory	Biologically based sexual instincts motivate behavior and steer development through five psychosexual stages, oral to genital.	b. More nature (biology drives development; early experience in the family influences it, too)	b. Passive (humans are influenced by forces beyond their control)	a. Discontinuous (stagelike)	a. Universal
Psychoanalytic Theory: Erikson's Psychosocial Theory	Humans progress through eight psychosocial conflicts, from trust vs. mistrust to integrity vs. despair.	c. Interactionist; nature and nurture equally	a. Active	a. Discontinuous (stagelike)	a. Universal (although stages may be expressed differently in different cultures)
Learning Theory: Skinner's Behavioral Theory	Development is the product of learning from the consequences of one's behavior through operant conditioning.	e. Mostly nurture	b. Passive (humans are shaped by environment)	c. Continuous (gradually increase or decrease in strength)	b. Context specific (direction of development depends on experiences)
Learning Theory: Bandura's Social Cognitive Theory	Development is the product of cognition, as illustrated by observational learning and human agency.	d. More nurture	a. Active (humans influence their environments)	c. Continuous	b. Context specific
Cognitive Developmental Theory: Piaget's Constructivism	Development proceeds through four stages of cognitive development, from sensorimotor to formal operations.	c. Interactionist (maturation interacting with experience guides all through the same stages)	a. Active	a. Discontinuous (stagelike)	a. Universal
Systems Theories: Bronfenbrenner's Bioecological Model	Development takes many directions depending on transactions between a changing person and a changing environment.	c. Nature and nurture co-acting, influencing one another	a. Active	b. Both continuous and discontinuous	b. Context specific
Your Answers: (From Engagement 2.1)		<i>Question 1:</i>	<i>Question 2:</i>	<i>Question 3:</i>	<i>Question 4:</i>

By contrast, learning theorists such as Watson, Skinner, and Bandura emphasize the role of environment more than the role of biological forces in development. Children cannot be expected to develop in healthy directions (or at least will never be Harvard material) unless they are exposed to particular learning experiences and shaped in certain directions.

Finally, systems theorists such as Bronfenbrenner view biology and environment as inseparable components of a larger system. Children contribute actively to the developmental process (as stage theorists such as Piaget maintain), but the environment is also an active participant in the developmental drama (as learning theorists maintain). The potential exists for both qualitative (stagelike) change and quantitative change. Development can proceed along many paths depending on the intricate interplay of nature and nurture.

Our understanding of human development has changed, and will continue to change, as one prevailing view gives way to another. From the beginning of the study of human development at the beginning of the 20th century through the heyday of Freud's psychoanalytic theory, a stage theory perspective with an emphasis on biological forces prevailed (Parke et al., 1994). In the 1950s and 1960s, learning theories came to the fore, and attention shifted from biology toward environment. Then, with the rising influence of cognitive psychology and Piaget's theory of cognitive development in the late 1960s and 1970s, a stage theory emphasizing an *interaction* of nature and nurture gained prominence. Finally, in the 1980s and 1990s, we gained a fuller appreciation of how multiple biological and environmental forces influence one another.

Where are we today? The broad perspective on key developmental issues taken by systems theorists such as Bronfenbrenner is the perspective that most 21st-century developmentalists have adopted. The field has moved beyond the black-or-white positions taken by many of its pioneers. We now appreciate that human development is always the product of ongoing transactions between nature and nurture; that both humans and their environments are active in the developmental

process; that development is both continuous and discontinuous in form; and that development has both universal aspects and aspects particular to certain cultures, times, and individuals. In short, the assumptions and theories that guide the study of human development have become increasingly complex as the incredible complexity of human development has become more apparent.

As we have emphasized, a main function of theories is to guide research. Thus, Freud stimulated researchers to study inner personality conflicts, Skinner inspired them to analyze how behavior changes when its consequences change, and Piaget inspired them to explore children's modes of thinking. Different theories make different assumptions, stimulate different kinds of research, and yield different kinds of facts about development and explanations of them, as you will see throughout this book. Theorists who view the world through different lenses not only study different things in different ways but are likely to disagree even when the same "facts" are set before them, because they will interpret those facts differently (Miller, 2016). This is the nature of science.

Theories also guide practice. As you have seen, each theory of human development represents a particular way of defining developmental issues and problems. Now that we have surveyed the major theories and seen how each might explain sexual risk taking in adolescence, how do you think each would go about trying to reduce it? **Application 2.1** offers some ideas and evidence and will serve, too, as a review of the theories. You might think the problem through yourself before you read the box.

You need not choose one favored developmental theory and reject others. Because different theories often highlight different aspects of development, one may be more relevant to a particular issue or to a particular age group than another. Many developmentalists today are theoretical **eclectics** who rely on many theories, recognizing that no major theory of human development can explain everything but that each has something to contribute to our understanding.

● APPLICATION 2.1

Using Developmental Theories to Reduce Sexual Risk Behavior among Teens

Often how you define a problem determines how you attempt to solve it. So how would psychoanalytic, cognitive developmental, learning, and bioecological theorists approach reducing sexual risk behavior in adolescence?

Psychoanalytic Theory

Psychoanalytic theorists tend to locate the causes of problems within the person—in their personality dynamics. They would want to identify teenagers who are at risk because they are experiencing especially difficult psychic conflicts and treat them through psychoanalysis

aimed at helping them resolve their conflicts. Freud might focus on anxieties related to developing as a sexual being, Erikson on broader identity issues. Although the psychoanalytic approach might work with teenagers who are indeed psychologically disturbed, most teenagers who become sexually active are not.

Cognitive Developmental Theory

According to Piaget's cognitive developmental perspective, the solution is improved sex education programs—programs that correct teens' many misconceptions, provide them with accurate

information and strategies for avoiding unwanted and unprotected sex, and help them think through the long-range consequences of their sexual decisions. For teens who are still primarily in Piaget's concrete operational stage rather than the formal operational stage, this education might need to involve concrete examples and demonstrations.

Carefully designed, comprehensive sex education programs can indeed delay teens from having sex, decrease the number of sexual partners and frequency of sex, and increase contraception use without having unintended negative effects such as increasing sexual activity

(continued)

● APPLICATION 2.1

Using Developmental Theories to Reduce Sexual Risk Behavior among Teens *(continued)*

(Chin et al., 2012; Franklin & Corcoran, 2000; Kirby & Laris, 2009). In fact, simply completing more years of school is associated with lower levels of sexual risk taking, sexually transmitted infections, and other unintended consequences of sex (De Graaf, Vanwesenbeeck, & Meijer, 2015). However, education alone is often not enough, so we need to consider solutions that locate the causes of teenage pregnancy in the environment rather than in the individual's psychological weaknesses or cognitive limitations.

Learning Theories

Learning theorists believe that changing the environment will change the person. In support of this belief, it appears that one effective approach to preventing the negative consequences of teen sex is to make contraceptives readily available to teens and teach them how to use them (Franklin & Corcoran, 2000). This approach reflects a Skinnerian philosophy of encouraging desired behavior by making it more reinforcing and less punishing. Albert Bandura's social cognitive theory suggests that it would also help to provide teenagers with more role models of responsible sexual behavior and fewer models of risky sexual behavior (Finnerty-Myers, 2011; Unger, Molina, & Teran,

2000). And it would help to change teens' perceptions of the consequences of using condoms in a positive direction (Balassone, 1991).

Bioecological Theory

Systems theorists such as Bronfenbrenner would recommend comprehensive programs that attempt to change *both* the person and the environment—or really, the whole system of interacting influences on development (Arbeit, 2014; Pilgrim & Blum, 2012). Interventions may need to address teenagers' broader needs as sexual and social beings and empower them to take charge of their own development (Allen, Seitz, & Apfel, 2007; Arbeit, 2014). Interventions may also need to alter contextual influences—for example, to change how adolescents and their parents, peers, and partners interact with each other, address problems associated with poverty and family instability, and enable youth in disadvantaged segments of society to perceive opportunities to succeed in life if they focus on

Sex education can combat the many misconceptions children and adolescents have about sex and can even change their behavior—but it is not the only answer.

Colin McConnell/Toronto Star/Getty Images

education and vocational preparation (Cowan, 2011; Jordahl & Lohman, 2009; Tanner et al., 2013).

You can see, then, that the theoretical position one takes has a profound effect on how one attempts to optimize development. In all likelihood, multiple approaches will be needed to address complex problems such as teen sexual risk behavior—and to achieve the larger goal of understanding human development.

● Checking Mastery

1. How have stands on the nature–nurture issue changed during the 20th century from (a) Freud to (b) Skinner to (c) Bronfenbrenner?
2. Of the theorists discussed in this chapter, who is the only one with something specific to say about development during adulthood?

● Making Connections

1. You have decided to become an eclectic. What would you identify as the one greatest insight from each of the four major perspectives in this chapter (psychoanalytic, learning, cognitive developmental, and systems theory)—and why?
2. We like to think that there is progress in science. Looking at the theories in this chapter, to what extent do you see progress over the 20th century?

Chapter Summary

2.1 Developmental Theories and the Issues They Raise

- Theories organize and explain the facts of human development and should be internally consistent, falsifiable, and supported by data.
- The four major issues in the study of human development are nature and nurture, activity and passivity, continuity and discontinuity, and universality and context specificity.

2.2 Psychoanalytic Theory

- In Freud's psychoanalytic theory, humans are irrational beings primarily driven by inborn biological instincts of which they are largely unconscious. The personality is partitioned into the id, ego, and superego (which emerge in that order).
- Libido is rechanneled across five psychosexual stages—oral, anal, phallic, latent, and genital. Each stage involves psychic conflicts that can result in fixation at a stage, create the need for defense mechanisms, and have lasting effects on personality.

- Biological needs drive development, but parents affect a child's success in dealing with conflicts and can contribute to emotional problems, especially if they are overly restrictive or punitive.
- Compared with Freud, neo-Freudian Erik Erikson emphasized biological urges less and social influences more; emphasized id less and ego more; held a more optimistic view of human nature; and theorized about the whole life span.
- According to Erikson's psychosocial theory, development proceeds through eight psychosocial stages involving issues of trust, autonomy, initiative, industry, identity, intimacy, generativity, and integrity. Parents, peers, and the larger culture influence how conflicts are resolved.
- Although Freud made huge contributions by calling attention to the unconscious, early experiences in the family, and emotional aspects of development, his theory is not easily falsifiable and many of its specifics lack support. Although Erikson deserves credit for broadening Freud's theory and considering the whole life span, aspects of his theory have also been difficult to test.

2.3 Learning Theories

- Learning theorists maintain that humans change gradually and can develop in many directions depending on environmental influences.
- Behaviorist Watson focused on the role of Pavlov's classical conditioning in the learning of emotional responses, and Skinner highlighted operant conditioning and the roles of reinforcement and punishment.
- Bandura's social cognitive theory emphasizes the importance of cognitive processes in learning, observational learning as the most important type of human learning, and self-efficacy; reciprocal determinism among person, behavior, and environment shapes development.
- Learning theories are well supported and applicable across the life span, but they do not necessarily explain normal developmental changes and they underemphasize biological influences on development.

2.4 Piaget: Cognitive Developmental Theory

- Piaget's cognitive developmental perspective holds that humans adapt to and create new understandings of the world through their active interactions with it (constructivism).

- The interaction of biological maturation and experience causes children to progress through four universal, invariant, and qualitatively different stages of thinking: sensorimotor, preoperational, concrete operational, and formal operational.
- Despite Piaget's immense influence, critics think his concept of broad stages is flawed, that he underestimated young children, and that he put too little emphasis on social and cultural influences on development (according to Vygotsky's sociocultural perspective) and on cognitive processes such as attention and memory (according to the information-processing approach).

2.5 Systems Theories

- Systems and contextual theories view development as the product of ongoing transactions and mutual influence between the individual and the environment.
- Bronfenbrenner's bioecological model portrays person and environment (at the microsystem, mesosystem, exosystem, and macrosystem levels) as mutually influencing each other over time (chronosystem).
- Bronfenbrenner called attention to development-producing proximal processes and asked developmental scientists to study process, person, context, and time in his PPCT model.
- Systems theories are incomplete, however, and do not provide a coherent picture of human development.

2.6 Theories in Perspective

- During the 20th century, stage theories such as Freud's emphasizing biological forces gave way to learning theories emphasizing environmental influences and then to Piaget's cognitive developmental theory and an emphasis on the interaction of nature and nurture.
- Today's developmentalists prefer the perspective of complex systems theories, such as Bronfenbrenner's bioecological theory, in which developmental outcomes are more or less probable depending on the ongoing transactions between person and the environment.
- Theories influence both research and practice, and many developmentalists are theoretical eclectics.

3.5 Gene–Environment Interplay

- Gene–Environment Interactions
- Gene–Environment Correlations
- Epigenetic Effects on Gene Expression
- Controversies Surrounding Genetic Research

A newspaper story about Jim Lewis and Jim Springer inspired Thomas Bouchard Jr. and his associates at the University of Minnesota to undertake a study in which they reunited identical twins who had been separated soon after birth and asked them to complete a 50-hour battery of tests (Bouchard, 1984; Bouchard et al., 1990; and see Segal, 2012, for a summary of this study's many findings). Together after spending all but the first 4 weeks of their 39 years apart, Jim and Jim discovered that they had both married women named Linda—and then women named Betty. They named their first sons James Alan and James Allan, had dogs named Toy, and liked Miller Lite beer and Salem cigarettes. They liked math and hated spelling and enjoyed the same vacation spot in Florida.

Yet identical twins Jessica and Rachel Wessell, despite having the same genes, growing up together, and being close, are far from identical. One excels in math, the other in English. One has cerebral palsy and is in a wheelchair, possibly because of lack of oxygen to her brain at birth; the other was in the marching band in high school (Helderman, 2003).

Do similarities between identical twins arise mainly because identical twins have identical genes, or is it because people treat individuals who look so alike the same way? How can we explain differences between individuals who have identical genes and grow up in the same environment?

The influence of genes on development must be taken seriously—but so must the influence of environment. How do nature and nurture, heredity and environment, contribute to the shaping of our physical and psychological characteristics? That is the complex puzzle we grapple with in this chapter—and throughout the book. Reading this chapter should increase your appreciation of genetic contributions to development, give you new insights into the importance of environmental influences, and most importantly, reveal the fascinating ways in which nature and nurture

work together to guide development. We invite you to take the short quiz in **Engagement 3.1** to find out whether you come to this chapter with any misconceptions about genetic influence. The correct answers will become clear as you read and are also provided in the box.

We begin with a brief look at evolution and ways in which genes make humans similar. Then we turn to what each individual inherits at conception and how this genetic endowment, in combination with environmental factors, influences the individual's traits. Then the chapter explores research findings on how genes and environment contribute to differences among people in intelligence, personality, and other important characteristics. Finally, we examine key ways in which genes and environment work together—and influence one another—over the life span.

3.1

Evolution and Species Heredity

LEARNING OBJECTIVES

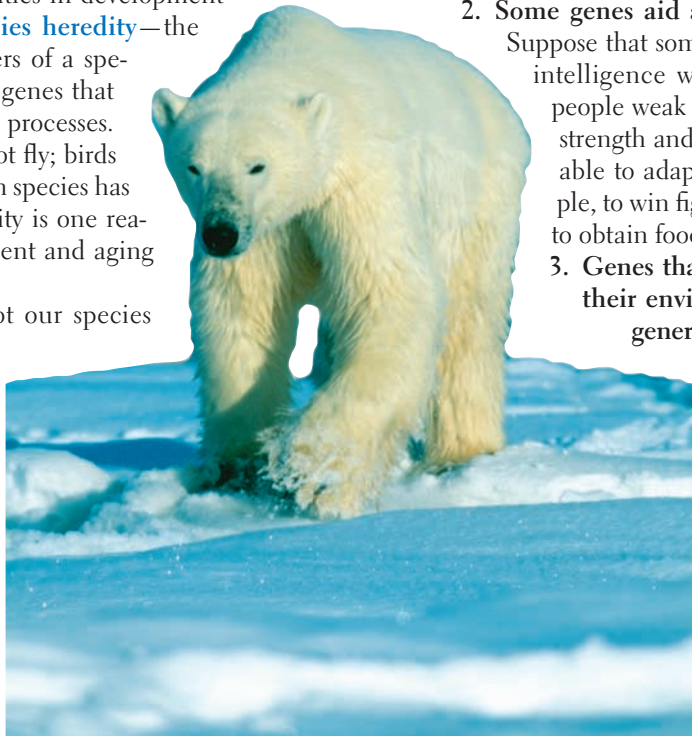

- Summarize the basic argument of Darwin's theory of evolution and the significance of the theory for the study of development.
- Compare and contrast biological evolution and cultural evolution.

Most descriptions of heredity focus on its role in creating differences among people. Some individuals inherit genes for blue eyes, others genes for brown eyes; some inherit genes for blood type O, others genes for blood type A or B. But isn't it remarkable that almost every one of us has two eyes and that we all have blood coursing through our veins? Virtually all of us also develop in similar ways at similar ages—walking and talking around 1 year, maturing sexually from 10 to 14, watching our skin wrinkle in our 40s and 50s. Such similarities in development and aging are a product of **species heredity**—the genetic endowment that members of a species have in common, including genes that influence development and aging processes. Humans can feel guilty but cannot fly; birds can fly but cannot feel guilty. Each species has a distinct heredity. Species heredity is one reason certain patterns of development and aging are universal.

To understand where we got our species heredity, we must turn to evolutionary theory—to the path-blazing work of Charles Darwin (1809–1882; see Dewsbury, 2009). Darwin's theory of evolution sought to explain how the characteristics of a species change over time and how new species evolve from earlier ones (Darwin, 1859). The theory has been and continues to be controversial, but it is strongly supported by a wealth of evidence

and guides scientific research not only in biology but in psychology and other fields (D. M. Buss, 2012). Darwin's theory makes these main arguments:

1. **There is genetic variation in a species.** Some members of the species have different genes than other members of the species do. If all members of the species were genetically identical, there would be no way for the genetic makeup of the species to change over time in response to changes in the environment.
2. **Some genes aid adaptation more than others do.** Suppose that some genes contribute to strength and intelligence whereas other genes tend to make people weak and dull. People with the genes for strength and intelligence would likely be better able to adapt to their environment—for example, to win fights for survival or to figure out how to obtain food.
3. **Genes that aid their bearers in adapting to their environment will be passed to future generations more frequently than genes that do not.** This is the key principle of **natural selection**—the idea that nature “selects,” or allows to survive and reproduce, those members of a species

Each species has evolved through natural selection to be adapted to its environment. What will happen to polar bears as global warming melts their icebergs?

● ENGAGEMENT 3.1

Genetic Influence: What is Myth, What is Reality?

Answer each of the following questions True or False to identify, before reading this chapter, any misconceptions about genetic influences you may have. Then watch for the correct answers and their explanations throughout the chapter and return to review the answers (printed upside down in this box).

1. The most important reason that identical twins are similar psychologically is that they are treated similarly.
2. The father, not the mother, determines the sex of a child.
3. If a trait is highly influenced by genes, it is generally extremely hard for environmental forces to change it.
4. Most important psychological traits, such as intelligence and extraversion, are influenced by a single pair of genes.
5. Environmental influences such as stress and a poor diet can cause certain genes to become inactive.
6. Homosexuality is genetically influenced, although environment plays an important role in its development too.
7. Prenatal experiences can change the functioning of an individual's genes.
8. The contribution of genes to differences in intelligence typically decreases with age during childhood and adolescence as the effects of learning experiences become more evident.
9. Biological siblings turn out about as similar in personality if they grow up apart as if they grow up in the same home.
10. People's social attitudes and interests are influenced by environment rather than heredity.

Answers: 1. F (twins are treated similarly because they are so similar) 2. T (because sperm have either an X or a Y chromosome) 3. F (for example, genetically influenced IQ scores can be raised by enriched environments) 4. F (most are influenced by multiple genes) 5. T (environment influences gene expression) 6. T (genes and environment both contribute to homosexuality) 7. T (through what are called epigenetic effects, environmental factors such as stress can alter gene expression) 8. F (heritability, a measure of the magnitude of genetic influence on individual differences, often increases from childhood to adulthood as intellectually inclined children seek out more intellectually stimulating than their less intellectually inclined peers) 9. T (shared environment has little effect on personality) 10. T (attitudes and interests are mostly influenced by genetic makeup)

whose genes help them adapt to their environment. Genes that increase the chances of surviving and reproducing will become more common over time because they will be passed to many offspring. Through natural selection, then, the genetic makeup of a species slowly changes—and will continue to change as long as individuals with certain genetic makeups reproduce more frequently than individuals with other genetic makeups. Change can eventually be sufficient to produce a new species. The result is what Darwin marveled at when he conducted observations in the Galapagos Islands: the incredible diversity of species on earth, each well adapted to its environment.

Consider a classic example of evolution in action. H. B. D. Kettlewell (1959) carefully studied moths in England. There is genetic variation among moths that makes some dark and others light. By placing light and dark moths in several sites, Kettlewell found that in rural areas light-colored moths were more likely to survive but that in industrial areas dark moths were more likely to survive. The explanation? In rural areas, light-colored moths blend in well with light-colored trees and are therefore better protected from predators. Natural selection favors them. However, in sooty industrial areas, light-colored moths are easy pickings against the darkened trees, whereas dark moths are well disguised. When industry came to England, the proportion of dark moths increased; as pollution was brought under control in some highly industrialized areas, light-colored moths became more common again (Bishop & Cooke, 1975).

Notice, then, that evolution is not just about genes. It is about the *interaction between genes and environment*. A particular genetic makeup may enhance survival in one kind of environment but prove maladaptive in another. Which genes are advantageous, and therefore which become more common in future generations, depends on what environment a group experiences and what traits that environment demands. Genes that helped our ancestors hunt prey may not be as important in today's world as genes that help people master iPhone apps and Excel spreadsheets.

According to evolutionary theory, then, humans, like any other species, are as they are and develop as they do partly because they have a shared species heredity that evolved through natural selection. But modern evolutionary theorists and developmental scientists understand that we need to get away from “nature versus nurture” thinking. The two forces are completely intertwined over the course of evolution as well as over the course of an individual's development (Lickliter & Honeycutt, 2015).

Modern **evolutionary psychology** is the application of evolutionary theory to understanding why humans think and behave as they do. Evolutionary psychologists ask important questions about how the characteristics and behaviors we observe in humans today may have helped our ancestors adapt to their environments and consequently may have become part of the shared genetic endowment of our species (Bjorklund & Pellegrini, 2002; D. M. Buss, 2012). They ask, for example, whether humans are basically cooperative and helpful or selfish and aggressive, whether we have evolved special brain modules to handle critical cognitive

functions such as recognizing faces, whether gender differences have origins in evolution, why humans mate and raise children as they do, and why human children develop as they do.

Not all human similarity is because of genes, however. Through the process of **cultural evolution**, we “inherit” from previous generations a characteristically human environment and tried and true ways of adapting to it, invent better ways of adapting and adjusting to changing conditions, and pass on what we learn to the next generation (Bjorklund & Pellegrini, 2002). We teach others methods of building igloos or building condos, cooking over fires or cooking in microwaves, sending smoke signals or sending text messages. Cultural evolution through learning and socialization of the young works much more quickly than biological evolution, especially in our age of globalization and instant communication. In the end, the most significant legacy of biological evolution may be a powerful and very flexible brain that allows humans to learn from their experiences, to devise better ways of adapting to their environments and even changing their environments to suit them better, and to communicate what they have learned (Bjorklund & Pellegrini, 2002).

● Checking Mastery

1. Biological evolution will not necessarily make humans better and better over time, but it *will* make them _____.
2. For natural selection to work and for a species to evolve, what must be true of the genetic makeup of a species?
3. What does evolutionary psychology try to explain?

● Making Connections

1. Think of two human behaviors that you believe are so universal that they are probably built into the heredity of our species. Now, why might genes underlying these behaviors have been selected for in the course of evolution?
2. Think about people with a slow metabolism. Can you imagine an environment in which it would be beneficial to have a slow metabolism and another environment in which it could be harmful? What does this tell you about the “adaptiveness” of this human trait?

3.2

Individual Heredity

LEARNING OBJECTIVES

- Describe the basics of the genetic code and what we inherit from our parents.
- Distinguish and give examples of the major mechanisms of inheritance (single gene-pair, sex-linked, and polygenic inheritance), mutations, copy number variations (CNVs), and chromosome abnormalities.
- Summarize what we know about the nature, inheritance, diagnosis, and treatment of selected genetic diseases such as sickle-cell disease, Huntington’s disease, and phenylketonuria (PKU) and compare the major techniques of prenatal diagnosis of diseases and disorders.

To begin to understand how genes contribute to *differences* among humans, we must start at **conception**—the moment when an egg is fertilized by a sperm—look at the workings of genes, and then consider the mechanisms through which genes can influence traits.

The Genetic Code

A sperm cell and an ovum each contribute 23 chromosomes to the **zygote**, or fertilized egg, to give it 46 chromosomes total, organized into 23 pairs. **Chromosomes** are threadlike bodies in the nucleus of each cell and contain stretches called *genes*, the basic units of heredity (■ Figure 3.1). Thus, of each chromosome pair—and of each pair of genes located on corresponding sites on a chromosome pair—one member came from the father and one member came from the mother.

Sperm and ova, unlike other cells, have only 23 chromosomes because they are produced through the specialized process of cell division called **meiosis**. At the start of this process, a reproductive cell in the ovary of a female or the testis of a male that contains the usual 46 chromosomes splits to form two 46-chromosome cells,

and then these two cells each split again to form a total of four cells. In this last step, though, each resulting cell receives only 23 chromosomes. The end product is one egg (and three nonfunctional cells that play no role in reproduction) in a female or four sperm in a male. Each resulting sperm cell or ovum thus has only one member of each of the parent’s 23 pairs of chromosomes. Ova are formed prenatally and later ripen one by one during menstrual cycles; sperm production starts in puberty and continues throughout adulthood.

A few hours after a sperm cell penetrates an ovum, the sperm cell begins to disintegrate, releasing its genetic material. The nucleus of the ovum releases its own genetic material, and a new cell nucleus is created from the genetic material provided by mother and father. This new cell, called a zygote and only the size of a pin-head, is the beginning of a human. Conception has occurred.

The single-celled zygote formed at conception becomes a multiple-celled organism through the more usual process of cell division, **mitosis**. During mitosis, a cell (and each of its 46 chromosomes) divides to produce two identical cells, each containing the same 46 chromosomes. As the zygote moves through the fallopian

■ **Figure 3.1** The chromosomes in each cell consist of strands of DNA made up of sequences of the base chemicals A, T, C, and G. Some sequences are functional units called genes.

Source: National Institute of General Medical Sciences, publications.nigms.nih.gov/insidelifescience/genetics-numbers.html

tube toward its prenatal home in the uterus, it first divides into two cells. The two then become four, the four become eight, and so on, all through mitosis. Except for sperm and ova, all normal human cells contain copies of the 46 chromosomes provided at conception. Mitosis continues throughout life, creating new cells that enable growth and the replacement of old cells that are damaged. (● **Table 3.1** compares mitosis and meiosis.)

Both members of a chromosome pair—one from the mother and one from the father—influence the same characteristics. Each chromosome consists of strands of deoxyribonucleic acid (**DNA**), the double helix molecule whose chemical code is our genetic endowment. DNA is made up of sequences of four chemicals known by the letters A (adenine), C (cytosine), G (guanine), and T (thymine). Some of these sequences are functional units called genes. There are 20,000–25,000 genes (International Human Genome Sequencing Consortium, 2004). Each gene, of which there can be two or more different versions or variants, provides instructions for the production of particular proteins, the building blocks of all bodily tissues and of essential substances such as hormones, neurotransmitters, and enzymes.

The Human Genome Project

Through the federally funded **Human Genome Project**, completed in 2003, researchers mapped the sequence of the chemical units or “letters” that make up the strands of DNA in a full set of 46 human chromosomes (Weiss, 2003; and see www.genome.gov/10001772). The human genome has about 3.1 billion of the chemical constituents A, C, G, and T. However, it turns out that only about 3% of the human genome consists of what has traditionally been defined as genes: stretches of DNA that are transcribed into RNA (ribonucleic acid), which then serves as a template for the production of particular proteins (Brown & Boytchev, 2012; Plomin, 2013). The remaining stretches of DNA were at first called “junk DNA,” but it soon became clear that they are not junk at all. These other segments of DNA play critical roles in regulating the activity of genes, helping to choreograph, along with environmental influences, how genes turn on and off in different types of cells at different times.

The Human Genome Project and the massive genome analysis projects that have followed it are yielding astounding new discoveries like this every year. One project, for example, described

● **Table 3.1** Mitosis and Meiosis Compared

	Mitosis	Meiosis in Males	Meiosis in Females
Begins	Conception	Puberty	Early in prenatal period when unripened ova form
Continues	Throughout life span	Throughout adolescence and adulthood	Throughout reproductive years; an ovum ripens each month of the menstrual cycle
Produces	Two identical daughter cells, each with 46 chromosomes like its parent	Four sperm, each with 23 chromosomes	One ovum and three nonfunctional polar bodies, each with 23 chromosomes
Accomplishes	Growth of human from fertilized egg, renewal of the body's cells	Formation of male reproductive cells	Formation of female reproductive cells

the genetic similarities and differences among 270 people from a variety of racial and ethnic groups around the world (Turnpenny & Ellard, 2012). It turns out that about 999 of 1,000 base chemicals are identical in all humans; it is the remaining 1 of 1,000 that makes us each unique. Analysis of DNA samples is also shedding light on evolution. For example, it has revealed that gene variants that allow people to tolerate lactose in milk spread quite rapidly among Europeans as dairy farming became common in Europe, presumably because tolerating milk enhanced survival (McCabe & McCabe, 2008; Voight et al., 2006). Through such studies, researchers are gaining new insights into how the human species evolved and how humans are similar to and different from one another.

Genetic Uniqueness and Relatedness

People are both different from and like their relatives genetically because when a pair of parental chromosomes separates during meiosis, which of the two chromosomes ends up in a particular sperm or ovum is a matter of chance. And because each chromosome pair separates independently of all other pairs and each sperm or ovum contains 23 pairs of chromosomes, a single parent can produce 2^{23} —more than 8 million—genetically different sperm or ova. Any couple could theoretically have at least 64 trillion babies without producing 2 children with identical genes.

The genetic uniqueness of children of the same parents is even greater than this because of a quirk of meiosis known as **crossing over**. When pairs of chromosomes line up before they separate, they cross each other and parts of them are exchanged, much as if you were to exchange a couple of fingers with a friend at the end of a handshake. In short, it is incredibly unlikely that there ever was or ever will be another human exactly like you genetically. The one exception is **identical twins** (or identical triplets, and so on), also called **monozygotic twins** because they result when one fertilized ovum divides to form two or more genetically identical individuals. This happens in about 1 of every 250 births (Segal, 2005).

How genetically alike are parent and child or brother and sister? You have 50% of your genes in common with your mother and 50% in common with your father because you received half of your chromosomes (and genes) from each parent. But if you have followed our mathematics, you will see that siblings may

have many genes in common or few depending on the luck of the draw during meiosis. Because siblings receive half of their genes from the same mother and half from the same father, their average genetic resemblance to each other is 50%, the same genetic resemblance as that of parent and child. The critical difference is that they share half of their genes *on average*; some siblings share more and others fewer. Indeed, we have all known some siblings who are almost like twins and others who could not be more different if they tried.

Fraternal twins (also called dizygotic twins because two eggs are involved) result when two ova are released at approximately the same time and each is fertilized by a different sperm, as happens in about 1 of every 125 births (Plomin, 1990). Fraternal twins are no more alike genetically than brothers and sisters born at different times and can be of different sexes. Fraternal twins tend to run in families and have become more common in recent years because more couples are taking fertility drugs and undergoing in vitro fertilization (Segal, 2005).

Grandparent and grandchild, aunt or uncle and niece or nephew, and half brothers and half sisters share 25% of their genes in common on average. Thus, everyone except an identical twin is genetically unique, but each person also shares genes with kin that contribute to family resemblances.

Determination of Sex

Of the 23 pairs of chromosomes that each individual inherits, 22 are similar in males and females. The chromosomes of the 23rd pair are the sex chromosomes. A male child has one long chromosome called an **X chromosome** and a shorter companion with far fewer genes called a **Y chromosome**. Females have two X chromosomes. The photos on page 65 show male and female chromosomes that have been photographed through a powerful microscope, then arranged in pairs and rephotographed in a pattern called a *karyotype*, which allows their number and form to be studied.

Because a mother's egg has only X chromosomes and a father's sperm cell has either an X chromosome or a Y chromosome (depending on which sex chromosome a sperm receives during meiosis), it is the father who determines a child's gender. If an ovum with its one X chromosome is fertilized by a sperm bearing a Y chromosome, the product is an XY zygote—a genetic male.

The male karyotype (*left*) shows the 22 pairs of autosomal chromosomes and the 2 sex chromosomes—an elongated X and a shorter Y chromosome. The photographic arrangement of a female’s chromosomes (*right*) shows 2 X chromosomes.

CNRI/Science Source

A gene on the Y chromosome then sets in motion the biological events that result in male sexual development (see Chapter 12). If a sperm carrying an X chromosome reaches the ovum first, the result is an XX zygote—a genetic female. Perhaps if these facts had been known in earlier eras, women would not have been criticized, tortured, divorced, and even beheaded for failing to bear male heirs.

So a genetically unique boy or girl has a genome in each of its cells with 20,000–25,000 protein-coding genes and lots of regulatory DNA on 46 chromosomes arranged in 23 pairs. How do these genes, along with environmental factors, influence the individual’s characteristics and development? The mystery is far from solved, but knowledge is expanding by leaps and bounds.

From Genotype to Phenotype

One does not have to understand cell biology to appreciate that environmental factors help determine how genetic codes translate into physical and psychological characteristics. For example, some people inherit genes calling for exceptional height, and others inherit genes calling for a short stature. But **genotype**, the genetic makeup a person inherits, is different from **phenotype**, the characteristic or trait the person eventually has (for example, a height of 5 feet 8 inches). An individual whose genotype calls for exceptional height may or may not be tall. Indeed, a child who is severely malnourished from the prenatal period onward may have the genetic potential to be a basketball center but may end up too short to make the team. Genes and environment combine to determine how a particular genotype is translated into a particular phenotype—the way a person looks, thinks, feels, or behaves.

As you have seen, genes provide information that is used in the production of particular proteins. For example, genes help set in motion a process that lays a pigment called *melanin* in the iris of the eye. Some people’s genes call for much of this pigment, and the result is brown eyes; other people’s genes call for less of it, and the result is blue eyes. Genetically coded proteins also guide the formation of cells that become neurons in the brain, influencing potential intelligence and personality. But genes both influence and are influenced by the biochemical environment surrounding them (Gottlieb & Halpern, 2008; Lickliter & Honeycutt, 2015; Meaney, 2010). During embryonic development, a particular cell can become part of an eyeball or part of a kneecap depending on what cells are next to it and what they are doing. Because all of a person’s cells have the same genes on the same chromosomes, what makes neurons, blood cells, and other cells of the body different from each other is not what genes they contain but which of those genes are *expressed*.

Gene expression is the activation of particular genes in particular cells of the body at particular times; only if a gene is “turned on” is it influential. Gene expression, then, is what ultimately influences our traits. And gene expression is guided by genetic influences (the action of regulatory DNA) and by environmental influences. As we will see at the end of the chapter (see Section 3.5, Epigenetic Effects on Gene Expression), great excitement now surrounds the discovery that gene expression can be altered, starting prenatally but throughout the life span, and sometimes in lasting ways, by environmental factors such as diet, stress, drugs, toxins, early parenting, and more (Moore, 2015; Zhang & Meaney, 2010). You should therefore think of

the genetic “code” as sketched in erasable pencil rather than in indelible ink. Genes do not “determine” anything. Rather, genes and environment interact and coact to influence gene expression and, in turn, development and behavior throughout the life span.

Mechanisms of Inheritance

Let us now consider the major mechanisms of inheritance—how parents’ genes influence their children’s genotypes and phenotypes. There are three main mechanisms of inheritance: single gene-pair inheritance, sex-linked inheritance, and polygenic (or multiple gene) inheritance (Nussbaum, McInnes, & Willard, 2016; Turnpenny & Ellard, 2012).

Single Gene-Pair Inheritance

Through **single gene-pair inheritance**, each of thousands of human characteristics are influenced by only one pair of genes—one from the mother, one from the father. Although he knew nothing of genes, the 19th-century monk Gregor Mendel contributed greatly to our knowledge of single gene-pair inheritance and earned his place as the father of genetics by cross-breeding different strains of peas and carefully observing the outcomes (Henig, 2000). As an illustration of the principles of Mendelian inheritance, consider the remarkable fact that about three-fourths of us can curl our tongues upward into a tubelike shape, whereas

one-fourth of us cannot. (We have no idea why.) It happens that there is a gene associated with tongue curling; it is a **dominant gene**, meaning that it will be expressed when paired with a **recessive gene**, a weaker gene that can be dominated (like one associated with the absence of tongue-curling ability).

The person who inherits one “tongue-curl” gene (label it *U*) and one “no-curl” gene (call it *-*) would be able to curl his tongue (that is, would have a tongue-curling phenotype) because the dominant tongue-curl gene overpowers the recessive no-curl gene. Using **Figure 3.2** as a guide, you can calculate the odds that parents with various genotypes for tongue curling will have children who can or cannot curl their tongues. Each of the nine cells of the figure shows the four possible types of children that can result when a father contributes one of his two genes to a sperm and a mother contributes one of her two genes to an ovum and a child is conceived.

If a father with the genotype *UU* (a tongue curler) and a mother with the genotype *--* (a non-tongue curler) have children, each child they produce will have one dominant gene for tongue curling and one recessive gene for a lack of tongue curling (genotype *U-*) and each will be a tongue curler because the tongue-curl gene will rule. You can say that this couple has a 100% chance of having a tongue-curling child. Notice that two different genotypes, *UU* and *U-*, both produce the same phenotype: an acrobatic tongue.

A tongue-curling man and a tongue-curling woman can surprise everyone and have a child who lacks this amazing talent.

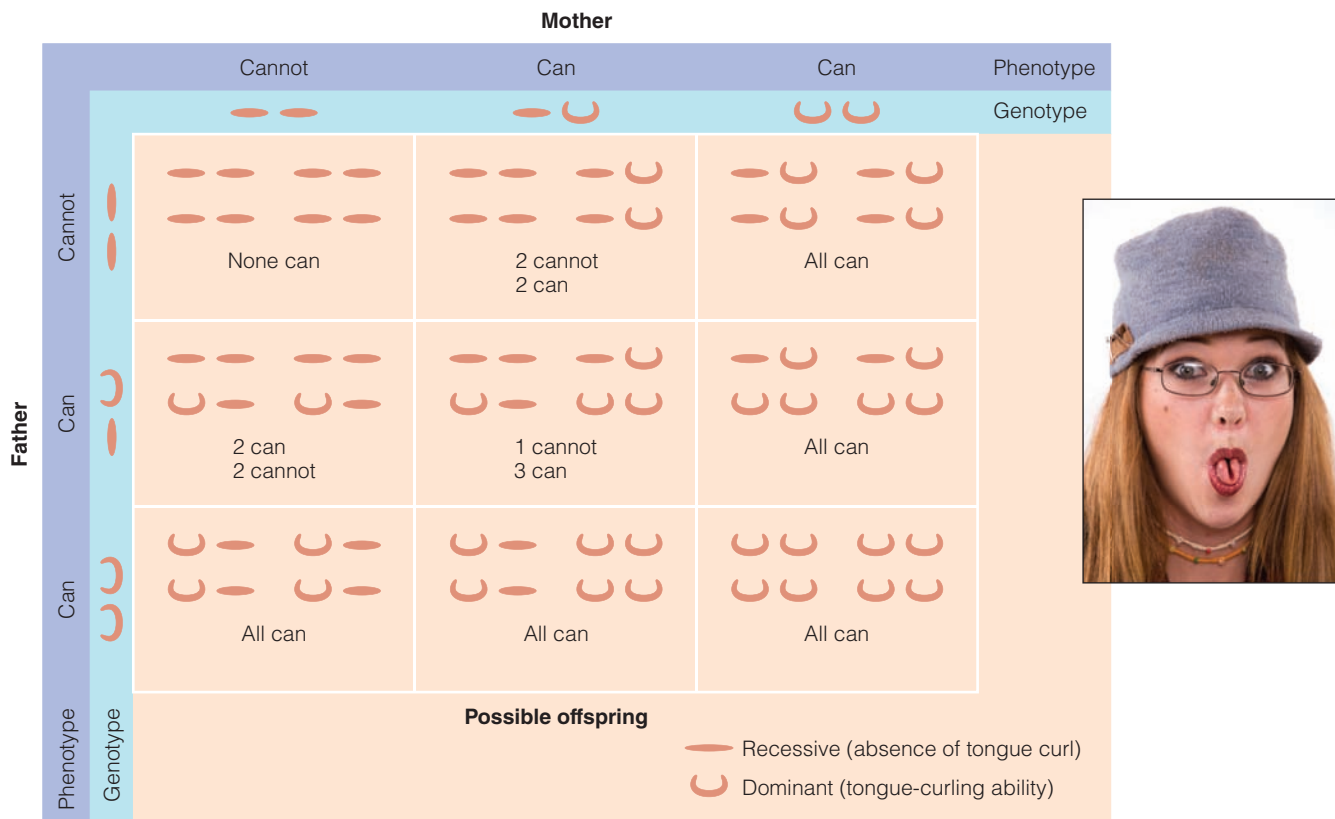

Figure 3.2 Can you curl your tongue as shown? Tongue-curling ability is determined by a dominant gene. If you can curl your tongue, then either your mother or your father can, because one of them must have the dominant gene. All possibilities are shown in the figure; each of the nine boxes shows the gene combinations of the four possible children a particular mother and a particular father can have.

These two parents both must have the *U*-genotype. If the father's recessive gene and the mother's recessive gene happen to unite in the zygote, they will have a non-tongue-curling child (with the genotype --). The chances are 25%—one out of four—that this couple will have such a child. Of course, the laws of conception are much like the laws of cards. This couple could beat the odds and have a whole family of non-tongue-curling children, or they could have none. Because people who cannot curl their tongues must have the -- genotype, two non-tongue-curling parents will have only non-tongue-curling (--) children.

● **Table 3.2** lists a few examples of dominant and recessive traits associated with single gene-pair inheritance. In some cases, a dominant gene incompletely dominates a recessive partner gene and the result is a blend of the parents' traits—as when crossing red and white flowers produces pink ones or when dark-skinned and light-skinned parents have a child with light brown skin. In other cases, two genes influence a trait but each is expressed in the product because they codominate, as when crossing red and white flowers produces flowers with red and white streaks. For example, an AB blood type is a mix of A and B blood types. So, Gregor Mendel, despite not knowing about the existence of genes, got the basics of single gene-pair inheritance mostly right.

Sex-Linked Inheritance

In **sex-linked inheritance**, a characteristic is influenced by single genes located on the sex chromosomes rather than on the other 22 pairs of chromosomes. Indeed, you could say *X-linked* rather than *sex-linked* because most of these attributes are associated with genes located on X but not Y chromosomes.

Why do far more males than females display red-green color blindness? The inability to distinguish red from green is caused by a recessive gene that appears only on X chromosomes. Recall that Y chromosomes are shorter than X chromosomes and have fewer genes. If a boy inherits the recessive color-blindness gene on the X chromosome his mother provides to him, there is no color-vision gene on his Y chromosome that could dominate the color-blindness gene. He will be color blind. By contrast, a girl who inherits the gene usually has a normal color-vision gene on her other X chromosome that can dominate the color-blindness gene. She would have to inherit two of the recessive color-blindness genes to be color blind. **Hemophilia**, a deficiency in the blood's ability to clot, is also far more common among males than females because it is a sex-linked disorder associated with a recessive gene on X chromosomes.

Polygenic Inheritance

So far we have considered only the influence of single genes or gene pairs on human traits. Every week, it seems, we read in the newspaper that researchers have identified “the gene” for high blood pressure, happiness, or some other human trait. In fact, most important human characteristics are influenced by **polygenic inheritance**—by multiple pairs of genes, interacting with multiple environmental factors, rather than by a single pair of genes. Examples of polygenic traits include height, weight, intelligence, personality, susceptibility to cancer and depression, and much more.

When a trait like intelligence is influenced by multiple genes, many degrees of it are possible, depending on how many of the genes associated with high levels of the trait individuals

● **Table 3.2** Examples of Traits Influenced by Dominant and Recessive Genes

Dominant Trait	Recessive Trait
Brown eyes	Gray green, hazel, or blue eyes
Dark hair	Blond hair
Nonred hair	Red hair
Curly hair	Straight hair
Normal vision	Nearsightedness
Farsightedness	Normal vision
Broad lips	Thin lips
Double jointed	Normal joints
Pigmented skin	Albinism
Type A blood	Type O blood
Type B blood	Type O blood

Source: Burns & Bottino, 1989; McKusick, 1990

inherit. Most people will get some “high IQ” genes and some “low IQ” genes, so are likely to have pretty average IQs. A few at the extremes will inherit only “low IQ” genes or only “high IQ” genes. The trait will therefore tend to be distributed in the population according to the familiar bell-shaped or normal curve: Many people are near the average of the distribution; fewer are at the extremes. This is in fact the way intelligence and most other measurable human traits are distributed. At this point, we do not know how many gene pairs influence intelligence or other polygenic traits. What we can say is that many, many genes, interacting with many environmental forces, create a range of individual differences in most important human traits (Plomin et al., 2013).

Mutations

So far, we have described the three major mechanisms by which the genes inherited at conception influence traits: single gene-pair, sex-linked, and polygenic inheritance. Occasionally, however, a new gene appears as if out of nowhere; neither parent has it. A **mutation** is a change in the structure or arrangement of one or more genes. Mutations can be either beneficial or harmful, depending on their nature and on the environment in which their bearers live.

Experts believe that the recessive gene for the sex-linked disorder hemophilia was a mutation first introduced into the royal families of Europe by Queen Victoria and then passed on to some of her descendants. New cases of hemophilia, then, can be caused by either sex-linked inheritance or spontaneous mutations. The odds that mutations will occur are increased by environmental hazards such as radiation and toxic industrial waste, but most mutations are just spontaneous errors during cell division (Lewis, 2015). Recently it has been discovered that fathers contribute about four times the number of new mutations as mothers do overall and that the odds of mutations increase steadily as fathers get older because more errors are made during sperm production, or meiosis (Kong et al., 2012). Mutations associated with autism (O’Roak et al., 2012), schizophrenia (Frans et al., 2011), and other disorders become more likely as a father’s age increases.

Copy Number Variations

Still another major discovery of the Human Genome Project is the importance of **copy number variations (CNVs)**, instances in which part of the genome is either deleted or duplicated (Gershon & Alliey-Rodriguez, 2013; Lewis, 2015). A CNV is more extensive than a mutation, which is typically just a different version of a particular gene. CNVs can extend over a large stretch of DNA containing multiple genes and they can mean that, instead of having two paired genes, the person may have only one gene (due to a deletion) or three or four copies of the gene (due to a duplication). Like mutations of specific genes, CNVs are errors that can either be inherited from a parent or arise spontaneously.

Increasingly, researchers are discovering that CNVs happen quite often and can significantly increase the risks of a number of polygenic disorders involving the nervous system, among them autism, schizophrenia, bipolar disorder, attention deficit hyperactivity disorder (ADHD), and Alzheimer's disease (Gershon & Alliey-Rodriguez, 2013; Hohmann et al., 2015; Swaminathan et al., 2012). As a result, genetic tests now check for CNVs.

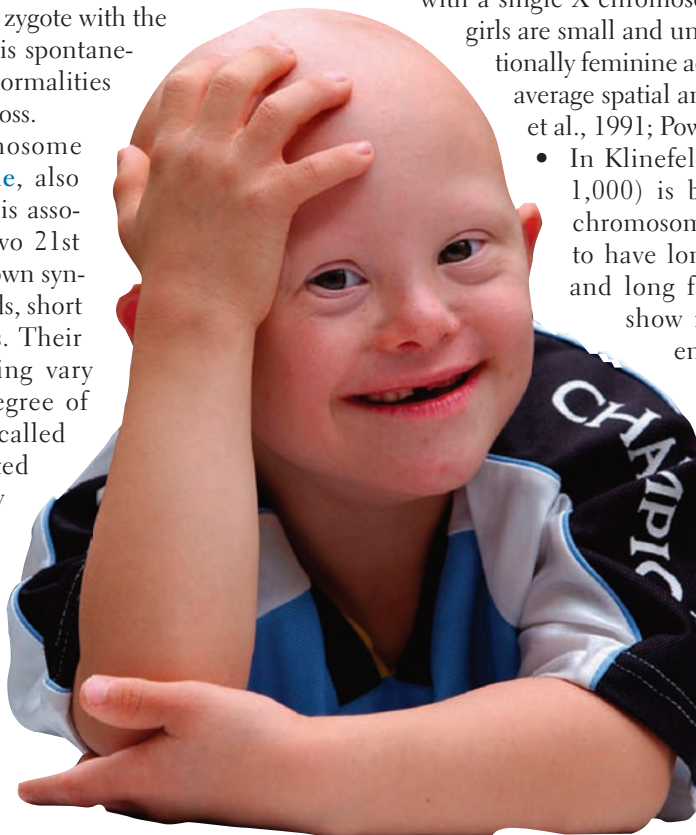

Chromosome Abnormalities

Genetic endowment can also influence human development through **chromosome abnormalities**, in which a child receives too many or too few chromosomes (or abnormal chromosomes) at conception (Gardner, Sutherland, & Shaffer, 2012). Most such abnormalities are caused by errors in chromosome division during meiosis. Through an accident of nature, an ovum or sperm cell may be produced with more or fewer than the usual 23 chromosomes. In most cases, a zygote with the wrong number of chromosomes is spontaneously aborted; chromosome abnormalities are the main cause of pregnancy loss.

The most familiar chromosome abnormality is **Down syndrome**, also known as *trisomy 21* because it is associated with three rather than two 21st chromosomes. Children with Down syndrome have distinctive eyelid folds, short stubby limbs, and thick tongues. Their levels of intellectual functioning vary widely, but most have some degree of *intellectual disability* (formerly called mental retardation and associated with an IQ of below 70). They therefore develop and learn at a slower pace than most children, but they can benefit greatly from early stimulation programs, special education, and

Children with Down syndrome have distinctive eyelid folds, short limbs, and thick tongues.

Peter Casolino/Alamy Stock Photo

vocational training (Hazlett, Hammer, Hooper, & Kamphaus, 2011; Roizen & Patterson, 2003). Witness Lauren Potter, the young woman with Down syndrome who played a cheerleader on the TV program *Glee*, and others of her generation who are working and even attending college (Rochman, 2012). In some parts of the world, over half of children with Down syndrome die in infancy, most often because of heart defects (Christianson, Howson, & Modell, 2006). However, in the United States and other wealthy nations, many people with Down syndrome are now living into middle age and beyond, when many of them show signs of premature aging, including early Alzheimer's disease (Berney, 2009; Zigman, 2013).

Overall, the chances of having a baby with Down syndrome are about 12 births in 10,000 in the United States (Zigman, 2013). What determines who has a child with Down syndrome and who does not? Chance, partly. The errors in meiosis responsible for Down syndrome can occur in any mother—or father. However, the odds increase with a mother's age, especially from about age 35 on, as well as with a father's age (■ Figure 3.3). Indeed, couples older than 40 have about six times the risk of having a child with Down syndrome as couples younger than 35 (Fisch et al., 2003).

Most other chromosome abnormalities involve a child's receiving either too many or too few sex chromosomes. Like Down syndrome, these **sex chromosome abnormalities** can be attributed mainly to errors in meiosis, errors that become increasingly likely in older parents and parents whose chromosomes have been damaged by environmental hazards such as radiation (Wodrich, 2006). Examples:

- In Turner syndrome, a female (about 1 in 2,000–3,000) is born with a single X chromosome rather than two (XO). These girls are small and underdeveloped, typically favor traditionally feminine activities, and often have lower-than-average spatial and mathematical abilities (Downey et al., 1991; Powell & Schulte, 2011).
- In Klinefelter syndrome, a male (1 in 500–1,000) is born with one or more extra X chromosomes (XXY). Klinefelter males tend to have long limbs and sometimes big ears and long faces, and, at puberty, they may show feminine characteristics such as enlarged breasts. Most have normal IQs, but many have language learning disabilities (Hazlett, De Alba, & Hooper, 2011; Mandoki et al., 1991).
- In XYY syndrome, a male (as many as 1 in 1,000) is born with an extra Y chromosome (XYY). These males tend to be tall and strong and often have learning disabilities. The common belief that XYY syndrome results in aggression and criminal behavior is not well-supported (Re & Birkhoff, 2015).

Figure 3.3 The rate of Down syndrome births increases steeply as the mother’s age increases. (Father’s age is also a factor.)

Source: “Down Syndrome Prevalence at Birth”—United States, 1983–1990 (1994, August 26). *Mortality and Morbidity Weekly Reports*, 43, 617–622.

Genetic Diseases and their Diagnosis

Diseases and disorders associated with a single gene or pair of genes, polygene disorders, mutations and copy number variations, and chromosome abnormalities, although rare, can profoundly affect human development. Today’s genetic counselors have more information than ever about genetic disorders and can quickly and quite inexpensively collect and analyze DNA samples by swabbing the inside of people’s cheeks or drawing small samples of their blood and informing people of what the results mean.

Examples of Genetic Diseases

To illustrate issues in genetic diagnosis and the workings of important genetic disorders, consider sickle-cell disease, Huntington’s disease, and PKU. **Sickle-cell disease**, a blood disease, common among African Americans, in which red blood cells take on a sickle shape, become entangled, and distribute less oxygen through the circulatory system than round blood cells do, causing breathing problems and pain (Serjeant, 2010; Smith & Baker, 2011). The gene responsible probably started as a mutation which, because it protected its bearers from malaria, became

more common through natural selection over many generations in Africa, Central America, and other tropical areas. The life expectancy of children with sickle-cell disease used to be around 14 years; they often died early as a result of blood clots, strokes, and heart or kidney failure. Now improved treatment is prolonging lives; average life expectancy is more like 50 years (Hambleton, 2014; National Human Genome Research Institute, 2015).

About 9% of African Americans in the United States have the genotype we will call Ss ; they carry one dominant gene (S) that calls for round blood cells and one recessive gene (s) that calls for sickle-shaped blood cells. Such people are **carriers**; although they do not have the disease, they can transmit the gene for it to their children. The child who inherits two recessive sickle-cell genes (ss) will have sickle-cell disease. An Ss father and an Ss mother (two carriers) have a one-in-four, or 25%, chance of having a child with sickle-cell disease (ss). Two carriers also have a two-in-four, or 50%, chance of having a child who will be a carrier like themselves.

A blood test is used to screen all newborns in the United States for sickle-cell disease. Affected children begin a life of treatment with blood transfusions, antibiotics to prevent infections, and more recently a drug called hydroxyurea that prevents the sickling of blood cells. Early interventions can help optimize children’s intellectual development (Smith & Baker, 2011). In less developed areas of sub-Saharan Africa and central India, where rates of sickle-cell disease are high, screening of newborns could do much good but is lacking (Serjeant, 2010).

Now consider **Huntington’s disease**, a famous (and terrifying) example of a genetic disorder associated with a single dominant gene. This disease typically strikes in middle age—after a person has typically had children—and disrupts the expression of genes in the nervous system, resulting in motor problems, personality changes, and dementia or loss of cognitive abilities (Anderson et al., 2008; Bishop & Waldholz, 1990; Sutton-Brown & Suchowersky, 2003). The child of a parent with the dominant (and fortunately rare) Huntington’s gene has a 50%

Sickle-shaped (elongated) and normal (round) blood cells from a carrier of the sickle-cell gene.

Science Source

● **Table 3.3** Some Genetic Disorders

Disease	Description	Genetic Mechanism	Diagnosis and Treatment
Cystic fibrosis	Glandular problem results in mucus buildup in lungs that makes breathing difficult and shortens life; common among Caucasians	Recessive gene pair; carriers were protected from epidemics of diarrhea in Europe	DNA test can identify most carriers, but not all of the hundreds of possible mutations can be tested for; hours of physical therapy and antibiotics delivered by aerosol spray to keep lungs clear can prolong life; experimental gene therapy replacing genes in lung tissue has had some success
Fragile X syndrome	Most common inherited cause of intellectual disability; associated with an X chromosome in which an arm looks ready to break off	Sex-linked inheritance (dominant gene on X chromosome); a copy number variation (CNV) in a gene important in brain development is involved; the CNV and resulting intellectual disability can become worse over family generations	Genetic testing can detect the CNV involved; no cure is available but special education and other treatments can help
Hemophilia	Deficiency in blood's ability to clot; more common in males than in females	Sex-linked inheritance (gene on X chromosome)	Genetic testing can find the disease-causing gene variant; DNA analysis can detect it in the fetus; blood transfusions and medication can improve clotting and reduce the negative effects of internal bleeding; gene therapy holds promise
Huntington's disease	Deterioration of the nervous system in middle age; associated with dementia, jerky movements, personality changes	Dominant gene; a CNV, an abnormal number of repetitions of a DNA sequence, implicated	Genetic test can tell relatives whether they have the gene; preimplantation genetic diagnosis of embryonic cells may be used to ensure a healthy child
Phenylketonuria (PKU)	Lack of enzyme needed to metabolize phenylalanine in milk results in conversion of phenylalanine into an acid that attacks the nervous system and causes intellectual disability	Recessive gene pair	Genetic test can identify carriers; routinely screened for with a blood test at birth; special diet low in phenylalanine prevents brain damage, must be maintained for life
Sickle-cell disease	Blood cells are sickle-shaped rather than round; stick together, make breathing difficult; and cause painful swelling of joints and blood clots; common in African Americans	Recessive gene pair; carriers were protected from malaria in Africa	Blood test can identify carriers; newborns in most states of the U.S. are screened with a blood test; antibiotics, the drug hydroxyurea, and blood transfusions prevent infections and relieve symptoms; gene therapy holds promise
Tay–Sachs disease	Metabolic defect results in accumulation of fat in a child's brain, degeneration of the nervous system, and early death; common in Jewish people from Eastern Europe	Recessive gene pair	Blood test can identify carriers; fetal DNA analysis can determine whether a child is affected; medication may help, but most victims die in childhood

Sources: Goldstein & Reynolds, 2011; Kingston, 2008; Nussbaum, McInnes, & Willard, 2016; Pritchard & Korf, 2008; Turpenny & Ellard, 2012. Also consult the website of the National Human Genome Research Institute: www.genome.gov/10001204

chance of inheriting the gene and developing Huntington's disease later in life. A genetic test can enable the relatives of Huntington's victims to find out whether or not they inherited the gene, but some prefer to live with uncertainty rather than with the knowledge that they will develop this awful and incurable disease (Bombard, 2009; Sutton-Brown & Suchowersky, 2003).

Finally, a success story. **Phenylketonuria (PKU)** is a metabolic disorder caused by a single pair of recessive genes that results in brain damage and intellectual disability (Waisbren, 2011; Widaman, 2009). About 1 in 50 people in the United States are carriers of the PKU gene (Waisbren, 2011). Two carriers have a one-in-four, or 25%, chance of having a child with PKU. Affected children lack a critical enzyme needed to metabolize phenylalanine, a component of many foods, including milk. As phenylalanine accumulates in the body, it is converted to a harmful acid that attacks the nervous system and causes intellectual disability and hyperactivity.

Today, newborn infants are routinely screened for PKU with a blood test, and affected children are immediately placed on a

special (and, unfortunately, distasteful) diet low in phenylalanine. They are advised to stay on the diet, at least to some extent, for the rest of their lives to prevent deterioration of their intellectual functioning (Waisbren, 2011; Widaman, 2009). Sickle-cell disease, Huntington's disease, PKU, and a few other genetic diseases are summarized in ● **Table 3.3** (and see www.genome.gov/10001204 for more).

Prenatal Diagnosis

Individuals who have a disorder in their family history or have been tested and know they carry the gene for one, as well as older parents concerned about mutations, copy number variations, and chromosome abnormalities may wish to use prenatal diagnosis procedures that can detect many genetic abnormalities prenatally. Three widely used techniques—ultrasound, amniocentesis, and chorionic villus sampling—as well as the newer methods of maternal blood sampling and preimplantation genetic diagnosis are described in ● **Application 3.1**.

● APPLICATION 3.1

Prenatal Detection of Abnormalities

Pregnant women, especially those over 35 or 40, turn to a variety of medical techniques to tell them in advance whether their babies are likely to be normal (Nussbaum et al., 2016; Turnpenny & Ellard, 2012; Winerman, 2013). How much can they learn? And what are the pros and cons of various prenatal diagnostic techniques?

Ultrasound

The easiest and most commonly used method is **ultrasound**, the use of sound waves to scan the womb and create a visual image of the fetus on a monitor screen. Ultrasound can indicate how many fetuses are in the uterus, their sex, and whether they are alive, and it can detect genetic defects that produce visible physical abnormalities. Ultrasound is widely used even when abnormalities are not suspected because it is considered very safe.

Amniocentesis

To detect chromosome abnormalities such as Down syndrome and to determine, through DNA analysis, whether the genes for a particular single gene-pair disorder or some other genetic variation are present, **amniocentesis** is used. A needle is inserted into the abdomen,

a sample of amniotic fluid is withdrawn, and fetal cells that have been shed are analyzed. A risk of miscarriage exists but it is very low, making the procedure relatively safe and advisable for pregnant women over age 35. Its main disadvantage is that it is not considered safe until the fifteenth week of pregnancy.

Chorionic Villus Sampling

Chorionic villus sampling (CVS) involves inserting a catheter through the mother's vagina and cervix (or, less commonly, through her abdomen) into the membrane called the *chorion* that surrounds the fetus, and then extracting tiny hair cells from the chorion that contain genetic material from the fetus. Sample cells are then analyzed for the same genetic conditions that can be detected using amniocentesis. The difference is that chorionic villus sampling can be performed as early as the tenth week of pregnancy. The risks of CVS are only slightly greater than those of amniocentesis.

Maternal Blood Sampling

Maternal blood sampling has been used for a number of years to test the mother's blood for various chemicals that can indicate

abnormalities in the fetus. However, now it can also be used to obtain loose embryonic DNA that has slipped through the placenta into the mother's blood—DNA that can then be analyzed for chromosome abnormalities and genetic diseases *with no risk at all to the fetus* (Benn & Chapman, 2009; Fan et al., 2012; Winerman, 2013). Methods for detecting Down syndrome with high accuracy at around 9 or 10 weeks after conception are now available (Rubin, 2012; Verweij et al., 2012). Maternal blood sampling of fetal DNA has the tremendous advantages of being noninvasive and usable early in the pregnancy, but it is normally followed up with amniocentesis or CVS to be 100% certain (Winerman, 2013).

Preimplantation Genetic Diagnosis

Finally, parents who know they are at high risk to have a baby with a serious condition can minimize their risk through **preimplantation genetic diagnosis**. This involves fertilizing a mother's eggs with a father's sperm in the laboratory using *in vitro fertilization (IVF) techniques* (see Chapter 4), conducting DNA tests on the first cells that result from mitosis of each fertilized egg, and implanting in the mother's uterus only eggs that do not have

(continued)

● APPLICATION 3.1

Prenatal Detection of Abnormalities (continued)

chromosome abnormalities or genes associated with disorders (Geddes, 2013). Although costly, this option may appeal to couples who would not consider abortion but do not want to have a child with a serious defect.

Pros and Cons

Prenatal diagnostic techniques such as ultrasound, amniocentesis, CVS, maternal blood sampling, and preimplantation genetic diagnosis can provide tremendously important information

when there is reason to suspect a problem. They can prevent serious disorders and diseases and open the door to early interventions that can save the lives of babies with problems or set them on a healthier developmental path. DNA sequencing of the genomes of newborns is already being used to help pinpoint what is wrong with babies in neonatal intensive care units in order to treat them more effectively (Saunders et al., 2012).

However, the prospect that all pregnant women may soon have their blood analyzed

for evidence of genetic abnormalities is raising ethical red flags, especially about the possibility that abortion rates will increase if more parents decide that they do not want babies with Down syndrome or other “undesirable” characteristics or if parents try to create through in vitro fertilization “designer” babies who are likely to be healthy, smart, and of the desired gender (Benn & Chapman, 2009). There is much for society and prospective parents to weigh here.

For the parents whose tests reveal a normal embryo or fetus, there is relief. For the parents who learn that their fetus may develop a serious defect, the choice between abortion and bearing a child with a serious disorder can be agonizing. For the many conditions that are polygenic in origin, it is usually not possible to do a definitive test or even give solid odds, but genetic counselors can educate families and attempt to correct their misunderstandings (Gershon & Alliey-Rodriguez, 2013). It makes sense for all of us to become educated about any genetic conditions in our family trees.

● Checking Mastery

1. Ted and Ned, fraternal twins, are not very alike at all. Give both a “nature” explanation and a “nurture” explanation of their differences.
2. Huge nose syndrome (we made it up) is caused by a single dominant gene, *H*. Using diagrams such as those in Figure 3.2, figure out the odds that Herb (who has the genotype

Hh) and Harriet (who also has the genotype *Hh*) will have a child with huge nose syndrome. Now repeat the exercise, but assume that huge nose syndrome is caused by a recessive gene, *h*, and that both parents again have an *Hh* genotype.

3. Juan has red–green color blindness. Knowing that he is color blind, what can you infer about his parents?

● Making Connections

1. A DNA sample taken by swabbing a person’s cheek can now reveal the person’s entire genome. What do you think will be the positive and negative consequences of this scientific breakthrough for society?
2. Are you aware of any genetically influenced diseases that run in your family? If so, what are they and what do you know (or what can you learn) about the mechanism involved?

3.3

Studying Genetic and Environmental Influences

LEARNING OBJECTIVES

- Define the main goal and research methods of behavioral genetics and the meaning of *heritability*.
- Distinguish among the effects of genes, shared environmental influences, and nonshared environmental influences, and explain how a study of identical and fraternal twin pairs raised together versus raised apart can shed light on the importance of each of these influences.
- Explain what molecular genetics studies tell us that behavioral genetics studies cannot.

We now ask a critical question: How do researchers learn about the contributions of genes and environment to variation among us in physical and psychological traits? **Behavioral genetics** is the scientific study of the extent to which genetic and environmental differences among people or animals are responsible for

differences in their physical and psychological traits (Plomin et al., 2013; Rutter, 2006). It is impossible to say that a given person’s intelligence test score is the result of, say, 80%, 50%, or 20% heredity and the rest environment. The individual would have no intelligence without both genetic makeup and experiences, and

their contributions cannot be separated. It is, however, possible for behavioral geneticists to estimate the **heritability** of measured IQ and of other traits or behaviors. Heritability is the proportion of all the variability in the trait within a large sample of people that can be linked to genetic differences among those individuals. To say that measured intelligence is *heritable*, then, is to say that differences in tested IQ among the individuals studied are to some degree attributable to the different genetic endowments of these individuals (Plomin et al., 2013).

It may seem from their name that *behavioral geneticists* would tell us only about genetic contributions to development, but in fact their work tells us about the contributions of both genetic and environmental factors to differences among people. The variability in a trait that is not associated with genetic differences is associated with differences in environment.

Behavioral geneticists who study animals can gather evidence through experimental breeding studies. For example, if a trait like learning ability is genetically influenced, breeding animals with high learning ability with each other should produce more offspring with high learning ability over several generations than breeding animals with low learning ability together does (Plomin et al., 2013). Experimental breeding studies have shown that genes contribute to learning ability, activity level, emotionality, aggressiveness, sex drive, and many other attributes in rats, mice, and chickens (Plomin et al., 2013).

But people do not take kindly to the idea of being selectively bred. So how can researchers try to separate the contributions of genes and environment to human differences? How can they tell whether family resemblances are due to common genes or common experiences? Behavioral genetics research in humans has relied primarily on determining whether the degree of genetic similarity between pairs of people is associated with the degree of physical or psychological similarity between them. Twin, adoption, and other family studies provide this information. More recently, molecular genetics techniques that allow studying the effects of specific genes have expanded our knowledge (see Plomin et al., 2013).

Twin, Adoption, and Family Studies

Twins have long been recognized as important sources of evidence about the effects of heredity. A simple type of **twin study** to untangle genetic and environmental influences involves determining whether identical twins reared together are more similar to each other in traits of interest than fraternal twins reared together. If genes matter, identical twins should be more similar because they have 100% of their genes in common, whereas fraternal twins share only 50% on average.

More complex twin studies include not only identical and fraternal twin pairs raised together but also identical and fraternal twins reared apart—four groups in all, differing in both whether they share 100% or 50% of their genes and whether they shared the same home environment. Identical twins separated near birth and raised in different environments—like the twins introduced at the beginning of the chapter—are particularly informative because any similarities between them cannot be attributed to common family experiences.

Although it is basically sound and widely used, the twin method has some limitations (Brendgen, Vitaro, & Girard, 2012; Lickliter & Honeycutt, 2015). First, identical twins could be more psychologically similar than fraternal twins, even if they were separated at birth, because they shared a more similar prenatal environment than fraternal twins did. Second, the fact that identical twins are often treated more similarly than fraternal twins could explain their greater psychological similarity. As it turns out, though, there appears to be little relationship between how similarly twins are treated and how similar they turn out to be psychologically. More likely, twins' similarities result in their being treated similarly (Loehlin, 1992; Brendgen et al., 2012).

A second commonly used method in behavioral genetics research is the **adoption study**. Are children adopted early in life psychologically similar to their biological parents, whose genes they share, or are they similar to their adoptive parents, whose environment they share? If adopted children resemble their biological parents in intelligence or personality, even though those parents did not raise them, genes must be influential. If they resemble their adoptive parents, even though they are genetically unrelated to them, a good case can be made for environmental influence.

Like the twin method, the adoption method has proved useful but has its limitations (Lickliter & Honeycutt, 2015). Researchers must appreciate that not only the genes of a biological mother but also the prenatal environment she provided influence how an adopted child turns out. Researchers must also be careful to correct for the tendency of adoption agencies to place children in homes similar to those they were adopted from. Finally, researchers must recognize that because adoptive homes are generally above-average environments, adoption studies may underestimate the effects of the full range of environments children can experience.

Finally, today's researchers are conducting complex **family studies** that include pairs of siblings who have a variety of different degrees of genetic similarity—for example, identical twins, fraternal twins, full biological siblings, half siblings, and unrelated stepsiblings who live together in stepfamilies (Plomin et al., 2013; Reiss et al., 2000). They are also measuring qualities of these family members' experiences to determine how similar or different the environments of siblings are. Finally, they are looking at twins and other pairs of relatives in longitudinal studies to assess the contributions of genes and environment to continuity and change in traits as individuals develop.

Estimating Influences

Having conducted a twin, adoption, or family study, behavioral geneticists use statistical calculations to estimate the degree to which heredity and environment account for individual differences in a trait of interest. When they study traits that a person either has or does not have (for example, a smoking habit or diabetes), researchers calculate and compare **concordance rates**—the percentage of pairs of people studied (for example, pairs of identical twins or adoptive parents and children) in which if one member of a pair displays the trait, the other does too. If concordance rates are higher for more genetically related than for less genetically related pairs of people, the trait is heritable.

Is homosexuality heritable? Researchers interested in this question might locate men who are gay and are twins, either identical or fraternal, locate their twin siblings, and find out whether they, too, are gay. In one study of this type (Bailey & Pillard, 1991), the concordance rate for identical twins was 52% (29 of the 56 twins of gay men were also gay), whereas the concordance rate for fraternal twins was much lower, 22% (12 of 54 twins of gay men were also gay). Studies like this indicate that genes contribute to both men's and women's sexual orientation (Bailey, Dunne, & Martin, 2000; Dawood, Bailey, & Martin, 2009). Importantly, though, identical twins are *not* perfectly concordant, so environmental factors must also affect sexual orientation. After all, Bailey and Pillard found that in 48% of the identical twin pairs, one twin was gay but the other was not, despite their identical genes.

When a trait can be present in varying degrees, as is true of height or intelligence, correlation coefficients rather than concordance rates are calculated. In a behavioral genetics study of IQ scores, a correlation would indicate whether the IQ score of one twin is systematically related to the IQ score of the other, such that if one twin is bright, the other is bright, and if one is not so bright, the other is not so bright. The larger the correlation for a group of twins, the closer the resemblance between members of twin pairs.

To better appreciate what can be learned from behavioral genetics studies, consider what Robert Plomin and his colleagues (1988) found when they assessed aspects of personality among twins in Sweden whose ages averaged 59. One of their measures assessed an aspect of emotionality—the tendency to be angry or quick tempered. The scale was given to many pairs of identical twins and fraternal twins—some pairs raised together, others separated near birth and raised apart. Correlations reflecting the degree of similarity between twins are presented in **Table 3.4**. From such data, behavioral geneticists—and you too—can estimate the contributions of three factors to individual differences in angry emotionality: genes (heritability), shared environmental influences, and nonshared environmental influences.

- Genes (heritability).** In the example in **Table 3.4**, genetic influences are clearly evident, for identical twins are consistently more similar in angry emotionality than fraternal twins are. (Remember, these correlations tell us how similar twin pairs are—not how high or low they score in angry emotionality.) The greater-than-zero correlation of 0.33 for identical twins reared apart also testifies to the role of genetic makeup. These data suggest that angry emotionality is heritable. Specifically, Plomin et al. (1988) estimated that about a third of

Twins are concordant for a trait of interest such as smoking if they both display it.

Anna Peisl/Corbis/Getty Images

the variation in emotionality in the sample they studied can be linked to variations in genetic makeup.

- Shared environmental influences.** Individuals growing up in the same environment experience **shared environmental influences**, common experiences that work to make them similar—for example, a common parenting style or exposure to the same toys, peers, schools, and neighborhood. In **Table 3.4**, notice that both identical and fraternal twins are slightly more similar in angry emotionality if they are raised together than if they are raised apart. These correlations tell us that shared environmental influences are evident but are weak: Twins are almost as similar when they grow up in different homes as when they grow up in the same home.
- Nonshared environmental influences.** Experiences unique to the individual—those that are not shared by other members of the family and that work to make individuals different from each other—are referred to as **nonshared environmental influences**. Whether they involve being treated differently by parents, having different friends or teachers, undergoing different life crises, or even being affected differently by the same life events, nonshared environmental influences make members of the same family different (Rowe, 1994). Notice in **Table 3.4** that identical twins raised together are not identical in angry emotionality, even though they share 100% of their genes *and* the same family environment. The fact that the correlation of 0.37 for identical twins raised together is much lower than a perfect correlation of 1.00 tells us that nonshared environmental influences are at work—making identical twins raised together different from each other.

Table 3.4 Correlations from a Twin Study of the Heritability of Angry Emotionality

	Raised Together	Raised Apart
Identical twin pairs	0.37	0.33
Fraternal twin pairs	0.17	0.09

Pointing to specific correlations in this table, can you find evidence that genes, shared environment, and nonshared environment all contribute to individual differences in angry emotionality?

Source: From Plomin, R. et al. (1988). EAS temperaments during the last half of the life span: Twins reared apart and twins reared together. *Psychology and Aging*, 3, 43–50.

If you have brothers and sisters, do you think your parents treated you and your siblings differently? If so, what might have been the effects of these nonshared environmental influences on your development?

Tetra Images/Getty Images

Molecular Genetics

Behavioral genetics studies do not tell us which genes are responsible when they find that a trait is heritable. The Human Genome Project, by providing a map of the human genome, has opened the door to exciting new approaches to studying genetic and environmental influence. **Molecular genetics** is the analysis of particular genes and their effects (Plomin et al., 2013). It involves identification of specific variants of genes that influence particular traits and comparisons of animals or humans who have these genes with those who do not. It also allows researchers to study the effects of specific genes in combination with the effects of specific environmental influences.

If researchers are not sure which genes contribute to a trait, they can analyze research participants' entire genomes to identify which genes distinguish individuals who do or do not have the trait (Butcher et al., 2008; Plomin & Davis, 2009). Molecular genetics can therefore help identify the multiple genes that contribute to polygenic traits—the genes behind evidence from twin and adoption studies that these traits are heritable (Plomin et al., 2013). The goal is to be able to say, for instance, “This gene accounts for 20% of the variation, and these two other genes each account for 10% of the variation” in a phenotype or trait of interest. So far, molecular genetics studies have failed to identify genes that account for large percentages of the variation in psychological traits like intelligence. Rather, large numbers of genes seem to contribute to each polygenic trait or disorder and each gene's contribution is very small (Chabris et al., 2012; Davis et al., 2010).

If a specific gene's location and function are already known, researchers may test people's DNA for the presence of the gene and study how people who have a particular variant of a gene differ from those who have other variants. Consider Alzheimer's disease,

the most common cause of dementia in later life (to be discussed in Chapter 16). Twin studies indicate that it is heritable (Gatz et al., 2006), but what genes are behind it? One variant of a gene called *Apolipoprotein E*, *APOE4*, has been linked to a higher-than-average risk of Alzheimer's. Although *APOE4* is only one of many contributors to Alzheimer's disease, researchers have been busily studying the brains and cognitive functioning of individuals with the gene compared to individuals without it (Fouquet et al., 2014). For example, they find that elderly adults with the *APOE4* gene show greater deterioration in memory and reasoning over the years than do individuals without it—long before some develop diagnosable Alzheimer's disease (Hofer et al., 2002; Schiepers et al., 2012). Moreover, having the *APOE4* gene *and* experiencing an environmental risk factor for dementia such as a traumatic brain injury increases the odds of Alzheimer's disease still further—something college football and soccer players and boxers might want to note

(Chauhan, 2014). Such research can help make possible early identification and help for people likely to develop Alzheimer's disease and other conditions that are genetically influenced.

Despite its limitations, behavioral genetics research involving experimental breeding studies of animals and twin, adoption, and family studies of humans has revealed a great deal about the contributions of genes (heritability), shared environment, and nonshared environment to similarities and differences among us. Molecular genetics research is now leading to important discoveries about which specific genes, interacting with which environmental factors, are involved.

● Checking Mastery

1. What does the following (hypothetical) table of correlations tell you about the contributions of genes, shared environment, and nonshared environment to frequency of use of marijuana?

	Raised Together	Raised Apart
Identical twins	+0.70	+0.40
Fraternal twins	+0.40	+0.10

2. What are two problems with adoption studies of genetic influence?
3. If twin studies show that depression is heritable, what good would it do to conduct molecular genetics studies of the disorder?

● Making Connections

1. Design both a twin study and an adoption study to examine the contributions of genes and environment to creativity. Explain what patterns of results would provide evidence of genetic and environmental influence.
2. Speculate about how genes, shared environmental influences, and nonshared environmental influences could each help explain why some teenagers abuse alcohol and others do not. Then design a study to find out which of these factors are most important.

3.4

Selected Behavioral Genetics Findings

LEARNING OBJECTIVES

- Summarize the main messages of behavioral genetics research on intelligence, personality, and psychological disorder about the roles of genes, shared environment, and nonshared environment.
- Compare the average heritabilities of physical traits, intelligence, personality, psychological disorder, and attitudes and interests.

Findings from behavioral genetics studies have challenged and changed our understandings of human development, as you will see throughout this book. We give a few examples here to illustrate major themes in this research, drawing from studies of intellectual abilities, temperament and personality, and psychological disorders (see Plomin et al., 2013). Expect some surprises.

Intellectual Abilities

How do genes and environment contribute to individual differences in intellectual functioning? Consider the average correlations between the IQ scores of different pairs of relatives presented in ● Table 3.5. Clearly, correlations are higher when pairs of people are closely related genetically than when they are not and are highest when they are identical twins. Overall, the heritability of IQ scores is about 0.50, meaning that genetic differences account for about 50% of the variation in IQ scores and environmental differences account for the other half of the variation in the samples studied (Plomin et al., 2013; Segal & Johnson, 2009).

Can you detect the workings of environment in the table? Notice that (1) pairs of family members reared together are somewhat more similar in IQ than pairs reared apart; (2) fraternal twins, who should have especially similar family experiences because they grow up at the same time, tend to be more alike than siblings born at different times; and (3) the IQs of adopted individuals are related to those of their adoptive parents (that is, the correlation is greater than 0). All these findings suggest that *shared* environmental influences tend to make individuals more alike. Notice, however, that even genetically identical twins reared together are not perfectly similar. This is evidence that their unique or *nonshared* experiences have made them different.

Do the contributions of genes and environment to differences in intellectual ability change over the life span? Might genetic influence on individual differences decrease as we accumulate learning experiences? It seems logical, but it's wrong. Genetic endowment appears to *gain* rather than lose importance from infancy to adulthood as a source of individual differences in intellectual performance (McCartney, Harris, & Bernieri, 1990; Tucker-Drob, Briley, & Harden, 2013). The change is large: from a heritability of under 25% of the variation in intelligence in infancy to a heritability of more like 70% by adolescence (Tucker-Drob et al., 2013). Genetic influences on individual

● **Table 3.5** Average Correlations Between the IQ Scores of Pairs of Individuals

Family Pairs	Raised Together	Raised Apart
Identical twins	0.86	0.72
Fraternal twins	0.60	0.52
Biological siblings	0.47	0.24
Biological parent and child	0.42	0.22
Half siblings	0.31	—
Adopted siblings	0.34	—
Adoptive parent and adopted child	0.19	—
Unrelated siblings (same age, same home)	0.26	—

Source: All but two of these averages were calculated by Bouchard and McGue (1981) from studies of both children and adults. The correlation for fraternal twins reared apart is based on data reported by Pedersen et al. (1985); that for unrelated children in the same home is based on data reported by Segal (2000).

differences in intellectual functioning remain evident in old age (Finkel & Reynolds, 2010; Sachdev et al., 2013).

Whereas the heritability of intelligence test performance increases with age, shared environmental influences tend to become less significant with age, explaining about 30% of the variation in IQ in childhood but much less in adulthood (Tucker-Drob et al., 2013). Siblings are probably exposed to similar (shared) learning experiences when they are young and spend a good deal of time with their parents. As they age, they seek and have different (nonshared) life experiences. Partly because of their different genetic makeups, they may elicit different reactions from their parents, join different peer groups, encounter different teachers, develop different hobbies, go on to different colleges or universities and careers, and so on.

Estimates of heritability and environmental influence not only differ depending on the ages of the individuals studied but also vary quite dramatically depending on their socioeconomic background. Eric Turkheimer and his colleagues (2003) studied the heritability of IQ among children from very low-income families and children from affluent homes. As shown in

Figure 3.4 The proportions of variance in child IQ scores explained by genes, shared environment, and nonshared environment differ for children from low versus high socioeconomic status (SES) environments.

Source: From Turkheimer, E., Haley, M., D’Onofrio, B., & Gottesman, I. I. (2003). Socio-economic status modifies heritability of IQ in young children, *Psychological Science*, 14(6), 623–628. Reprinted by permission of Sage Publications.

Figure 3.4, among children from wealthy (high SES) families, genes accounted for 72% of the variation in IQ, whereas shared environment was not very important—as in most previous studies. By contrast, genes explained only about 10% of the variation in IQ among children from poor (low SES) families, whereas shared environmental influences accounted for almost 60% of the variation (see also Harden, Turkheimer, & Loehlin, 2007; Tucker-Drob et al., 2013).

Why might this be? In affluent environments, it is likely that children have plenty of opportunities to build niches that allow them to develop whatever genetically based potentials and interests they have, intellectual or otherwise (Tucker-Drob et al., 2013). By contrast, deprived and unstimulating environments may drag many poor children down, regardless of their genetic potential. However, some parents may be more able than others to offer a home environment that helps their children thrive intellectually despite economic disadvantage.

Interestingly, this pattern of higher heritability in more affluent samples is seen in other studies done in the United States but is not evident in Western Europe and Australia. There, heritability is quite similar for low- and high-SES individuals, possibly because social welfare programs in those countries protect families from extreme poverty (Tucker-Drob & Bates, 2016). The point is this:

The temperament of infants is genetically influenced. These identical twins seem like easy babies, eager to socialize.

Stu Monk Images/Alamy Stock Photo

The heritability of a trait is not one number written in stone. It can differ greatly depending on the age, socioeconomic status, culture, and other characteristics of the sample studied.

Does evidence of the heritability of IQ scores mean that we cannot improve children’s intellectual development by enriching their environment? Not at all. True, the IQs of adopted children are, by adolescence, correlated more strongly with the IQs of their biological parents than with the IQs of their adoptive parents. However, the *level* of intellectual performance that adopted children reach can increase dramatically (by 20 points on an IQ test) if they are adopted into more intellectually stimulating homes than those provided by their biological parents (Scarr & Weinberg, 1978, 1983; van IJzendoorn & Juffer, 2005). It is critical for parents, teachers, and others concerned with optimizing development to understand that they can make a difference—that genetically influenced qualities can very often be altered.

Temperament and Personality

As parents know well, different babies have different personalities. In trying to describe infant personality, researchers have focused on aspects of **temperament**—tendencies to respond in predictable ways, such as sociability and emotional reactivity, that serve as the building blocks of later personality (see Chapter 11). Genes contribute to individual differences in both early temperament and later personality (Davis et al., 2015; Krueger & Johnson, 2008; Saudino & Micalizzi, 2015).

Arnold Buss and Robert Plomin (1984) reported average correlations of around 0.50 to 0.60 between the temperament scores of identical twins. The corresponding correlations for fraternal twins were not much greater than zero. Think about that: A zero correlation is what you would expect if fraternal twins were strangers living in different homes rather than siblings who, on average, share half their genes, the same home, and often the same bedroom! It does not seem to matter whether researchers look at fraternal twin pairs, ordinary siblings, or unrelated children adopted into the same family: *Living in the same home generally does not do much to make children more similar in temperament and personality* (Plomin et al., 2013). This does not mean that the

family is unimportant. It means that family influences do more to make children different from each other than to make them alike—that nonshared environment is more influential than shared environment.

As shown in **Figure 3.5**, about 40% of the variation among adults in major dimensions of personality is attributable to genetic differences among them (Loehlin, 1985; Vukasović & Bratko, 2015). Only about 5% of the variation reflects the

■ **Figure 3.5** Average contributions of genes, nonshared environment, and shared environment to differences in adult personality. Growing up in the same home does not do much to make children alike in personality. Based on data from Loehlin (1985).

effects of shared family environment. The remaining 55% of the variability in adult personalities is associated with nonshared environmental influences that make siblings different from each other.

Shared environmental influences sometimes prove more important than these summary statistics would suggest. Yet behavioral geneticists have discovered repeatedly that for many aspects of temperament and personality, unique, nonshared environmental influences seems to be more significant than shared ones (Plomin et al., 2013; Reiss et al., 2000). There is little evidence that parents mold all their children's personalities in similar directions. There is plenty of evidence that parents treat different children differently, guided in part by their children's personality tendencies and behavior.

Psychological Disorders

Both genes and environment contribute to psychological disorders across the life span—to alcohol and drug abuse, autism, depression, attention deficit hyperactivity disorder, eating disorders, aggressive and criminal behavior, Alzheimer's disease, and every other psychological disorder that has been studied (Plomin et al., 2013; and see Chapter 16). Usually it's a matter of multiple genes, along with multiple environmental influences, each making small contributions to the development of a disorder.

Consider just one example. **Schizophrenia** is a serious mental illness that involves disturbances in logical thinking, emotional expression, and social behavior. It typically emerges in late adolescence or early adulthood. Genes contribute substantially to this disorder (Gottesman & Hanson, 2005). The average concordance rate for schizophrenia in identical twin pairs is 48%; that is, if one twin has the disorder, in 48% of the cases the other has it too (Gottesman, 1991; Owen & O'Donovan, 2003). By comparison, the concordance rate for fraternal twins is only 17%. As a result, the heritability of schizophrenia is estimated to be 80% or higher (Cardno & Pepper, 2014). What's more, children who have at least one biological parent with the disorder have an increased risk of schizophrenia *even if they are adopted away early in life* (Heston, 1970). Thus, the increased risk these children face has more to do with their genes than with being brought up by a schizophrenic adult.

But not all children of a parent with schizophrenia develop it. Here are the facts: Whereas about 1% of people in the general population develop schizophrenia, about 10% of children who have a schizophrenic parent become schizophrenic (Gottesman,

1991; Plomin et al., 2013). If certain copy number variations are involved, the odds can become much higher (Gershon & Alliey-Rodriguez, 2013; Hall et al., 2015).

Notice, though, that the odds for an identical twin whose twin develops schizophrenia are not 100% but around 50%. This means that environmental factors also contribute significantly to this mental illness (King, St. Hilaire, & Heidkamp, 2010). For example, genetically at-risk children are more likely to develop schizophrenia if their mothers come down with an infectious illness during pregnancy, such as the flu, if their mothers experience complications during delivery that deprive the fetus of oxygen, or if they grow up in a dysfunctional family after birth (Laurens et al., 2015). Differences in the expression of twins' genes caused by differences in their prenatal experiences may also help explain why one twin develops schizophrenia but the other does not (Debnath, Venkatasubramanian, & Berk, 2015).

In short, children do not inherit psychological disorders. Some inherit genetically based *predispositions* to develop disorders, but their experiences will interact with their genetic makeup to determine how well adjusted they turn out to be.

The Heritability of Different Traits

Genes contribute to variation in virtually all the human traits that have been studied, yet some traits are more heritable than others (Polderman et al., 2015; Segal, 2012). ■ **Figure 3.6** presents, by way of summary, correlations obtained in the Minnesota Study of Twins Reared Apart between the traits of identical twins raised apart and reunited as adults.

Observable physical characteristics, from eye color to height, are strongly associated with individual genetic endowment. Even weight is highly heritable; genes explain about 70% of variation in weight (Plomin et al., 2013), and adopted children resemble their biological parents but not their adoptive parents in weight, even though their adoptive parents feed them (Grilo & Pogue-Geile, 1991). Certain aspects of physiology, such as measured brain activity and reactions to alcohol, are highly heritable, too (Lykken, Tellegen, & Iacono, 1982; Neale & Martin, 1989).

In addition, genetic differences among older adults contribute to differences in their physical functioning and aging processes (Finkel & Reynolds, 2010). Genes also contribute to susceptibilities to many chronic diseases associated with aging. In the end, genes account for about 35–40% of the variation in longevity, leaving plenty of room for lifestyle and other environmental factors to make a difference (Finkel et al., 2014).

If physical and physiological characteristics are typically strongly heritable, general intelligence is moderately heritable: 50% or more of the variation in IQ scores is attributable to genes. Temperament and personality are somewhat less heritable. Many psychological disorders are also at least moderately heritable, with degree of heritability varying from condition to condition. Finally, and most surprisingly, differences in genetic endowment even contribute, though modestly, to differences in attitudes and interests—for example, religiousness, political conservatism or liberalism, political party identification, and vocational interests (Bell & Kandler, 2015; Segal, 2012). As you can see, it has proven difficult to find a human characteristic that is *not* to some degree heritable.

Checking Mastery

1. Professor Gene Ohm is studying genetic and environmental influences on individual differences in extraversion/introversion. Based on previous behavioral genetics studies, what should he expect?
2. Ayaan’s biological mother had schizophrenia, so he was placed in an adoptive home when he was only 2 months old. He grew up with his adoptive parents (neither of whom had any psychological disorders) in a stable, loving family. What would you tell Ayaan, now age 18, about his chances of developing schizophrenia if you were a genetic counselor?

Making Connections

1. There’s surely no single gene that directly makes people politically liberal or politically conservative, yet political liberalism/conservatism is heritable. Develop an explanation of how genes could influence it. While you’re at it, how might shared environment and nonshared environment influence it?
2. What in the behavioral genetics evidence we have reviewed in this section most convinces you of the importance of genes—and what most convinces you of the importance of environment?

3.5

Gene–Environment Interplay

LEARNING OBJECTIVES

- Distinguish between gene–environment interaction (and the diathesis–stress and differential susceptibility concepts) and gene–environment correlation (and passive, evocative, and active types of gene–environment correlations).
- Explain how genetic makeup can affect measures of environment and how genetically informed studies can help determine whether parenting and other environmental influences on development really matter.
- Explain what epigenetic effects are and what they say about the relationship between genes and environment.
- Explain why genetic research and behavioral genetic research are controversial.

Genes do not orchestrate our growth before birth and then leave us alone. Instead, they are “turning on” and “turning off” in patterned ways throughout the life span, helping shape our characteristics and behavior. No less important are ever-changing environmental influences, from conception to death. But genes and environment do not operate independently; they are interrelated in important ways.

As you have seen throughout this chapter, behavioral geneticists try to establish how much of the variation in human traits such as intelligence can be attributed to individual differences in genetic makeup and how much can be attributed to individual

differences in experience. Useful as that research is, it does not take us far in understanding the complex interplay between genes and environment over the life span (Meaney, 2010). As Ann Anastasi (1958) noted many years ago, instead of asking *how much* is because of genes and how much is because of environment, researchers should be asking *how* heredity and environment work together to make us what we are. With that in mind, let’s examine the workings of three tremendously important forms of gene–environment interplay: gene–environment interactions, gene–environment correlations, and epigenetic effects on gene expression (Brendgen et al., 2012; Plomin et al., 2013).

Gene–Environment Interactions

Genes provide us with potentials that are or are not realized depending on our experiences. You have encountered some examples already but consider another one. Using the molecular genetics approach, Avshalom Caspi and his colleagues (2003) sought to understand why stressful life experiences cause some people but not others to become depressed. They performed DNA analysis on a large sample of New Zealanders to determine which variants of a now famous gene called *5-HTTLPR* each person had. They knew that this gene affects stress reactivity by affecting levels of the neurotransmitter serotonin in the brain, and they knew that a low serotonin level is linked to depression. Caspi and colleagues also administered surveys to measure the stressful events each person had experienced between ages 21 and 26, and whether at age 26 each person had experienced a diagnosable episode of depression in the past year.

In **Figure 3.7**, you can see the results, which illustrate wonderfully the concept of **gene–environment interaction**: The effects of our genes depend on what kind of environment we experience, and how we respond to the environment depends on what genes we have. In **Figure 3.7**, you see that individuals with two of the high-risk variants of the *5-HTTLPR* gene are more vulnerable to depression than people with two of the protective variants of the gene—but only if they experience multiple stressful events. By comparison, even multiple stressful events will not easily cause people with the protective variants of the gene to become depressed. Thus, the genes people have make a difference only when their environment is stressful, and a stressful environment has an effect only on individuals with a genotype that predisposes them to depression. Genes and environment interact.

Both human and animal studies indicate that the *5-HTTLPR* gene affects stress reactivity and can put individuals at risk for—or

Figure 3.7 The odds of a depressive episode at age 26 are highest for individuals who: (1) inherit two *5-HTTLPR* gene variants known to increase the risk of depression rather than a pair known to protect against depression, and (2) experience four or more stressful life events between ages 21 and 26. This is an example of gene–environment interaction: The effects of genetic makeup on depression depend on how stressful a person’s environment is, and the effects of stressful life events depend on the person’s genotype.

protect them from—a number of psychological disorders (Booij et al., 2015; Caspi et al., 2011; Karg et al., 2011). For example, bullying is more likely to be linked to emotional problems in victims of bullying who have the risky variants of *5-HTTLPR* than in victims with the protective variants (Sugden et al., 2010), and the combination of the risky *5-HTTLPR* genes and chronic stress stemming from peer relationships increases the odds of clinical depression in adolescents (Hankin et al., 2015).

Generally, it often takes a combination of high-risk genes and a high-risk environment or stressful experiences to trigger psychological problems (Dick et al., 2011; Dodge & Rutter, 2011). This is the message of the **diathesis–stress model** of psychopathology: Psychological disorder results from an interaction of a person’s predisposition or vulnerability to problems (whether rooted solely in genes or in characteristics that have arisen from both genetic and environmental influences) and the experience of stressful events.

From an applied standpoint, we could prevent psychological problems more effectively if we could identify and help those individuals whose genes predispose them to problems. For example, Gene Brody and his colleagues (2009) showed that 11-year-olds with the high-risk *5-HTTLPR* genes could be protected from high rates of problem behaviors such as substance use and early sexual intercourse if their families participated in a prevention program that stressed good parenting skills and parent–child communication. Control group youth who had the high-risk genes but did not receive the prevention program engaged in problem behaviors at twice the rate of youth with the high-risk genes who participated in the prevention program and peers who did not have high-risk genes (see also Brody, Yu, & Beach, 2015).

More and more evidence of gene–environment interactions involving the *5-HTTLPR* gene and a number of other important genes affecting neurotransmitter activity in the brain is emerging as researchers use the molecular genetics approach to study interactions between specific genes and specific experiences. But another fascinating discovery has been made: The diathesis–stress model of psychopathology may be only part of the story. Some of the very genes that have been labeled as “risk genes” are turning out to be genes that not only make people more susceptible to the damaging effects of stressful environments but also allow them to benefit more than others from nurturing environments. **Exploration 3.1** examines this **differential susceptibility hypothesis**, which says that some people’s genetic makeup makes them more reactive than other people to environmental influences, whether good or bad. Our knowledge of forms of gene–environment interaction such as diathesis–stress and differential susceptibility is expanding rapidly.

Gene–Environment Correlations

Not only do genes and environment interact, but each person’s genetic makeup influences the kinds of experiences she seeks and has. Sandra Scarr and Kathleen McCartney (1983), drawing on the theorizing of Robert Plomin, John DeFries, and John Loehlin (1977), proposed three kinds of **gene–environment correlations**, or ways in which a person’s genes and his environment or experiences are interrelated: passive, evocative, and active. The concept of gene–environment *interactions* tells us that people with different genes react differently to the experiences they have.

● EXPLORATION 3.1

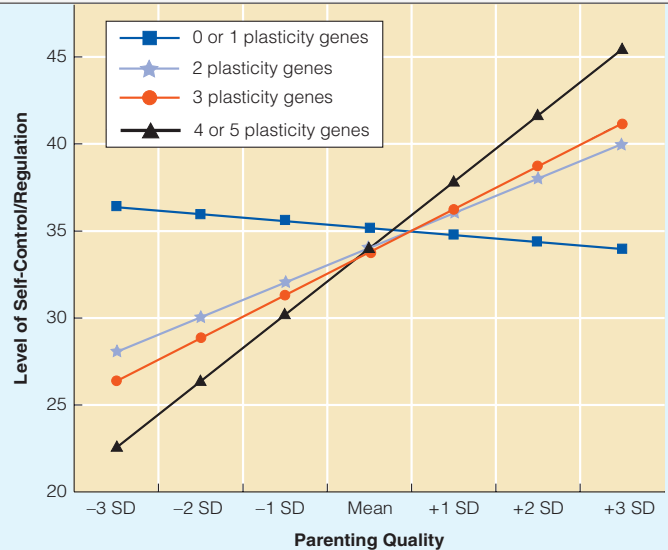

Differential Susceptibility: Orchids and Dandelions

Something interesting happened when researchers Bruce Ellis, Thomas Boyce, Jay Belsky, and others looked more closely at some of the genes like *5-HTTLPR* that had been identified as “risk genes” for disorders such as depression and antisocial behavior. They discovered that individuals with these genes not only displayed more psychological problems if they were exposed to stressful, negative environments but responded better than individuals without the genes to positive environments. According to the *differential susceptibility hypothesis*, some individuals, by virtue of their genetic makeup, are simply more responsive than other people to environment influences—good or bad. The “susceptible to environmental influence” individuals have been likened to orchids, which thrive in just the right conditions but wilt in poor conditions; the less environmentally responsive individuals have been likened to dandelions, which grow pretty well almost anywhere (Boyce & Ellis, 2005).

Consider a study by Jay Belsky and Kevin Beaver (2011) of self-control among eleventh-grade students raised by more or less supportive mothers. These researchers focused on variants of five genes, including *5-HTTLPR*, that had previously been identified as risk genes and counted how many of the risky versions each teen had. They also assessed the extent to which teens’ mothers were involved with and attached to them. Finally, self-regulation was assessed with a 23-item scale completed by both teens and their mothers that asked about such behaviors as having a temper and being reliable or trustworthy.

The results supported the differential susceptibility hypothesis for males but not for females. As shown in Figure 3.8, males with a large number of risk genes (which Belsky and Beaver relabeled “plasticity” genes), had the highest level of self-control when they had supportive mothers but the lowest self-control when they had unsupportive mothers. Among the “dandelion” youth who had 0 or only 1 of these genes, the degree of self-regulation was unrelated to how supportive their mothers were. Researchers were not sure why the differential susceptibility effect was evident only among males, as other studies suggest it works in both sexes (Buil et al., 2015; DiLalla et al., 2015; Sumner et al., 2015).

The message is clear: The diathesis-stress model tells only part of the story. The “risk” genes that combine with stressful and negative experiences to put some individuals on a path to psychopathology do just that in unsupportive environments but also help the same individuals thrive in highly supportive environments (see Ellis et al., 2011, for more examples). It

■ **Figure 3.8** Male adolescents who had 4 or 5 of the “risk” genes identified in previous research (the black line) showed very low self-control if their mothers were unsupportive—support for the diathesis-stress model. However, they also showed exceptionally good self-control if raised by supportive mothers—support for the differential susceptibility hypothesis, and a good reason to relabel these genes “plasticity” genes rather than “risk” genes.

Source: Belsky, J., & Beaver, K. M. (2011). Cumulative-genetic plasticity, parenting and adolescent self-regulation. *Journal of Child Psychology and Psychiatry*, 52(5), 619–626. Figure 1, p. 624.

makes good sense, then, to identify children who may be at risk for problems and target them for interventions such as positive parenting training so that these orchids have a chance to blossom (as in the Brody, 2009, study described in the text).

By contrast, the concept of gene–environment *correlations* says that people with different genes have different experiences (Loehlin, 1992). As an illustration, imagine children with a genetic potential to be highly sociable and other children whose genes are likely to make them shy.

Passive Gene–Environment Correlations

The kind of home environment that parents provide for their children is influenced partly by the parents’ genotypes. **Passive gene–environment correlations** work like this: Because parents provide children with both their genes and a home environment

compatible with those genes, the home environments to which children are exposed are correlated with (and are typically likely to reinforce) their genotypes.

For instance, sociable parents not only transmit their “sociable” genes to their children but also, because they have “sociable” genes themselves, create a highly social home environment—inviting their friends over, taking their children to social gatherings, and so on. The combination of genes for sociability and a sociable environment may make their children more sociable than they would otherwise be. By contrast, the child with shy parents may receive genes for shyness *and* a correlated environment without as much social stimulation.

Evocative Gene–Environment Correlations

In **evocative gene–environment correlations**, a child’s genotype also *evokes* certain kinds of reactions from other people. The smiley, sociable baby is likely to get more smiles, hugs, and social stimulation—and more opportunities to build social skills—than the wary, shy baby who makes you worry he will howl if you try anything. Similarly, the sociable child may be chosen more often as a playmate by other children, the sociable adolescent may be invited to more parties, and the sociable adult may be given more work assignments involving public relations. In short, genetically based tendencies may affect the reactions of other people to an individual and, hence, the kind of environment the individual will experience through life.

Active Gene–Environment Correlations

Finally, through **active gene–environment correlations**, children’s genotypes influence the kinds of environments they *seek*. The individual with a genetic predisposition to be extraverted is likely to go to every party in sight, invite friends over, join organizations, collect Facebook friends, and otherwise build a “niche” that is highly socially stimulating and that strengthens social skills. The child with genes for shyness may actively avoid large group activities and instead develop solitary interests.

Scarr and McCartney (1983) suggest that the balance of the three types of genotype–environment correlations shifts during development. Because infants are at home a good deal and are dependent on their caregivers, their environment is largely influenced by their parents through passive influences. Evocative influences operate throughout life; our genetically influenced traits consistently evoke certain reactions from other people. Finally, as humans develop, they become increasingly able to build their own niches, so active gene–environment correlations become increasingly important.

Implications of Gene–Environment Correlations

How much evidence is there for Scarr and McCartney’s claim that people’s genes are correlated with, and possibly influence, their experiences in life? A good deal. It turns out that many measures of aspects of the environment are heritable (Butcher & Plomin, 2008). What this means is that identical twins are more similar than fraternal twins, and biological siblings are more similar than adoptive siblings, in the environments they experience and in their perceptions of those environments. For example, genetic makeup is related to the following:

- Aspects of parenting, such as the warmth and quality of the parent–child relationship (Plomin & Bergeman, 1991; Reiss, 2005)
- Time spent watching television (Plomin et al., 1990)
- Number of stressful life events experienced (Kendler et al., 1993)

If our genetically influenced personality traits affect how others treat us and what experiences we seek and have, these findings make sense. For example, identical twins who are irritable and difficult could help create a conflict-ridden family environment, whereas calm, self-controlled twins could help create a cohesive family environment (Krueger, Markon, & Bouchard, 2003).

Such findings challenge our usual assumptions about human development. They say that what we thought were purely environmental influences on development partly reflect the workings of

heredity (Reiss et al., 2000; Rowe, 1994). Leading behavioral geneticist Robert Plomin (1990) gives us this example to ponder: Suppose we find that parents who read to their children have brighter children than parents who do not read to their children. In the not-so-distant past, most developmentalists would have interpreted this finding rather uncritically as evidence that parents make important contributions to their children’s intellectual development by reading to them. Without denying the importance of parents, consider this alternative interpretation: Parents and children whose genes predispose them to be highly intelligent are more likely to seek opportunities to read than parents and children who are less intellectually inclined. If this is the case, can we be so sure that reading to children *causes* them to be brighter? Would we be able to show that reading to children is beneficial even when the parents and children involved are genetically unrelated?

Some of the strongest evidence of the importance of gene–environment correlations comes from an ambitious family study by David Reiss, Jenae Neiderhiser, E. Mavis Hetherington, and Robert Plomin (2000). These researchers studied 720 pairs of same-sex adolescents who differed in their degree of biological relationship, from identical twins to biological siblings to unrelated stepsiblings. They measured environmental variables such as quality of parent–child interaction and adolescent adjustment variables such as self-esteem, sociability, depression, and antisocial behavior.

Repeatedly, genes shared by parents and adolescents partly or even largely accounted for relationships between children’s experiences in the family and their developmental outcomes—for example, between a negative parenting style and antisocial behavior on the part of adolescents. Taking this and other evidence into account, we must conclude that *reciprocal influences* are at work in human development. For example, harsh, negative parenting contributes to antisocial behavior in children, but children genetically predisposed to be antisocial also provoke and bring out the worst in their parents (Larsson et al., 2008; O’Connor et al., 1998).

In short, simple correlational studies that show a relationship between some aspect of experience and some aspect of development cannot establish that experience really affects development. As a result, more and more researchers are conducting **genetically informed studies**, like the Reiss et al. (2000) study just described, that try to determine whether there are genetic explanations for apparent environmental effects and establish more firmly whether environment matters (Johnson et al., 2009; Plomin et al., 2013).

One approach to genetically informed research is to determine whether an environmental influence is just as evident among adoptive children—that is, with genetic resemblance between parent and child out of the picture—as among biological children. For instance, Amato and Cheadle (2008) showed that the relationship between marital conflict and child behavior problems was equally strong in biological and adoptive families, suggesting a true environmental effect.

Another genetically informed research tactic is to study identical twins to see if differences in their development are systematically related to differences in their experiences. Since they have identical genes and grew up in similar prenatal and postnatal environments, differences in their behavior or development can be credited to differences in their experiences—to nonshared environmental influences. So, for example, identical twins who

If the child of a top athlete turns out to be a good athlete, is it because of genetic endowment or experience? We cannot say because genes and environment are correlated. How might passive, evocative, and active gene-environment correlation influence this child’s development as an athlete?

Jeff Greenberg/Alamy Stock Photo

receive more negative discipline from their parents at age 7 than their co-twins turn out to have more conduct problems at age 12 (Viding et al., 2009). And twins who are bullied by peers have more atypical hormonal responses to stressful experiences and are more likely to develop emotional problems than their non-bullied co-twins (Ouellet-Morin et al., 2011; Sugden et al., 2010).

These kinds of genetically informed studies often offer the most convincing evidence we have that environment truly matters. We end up appreciating that, through gene–environment correlations, genes influence how parents, peers, and others treat us and that how we are treated then contributes on its own to our development, often reinforcing our genetically based predispositions.

Epigenetic Effects on Gene Expression

Having seen that genes can influence one’s environment through gene-environment correlations, let’s now look at how environment can influence genes. **Epigenesis** (*epi-* = “over and above” + *genesis* =

“birth or origin”) is a term for the general process through which nature and nurture co-act to bring about development (Moore, 2015). Think of it as what happens as a fertilized egg becomes a human being. It is now abundantly clear that genes do not dictate development (Lickliter & Honeycutt, 2015; Moore, 2015). Rather, genes and environment interact with and influence each other from conception on to shape development, to the point that their influences cannot be separated.

Nowhere is this clearer than in what are now called **epigenetic effects**, ways in which environmental factors influence the expression of particular genes in particular cells (Boyce & Kobor, 2015; Champagne, 2013; Meaney, 2010; Moore, 2015). Through epigenetic effects, factors such as diet, stress, alcohol and drugs, environmental toxins, and early parental care leave records, chemical codings on top of certain genes that affect whether those genes are turned on or off. Analysis of RNA can now reveal these patterns of gene expression.

So, on top of the complex genome in each cell, we also have a complex “epigenome” consisting of all kinds of these epigenetic markings. The genes themselves are not altered when epigenetic effects occur. Rather, their expression is altered—in ways that can affect cognition, emotion, behavior, health, and mental health. Epigenetic markings can be long-lasting and can lead to continuity in development (as when these codings cause a blood cell or liver cell to continue to act like a blood cell or liver cell for life), but they can also produce change in response to changes in the environment, acting as a source of plasticity or flexibility in development (Boyce & Kobor, 2015).

Epigenetic effects are especially important during prenatal development, when regulatory DNA and environmental influences orchestrate early development (see Chapter 4 on fetal programming in response to factors such as maternal diet). However, epigenetic effects continue throughout the life span. A temporary rise in the most well-studied type of epigenetic coding, DNA methylation, has been observed in the cells of adults who complete a social stress test in the laboratory (Unternaehrer et al., 2012). And epigenetic changes involving genes associated with neurotransmitters in the brain happen every time we learn something, and are critical in brain development and aging (Mather et al., 2014; Moore, 2015). Let’s look at three examples of some of the remarkable discoveries about epigenetic effects that have been made recently: a study of differences between identical twins, a study of the implications of early parenting for rat pup development, and research on the implications of a father’s overeating for his children’s health.

Epigenetic Effects and Differences Between Twins

Epigenetic effects may help explain why, despite their identical genes, identical twins often differ. Mario Fraga and his colleagues (2005) conducted analyses of the DNA and RNA of 40 pairs of identical twins ranging in age from 3 to 74. Analysis of the RNA of 3-year-old twins showed that the genes of these young children had very similar patterns of expression. If a gene was turned on in one twin, it was turned on in the other; if it was turned off in one twin, it was turned off in the other. By contrast, the genes of 50-year-old twins were expressed very differently; many genes that were activated in one twin were deactivated in the other.

What’s more, those adult twins who had spent less of their lives together and had led quite different lifestyles—for example, who

Identical but not identical. “We think the same. We’ve even bought each other the same birthday cards,” says Geraldine (*right*) about herself and her identical twin, Christine. Yet Christine has arthritis and Geraldine does not. Could epigenetic effects be one way in which environmental influences make these identical twins different?

Karen Kasmauski/Science Faction/Getty Images

had different diets, levels of physical activity, and use of tobacco, alcohol, and drugs—showed greater differences in their patterns of gene expression than did twins who had led similar lives. Some differences in the epigenetic markings of identical twins are detectable from birth, suggesting that differences in identical twins’ prenatal experiences, recorded in their epigenomes, may also help explain why they often differ (Moore, 2015; and see Chapter 4).

Epigenetic Effects of Nurturing and Neglect

Now consider the groundbreaking work on the epigenetic effects of early caregiving on the development of rat pups by Michael Meaney, Frances Champagne, and their colleagues. These researchers have shown through a series of elegant studies how the early experience of rat pups can affect the activity of their genes and, in turn, not only their own development but that of their offspring (see Champagne, 2013; Francis et al., 1999; Kaffman & Meaney, 2007).

Here’s how it goes: If mother rats are nurturant—if they regularly lick and groom their pups and nurse them with an arched back in the first week of life—the pups grow up able to handle stress well. If rat moms are neglectful and do not provide this tender tactile care, rat pups become timid and easily stressed adults. But how? The differences in pups’ reactivity to stress were not due to heredity. Raising the pups of nurturant mothers with neglectful mothers and the pups of neglectful mothers with nurturant mothers demonstrated that it was rearing that mattered, not heredity.

A mother rat’s nurturing—or neglect—influences her pups’ reactions to stress, through epigenetic effects, and later their parenting behavior.

Eric Isselee/Shutterstock.com

Rats turned out to be stress resistant if raised by nurturant mothers and stress reactive if raised by neglectful mothers, regardless of their biological parentage.

But these styles of responding to stress also were not acquired through learning, either—for example, by watching a stressed-out mother. Rather, Meaney and his colleagues discovered that early licking and grooming affect the development of the stress response system through epigenetic effects. In nurtured pups, certain genes in cells in the hippocampus of the brain that influence the regulation of stress hormones stayed turned on, whereas in neglected pups these genes were turned off by DNA methylation, making the hippocampus less able to tone down stress hormone responses. Early caregiving therefore had a lasting effect on development by altering gene expression.

Too little licking and grooming in infancy also turns off genes that affect sensitivity to female hormones and later maternal behavior (Champagne, 2013). As a result, the daughters of neglectful mothers turn into neglectful mothers themselves! Here, then, we see epigenetic transmission of neglectful (or nurturing) parenting styles across generations.

Epigenetic effects like this example represent no less than a whole new way in which parents influence their children besides genetic inheritance and social learning: *environmental influence on gene expression*. And there’s now suggestive evidence that epigenetic marks similar to those observed in rat pups may help explain the transmission from mother to daughter of abusive and neglectful parenting in both monkeys and humans, as well as the increased susceptibility to mental health problems associated with early abuse and neglect (Mastrisieri, Lindell, & Higley, 2007; McGowan, 2013; McGowan et al., 2009). But the cycle of neglect and abuse may be breakable: Meaney and his colleagues showed that epigenetic effects of neglectful parenting on stress response and parenting style in rats can be reversed if young animals are raised by sensitive, nurturing mothers or if drugs that affect gene expression in critical parts of the brain are administered (McGowan, Meaney, & Szyf, 2008; Zhang & Meaney, 2010).

Epigenetic Effects and Obesity

Finally, consider another study of rats that appears to have implications for humans too. It seems that feeding a *father* rat a high-fat diet and making him overweight changes epigenetic marks on genes in his sperm (Ng et al., 2010; and see Chapter 4 on fetal programming). The marks then become part of his daughter’s epigenetic profile and change her physiology in ways that make her more prone to obesity and diabetes—even though both she and her mother ate healthy diets! There’s now suggestive evidence that overweight human fathers can also pass on epigenetic marks through their sperm that are likely to increase their children’s odds of obesity and related problems—and that in men who lose weight after undergoing gastric bypass surgery, many of the markings associated with obesity are reversed (Donkin et al.,

2016). Findings like this are truly astonishing; they are giving new life to an idea that was discredited in Charles Darwin’s time: the notion that characteristics acquired during an individual’s lifetime can be inherited by the individual’s descendants (Moore, 2015).

So, although the chromosomes are generally wiped clean of epigenetic marks soon after conception, *some* epigenetic codings etched on top of genes during a parent’s life can affect his or her offspring (Boyce & Kobor, 2015; Moore, 2015). As we have seen, this can happen in two ways: (a) through social transmission (illustrated when the caregiving behavior of mother rats affects their pups’ epigenetic codings and later behavior), and (b) through epigenetic inheritance, in which epigenetic codings in a parent’s sperm or egg are inherited by an embryo. Remarkably, some epigenetic marks have been shown to survive in animals across multiple generations (Moore, 2015).

It’s not yet clear where epigenetic research will lead, how often epigenetic marks are inherited by our children and grandchildren, or how often they actually cause later physical and mental health problems. However, it *is* clear that environment can influence gene expression and, in turn, traits and behavior. By altering gene expression, some epigenetic effects may contribute to greater plasticity, helping organisms and their offspring adapt flexibly to whatever environmental conditions they encounter rather than wait generations for biological evolution to do its work (Champagne, 2013; Meaney, 2010).

In the end, no one completely understands the remarkable epigenetic process that transforms a single cell with its genetic endowment into millions of diverse cells—blood cells, nerve cells, skin cells, and so on—all organized into a living, behaving human. However, we are learning a tremendous amount from studies of gene–environment interactions, gene–environment correlations, and epigenetic effects (see • Table 3.6 for a summary). Genes and environment are active partners in the developmental process at every step.

Controversies Surrounding Genetic Research

Our society is grappling with the complex and troubling public policy and ethical issues that have arisen as geneticists have gained the capacity to identify the carriers and potential victims of diseases and disorders, to give parents information that might prompt them to abort a fetus that is not of the desired health status or intellect, and to experiment with techniques for altering an individual’s genetic makeup through **gene therapy** (Lewis, 2012, 2015; Nussbaum et al., 2016). Gene therapy to treat such genetic disorders as hemophilia (through infusions of normal genes into the blood), the lung disease cystic fibrosis, and recently sickle-cell disease have had some success and are likely to have more. New techniques for “editing” the genome and inserting new genes in patients’ bodies promise to revolutionize gene therapy—and raise all kinds of ethical issues and concerns about unintended consequences (Achenbach, 2015). Now, of course, researchers are also studying the epigenetic markings of individuals who have diseases and disorders and scrambling to develop drugs and dietary treatments to alter these codings (Boyce & Kobor, 2015; Moore, 2015).

If you think about it, though, it may be simpleminded to think that gene therapies will ever prevent or cure most diseases and disorders. Why? Because, as you now understand, most conditions are the product of the interaction of multiple genes and multiple environmental influences, including epigenetic effects on genes. Researchers not only must deliver the right genes to the body in sufficient number to have the desired effect but also must get them to turn on and off when they should and control important environmental influences as well. No “quick fixes” such as the PKU diet are likely for most conditions, especially those that are polygenic in origin. Still, genetic and epigenetic diagnosis and

• **Table 3.6** Types of Gene-Environment Interplay

Type	Meaning	Example	Significance
Gene–environment interaction	People with different genes are affected differently by environmental influences	Stress triggers depression only if a person has high-risk genes	Nature and nurture combine. <i>Diathesis-stress model</i> of psychopathology (vulnerability + stress leads to problems) and <i>differential susceptibility hypothesis</i> (some individuals are more sensitive to both good and bad environments)
Gene–environment correlation	People with different genes experience different environments—environments correlated with their genes (through passive, evocative, and active G–E correlations)	Children who have genes associated with sociability have sociable parents, evoke sociable responses from others, and actively seek social interaction	Nature affects nurture. Genetic predispositions influence experiences, which often strengthen genetically based tendencies. Measures of environment are not purely environmental; they are genetically influenced
Epigenetic effects	Environment affects gene expression through chemical codings on genes, e.g., DNA methylation	Early abuse/neglect results in an overly reactive stress response system and later psychological disorders	Nurture affects nature. Environmental influences alter the functioning of genes; some epigenetic marks are passed on to offspring

therapy techniques will improve, and we as a society will have to decide how—and how not—to use them.

Likewise, behavioral genetics research is controversial. On the one hand, it has provided truly important insights into human development: that differences in genetic makeup between us contribute to differences in virtually all of our physical and psychological characteristics, that our unique experiences are often more influential than those we share with siblings, that gene–environment interactions mean that we differ in our responses to the same experiences, that gene–environment correlations mean that we create our own environments, and that experiences get “under our skin” through epigenetic effects to shape the way our genes and physiologies function.

Nonetheless, some developmentalists question the whole idea of trying to separate the influences of genes and environment on differences between individuals when the two are so inseparable in each individual’s development. They insist that behavioral genetics research will never tell us about what we should really want to understand: *epigenesis*, that long and complex process through which the interplay of genes and environment brings about development. Our best bet as parents and practitioners is to be sensitive to each child’s genetically based predispositions as well as knowledgeable about ways to optimize development so that we can strengthen each child’s adaptive tendencies and weaken or work around the maladaptive ones. Providing children with optimal experiences, of course, depends on knowing which environments stimulate healthy development and which do not. It is fitting, then, that the next chapter looks more closely at the critical importance of early environmental influences on development.

● Checking Mastery

Label each example below as an example of (a) gene–environment interaction, (b) passive gene–environment correlation, (c) evocative gene–environment correlation, (d) active gene–environment correlation, or (e) epigenetic effects.

1. Roger inherited genes for artistic creativity from his parents and grew up watching them sketch and paint.
2. Tamara was abused as a child and this seems to have made her stress response system overly reactive.
3. Kayla inherited genes for mathematical ability and has been taking extra math and science courses in college.
4. Sydney inherited a gene that can cause intellectual disability but only in children who do not receive enough folic acid in their diet.
5. Jorge got genes for anxiety, and his anxious behavior makes his parents overprotective of him.

● Making Connections

1. Assume that genes predispose some people to be highly religious and some people to be unreligious and that some environments nurture religiousness and others do not. Explain how a gene–environment interaction and a gene–environment correlation could each help make Peter more religious than Paul.
2. What information in this chapter makes you think you will turn out very much like your parents—and what information suggests that this may not be the case at all?

Chapter Summary

3.1 Evolution and Species Heredity

- As humans, we develop similarly in part because we share a species heredity, the product of evolution.
- According to Darwin’s theory of biological evolution, if there is genetic variation in a species—and if some genes aid members of the species in adapting to their environment and reproducing—those genes will become more common in the population over time through natural selection.
- Humans also adapt to changes in their environments through the faster process of cultural evolution.

3.2 Individual Heredity

- Each human has an individual heredity provided at conception, when sperm and ovum, each with 23 chromosomes (thanks to meiosis), unite to form a single-cell zygote with 46 chromosomes. Parent and child share 50% of their genes in common; siblings share 50% on average.
- The chromosomes contain some 20,000–25,000 protein-building genes, along with regulatory DNA; the Human Genome Project and related studies have mapped these genes and revealed similarities and differences between the genes of different human groups and species.

- Environmental factors influence how a genotype (genetic makeup) is translated into a phenotype (actual traits); regulatory DNA and environmental factors influence the important process of gene expression.
- The three main mechanisms of inheritance are single gene-pair inheritance, sex-linked inheritance, and polygenic (multiple gene) inheritance. Some children are also affected by new or inherited changes in gene structure (mutations, copy number variations); others, because of errors in meiosis, have chromosome abnormalities such as Down syndrome or a sex chromosome abnormality.
- Couples can obtain information about genetic diseases such as sickle-cell disease, Huntington’s disease, and PKU from genetic counselors, and many genetic abnormalities can be detected prenatally through ultrasound, amniocentesis, chorionic villus sampling, maternal blood sampling, and preimplantation genetic diagnosis.

3.3 Studying Genetic and Environmental Influences

- Behavioral geneticists conduct twin, adoption, and other family studies that describe resemblances between pairs of people using concordance rates and correlation coefficients. They then estimate the heritability of traits and the contributions of shared (with siblings) and nonshared (unique) environmental influences.

- Techniques of molecular genetics are used to identify and study particular gene variants and to compare people who do and do not have them.

3.4 Selected Behavioral Genetics Findings

- Performance on measures of intelligence is a heritable trait. From infancy to adulthood, individual differences in mental ability more strongly reflect both individual genetic makeup and non-shared environmental influences, whereas shared environmental influences wane.
- Aspects of temperament and personality are also genetically influenced, and nonshared environmental influences are significant whereas shared environmental influences are typically not.
- Similarly, psychological disorders such as schizophrenia have a genetic basis, but it often takes an interaction of genes and environmental stressors to produce disorder.
- Overall, physical and physiological characteristics are more strongly influenced by genetic endowment than are intellectual

abilities and, in turn, temperament and personality, psychological disorders, and finally, attitudes and interests.

3.5 Gene–Environment Interplay

- Gene–environment interactions mean that genes influence how people react to the environment, as illustrated by the diathesis-stress model and differential susceptibility hypothesis.
- Passive, evocative, and active gene–environment correlations suggest that people experience and seek out environments that often match and reinforce their genetic predispositions. As a result, measures meant to assess environmental influences partly reflect genetic makeup, and we need genetically informed studies.
- Epigenetic effects, effects of the environment on gene expression, further illustrate how completely intertwined nature and nurture are in development.
- Genetic research is controversial, as illustrated by issues in gene therapy and by criticisms of behavioral genetics.

At age 26, Serena was not thinking about getting pregnant. She and her boyfriend, Tony, were both getting adjusted to new jobs and working long hours. Serena tried to keep up with her regular exercise routine and struggled through a nasty sinus infection requiring treatment with antibiotics. She wasn't too concerned when she gained a few pounds but began to worry when she missed several menstrual periods. A visit to her doctor revealed that she was nearly 5 months pregnant, probably a result of the antibiotics decreasing the effectiveness of her birth control. Serena's mind raced as she considered all the things she had—or had not—done during recent months that might have influenced her unborn baby. Did she drink too much alcohol? Had she eaten a healthy diet? These thoughts were quickly followed by concerns about what the childbirth experience would be like and how she and Tony would adjust to this rather unexpected change in their lives.

We will answer these questions and more in this chapter on prenatal development, the birth experience, and the first hours and days of life. You will learn why the environment of the womb is so important and how it can set the stage for healthy development

across the entire life span. The material in this chapter is a good illustration of how developmentalists seek to optimize development by using research to guide practices before, during, and after pregnancy.

4.1

Prenatal Development

LEARNING OBJECTIVES

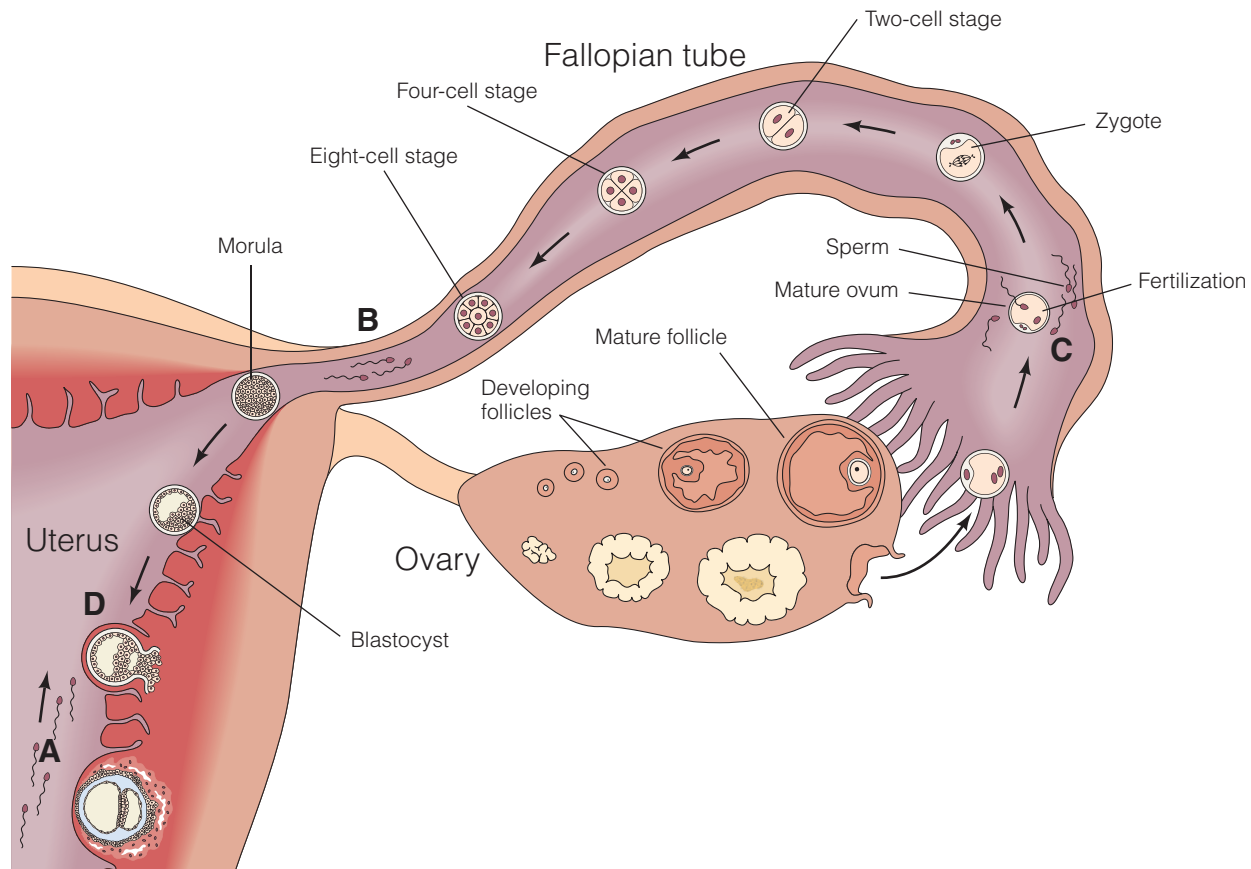

- Summarize the main events and three phases of the prenatal period.
- Explain the major changes in brain development during the prenatal period.

Perhaps at no time in the life span does development occur faster, or is environment more important, than between conception and birth. What maturational milestones normally occur during this period?

Conception

Midway through the menstrual cycle, every 28 days or so, females ovulate: A follicle that has been growing inside the ovary erupts and releases an egg, thanks, in part, to follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Once released, the

egg cell, called an ovum, begins its journey through the nearest fallopian tube to the uterus. Usually the egg disintegrates and leaves the body as part of the menstrual flow. However, if the woman has intercourse with a fertile man around the time of ovulation, the 300 million or so sperm cells in his seminal fluid swim, tadpole style, in all directions. Of the approximately 300 sperm that survive the 6-hour journey into the fallopian tubes, one may meet and penetrate the ovum on its descent from the ovary (Sadler, 2015; see also ■ **Figure 4.1**). Although fertilization usually takes place within 12 hours of ovulation, sperm can

■ **Figure 4.1** Fertilization and implantation. (A) Millions of sperm cells have entered the vagina and are finding their way into the uterus. (B) Some sperm are moving up the fallopian tube (there is a similar tube on the other side) toward the ovum. (C) Fertilization occurs. The fertilized ovum drifts down the tube, dividing and forming new cells as it goes, until it implants itself in the wall of the uterus (D) by the seventh or eighth day after fertilization.

survive for up to 6 days in the reproductive tract, which means pregnancy can result from intercourse that has occurred as much as 6 days prior to ovulation (Sadler, 2015). Once a single sperm penetrates the egg cell, a biochemical reaction occurs that repels other sperm and keeps them from entering the already fertilized egg. As explained in Chapter 3, conception, the beginning of life, occurs when the genetic material of the sperm and egg unite to form a single-celled zygote.

For many couples, the process proceeds smoothly and swiftly leads to a pregnancy, but for as many as one in four couples, the experience of conceiving is fraught with difficulties. **Infertility**—not being able to get pregnant after a year of trying—is equally likely to be traced to the man as to the woman and stems from a variety of causes. For example, adolescents and adults—both male and female—who have contracted sexually transmitted infections (STIs) may become infertile. Some men have a condition called *varicocele* in which enlarged veins on their testicles raises the temperature in the testes, interfering with sperm production (Sohrband, et al., 2015). Infertility traced to women may be related to problems with ovulation, blocked fallopian tubes, or **endometriosis**, a condition arising when bits of tissue lining the uterus grow outside the uterus. Depending on the suspected cause of infertility, couples may be helped to conceive with simple solutions. A man may be advised to wear loose boxer shorts rather than tighter briefs that might elevate testicular temperature. A woman may be able to track her morning body temperature to determine when she ovulates and is therefore most likely to become pregnant. As **Figure 4.2** shows, ovulation is accompanied by a rise in body temperature along with a spike in follicle-stimulating hormone (FSH) and luteinizing hormone (LH).

When simpler methods fail, some couples move on to more elaborate (and expensive) assisted reproductive technologies (ARTs), medical techniques used to increase fertility. ART techniques typically start with or include prescription drugs for the woman to stimulate her ovaries to ripen multiple follicles, leading to the release of several eggs. If this is unsuccessful, couples and their doctors may proceed to **artificial insemination** (also called intrauterine insemination), which involves injecting sperm, either from a woman's partner or from a

donor, into her uterus. Or they may use **in vitro fertilization (IVF)**, in which several eggs are removed from a woman's ovary and manually combined with sperm in a laboratory dish before being returned to a woman's uterus in hopes that one egg will implant on the wall of the uterus. We should note that there are many variations of IVF, depending on who provides the eggs and the sperm. A couple wanting to have a child could donate both eggs and sperm and have the biological mother carry the baby to term. At the other end of the spectrum, an infant conceived through IVF could wind up with five “parents”: a sperm donor, an egg donor, a surrogate mother in whom the fertilized egg is implanted, and a caregiving mother and father. This raises intriguing issues about the meaning of family, which we will return to in a later chapter.

Infertility is costly, both economically and emotionally. Worldwide, the cost of IVF is highest in the United States, where each attempt runs between \$12,000 and \$15,000. The success rate for women who use their own fresh (rather than frozen) eggs is about 1 in 4 overall, but decreases as mothers get older. IVF results in a live birth in 40% of women under 35 years but in only 5% of women 43–44 years of age (CDC, 2015). Several recent advances in selecting eggs based on their mitochondria or energy levels (an indication of egg health), changing the time of when eggs are harvested for fertilization, and even augmenting egg cells with a bath of mitochondrial cells retrieved from the ovaries show promise for increasing the success rates of IVF (Fragouli et al., 2015; Tilly & Sinclair, 2013; Wu et al., 2015).

Couples report that infertility is stressful as they are going through it, but most couples do not regret going through the process, regardless of outcome. In one study, researchers in Germany followed up with couples 10 years after their fertility treatments. Couples with children showed somewhat greater growth in self-esteem over the 10 years relative to couples without children, but women without children reported greater job satisfaction and indicated that there were positive aspects to not having children (Wischmann et al., 2012). All couples, with and without children, reported similar levels of satisfaction with their friendships, their sex lives, and life in general. A study conducted in Sweden 20 years after women had undergone IVF treatment found somewhat

Figure 4.2 Levels of luteinizing hormone and follicle-stimulating hormone spike and there is a rise in body temperature at about the midpoint of a woman's cycle, signaling ovulation.

negative outcomes, such as higher rates of depression, for women whose treatment was unsuccessful (Vikström et al., 2015). The authors noted that, 20 years after IVF treatment, many women were in a peer group beginning to experience or anticipate grandparenthood, which may have contributed to elevated depression levels.

Coping skills contribute to how successfully individuals and couples readjust their thinking from possible parenthood to parenthood not being a likely life outcome. Those women who maintain a strong desire for children in the years following infertility treatment are more likely to experience adjustment or mental health problems, but

these women represent only a small minority of those who go through infertility treatments (Gamiero et al., 2014; Wischmann et al., 2012). Finally, women seem to fare better when they know that the cause of infertility is not directly attributable to them (Gamiero et al., 2014). Overall, then, despite the stress experienced during treatment for infertility, there does not seem to be significant or long-lasting negative outcomes for most women or couples.

Prenatal Stages

The zygote contains the 46 chromosomes that are the genetic blueprint for the individual's development. It takes about 266 days, or roughly 9 months, for the zygote to become a fetus of billions of cells that is ready to be born. Experts called **embryologists**, who study early growth and development, divide prenatal development into three stages or periods: the germinal period, the embryonic period, and the fetal period. More commonly, parents-to-be and their obstetricians organize pregnancy into trimesters corresponding to the first 3 months, the middle 3 months, and the last 3 months of the prenatal period.

The Germinal Period

The first trimester begins with the **germinal period**, which lasts approximately 2 weeks; the important events of this period are outlined in **Table 4.1**. For the first week or two, the zygote divides many times through mitosis, forming the **blastocyst**, a hollow ball of about 150 cells that is the size of the head of a pin. When the blastocyst reaches the uterus around day 6, it implants tendrils from its outer layer into the blood vessels of the uterine wall. This is quite an accomplishment; only about half of all fertilized ova are successfully implanted in the uterus. In addition, not all implanted embryos survive the early phases of prenatal development. Although estimates vary widely, somewhere between as few as 8% and as many as 50% of pregnancies are short-lived, ending in **miscarriage** (also called spontaneous abortion) before survival outside the womb is possible, with many of these losses occurring before the pregnancy has even been detected (Sadler, 2015; Tulandi, 2015). Many such early losses are because of genetic defects and are, perhaps, the body's natural way of eliminating an embryo or fetus that will not survive.

Table 4.1 Events of the Germinal Period

Day	Event
1	Fertilization usually occurs within 24 hours of ovulation.
2	The single-celled zygote begins to divide 24–36 hours after fertilization.
3	The mass has 12–16 cells and is called a morula; it is traveling down the fallopian tube to the uterus.
4–5	An inner cell mass forms; the entire mass is called a blastocyst and is the size of a pinhead.
6–7	The blastocyst attaches to the wall of the uterus.
8–14	During the second week, the blastocyst becomes fully embedded in the wall of the uterus. It now has about 250 cells.

About a month after conception, this embryo is shown up against a cross-section of the placenta. The umbilical cord is shown at the bottom of the photo, connecting the embryo to its vital source of life in the womb. The eyes are clearly visible, as are the arms, legs, and ear buds. The fingers are just beginning to differentiate, and the mouth is formed.

Mark Alberhasky/RGB Ventures LLC dba SuperStock/Alamy Stock Photo

The Embryonic Period

The first trimester continues with the **embryonic period**, which occurs from the third to the eighth week after conception. During this short time, every major organ takes shape, in at least a primitive form, in a process called **organogenesis** (**Table 4.2**). The layers of the blastocyst

Table 4.2 Events of the Embryonic Period

Week	Event
3	Now an embryo, the person-to-be is just 1/10 of an inch (2 mm) long. It has become elongated, and three layers emerge—the ectoderm, mesoderm, and endoderm.
4	The embryo is so curved that the two ends almost touch. The outer layer (ectoderm) folds into the neural tube. From the mesoderm, a tiny heart forms and begins to beat. The endoderm differentiates into a gastrointestinal tract and lungs. Between days 21 and 28, eyes develop.
5	Ears, mouth, and throat take shape. Arm and leg buds appear. The handplate, from which fingers will emerge, appears. The heart divides into two regions, and the brain differentiates into forebrain, midbrain, and hindbrain.
6–7	The embryo is almost 1 inch long. The heart divides into four chambers. Fingers emerge from the handplate, and primitive facial features are evident. The important process of sexual differentiation begins.
8	Most structures and organs are present. Ovaries and testes are evident. The embryo begins to straighten and assumes a more human appearance.

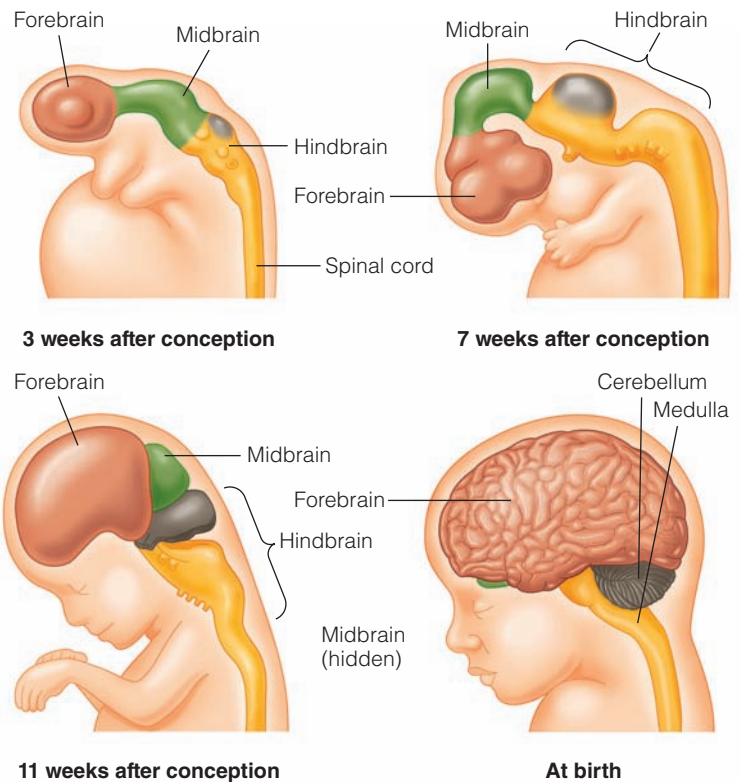

differentiate, forming structures that sustain development. The outer layer becomes both the **amnion**, a watertight membrane that fills with fluid that cushions and protects the embryo, and the **chorion**, a membrane that surrounds the amnion and attaches rootlike extensions called *villi* to the uterine lining to gather nourishment for the embryo. The chorion eventually becomes the lining of the **placenta**, a tissue fed by blood vessels from the mother and connected to the embryo by the umbilical cord. Through the placenta and umbilical cord, the embryo receives oxygen and nutrients from the mother and eliminates carbon dioxide and metabolic wastes into the mother's bloodstream. A membrane called the *placental barrier* allows these small molecules to pass through, but it prevents the large blood cells of embryo and mother from mingling. It also protects the developing child from many harmful substances, but as you will see shortly, it is not infallible; some dangerous substances slip through.

Meanwhile, the cells in the interior of the blastocyst give rise to the ectoderm, mesoderm, and endoderm. These will eventually evolve into specific tissues and organ systems, including the central nervous system (brain and spinal cord) from the ectoderm; muscles, bones, cartilage, heart, arteries, kidneys, and gonads from the mesoderm; and gastrointestinal tract, lungs, and bladder from the endoderm (Sadler, 2015).

Development proceeds at a breathtaking pace. The beginnings of a brain are apparent after only 3–4 weeks, when the neural plate folds up to form the neural tube (■Figure 4.3). The bottom of the tube becomes the spinal cord. “Lumps” emerge at the top of the tube and form the forebrain, midbrain, and hindbrain (■Figure 4.4). The so-called primitive or lower portions of the brain develop earliest. They regulate such biological functions as digestion, respiration, and elimination; they also control sleep–wake states and permit simple motor reactions. These are the parts of the brain that make life possible.

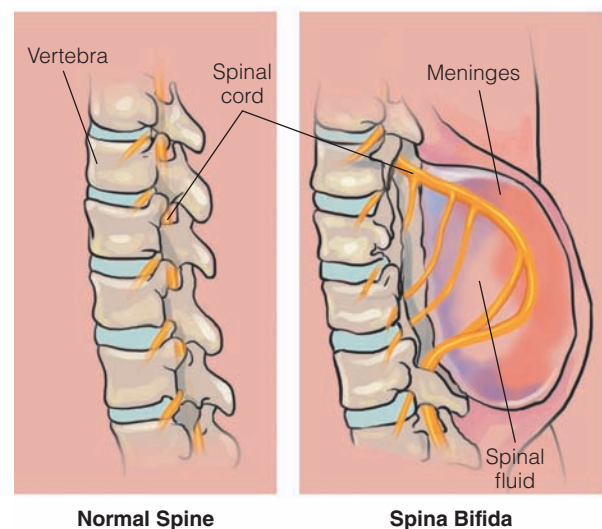

■ **Figure 4.3** The nervous system emerges from the neural plate, which thickens and folds to form the neural groove. When the edges of the groove meet, the neural tube is formed. All this takes place between 18 and 26 days after conception.

■ **Figure 4.4** The brain at four stages of development, showing hindbrain, midbrain, and forebrain.

In approximately 1 out of 2,000 pregnancies, the neural tube fails to fully close (Liptak, 2013). When this happens at the bottom of the tube, it can lead to **spina bifida**, in which part of the spinal cord is not fully encased in the protective covering of the spinal column (■Figure 4.5). Children with spina bifida typically have neurological problems ranging

■ **Figure 4.5** Unlike the normal spine, spina bifida is characterized by an opening in the spinal cord that may be relatively small and invisible, or may be large enough to allow part of the spinal cord and nerves to bulge out of the protective spinal column.

from very mild to severe depending on the location and size of the opening. Failure to close at the top of the neural tube can lead to **anencephaly**, a lethal defect in which the main portion of the brain above the brain stem fails to develop. Neural tube defects occur by 26 days after conception and are more common when the mother is deficient in folate, a type of B vitamin that is critical for normal gene function (Liptak, 2013). There are various reasons why folate levels might become diminished, including use of birth control pills and poor nutrition (deRegnier & Desai, 2010). Folate deficiency has helped highlight the importance of good maternal nutrition for development, about which we will have more to say in a later section.

Other critical organs are also taking shape. Just 4 weeks after conception, a tiny heart not only has formed but also has begun to beat. The eyes, ears, nose, and mouth rapidly take shape in the second month, and buds appear that will become arms and legs. During the second month, a primitive nervous system also makes newly formed muscles contract. Only 60 days after conception, at the close of the embryonic period, the organism is a little over an inch long and has a distinctly human appearance.

The important process of sexual differentiation begins during the seventh and eighth prenatal weeks. First, undifferentiated tissue becomes either male testes or female ovaries: If the embryo inherited a Y chromosome at conception, a gene on it calls for the construction of testes; in a genetic female with two X chromosomes, ovaries form instead. The testes of a male

embryo secrete **testosterone**, the primary male sex hormone that stimulates the development of a male internal reproductive system, and another hormone that inhibits the development of a female internal reproductive system. In the absence of these hormones, the embryo develops the internal reproductive system of a female.

Clearly the embryonic period is dramatic and highly important because it is when the structures that make us human evolve. Yet many pregnant women, either because they do not yet know they are pregnant—like Serena from the chapter opening story—or because they do not appreciate the value of early prenatal care, do not go to a doctor until *after* the eighth week of prenatal development. By this time, it may be too late to prevent the damage that can be caused by an unhealthy lifestyle.

The Fetal Period

The **fetal period** lasts from the ninth week of pregnancy until birth, which means it encompasses part of the first trimester and all of the middle and last trimesters (● Table 4.3). It is a critical

Here we see what the developing fetus looks like in the womb at 10 weeks after conception. Right, we see how things look at this same time on the outside: a “baby bump” is just barely visible on the mother, despite the amazing changes that have been taking place inside.

● **Table 4.3** Events of the Fetal Period

Week	Event
9	Bone tissue emerges, and the embryo becomes a fetus. The head of the fetus looks huge relative to the rest of the body—it takes up about half the total length of the fetus. The fetus can open and close its mouth and turn its head.
10–12	Fingers and toes are clearly formed. External genitalia have developed. Movements have increased substantially—arms and legs kick vigorously, but the fetus is still too small for the mother to feel all these movements. The fetus also shows “breathing” movements with its chest and some reflexes.
13–16	The heartbeat should be audible with a stethoscope. Fetal movements may become apparent to the mother. The fetus is about 4½ inches long, and the skeleton is becoming harder.
17–22	Fingernails and toenails, hair, teeth buds, and eyelashes grow. Brain development is phenomenal, and brainwaves are detectable.
23–25	These weeks mark the age of viability, when the fetus has a <i>chance</i> of survival outside the womb. It is about 12 inches long and weighs about 1 pound.
26–32	The fetus gains weight, and its brain grows. The nervous system becomes better organized.
33–38	The last 6 weeks of a full-term pregnancy bring further weight gain and brain activity. The lungs mature and begin to expand and contract.

period for brain development, which involves three processes: proliferation, migration, and differentiation. **Proliferation** of neurons involves their multiplying at a staggering rate during this period; by one estimate, the number of neurons increases by hundreds of thousands every minute throughout all of pregnancy, with a concentrated period of proliferation occurring between 6 and 17 weeks after conception (du Plessis, 2013; McDonald, 2007). As a result of this rapid proliferation, the young infant has around 100 billion neurons. Another period of proliferation takes place after birth, but this produces an increase in glial cells, not nerve cells. Glial cells function primarily as support cells for neurons.

■ **Figure 4.6** Neurons move to their final destinations in the brain by attaching themselves to strands of glial fiber and then slowly progressing along the surface of the glial fiber.

In **migration**, the neurons move from their place of origin in the center of the brain to particular locations throughout the brain where they will become part of specialized functioning units. Migration is influenced by genetic instructions and by the biochemical environment in which brain cells find themselves. Some neurons migrate passively by getting pushed out of the way to make room for other neurons being born (Johnson & de Haan, 2015). This form of migration is typical for neurons that will end up in the brain stem and thalamus. Other neurons, such as those that will form the cerebral cortex, take a more active role: They travel along the surface of glial cells and detach at programmed destinations in the developing brain (■ **Figure 4.6**). The first neurons to migrate stop at the closest or innermost layer of what will be the cerebral cortex. Other groups of neurons follow suit but need to travel farther until all six layers of the cerebral cortex have been formed. Although this process occurs throughout the prenatal period, much of it occurs between 8 and 15 weeks after conception (McDonald, 2007). Once a neuron reaches its “home,” it begins to communicate with the surrounding neurons.

Along with proliferation and migration of cells, a third process of **differentiation**, or transformation of cells, is occurring (● **Table 4.4** summarizes these events). Neurons may evolve into a particular type or function based on where they land following migration. Alternatively, another theory is that cells may “know” what they are supposed to be and where they are intended to go on their migratory path *before* reaching their final destination (Johnson & de Haan, 2015). Under normal circumstances, this proliferation-migration-differentiation process proceeds smoothly and everything ends up where it should be. In some cases, though, as we’ll see later in this chapter, cells get slowed down or sidetracked along their migratory path or they do not properly differentiate at their endpoint. This can lead to a nervous system that does not function as well as it could (McDonald, 2007).

Organ systems that formed during the embryonic period continue to grow and begin to function. Harmful agents will no longer cause major malformations because organs have already

● **Table 4.4** Processes of Prenatal Brain Development

Process	Explanation
Proliferation	An intense period of cell growth, originating from stem cells undergoing rapid cell division.
Migration	Cells move or travel to their intended location in the nervous system. Chemical signals may serve as a neural GPS, guiding cells to their destination.
Differentiation	Cells change or transform into a particular type. At their destination, they set up camp and begin to communicate with surrounding neurons.

formed, but they can stunt the growth of the fetus and interfere with the wiring of its rapidly developing nervous system.

In the third month of pregnancy, distinguishable external sex organs appear, the bones and muscles develop, and the fetus becomes frisky: By the end of the first trimester of pregnancy, it moves its arms, kicks its legs, makes fists, and even turns somersaults in its own little amniotic fluid-filled gymnasium. The mother probably does not yet feel all this activity because the fetus is still only about 3 inches long. Nonetheless, all of this moving around and bumping into the walls of the uterus may help create a “body sense” that will later evolve into a meaningful sense of self (Piontelli, 2015). Other behaviors are also evident at this stage: swallowing, yawning, hiccupping, and urinating. These early actions contribute to the proper development of the nervous system, respiratory system, digestive system, and other systems of the body, and they are consistent with the behaviors that we observe *after* birth (Piontelli, 2015).

During the second trimester, more refined activities such as occasional thumb sucking appear and fetuses spend more time touching themselves, especially their faces (Piontelli, 2015). By the end of this period the sensory organs are functioning: Premature infants as young as 25 weeks respond to loud noises and bright lights (Allen & Capute, 1986; Sadler, 2015). At about 23 weeks after conception, midway through the fifth month, the fetus reaches the **age of viability**, when survival outside the uterus is possible *if* the brain and respiratory system are sufficiently developed. The age of viability is earlier today than at any time in the past because medical techniques for keeping fragile babies alive have improved considerably over the past few decades. Although there are cases of “miracle babies” who survive severely premature birth, many infants born at 22–25 weeks do not survive, and of those who do, many experience chronic health or neurological problems. Among infants born at the cusp of survivability—22–23 weeks—92% do not survive beyond a few hours or

days despite the use of aggressive medical therapies (Swamy et al., 2010). At 23 weeks, 25% of premies survive, and with just one more week in the womb, the survival rate jumps to 55% (Berger et al., 2012). Thus, the age of viability is an indicator of when survival *may be possible*, but it is by no means a guarantee of life or health. Further, as ■ **Figure 4.7** shows, the odds of survival may also depend on the country where you live and even the birthing location within a country. Such differences likely reflect variations in how aggressively premature infants are resuscitated and treated, something we will say more about later in this chapter (Berger et al., 2012; Serenius et al., 2013).

In terms of growth, it is primarily all about length during the second trimester and then weight during the third trimester. Not surprisingly, this increased size of the fetus means the little bundle of joy gradually makes its presence known to mom as it tries to move within the increasingly tight space of the womb. The third trimester is also critical in the development of the brain, as is the entire prenatal period (more on this in Chapter 5). Early in pregnancy, the basic architecture of the nervous system is developed. During the second half of pregnancy, neurons not only multiply at an astonishing rate (proliferation) but they also increase in size and develop an insulating cover, **myelin**, that improves their ability to transmit signals rapidly. Most importantly, guided by both a genetic blueprint and early sensory experiences, neurons connect with one another and organize into working groups that control vision, memory, motor behavior, and other functions. For good reason, parents should be concerned about damage to the developing human during the first trimester, when the brain and other organs are forming. However, they should not overlook the significance of the second and third trimesters,

■ **Figure 4.7** Percentage survival at 22, 23, 24, and 25 weeks gestation. At 22 weeks gestational age, the chances of survival are very bleak. But with each additional week in the womb, the odds of survival improve. There are also cross-national variations: Babies born very prematurely in Sweden have the best chances of survival relative to similarly premature babies born in one of the other countries shown here.

Trends and centre-to-centre variability in survival rates of very preterm infants (<32 weeks) over a 10-year-period in Switzerland. *Archives of Disease in Childhood-Fetal and Neonatal Edition*, 97, F323–F328.

which are critical to normal brain functioning and therefore to normal development.

As the brain develops, the behavior of the fetus becomes more like the organized and adaptive behavior seen in the newborn. For example, Janet DiPietro and her colleagues (2006, 2007) assessed heart rates and activity levels at various points prenatally and postnatally. Heart rate was relatively stable from the prenatal period into early childhood. By 36 weeks of gestation, heart rate activity and movement become increasingly organized into coherent patterns known as *infant states*. Fetuses whose heart rates and movements were concordant (that is, matched) at 36 weeks showed better regulation of their behavioral states at 2 weeks old. They were more alert, less irritable, better able to sustain their attention, and more likely to maintain control even during stressful parts of a postnatal examination. Beyond this, fetal heart rate variability was associated with mental development at age 2 and language development at age 2½. In particular, fetuses with slower and more variable heart rates had higher levels of mental and language development in early childhood compared with those who had faster and less variable heart rates. The researchers speculate that slow and variable heart rates may reflect optimal regulation of the nervous system.

With age, fetal heart rates also become increasingly responsive to such stimuli as a vibrator placed on the mother's abdomen or loud noises (DiPietro et al., 1996b). While it might be tempting to conclude that these fetal reactions and movements signify being awake, experts argue that fetuses are never truly awake (see Piontelli, 2015). Instead, they spend most of their time snoozing, either in quiet sleep or active sleep. As pregnancy progresses, fetuses experience “micro-awakenings,” when they might briefly open their eyes or grimace, but even these are short-lived and cannot be equated directly to the awake state of an infant. Most fetuses settle into a predictable pattern of quiet sleep-active sleep by 27–30 weeks. Such findings are important because they point to greater organization of the nervous system at about the time when premature infants are typically well equipped to survive. As the nervous system becomes more organized, so does behavior.

Interestingly, different fetuses display consistent differences in their patterns of heart rate and movement, and researchers have detected correlations between measures of fetal physiology and behavior and measures of infant temperament (DiPietro et al., 1996a, 2007; Werner et al., 2007). For example, active fetuses turn out to be active, difficult, and unpredictable babies, and fetuses whose states are better organized are also better regulated at 3 months old, as indicated by their waking fewer times during the night. This shows that newborn behavior does not spring from nowhere; it emerges long before birth. There is

The behaviors and facial expressions of the fetus (*left*, from 3D ultrasound) are remarkably similar to those exhibited by the infant after birth (*right*).

Thierry Berrod/Mona Lisa Production/Science Source

a good deal of continuity between prenatal behavior and postnatal behavior.

By the middle of the ninth month, the fetus is so large that its most comfortable position in cramped quarters is head down with limbs curled in (the “fetal position”). The mother's uterus contracts at irregular intervals during the last month of pregnancy. When these contractions are strong, frequent, and regular, the mother is in the first stage of labor and the prenatal period is drawing to a close. Under normal circumstances, birth will occur within hours.

● Checking Mastery

1. What is conception, and what techniques can be used to assist conception?
2. How does the development of the brain and nervous system unfold during the embryonic and fetal periods?
3. When is survival outside the womb possible?

● Making Connections

1. What ethical concerns should be considered with the use of artificial reproductive technologies? As technologies become more advanced in the future, what additional concerns may arise?
2. Based on what you know about the developments during the prenatal period, where would you focus attempts to optimize prenatal care and why?

4.2

The Prenatal Environment and Fetal Programming

LEARNING OBJECTIVES

- Discuss the concept of fetal programming, and evaluate its usefulness in understanding connections between prenatal events and postnatal outcomes.
- Organize teratogens according to the seriousness of their impact on development (that is, from major structural abnormalities to small or undetermined effects).
- Summarize characteristics of the parents-to-be that may influence pregnancy and its outcomes.

The mother's womb is the prenatal environment for the unborn child. Just as children are influenced by their physical and social environments, so too is the fetus affected by its surroundings. The physical environment includes everything from the molecules that reach the fetus's bloodstream before birth to the architecture of a home to the climate outside it. The social environment includes all the people who can influence and be influenced by the developing person and the broader culture. Although early theorists tended to view environment as a set of forces that shaped the individual, as though a person were just a lump of clay to be molded, we now know this is not the case. Recall the concept in Chapter 2's discussion of the bioecological model of *reciprocal influences*: People shape their physical and social environments and are, in turn, affected by the environments they have helped create. For example, if a woman uses cocaine during pregnancy, her newborn may be extraordinarily fussy: Environment has affected development. But a fussy baby is likely to affect his environment by irritating his mother, who then expresses her tenseness in her interactions with him; this makes him fussier, which aggravates his mother even more, and her aggravation, in turn, makes him even crankier. Such transactions between person and environment begin at the moment of conception. When all is right, the prenatal environment provides just the stimulation and support needed for the fetus to mature physically and to develop a repertoire of behaviors that allow it to seek more stimulation, which in turn contributes to the development of more sophisticated behavior.

The developing embryo-then-fetus is a vulnerable little creature. Where it was once believed that the placenta served as a screen to protect the fetus from harmful substances, we now know that this is not the case. Research increasingly shows that events of the prenatal period can have lifelong effects on physical health and mental development. In Chapter 3, we introduced the idea of *epigenetic effects* whereby gene expression may be modified by environmental factors. The period of greatest environmental influence is during the prenatal period when growth and changes are occurring at an astonishingly fast rate. During this time, factors originating inside the mother, such as her hormone levels or immune system functioning, as well as factors originating outside the mother, such as exposure to pollution, can alter the expression of genes throughout life (see Boyce & Kobor, 2015). As we explained in Chapter 3, experience leaves its "fingerprint" on top of certain genes in certain cells, which influences whether those genes are turned on or not.

A growing body of research indicates that developmental outcomes may be influenced by **fetal programming** brought about by such epigenetic effects of the environment (Boyce & Kobor, 2015). The general idea of fetal programming is that environmental events and maternal conditions during pregnancy may alter the expected genetic unfolding of the embryo/fetus or reset its physiologic functions. As a result of these alterations, prenatal experience can change a person's physiology and the wiring of the brain and influence how the individual responds to postnatal events. Conditions of the prenatal period, then, set the stage for susceptibility to later health and mental health problems, perhaps decades down the road. But that's not all.

As **Figure 4.8** illustrates, it is not only the unborn child who may be affected by prenatal environmental factors: The offspring of the unborn child may also be affected. Through epigenetic codings carried on the DNA of the reproductive cells of the developing fetus, a pregnant woman's health, diet, and environment may adversely affect her future grandchildren

Figure 4.8 A woman's experiences during pregnancy can impact not only her own health, but that of her unborn baby *and* her future grandchildren.

(Shrivastava et al., 2012). Epigenetics is a critical component in understanding fetal programming (Barouki et al., 2012; Sookoian et al., 2013). According to research with animals and increasingly humans, prenatal imbalances in nutrition and exposure to environmental toxins may alter molecular pathways in ways leading to disease and health challenges later in life. Adult health and mental health conditions such as obesity, heart disease, and schizophrenia may arise, in part, from the prenatal environment and fetal programming (Boyce & Kobor, 2015). Unfortunately, adverse prenatal conditions such as poor nutrition and exposure to pollution disproportionately affect women—and their children—who live in poverty. The growing body of research showing life-long effects of epigenetic processes helps contribute to our understanding of the oft-seen multigenerational impacts of poverty (Boyce & Kobor, 2015). On the bright side, though, *good* health may also have its origins in the prenatal period, suggesting that this is a period of opportunity, not just a period of vulnerability.

How then can development during this period be optimized? What hazards does the fetus face? In the next sections, your main mission is to discover the extent to which early environmental influences, interacting with genetic influences, make or break later development. The nature–nurture issue, then, is the central question to consider when thinking about prenatal development and its influence on the developing person. Early exposure to certain environmental factors interacts with genetic makeup throughout the life span to make us who we are. If a common genetic heritage (species heredity) can make different human beings alike in some respects, so can similar environments. If unique genes make one person different from another, so do unique experiences.

Teratogens

A **teratogen** is any disease, drug, or other environmental agent that can harm a developing fetus (for example, by causing deformities, blindness, brain damage, or even death). The list of teratogens has grown frighteningly long, and the environment contains many potential teratogens whose effects on development have not yet been assessed. Before considering the effects of some major teratogens, however, let us emphasize that *only 15% of newborns have minor problems, and even fewer—perhaps 3%—have more significant anomalies due to teratogens* (Sadler, 2015). We will start with a few generalizations about the effects of teratogens, which we will then illustrate with examples:

- **Critical period.** The effects of a teratogenic agent are worst during the critical period when an organ system grows most rapidly.
- **Dosage and duration.** The greater the level of exposure and the longer the exposure to a teratogen, the more likely it is that serious damage will occur.
- **Genetic makeup.** Susceptibility to harm is influenced by the genetic makeup of the unborn child as well as the mother's genotype. Some fetuses are more (or less) resistant to teratogens and some mothers are more (or less) able to detoxify teratogens (Cassina et al., 2012). Therefore, not all embryos and fetuses are affected, nor are they affected equally, by a teratogen.

- **Environment.** The effects of a teratogen depend on the quality of both the prenatal and the postnatal environments.

Look more closely at the first generalization, which is particularly important. A period of rapid growth is a **critical period** for an organ system—a time during which the developing organism is especially sensitive to environmental influences, positive or negative. As you will recall, organogenesis takes place during the embryonic period (weeks 3–8 of prenatal development). As **Figure 4.9** shows, it is during this time—before many women even realize they are pregnant—that most organ systems are most vulnerable to damage. Moreover, each organ has a critical period that corresponds to its own time of most rapid development (for example, weeks 3–6 for the heart and weeks 4–7 for the arms and fingers). Once an organ or body part is fully formed, it is usually less susceptible to damage. However, because some organ systems—above all, the nervous system—can be damaged throughout pregnancy, *sensitive periods* might be a better term than *critical periods*.

Drugs

The principles of teratology can be illustrated by surveying just a few of the many drugs—prescription, over-the-counter, and social—that can disrupt prenatal development. As many as 80% of pregnant women take either prescription or over-the-counter medications during pregnancy (Mitchell et al., 2011; Sadler, 2015). Women from lower socioeconomic backgrounds are especially likely to have a prescription during the time they are pregnant, with antibiotics the most commonly prescribed drug (Palmsten et al., 2015). Under a doctor's close supervision, medications used to treat ailments and medical conditions are usually safe for mother and fetus. However, certain individuals exposed to certain drugs in certain doses at certain times during the prenatal period are damaged for life.

Thalidomide. There is perhaps no more striking example of drug effects on prenatal development than **thalidomide** (Martinez-Frias, 2012). Approximately 50 years ago, this mild tranquilizer was widely used in Europe to relieve morning sickness (the periodic nausea and vomiting many women experience during pregnancy). Presumably, the drug was safe; it had no ill effects in tests on pregnant rats. Tragically, however, the drug had adverse effects on humans.

Thousands of women who used thalidomide during the first 2 months of pregnancy gave birth to babies with all or parts of their limbs missing, with the feet or hands attached directly to the torso like flippers, or with deformed eyes, ears, noses, and hearts. It soon became clear that there were critical periods for different deformities. If the mother had taken thalidomide 20–22 days after conception (34–36 days after the first day of a woman's last menstrual period), her baby was likely to be born without ears. If she had taken it 22–27 days after conception, the baby often had missing or small thumbs; if thalidomide was taken between 27 and 33 days after conception, the child was likely to have stunted legs or no legs. And if the mother waited until 35 or 36 days after conception before using thalidomide, her baby was usually not affected. Thus, thalidomide had specific effects on development,

Figure 4.9 Sensitive periods of prenatal development. Teratogens are more likely to produce major structural abnormalities during the third through the eighth prenatal week. Note, however, that many organs and body parts remain sensitive to teratogenic agents throughout the 9-month prenatal period.

depending on which structures were developing when the drug was taken.

Thalidomide had been banned for years, but it is again being prescribed by physicians, this time for treatment of conditions associated with leprosy, acquired immunodeficiency syndrome (AIDS), tuberculosis, and some forms of cancer. Given its tragic past association with birth defects, the manufacturers of thalidomide have taken significant steps to ensure it is used safely, including stamping each pill with a drawing of a pregnant woman inside a circle with a diagonal line through it (the universal “no” symbol) and including a picture of a baby with the characteristic stunted limbs on the packaging accompanying the pills. In addition, the prescribing physician and the patient must both abide by guidelines developed specifically for this drug (Celgene Corporation, 2016).

Tobacco. Warning labels on cigarette packages that smoking may damage fetuses have resulted in a decline, but not an absence, of smoking during pregnancy. During the first trimester, about 20% of mothers smoke, but by the third semester, this has dipped to 13% of pregnant women. Roughly 25% of non-pregnant women smoke, so clearly some women adjust their smoking behavior during their pregnancies (CDC, 2015;

Substance Abuse & Mental Health Services Administration, 2014). Rates of smoking during pregnancy vary by age and the race or Hispanic origin of the mother, with young white women most likely to smoke, and Asian and Hispanic women of any age least likely to smoke during pregnancy (Yang et al., 2014). Interestingly, the more that Asian and Hispanic women interact with white women, the more likely they—Asian and Hispanic women—are to smoke during pregnancy (Yang et al., 2014).

The effects of smoking during pregnancy are varied and may include:

- increased risk of miscarriage
- prematurity, growth retardation, and small size
- respiratory problems
- cleft lips (an opening in the top lip) and cleft palates (an opening in the roof of the mouth)
- central nervous system (CNS) impairment
- later health problems such as inflammatory bowel disease

Whether, and to what extent, infants experience ill effects from prenatal exposure to smoking depends, as our teratogenic principles would predict, on the length of exposure and the “dose.” For example, more than half of infants born to heavy smokers (20 or more cigarettes a day) end up in neonatal intensive care and experience some degree of CNS impairment. Infants born to lighter smokers (5 cigarettes a day) may not have the same degree of CNS impairment, but they are more irritable and score lower on standard assessments of behavioral functioning than infants born to nonsmokers (Behnke et al., 2013). The more a woman smokes during pregnancy, the more likely it is that her infant will experience growth retardation and neurological problems (see Behnke et al., 2013). Heavier smoking also raises the risk of **sudden infant death syndrome (SIDS)**, in which a sleeping baby suddenly stops breathing and dies. Further, the odds that problems from prenatal cigarette exposure will persist into childhood are greater when the mother was a heavier smoker (Burstyn et al., 2012; Duijts et al., 2012).

Smoking causes these effects by restricting blood flow to the fetus, which in turn reduces the levels of growth factors, oxygen, and nutrients that reach the fetus, leading to a variety of outcomes. It's not just the nicotine in cigarettes that contributes to the poorer outcomes for exposed infants. Cigarettes contain more than 4,000 other chemicals and smoking cigarettes produces carbon monoxide, which reduces the flow of blood and oxygen to the fetus.

A rather alarming conclusion from some researchers is that chronic prenatal exposure to nicotine—a legal substance—may have more negative effects on CNS development than sporadic exposure to the illegal drug cocaine (Bada et al., 2005; Slotkin, 1998). But there is good news: Even women who start their pregnancies as smokers can improve the outcome for their babies by quitting smoking during their pregnancy (Polakowski, Akinbami, & Mendola, 2009). The benefits are greatest for those women who quit during their first trimester but are also apparent for the babies of mothers who quit during their second trimester. Thus, women should be encouraged and supported to stop or reduce smoking during pregnancy.

Finally, we must consider that women who smoke during pregnancy are likely to be white or American Indians or Alaska

Natives, young, low-income, and less educated than women who do not smoke during pregnancy (Substance Abuse & Mental Health Services Administration, 2014). It may be that some of these other factors act independently or in conjunction with cigarette smoking to create the less-than-ideal outcomes seen among these exposed infants. A clever study by British researchers Frances Rice, Anita Thapar, and their colleagues (2007, 2009) helps clarify the connection between maternal smoking during pregnancy and genetic influences on some of the outcomes observed in infants and young children. They studied two groups of children conceived through in vitro fertilization: children who were the biological offspring of the mother (that is, the mother's own eggs were retrieved, fertilized, and then implanted in her womb) and children who were not biologically related to the mother (that is, a donor egg was fertilized and then implanted in a woman's uterus). The researchers looked at two dependent variables: birth weight and antisocial behavior at around age 6. Their findings were clear: Low birth weight occurred among infants whose mothers smoked during pregnancy regardless of whether the infant was biologically related to the mother or not (own egg versus donor egg). In contrast, elevated antisocial behaviors occurred among children whose mothers smoked during pregnancy only when they were biologically related to their mother (i.e., her own egg had been used), not when they were biologically unrelated to their mother (i.e., a donor egg had been used). Thus, a prenatal environment of smoke by-products does not increase antisocial behavior, but the mother's genetic contribution to her child does. There may be, for example, certain genetically influenced personality characteristics that make it more likely that a woman will smoke and that also contribute to antisocial behaviors in her offspring.

Alcohol. Alcohol consumed by the mother readily crosses the placenta, where it can directly affect fetal development in various ways. For one, prenatal alcohol exposure disrupts the normal process of neuronal migration, leading to cells that do not end

A young child with fetal alcohol syndrome, showing some of the characteristic facial features such as thin upper lip, low nasal bridge, short nose, and somewhat flat midface.

Rick's Photography/Shutterstock.com

up at their proper final destination in the nervous system. Prenatal alcohol exposure can also lead to neuronal death and impair the function of the glial cells—those nonneuronal cells that are needed to support and nourish neurons (Goodlett & Horn, 2001).

The most severe outcome of fetal alcohol exposure is a cluster of symptoms dubbed **fetal alcohol syndrome (FAS)**, with noticeable physical symptoms such as a small head and distinctive facial abnormalities including thin upper lip, short nose, and flat midface. Children with FAS are smaller and lighter than normal, and their physical growth lags behind that of their age-mates. Most importantly, children with FAS also show signs of CNS damage. As newborns, they are likely to display excessive irritability, hyperactivity, seizures, or tremors. Most children with FAS score well below average on IQ tests throughout childhood and adolescence, and many also exhibit hyperactive behavior and attention deficits (Bhatara, Loudenberg, & Ellis, 2006). As adults, many continue to experience problems, with higher rates of unemployment and psychiatric disorders compared to their peers who had not been diagnosed with FAS (Rangmar et al., 2015). Importantly, though, not every child with FAS exhibits problems in adulthood, raising the intriguing question of what factors may lead to the different outcomes. Before considering this question, though, how widespread is alcohol use during pregnancy?

Estimates of alcohol use during pregnancy vary widely from country to country, as well as across different regions within a country. Most surveys indicate approximately 10% of pregnant women in the United States drink some alcohol during pregnancy, about 3% admit to binge drinking, and less than 1% report heavy drinking (Substance Abuse & Mental Health Services Administration, 2014). As a result, as many as 3 in 1,000 babies in the United States are born with FAS and suffer its symptoms all their lives. In Italy, where many people partake in daily alcohol consumption with meals, the incidence of FAS and its milder forms may be as high as 37–47 out of 1,000 children (May et al., 2011). South Africa's Western Cape province region has as many as 70–80 FAS cases per 1,000 babies, but perhaps the highest FAS rates are found in some remote Aboriginal regions of western Australia, where the prevalence has been found to be 120 of 1000 children (Fitzpatrick et al., 2015).

Children who were exposed prenatally to alcohol but do not have FAS experience milder alcohol-related effects labeled either *fetal alcohol effects* or *alcohol-related neurodevelopmental disorder* (Nulman et al., 2007). These individuals do not have all the features of FAS but have physical, behavioral, or cognitive problems or a combination of these. How much drinking does it take to harm an unborn baby? In keeping with the dosage principle of teratology, mothers who consume larger quantities of alcohol are at greater risk for having children with alcohol-related complications (Roccella & Testa, 2003; Streissguth et al., 1999). The pattern of drinking is also important. Binge drinking (for women, consuming four or more drinks during a single session) has more negative effects on fetal development than consuming the same number of drinks across multiple sessions (Fraser et al., 2012; Jacobson & Jacobson, 1999). This makes sense when you consider that consuming four drinks in one evening results in higher blood alcohol levels for both mother and fetus than consuming one drink on each of four evenings. Finally, in keeping with the critical-period principle of teratogens, the effects of alcohol depend on which systems are developing at the time of exposure. The facial abnormalities associated with FAS result from consumption during the first

trimester, more precisely the second half of the first trimester, when the face and skull bones are forming (Feldman et al., 2012). During the second and third trimesters, there is much fetal growth as well as rapid brain development; thus, alcohol consumption during this latter part of pregnancy is likely to stunt growth and brain development.

No amount of drinking seems to be entirely safe, leading the American Academy of Pediatrics to issue a statement that pregnant women and those considering pregnancy should refrain from all alcohol consumption (see *Light Drinking During Pregnancy*, 2015). Even a mother who drinks less than an ounce a day is at risk to have a sluggish or placid newborn whose mental development is slightly below average (Jacobson et al., 1993). Other research shows that exposure to less than one drink per week during pregnancy is associated with mental health problems during childhood, at least among girls (Sayal et al., 2007). What is more, there is no well-defined critical period before or after which fetal alcohol effects cannot occur; drinking late in pregnancy can be as risky as drinking soon after conception.

Let's go back, now, to that intriguing question of why some offspring of drinking mothers suffer ill effects but others do not. To answer this, you need to consider the nature–nurture issue again. First, the chances of damage depend partly on the mother's physiology—for example, on how efficiently she metabolizes alcohol and therefore how much is passed to the fetus (Shepard & Lemire, 2010). Complicating the situation, problem drinkers often have other issues that can aggravate the effects of alcohol on the fetus or cause independent damage that can be difficult to disentangle from the effects of alcohol alone (Rodriguez et al., 2009). Women who consume unsafe levels of alcohol during pregnancy are also more likely to use drugs other than alcohol, smoke cigarettes, have inadequate prenatal care, and be young and single. Combining alcohol use with other risky behaviors increases the odds of pregnancy complications (Odendaal et al., 2009). In addition, consistent with the third principle of teratogenic effects, the embryo's genetic makeup and physical condition influence its ability to resist and recover from damage. Fraternal twins are 64% concordant (i.e., matched) for signs of FAS, whereas identical twins are 100% concordant (Streissguth & Dehaene, 1993). Thus, for example, one fraternal twin may show all the physical abnormalities associated with FAS, but the other twin, although exposed to the same prenatal environment, may show almost none; by contrast, identical twins respond very similarly when exposed to alcohol prenatally (Eberhart & Harris, 2013). As the third principle of teratology states, then, both the child's and the mother's characteristics influence the extent to which a given teratogen proves damaging. Thus, the genetic makeup of both the mother and the child interact with environmental forces to determine the effects of alcohol on development.

Finally, note that it is not just the mother's use of alcohol that can adversely affect development. Some research suggests that a father's use of alcohol can influence fetal development through transmission of the father's genes to his offspring (Knopik et al., 2009). How might this occur? There are two possibilities. One is that a man's use of alcohol, as well as other substances, may cause mutations of some DNA that is then passed to the offspring. A second possibility is that epigenetic effects are the culprit. That is, a father's alcohol use may alter the epigenome that “sits” on top of the genome, altering the expression of the gene, which may then be transmitted to the offspring through the father's sperm (Champagne, 2010; Curley, Mashoodh, &

Champagne, 2011). We should also note, however, that other research suggests that paternal drinking affects development indirectly through poor parenting (Knopik et al., 2009; Leonard & Das Eiden, 2002). Fathers who use or abuse alcohol may have parenting styles that differ from those of fathers who do not use or abuse alcohol. Thus, further research needs to be done to determine the pathways through which a father's alcohol use relates to his offspring's development.

Cocaine. Although there is no “cocaine syndrome” with characteristic physical abnormalities such as those associated with FAS, cocaine use can damage the fetus. It can cause spontaneous abortion in the first trimester of pregnancy and premature detachment of the placenta or fetal strokes later in pregnancy. Cocaine also contributes to fetal malnourishment, retarded growth, and low birth weight (Gouin et al., 2011; March of Dimes, 2015). At birth, a small proportion of babies born to cocaine users experience withdrawal-like symptoms such as tremors and extreme irritability and have respiratory difficulties (Patrick et al., 2012).

Cocaine-exposed infants show increased activity levels as well as greater reactivity in response to stimulation during their first year (Fallone et al., 2014). Infants may also show deficits on measures

of information processing. Some of the consequences of prenatal cocaine exposure persist into adolescence, with higher rates of delinquent behavior and continued deficits on problem solving and abstract reasoning tasks (Richardson et al., 2015). For problems that persist, it is unclear whether they are caused by the prenatal exposure to cocaine or by other prenatal or postnatal risk factors that affected infants may experience as the children of substance-abusing parents (Bandstra et al., 2010). For instance, as noted earlier for women who consume alcohol during pregnancy, women who use cocaine during pregnancy also tend to engage in more than one risky behavior. In addition, cocaine-using mothers are less attentive to their babies and engage in fewer interactions with them during the first year than non-drug-using mothers or mothers who use drugs other than cocaine (Minnes et al., 2005). Mother-child interactions continue to be of lower quality throughout early childhood (Mansoor et al., 2012). Children exposed to prenatal cocaine who are raised by adoptive or foster parents display fewer language problems at age 10 than those raised by their biological mother, suggesting that the quality of the postnatal environment matters (Lewis et al., 2011).

● **Table 4.5** catalogs several substances and their known or suspected effects on the child. What should you make of these

● **Table 4.5** Some Drugs Taken by the Mother that Affect the Fetus or Newborn (in addition to alcohol and tobacco, discussed in the chapter)

Drug	Effects
Accutane	Prescribed as an acne treatment, Accutane can result in small, abnormally shaped ears, cleft palate, facial defects, and small lower jaw.
Antiepileptic drugs	Drugs such as phenytoin (Dilantin), phenobarbital (Luminal), and carbamazepine (Tegretol), used to treat seizures, increase the incidence of cleft lip and palate, neural tube defects, kidney disease, and restricted growth (Włodarczyk et al., 2012). Approximately 1 in 12 infants exposed prenatally to antiepileptic drugs will develop a birth defect.
Antidepressant drugs	Treating pregnant women with antidepressant drugs such as Prozac or Zoloft (selective serotonin reuptake inhibitors) may place their infants at greater risk for heart malformations, neural tube defects, low-birth weight, and respiratory distress.
Over-the-counter pain/fever reducers (acetaminophen, aspirin, and ibuprofen)	An occasional low dose may be okay, but used in large quantities, such drugs may cause neonatal bleeding and gastrointestinal discomfort. Large amounts of these over-the-counter pain relievers have been associated with low birth weight, prematurity, and increased risk of miscarriage (Hernandez et al., 2012).
Chemotherapy drugs	Such drugs cross the placenta and attack rapidly dividing cells. They can increase malformations and lead to miscarriage, particularly when administered to the mother during the first trimester.
Marijuana	Heavy use of marijuana has been linked to premature birth, low birth weight, and mild behavioral abnormalities such as irritability at birth (Janisse et al., 2014). It may lead to small deficits in general intelligence as well as increased risk of hyperactivity (Brown & Graves, 2013).
Narcotics	Addiction to heroin, codeine, methadone, or morphine increases the risk of premature delivery and low birth weight. The newborn is often addicted and experiences potentially fatal withdrawal symptoms (e.g., vomiting and convulsions). Longer-term cognitive deficits are sometimes evident.
Sex hormones	Birth control pills containing female hormones have been known to produce heart defects and cardiovascular problems, but today's pill formulas are safer. Progesterone in drugs used to prevent miscarriage may masculinize the fetus. Diethylstilbestrol—the first synthetic estrogen—was once prescribed to prevent miscarriage, but it led to increased risk of cervical cancer and created infertility and pregnancy problems in exposed offspring (DESAction, 2015).
Stimulants	Caffeine, found in coffees, teas, and many sodas, is a stimulant and diuretic. As such, it can increase blood pressure, heart rate, and urination. Heavy caffeine use has been linked to miscarriages, higher heart rates, growth restriction, and irritability at birth, but it does not seem to have long-lasting effects on development (Loomans et al., 2012). Cocaine is an illegal stimulant that can cause premature delivery, spontaneous abortion, and low birth weight, and it may result in later learning and behavioral problems (see main text).

Sources: Modified from Creasy et al., 2013; Paulson, 2013; Liptak, 2013; Sadler, 2015; Shepard & Lemire, 2010.

findings? You now understand that drugs do not damage all fetuses exposed to them in a simple, direct way. Instead, complex transactions between an individual with a certain genetic makeup and the prenatal, perinatal, and postnatal environments influence whether or not prenatal drug exposure does lasting damage. Still, women who are planning to become pregnant or who are pregnant should avoid all drugs unless they are prescribed by a physician and essential to health. Fortunately, most women have gotten the message and significantly alter their behavior during pregnancy to eliminate or reduce such unhealthy practices as drinking alcohol and smoking cigarettes and to increase healthy behaviors such as eating nutritious foods and getting regular prenatal care.

Diseases and Infections

Just as drugs can jeopardize the prenatal environment, so can diseases and infections. Here we take a look at four problems—rubella, diabetes, AIDS, and syphilis—that illustrate principles of teratogens. ● **Table 4.6** summarizes several other maternal conditions that may affect prenatal development.

Rubella. In the early 1940s, a doctor discovered that many infants born to women affected by **rubella** (German measles) during pregnancy had one or more of a variety of defects, including blindness, deafness, heart defects, and intellectual disability. Because rubella was fairly common, there were enough cases for doctors to see that the environment of the womb leaves the fetus vulnerable to outside influences. Rubella is most dangerous during the first trimester, a critical period in which the eyes, ears, heart, and brain are rapidly forming. Nearly 25% of pregnant women with rubella miscarry or experience a fetal death and some may choose to terminate the pregnancy out of concern

for harmful consequences of the virus on the developing fetus (Andrade et al., 2006; Thompson et al., 2014). Yet not all babies whose mothers had rubella, even during the most critical period of prenatal development, will have problems. Birth defects occur in two-thirds of babies whose mothers had the disease in the first 2 months of pregnancy, in about half of those infected in the third month, and in relatively few of those infected in the fourth or fifth months (Waldorf & McAdams, 2013). Consistent with the critical-period principle, damage to the nervous system, eyes, and heart is most likely during that part of the first 8 weeks of pregnancy (the period of the embryo) when each of these organs is forming, whereas deafness is more likely when the mother contracts rubella in weeks 6–13 of the pregnancy. Today, doctors stress that a woman should not try to become pregnant unless she has been immunized against rubella or has already had it. As a result of successful immunization programs, many women are now immune to this previously common infection. Nevertheless, recent outbreaks of rubella have been reported in various spots around the world, including Italy and Netherlands in 2013 and Germany in 2015, among others (European Centre for Disease Prevention and Control, 2015).

Diabetes. Diabetes is a fairly common pregnancy complication, with most cases arising during pregnancy (gestational diabetes) rather than from preexisting diabetes. Diabetes results from elevated blood glucose levels. When glucose levels are well controlled with diet, there are few ill effects on the developing fetus. But in poorly controlled maternal diabetes, there is increased risk of premature delivery, stillbirth or miscarriage, immature lung development, congenital heart defects, and neural tube defects. Maternal diabetes is also associated with large-for-date fetuses,

● **Table 4.6** Maternal Illnesses and Conditions that May Affect an Embryo, Fetus, or Newborn

Disease or Condition	Effects
Chickenpox	Chickenpox can cause spontaneous abortion, premature delivery, and slow growth, although fewer than 2% of exposed fetuses develop limb, facial, or skeletal malformations.
Chlamydia	Chlamydia can lead to premature birth, low birth weight, eye inflammation, or pneumonia in newborns. This most common STI is easily treatable.
Cytomegalovirus (CMV)	This common infection shows mild flulike symptoms in adults. About 25% of infected newborns develop hearing or vision loss, mental retardation, or other impairments, and 10% develop severe neurological problems or even die.
Gonorrhea	This STI attacks the eyes of the infant during birth; blindness is prevented by administering silver nitrate eyedrops to newborns.
Herpes simplex (genital herpes)	This disease may cause eye and brain damage or death in the first trimester. Mothers with active herpes may be advised to undergo cesarean deliveries to avoid infecting their babies during delivery, because 85% of infants born with herpes acquire the virus during birth through the birth canal.
Influenza (flu)	The more powerful strains can cause spontaneous abortions or neural abnormalities early in pregnancy that may lead to decreased intelligence scores in adulthood (Eriksen, Sundet, & Tambs, 2009).
Toxemia	Affecting about 5% of mothers in the third trimester, its mildest form, preeclampsia, causes high blood pressure and rapid weight gain in the mother. Untreated, preeclampsia may become eclampsia and cause maternal convulsions, coma, and death of the mother, the unborn child, or both. Surviving infants may be brain damaged.
Toxoplasmosis	This illness, caused by a parasite in raw meat and cat feces, leads to blindness, deafness, and mental retardation in approximately 40% of infants born to infected mothers.

Sources: Reproductive Health, 2015; Sadler, 2015; Waldorf & McAdams, 2013.

which can complicate delivery. These complications arise from the abnormal glucose levels associated with diabetes and not from the insulin used to control this disease. This highlights why it is important to ensure that women who are, or may become, pregnant have access to good medical care.

Sexually Transmitted Infections. Several sexually transmitted infections (STIs) can affect development prenatally and beyond. The sexually transmitted infection of greatest concern in recent decades is **acquired immunodeficiency syndrome (AIDS)**, the life-threatening illness caused by the human immunodeficiency virus (HIV). AIDS destroys the immune system and makes victims susceptible to “opportunistic” infections that eventually kill them unless they are treated with multiple drugs. HIV-infected mothers can transmit the virus to their babies (1) prenatally, if the virus passes through the placenta; (2) perinatally, when blood may be exchanged between mother and child as the umbilical cord separates from the placenta; or (3) postnatally, if the virus is transmitted during breast-feeding. Without treatment, somewhere between 15% and 35% of babies born to HIV-infected mothers will become infected (Avert, 2016). The rate is much lower if these mothers are treated with antiretroviral drugs, or if they and their newborns are given a drug called nevirapine, which helps block transmission of HIV at birth (Avert, 2016; Stringer et al., 2004). Bottle-feeding further reduces the rate of HIV transmission from affected mothers to their infants but breast-feeding can be safe if managed effectively with treatment (Becquet et al., 2012). Infected infants now live longer than they did at the outset of the AIDS epidemic because of the development of appropriate treatments—50–75% in the United States are alive at age 5, and some survive into adolescence (Greenfield, 2012).

Although mother-to-child transmission of HIV in the United States has decreased significantly since peaking in 1992, it continues to be a tremendous problem in Africa and other parts of the world with AIDS epidemics. In 2010, for example, an estimated

An infant of an HIV-infected mother receives nevirapine syrup to help protect this little one from mother-to-infant transmission of HIV.

ANNA ZIEMINSKI/AFP/Getty Images

390,000 infants worldwide became infected with HIV from their mothers, most in sub-Saharan Africa (Avert, 2016).

Another sexually transmitted infection of concern is **syphilis**. Syphilis during pregnancy can cause miscarriage or stillbirth in as many as 25% of cases where the mother is infected with syphilis and does not receive treatment (Qin et al., 2014). Babies born alive to mothers who have syphilis and who do not receive treatment in a timely manner can end up suffering blindness, deafness, heart problems or brain damage, like those babies born to mothers who have rubella. This shows that different teratogens—here, syphilis and rubella—can be responsible for the same problem. However, whereas rubella is most damaging in the early stage of pregnancy, syphilis is most damaging in the middle and later stages of pregnancy. This is because syphilitic organisms cannot cross the placental barrier until the eighteenth prenatal week, providing a window of opportunity for treating the mother-to-be who finds out she has the disease. Even with appropriate treatment—penicillin—some infants are infected or die, although treatment substantially lowers this risk (Blencowe et al., 2011).

Environmental Hazards

A mother can control what she ingests, but sometimes she cannot avoid a hazardous external environment. Next we discuss two environmental conditions—radiation and pollutants—that may endanger the unborn child.

Radiation. Throughout the 20th century, there have been several notable events associated with the release of large quantities of radiation, allowing researchers to study the potential impact on unborn children. Perhaps the most dramatic radiological event was when atomic bombs were dropped on Hiroshima and Nagasaki in 1945: Not one pregnant woman who was within one-half mile of the blasts gave birth to a live child, and 75% of those who were within a mile and a quarter of the blasts had stillborn infants or seriously handicapped infants who died soon after birth (Apgar & Beck, 1974). Surviving children of these mothers had a higher-than-normal rate of intellectual disability and greater incidence of leukemia and cancers later in life (CDC, 2012b; Kodama, Mabuchi, & Shigematsu, 1996). Autopsies of these individuals would later reveal thinner-than-normal layers of cerebral cortex, an indication that neuronal migration had been disrupted (McDonald, 2007).

The Chernobyl nuclear disaster in 1986 similarly led to increased congenital defects among infants born to women who were in the area of exposure (Marples, 1996). Even across the Bay of Bothnia, in Sweden, women who were pregnant during the fallout from the Chernobyl accident experienced higher rates of congenital abnormalities among their babies despite much lower levels of radiation exposure (Almond, Edlund, & Palme, 2009).

Other research has examined exposure to radiation released during nuclear weapon testing (Black et al., 2014). This, too, is associated with lower IQ scores among those who were exposed in utero. In all cases, the greatest damage was during prenatal weeks 8–25, illustrating that timing is important. What’s happening during this time? Neurons are migrating and differentiating, a complex process that is disrupted by radiation. Dosage is important as well; children whose mothers were exposed to higher levels

of radiation experienced more significant deficits. Even clinical doses of radiation, such as those used in X-rays and cancer treatment, are capable of causing mutations, spontaneous abortions, and a variety of birth defects, especially if the mother is exposed between weeks 8 and 25. Therefore, expectant mothers are routinely advised to avoid X-rays or radiation unless they are essential to their own survival, as might be the case with women undergoing certain cancer treatments.

Pollutants. The air we breathe contains numerous pollutants, including ozone, carbon monoxide, nitrogen oxides, sulphur dioxides, and lead. Some of these originate from natural events such as volcanic eruptions, but others are by-products of fuel combustion from engines. Researchers seeking to understand the effects of pollutants on the developing fetus have evaluated pregnancy outcomes in select areas of the world such as Delhi, India, which has the dubious distinction of being the most polluted city in the world (Kumar et al., 2015). Sometimes, researchers have an opportunity to study the consequences of pollutants following an unexpected event, such as the tragic 9/11 attacks and collapse of the World Trade Centers in New York City, which exposed those living in the vicinity to large amounts of potentially toxic pollutants. These sorts of studies consistently show a connection between the by-products of pollution, measured in maternal blood and umbilical cord blood collected at birth, and such birth complications as prematurity and low birth weight (e.g., Lederman et al., 2004; van den Hooven et al., 2012). And that's not all. Three years after birth, some of the children exposed to pollution in utero show decreased cognitive abilities (Perera et al., 2007). In a large study conducted in various locations throughout Europe, children exposed to pollution in utero, specifically nitrogen oxides, showed delays in psychomotor development, although not in cognitive development (Guxens et al., 2014). It is important to note that those children who were exposed to multiple risk factors in utero experienced more problems than those exposed to a single

factor. In particular, prenatal exposure to pollution *in combination with* cigarette smoke led to further complications that were not present in the children who were exposed to just one of these prenatal risk factors. (Lederman et al., 2004; Perera et al., 2007). As we'll see later in this chapter, the more hazards that a child faces, the more likely it is that she will struggle to get back on track. Thus, with good postnatal care, children might overcome negative consequences of prenatal exposure to pollution or to cigarette smoke, but overcoming multiple risk factors is more of a challenge.

Exposure to heavy metals, such as lead in the air we breathe and the water we drink, is an ongoing concern. Children exposed prenatally to lead are smaller at birth and may be born preterm. They also show impaired intellectual functioning as children in proportion to the amount of lead in their umbilical cords (Canfield et al., 2003; Yorifuji et al., 2011). This finding holds true even after controlling for other differences among children, such as socioeconomic status. Postnatal lead exposure, usually from living in a home with lead dust from old paint or old lead water pipes, is also dangerous. Exposure to even very low levels of lead—lower than previously thought to be safe—is associated with lowered mental function during childhood (Jedrychowski et al., 2009).

Mercury exposure typically results from eating certain long-lived fish such as tuna, mackerel, and swordfish that have higher levels of mercury than shorter-lived fish such as salmon. Studies looking at prenatal exposure to mercury from maternal consumption of fish suggest adverse consequences, including delayed development and memory, attention, and language problems, with the effects related to the amount of mercury exposure (Paulson, 2013). As for whether mercury from vaccines that used to contain the mercury-based preservative thimerosal had toxic effects on development, the vast majority of the research concludes that it did not (Paulson, 2013; Waterhouse, 2013). Some parents whose children developed autism around the time of a vaccination continue to question whether there might be a link between the two events, but there is no credible evidence of this (see Chapter 16).

Finally, prenatal exposure to pesticides, dioxins, and polychlorinated biphenyls (PCBs) has also been associated with perinatal and postnatal problems (see Govarts et al., 2012). For example, prenatal exposure to PCBs from maternal consumption of contaminated foods is associated with poor reflexes in infants and later learning difficulties, including lower IQ scores at age 9 (Paulson, 2013; Stewart et al., 2008). PCBs were produced in various locations around the world, well after researchers had raised the alarm regarding toxicity of the substance. Another synthetic compound that has come under scrutiny is bisphenol-A (BPA), which is found in many plastics, including baby bottles.

Exposure to high levels of pollution during pregnancy can lead to preterm births and other adverse infant outcomes.

PRAKASH SINGH/Getty Images

Many companies began banning BPA in bottles in 2009, but now even the ‘safe’ alternative has come under fire for its connection to hyperactivity (Nutt, 2015; Tavernise, 2012). And then there are those pesticides. Children whose mothers were exposed to pesticides during pregnancy have greater body fat relative to children not exposed (Wohlfahrt-Veje et al., 2011). Boys exposed in utero to pesticides have smaller genitals than nonexposed boys and, consistent with the dose principle, the greater the exposure the smaller the genitals (Wohlfahrt-Veje et al., 2012a). And in girls, in utero exposure to pesticides is associated with earlier breast development, suggesting changes in hormone levels (Wohlfahrt-Veje et al., 2012b).

Clearly there is a critical need for more research aimed at identifying a huge number of chemicals, wastes, and other environmental hazards that may affect unborn children. There are more than 80,000 chemicals “out there” to which children may be exposed, but fewer than 3% of these have been evaluated for toxicity (Grandjean & Landigan, 2006; Paulson, 2013).

The message is unmistakable: The chemistry of the prenatal environment often determines whether an embryo or fetus survives and how it looks and functions after birth. A variety of teratogens can affect development; although, as you have learned, the influence of teratogens varies. Effects are worst in critical periods when organ systems are growing most rapidly, and effects are more serious with greater exposure to teratogens. Not all embryos or fetuses are equally affected by the same teratogen; the genetic makeup of both the mother and her unborn child and the quality of the prenatal and postnatal environments all play a role in determining the effects (Cassina et al., 2012). By becoming familiar with the information here and by keeping up with new knowledge, parents-to-be can do much to increase the already high odds that their unborn child will be normal as it approaches its next challenge: the birth process.

The Mother’s State

What can parents, especially the mother-to-be, do to sustain a healthy pregnancy? **Application 4.1** explores how parents can set the stage for a healthy pregnancy. Here we describe several characteristics of the mother—her age and race/ethnicity, emotional state, and nutritional status—that can affect the quality of the prenatal environment.

Age and Race/Ethnicity

At one end of the age spectrum, 11- and 12-year-old girls have given birth; at the other end of the spectrum, a 70-year-old woman from rural India made it to the record book by giving birth to twins after IVF. These are, however, unusual cases. The safest, and more typical, time to bear a child appears to be from about age 20 to age 40, as shown by the fetal mortality rates in **Figure 4.10**.

Figure 4.10 Fetal mortality varies with the mother’s age: Very young and very old mothers are at greater risk for fetal mortality. The best time to have a baby, if all other variables are the same, is when a woman is in her 20s or early 30s.

Source: CDC/NCHS, National Vital Statistics System, fetal mortality data, 2016.

Very young mothers have higher-than-normal rates of birth complications, including premature deliveries and **stillbirths**—fetal deaths late in pregnancy (20 or more weeks gestational age). The reproductive system of the teenager (19 years or younger) may not be physically mature enough to sustain a fetus to full term, making this group more vulnerable to having a low-birth-weight baby. However, the greater problem appears to be that teenagers often do not seek prenatal care and they are more likely to live in poverty and drink alcohol than mothers in their 20s and older (Substance Abuse and Mental Health Services Administration, 2014). Unfortunately, these conditions are likely to persist after the birth, leading to increased death rates before their first birthday among infants born to mothers 20 years or younger (Mathews, MacDorman, & Thoma, 2015).

As for older women, they are more likely to experience trouble getting pregnant. For those who do conceive, there is an increased risk of miscarriage, stillbirth, and low-birth-weight babies (Kenny et al., 2013; Laopaiboon et al., 2014). In the past, many fetal deaths in older women were caused by genetic abnormalities or defects arising during the first weeks after conception, when the major organs are forming. With today’s extensive prenatal testing of women older than 35, however, fewer babies are dying from genetic problems, partly because many such fetuses are identified early and aborted. Still, as Figure 4.10 shows, fetal death rates remain higher for older women, particularly for those over age 45 (MacDorman & Gregory, 2015). Compared with younger women, women over age 35 are more likely to release more than a single egg during ovulation, which increases their chances of conceiving fraternal twins (Beemsterboer et al., 2006). Though some women may be thrilled to learn that they are carrying twins, any multiple pregnancy and delivery carries additional health risks for the mother and the babies. Fetal mortality for higher-order pregnancies (three or more fetuses) is more than four times the rate for single pregnancies (MacDorman & Gregory, 2015). Finally, keep in mind that despite the increased risks older women face in childbearing, most have normal pregnancies and healthy babies.

● APPLICATION 4.1

Growing Healthier Babies

The more we learn about important environmental influences on human development, the better able we are to optimize environment and therefore to optimize development. Although the quality of an individual's environment matters throughout the life span, it seems sensible to do as much as possible to get a baby's life off to a good start because events of the prenatal period help set the stage for a lifetime of good (or poor) health. Ideally, pregnancies are planned rather than "discovered" after the fact, when it may be too late to make certain lifestyle changes. All women of childbearing age, for example, should eat a diet that contains the recommended amount of folic acid and should try to quit or reduce their smoking. Women who are thinking about getting pregnant should talk to their doctor about any prescription drugs they may be taking for ongoing medical conditions such as depression, high blood pressure, or diabetes. Doctors and mothers-to-be can develop a plan for how best to manage any preexisting conditions during a pregnancy.

Once a woman is pregnant, she should seek good prenatal care as quickly as possible so that she will learn how to optimize the well-being of both herself and her unborn child and so that any problems during the pregnancy can be managed appropriately. Prenatal care varies tremendously around the world, with some mothers-to-be seeing a health-care professional or midwife only once prior to delivery. Although the recommendations for pregnant women are not complicated, they are not always followed. They boil down to such practices as eating a good diet, taking prenatal vitamins, protecting oneself against diseases, and avoiding drugs and alcohol. Women who become ill during pregnancy should always

check with their doctor before taking even seemingly safe over-the-counter drugs. Women should avoid eating undercooked meat because of the risks of toxoplasmosis and *Escherichia coli* (*E. coli*) contamination, and they should be cautious of eating some fish, namely those larger fish that consume lots of little fish. These tend to have

higher concentrations of mercury.

Most women can continue to engage in all their regular activities, including exercise, during pregnancy unless advised against it by their health-care provider. Exercise can help keep muscles toned for the rigors of childbirth and also provides a sense of positive well-being. Exercise and a healthy diet during pregnancy may also influence the baby's metabolism and could set the stage for normal adult weight. In addition, researchers are beginning to find that prenatal exposure to certain environmental toxins may "program" the endocrine system in ways that lead to obesity across all stages of the life span (see, for example, Newbold et al., 2009).

Women who want to do some home renovations in preparation for the baby's arrival should be careful of lead paint that may be present in older homes and avoid inhaling paint fumes in poorly ventilated rooms. They may also want to have someone else clean the cat's

AMELIE-BENOIST/BSIP SA/Alamy Stock Photo

litter box, because cat feces is another source of the parasite that causes toxoplasmosis. For women who can't avoid litter box duty, having cats tested and treated before pregnancy can eliminate potential exposure to parasites.

Finally, many couples today also enroll in classes that prepare them for childbirth. These classes started in the 1940s to help reduce the fear and pain experienced by many women during labor and delivery. The **Lamaze method** of prepared childbirth teaches women to associate childbirth with pleasant feelings and to ready themselves for the process by learning exercises, breathing and pushing methods, and relaxation techniques that make childbirth easier. Couples who participate in childbirth preparation classes report a greater sense of control during labor and delivery, and this sense of control is associated with higher levels of satisfaction with the childbirth experience (Hart & Foster, 1997).

Does the mother's race/ethnicity impact pregnancy success? As **Figure 4.11** shows, fetal mortality rates do vary with the race/ethnicity of the mother. Most notable is that non-Hispanic black women have fetal mortality rates that are more than twice the rates experienced by other women. The reasons for this disparity are not completely understood but include poorer preconception health of the mother and less prenatal care. In addition, non-Hispanic black mothers are more susceptible to premature labor,

which creates numerous health concerns that we will discuss in a later section.

Emotional Condition

Is the prenatal environment affected by how the mother feels about being pregnant or how her life is going while she is pregnant? Life is filled with many stressors—both chronic (poverty, for example, or ongoing job stress) and acute (experiencing a serious

Figure 4.11 Fetal and neonatal mortality rates by race/ethnicity of mother. What factors might contribute to the markedly higher mortality rates for black infants (and fetuses)?

Source: Adapted from Figures 5 and 6 in MacDorman, M. F., Kirmeyer, S. E., & Wilson, E. D. (2012). Fetal and perinatal mortality, United States, 2006. *National Vital Statistics Reports*, 60 (8). Centers for Disease Control and Prevention/National Center for Health Statistics, National Vital Statistics System.

car accident, for example, or the unexpected death of a loved one). Being pregnant does not make stress disappear; indeed, for some women with unintended or mistimed pregnancies, pregnancy may increase stress levels. How might the fetus be affected by the mother’s experience of stress?

When a woman becomes emotionally aroused, her glands secrete powerful hormones such as adrenaline (also called epinephrine) that may cross the placental barrier and enter the fetus’s bloodstream. At the least, these hormones temporarily increase the fetus’s motor activity. A temporarily stressful experience such as falling or receiving a scare will generally not damage mother or fetus. It is only when a mother experiences *prolonged and severe* emotional stress and anxiety during her pregnancy (as a result, for example, of the death of her husband, chronic illness of another child, or unemployment) that long-lasting damage may be done. The most immediate effects on the fetus are a faster and more irregular heart rate and stunted prenatal growth, which can lower birth weight, cause premature birth, and lead to birth complications (Bussi eres et al., 2015). There is some evidence that female fetuses may be more susceptible to maternal stress than their male counterparts (Wainstock et al., 2015). Following birth, babies whose mothers had been highly stressed during pregnancy tend to be smaller, more active, more irritable, and more prone to crying than other

babies (de Weerth, van Hees, & Buitelaar, 2003; Wurmser et al., 2006). They may experience delays in cognitive development, exhibit greater fearfulness as young children, and have higher rates of depression at age 11 (Bergman et al., 2007; Laplante et al., 2008; Slykerman, et al., 2015). Finally, severe maternal stress during the first trimester has been linked to an increased likelihood of developing *schizophrenia*, a serious mental disorder whose symptoms typically emerge in adolescence or early adulthood (Barouki et al., 2012; Susser et al., 2008). Still, it is clear that not all stressed mothers have babies who are small and arrive early. The outcomes may depend on the effect that the stressful event has on the woman’s daily life. If the event significantly disrupts daily life, child outcomes may be worse than if the mother’s daily life is affected very little by the event.

Maternal stress likely stunts fetal growth and contributes to the offspring’s irritability and anxiety through fetal programming involving epigenetic effects of the environment on gene expression, as discussed earlier (Gudsnuk & Champagne, 2011). Prenatal exposure to maternal stress hormones may program the developing fetal nervous system in such a way to alter the postnatal stress response (Davis et al., 2011). Stress elevates levels of maternal cortisol, which crosses the placenta and influences, or sensitizes, developing fetal “stress” receptors in the brain. After birth, when a prenatally stressed infant is exposed to stressful events, their prenatally sensitized nervous system is more reactive, leading to poor stress regulation. This prenatal environmental influence does not rule out that there might also be a genetic component to infant stress response. But children who are conceived through IVF and are genetically unrelated to the mother who bore them also show this connection between prenatal stress and their own stress response, supporting the epigenetic connection between prenatal stress and infant-child outcomes (Rice et al., 2010). Also interesting to consider is research showing that significant *preconception* maternal stress is associated with higher rates of infant mortality (Class et al., 2013). Analyzing infant mortality rates in Sweden over a 30-year period in relation to preconception maternal stress, defined as the death of a close family member, revealed that stress experienced by the mother-to-be prior to pregnancy was associated with higher odds of infant mortality. The authors speculate that poor preconception nutrition of the mother, during the period of stress, may set in motion epigenetic effects that influence infant mortality.

Stress and anxiety are not the only maternal emotional states to consider. Maternal depression during pregnancy may contribute to preterm delivery and motor delays in newborns (Suri et al., 2014). Depression affects levels of neurotransmitters (brain chemicals) in both mothers and their newborns. Depression during pregnancy poses a challenge for women and their physicians because, left untreated, depression can affect fetal development, but some treatments for depression, namely prescription antidepressant medication, have also been found to negatively influence prenatal development (Suri et al., 2014).

Nutritional Condition

There was a time when doctors advised mothers to gain a mere 10–15 pounds while pregnant. With better understanding of nutrition and pregnancy, most doctors now recommend a well-balanced diet with about 300 additional calories per day, and a total weight gain of 25–35 pounds for normal-weight women. Healthy eating, including consuming lots of milk and leafy green vegetables,

during pregnancy can help reduce the risk of having low-birth-weight babies. Doctors know that inadequate prenatal nutrition and lack of weight gain can be harmful. It is perhaps surprising, then, that fewer than half of pregnant women report that their practitioner talked to them about weight guidelines (Phelan et al., 2011). Clearly, then, there is room for improvement here as the consequences can be significant.

Severe maternal malnutrition, which occurs during famine, stunts prenatal growth and produces small, underweight babies (Barouki et al., 2012). The effects of malnutrition depend on when it occurs. During the first trimester, malnutrition can disrupt the formation of the spinal cord, result in fewer brain cells, and even cause stillbirth. Restrictive dieting, use of diuretics, and disordered eating behaviors during the first trimester can also cause serious problems, such as neural tube defects (Carmichael et al., 2003). During the third trimester, malnutrition is most likely to result in smaller neurons, a smaller brain, and a smaller child overall.

The offspring of malnourished mothers sometimes show cognitive deficits as infants and children. Through fetal programming, poor prenatal nutrition may also put some children at risk for certain diseases in adulthood, including hypertension, coronary heart disease, diabetes, and even the serious mental disorder schizophrenia (Barouki et al., 2012; Susser, St. Clair, & He, 2008). But let's be clear: There may be latent effects of prenatal malnutrition on some children and adults, but because of the complicated interplay of genetics, epigenetics, and environment, other children and adults will show no apparent ill effects.

Among women who are adequately nourished, it is even more difficult to establish a connection between specific nutrients and birth outcome or later behaviors (Langley-Evans & Langley-Evans, 2003; Mathews, Youngman, & Neil, 2004). One exception to this is a deficiency of folate, a water-soluble B vitamin occurring naturally in some foods such as leafy green vegetables (see ■ Figure 4.12), which has been linked to neural

tube defects. In the mid-1990's, the United States and Canada initiated mandatory enrichment of cereal products with folic acid, the synthetic version of folate, in an effort to increase folate levels of women of childbearing age. These fortification programs have been associated with a decrease in the incidence of neural tube defects such as spina bifida, although some have questioned whether the benefits of such programs for women of child-bearing age come at some cost to others who may not need to ingest higher levels of folic acid (see Kim, 2007; Powers, 2007). Even with such fortification programs, it is often difficult to consume the “perfect” combination of foods to provide the full measure of recommended vitamins and minerals. Consequently, most health-care professionals prescribe prenatal vitamins for their pregnant patients.

Just as maternal malnutrition can lead to developmental issues, so too can maternal conditions associated with overeating. Maternal obesity, as well as excessive weight gain during pregnancy, is associated with offspring obesity and diabetes (Barouki et al., 2012). And we now have evidence from research with animals that paternal obesity is also associated with offspring obesity and diabetes. In Chapter 3, we described some research with male rats that became overweight from being fed a high-fat diet. This caused epigenetic changes in their sperm, which led to increased rates of obesity and diabetes indicators when passed on to female offspring, even when the daughters—and their mothers—ate healthy diets (Ng et al., 2010). Prenatal environmental conditions as well as preconception conditions of the parents help to build the architecture of the developing fetus and set the stage for how its body will react and respond to events postnatally. Still, much depends on whether a child receives an adequate diet and good care after birth. Best, of course, is appropriate nourishment before conception for the parents, as well as good nutrition before *and* after birth for the offspring.

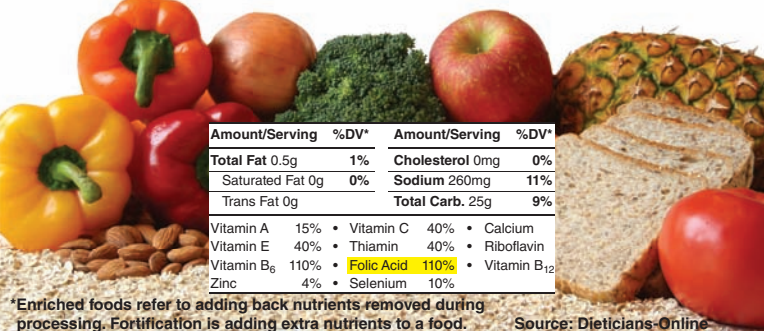

Now that we have had a chance to review the major teratogens that affect development during the prenatal period, go to **Engagement 4.1** to check your understanding of this material.

The Father's State

Does the father's state have any influence on the quality of the prenatal environment or the outcome of a pregnancy? Unfortunately, there is not a lot of research on the father's contributions to prenatal development beyond his genetic contribution. But researchers know that the father's age, just like the mother's age, can influence development (Sadler, 2015). We noted earlier that teenagers and women older than 35 are at greater risk of miscarriage than women in their 20s and 30s. Similarly, the odds of miscarriage increase with paternal age and are approximately twice the rate when fathers are in their 40s or 50s than when they are in their 20s or 30s (Belloc et al., 2008; Frattarelli et al., 2008). Children born to older fathers also face elevated risk of congenital heart defects, neural tube defects, and kidney problems, as well as preterm delivery and low birth weight (Alio et al., 2012; Shah, 2010). Like the risk of miscarriage, the odds of Down syndrome

Good Food Sources of Folic Acid (Folate)

- Leafy green vegetables, such as spinach, broccoli, and lettuce
- Beans, peas, and lentils
- Fruits such as lemons, bananas, and melons
- Enriched and fortified* products, such as some breads, juices, and cereals

Amount/Serving	%DV*	Amount/Serving	%DV*
Total Fat 0.5g	1%	Cholesterol 0mg	0%
Saturated Fat 0g	0%	Sodium 260mg	11%
Trans Fat 0g		Total Carb. 25g	9%

Vitamin A 15%	Vitamin C 40%	Calcium
Vitamin E 40%	Thiamin 40%	Riboflavin
Vitamin B ₆ 110%	Folic Acid 110%	Vitamin B ₁₂
Zinc 4%	Selenium 10%	

*Enriched foods refer to adding back nutrients removed during processing. Fortification is adding extra nutrients to a food. Source: Dieticians-Online

● ENGAGEMENT 4.1

Understanding Effects of Teratogens

Check your understanding of how teratogens can influence the health and development of an unborn child by answering the following true–false questions.

1. Most teratogens have their most devastating effects during the third trimester.
2. Women should monitor their fish consumption during pregnancy.
3. The fetus is protected from most environmental insults once it has fully implanted in the uterus and the umbilical cord has been completely established.
4. Women who drink any amount of alcohol at any time during pregnancy will give birth to a baby with fetal alcohol syndrome.
5. A woman's age and race/ethnicity affect the odds of a healthy pregnancy.

Answers: 1. F (The most serious problems occur during the first trimester when most major organs are forming.) 2. T (Some fish, such as swordfish, can contain high levels of the heavy metal mercury and should be avoided or eaten in small quantities.) 3. F (The umbilical cord is not a very good filter for many harmful substances. Carbon monoxide from cigarette smoke, for example, is actually "allowed" to cross the placenta before oxygen.) 4. F (Although FAS is a possibility, there are many variables that determine how an individual child will fare if exposed prenatally to alcohol. Certainly, the dosage generalization is important here: The more alcohol a woman drinks during pregnancy, the more likely it is that her child will

and genetic conditions caused by mutations are greater when both mother and father are older (Fisch et al., 2003; and see Chapter 3). As well, the offspring of *young* fathers (less than 20 years) are at greater risk for Down syndrome and some other anomalies (Wiener-Megnazi, Auslender, & Dirnfeld, 2012). Finally, researchers have consistently identified advanced paternal age (that is, 50 and older) as a risk factor for schizophrenia (see Chapter 3; Crystal et al., 2011).

A father's exposure to environmental toxins can also affect a couple's children. A father's prolonged exposure to radiation, anesthetic gases used in operating rooms, pesticides, or other environmental toxins can damage the genetic material in his sperm and cause genetic defects in his children (Soubry et al., 2014). We pointed out the adverse effects of maternal smoking. Paternal smoking also has an adverse effect that is independent of mother's smoking (Langley et al., 2012). In short, fathers, like mothers, should assess and, if need be, change their lifestyles and exposure to risk factors to optimize their chances of a healthy child.

● Checking Mastery

1. What principles can help us understand the effects of teratogens?
2. What have researchers learned about the effects on the child of alcohol consumption during pregnancy?
3. What effects are likely to be seen among babies born to mothers who smoked throughout their pregnancies?

● Making Connections

1. Consider Serena, whose story was summarized at the start of the chapter. What disadvantages might her child face, given Serena's lack of awareness of her pregnancy for the first 4–5 months?
2. A close friend of yours has just gotten a positive reading on a home pregnancy test. What information would you give her about her activities during pregnancy and the potential impact of these on the development and health of her child?

4.3

The Perinatal Environment

LEARNING OBJECTIVES

- Examine current childbirth practices and analyze the use of various interventions during delivery on neonatal outcomes.
- Compare cultural practices surrounding labor, delivery, and neonatal life and predict how these differences might affect later child development.

The **perinatal environment** is the environment surrounding birth; it includes influences such as drugs given to the mother during labor, delivery practices, and the social environment shortly after birth. Like the prenatal environment, the perinatal environment can greatly affect human development.

In most Western cultures, a dramatic shift in birthing practices occurred during the 20th century. In 1930, 8 out of 10 births

took place at home; by 1990, this figure had plummeted to just 1 out of 100 births before creeping back up to 1 in 90 births in recent years (MacDorman, Mathews, & Declercq, 2014). This change in birth setting was accompanied by a shift from thinking about birth as a natural family event that occurred at home to thinking about it as a medical problem to be solved with high technology (Cassidy, 2006). There is a small increase in mortality

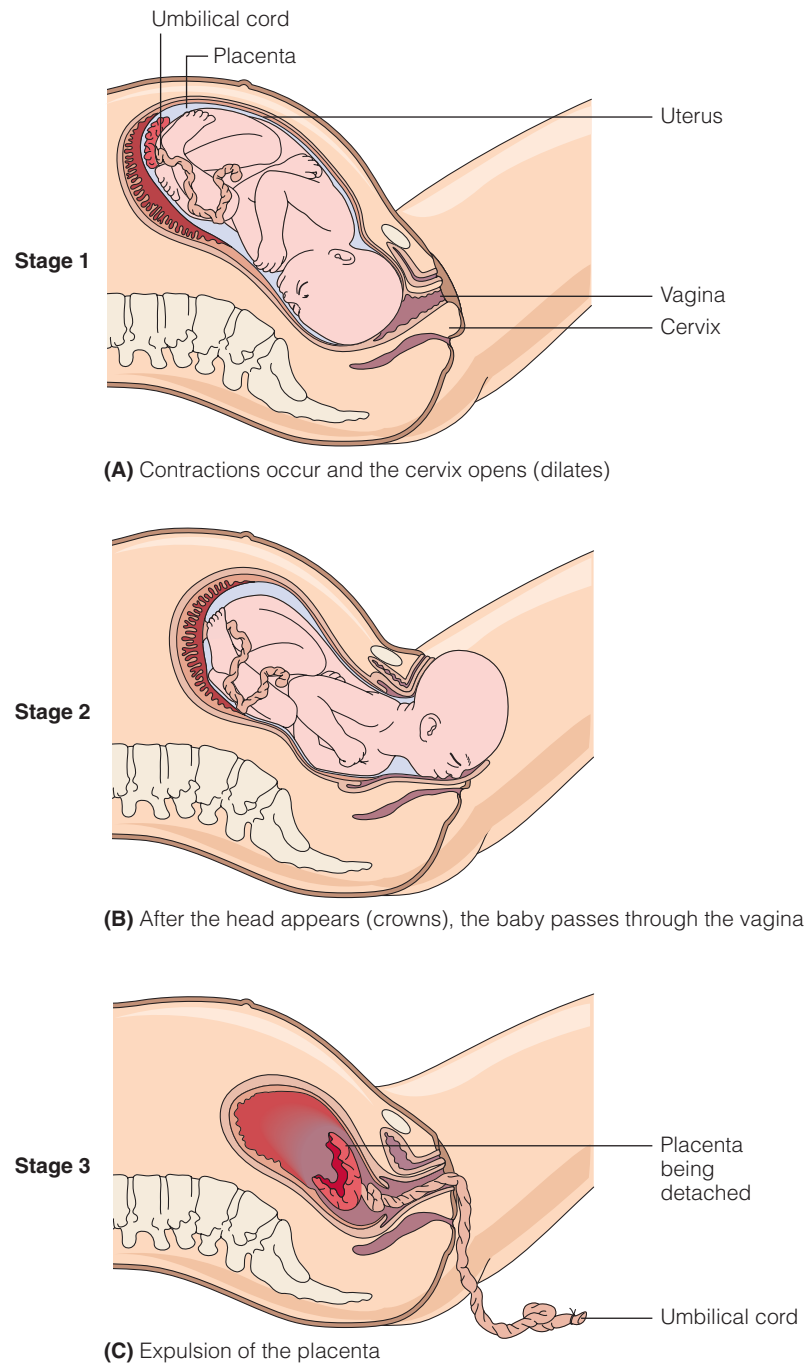

rates for home births, but the higher risk may be more related to the mother's income level than to location of the birth (Daysal et al., 2015; MacDorman et al., 2014). In the United States, women who give birth at home—or try to do so—often report that their decision is met with horror and disgust from others who believe the women are jeopardizing the well-being of their unborn baby (Cunha, 2015). In other parts of the world, home births are the norm.

What can couples do when they want the comfort and control of a home birth as well as the technology and modern interventions of a hospital? Many hospitals have restructured their labor and delivery rooms and practices to give parents greater flexibility and control when it comes time to deliver. Mothers-to-be have several choices when it comes to who will assist with their delivery, including family physicians, obstetricians, specialists in maternal–fetal medicine, and midwives. For high-risk pregnancies associated with delivery complications, a maternal–fetal specialist, or **perinatologist**, is recommended. However, for the majority of women, personal preference can determine the best caregiver for pregnancy and delivery. In many countries, such as England and France, midwives have been the traditional pregnancy caregivers. For the past century, most (around 90%) women in the United States have relied on physicians or obstetricians for pregnancy care, but the use of midwives is slowly increasing, from 4% in 1990 to 8% more recently (Declercq, 2012). In general, midwives view pregnancy and delivery as natural life events rather than as medical events requiring medical intervention. They partner with the laboring mother-to-be to assist her with delivery but do not dictate the conditions of labor and delivery.

Another change in the delivery room is the presence of a spouse, partner, mother, sister, and/or friend to provide support and share in the miracle of birth. Most women find the support provided by this familiar person helpful and reassuring. Some women have the support of a *doula*—an individual trained to provide continuous physical and emotional support throughout the childbirth process. Such support tends to shorten labor by as much as half and to reduce the need for pain medication and assisted delivery such as use of forceps or vacuum (Hodnett et al., 2013). The rate of cesarean sections is lower among women continuously supported by a doula, midwife, or other labor support person (Hodnett et al., 2013). Mothers with continuous labor support also report more positive feelings about the birth experience, fewer symptoms of postnatal depression, and greater likelihood of breast-feeding than nonsupported mothers. Clearly, then, the social context surrounding labor and delivery is important: Women who receive more support during childbirth have more positive experiences.

Childbirth is a three-stage process (■ **Figure 4.13**). The first stage of labor begins as the mother experiences regular contractions of the uterus and ends when her

cervix has fully dilated (widened) so that the fetus's head can pass through. This stage of labor lasts an average of 9 hours for firstborn children and 5 hours for later-born children, but these figures represent averages and may not be representative of a particular woman's experience. Approximately one-third of laboring women receive some assistance with this stage, usually the administration of **oxytocin** (brand name Pitocin), a hormone released by

■ **Figure 4.13** The three stages of labor. Stage 1: Contractions of the uterus cause dilation of the cervix. Stage 2: The mother pushes with each contraction, forcing the baby down the birth canal, and the head appears, followed by the shoulders and then the rest of the baby's body. Stage 3: With a few final pushes, the placenta is delivered.

the pituitary gland that can initiate and speed up contractions, moving labor along more quickly. The body naturally produces low levels of oxytocin throughout pregnancy, and administering synthetic oxytocin to assist delivery is considered very safe. In Chapter 14, we'll examine some of the other functions of oxytocin, which some have dubbed the “love hormone.” Just to be clear, though, oxytocin may speed up labor, but it speeds up what is typically a stalled or very slow-to-progress labor, so that women whose labor is assisted in this manner spend, on average, as much as 6–7 more hours in this stage than women who not need to be assisted (Harper, et al., 2012). This first stage of labor ends when the cervix has dilated to 10 centimeters.

The second stage of labor is delivery, which begins as the fetus's head passes through the cervix into the vagina and ends when the baby emerges from the mother's body. This is when the mother is often told to “bear down” (push) with each contraction to assist her baby through the birth canal. For first deliveries, this stage may take about 1 hour; for later deliveries, it can be 15–20 minutes. Finally, the third stage of the birth process is the delivery of the placenta, which lasts only a few minutes.

When the birth process is completed, the mother (and often the father, if he is present) is typically physically exhausted, relieved to be through the ordeal of giving birth, and exhilarated all at once. Meanwhile, the fetus has been thrust from its carefree but cramped existence into a strange new world.

Possible Hazards

In most births the entire process goes smoothly, and parents and newborn quickly begin their relationship. Occasionally, however, problems arise.

Anoxia

One clear hazard during the birth process is **anoxia**, or oxygen shortage (also called *asphyxia*). Anoxia can occur for any number of reasons—for example, because the umbilical cord becomes pinched or tangled during birth, because sedatives given to the mother reach the fetus and interfere with the baby's breathing, because mucus lodged in the baby's throat prevents normal breathing, or because the baby is in a **breech presentation** (feet or buttocks first) during a vaginal delivery. If identified in advance, fetuses in breech position can be safely delivered by cesarean section to avoid possible anoxia that may occur with a vaginal delivery. Anoxia is dangerous primarily because brain cells die if they are starved of oxygen for more than a few minutes. Severe anoxia can initially cause poor reflexes, seizures, heart rate irregularities, and breathing difficulties. In the long run, severe anoxia can lead to memory impairment or **cerebral palsy**, a neurological disability primarily associated with difficulty controlling muscle movements; it also increases the risk of learning or intellectual disabilities and speech difficulties (Fehlings, Hunt, & Rosenbaum, 2007). Milder anoxia makes some infants irritable at birth or delays their motor and cognitive development but usually does not lead to permanent problems.

Fetal monitoring procedures during labor and delivery can alert caregivers to the possibility of anoxia and allow them to take

preventive measures. For example, a vaginal delivery is nearly impossible for the 1 fetus in 100 that is found lying sideways in the uterus. The fetus must be turned to assume a head-down position or be delivered by **cesarean section**, a surgical procedure in which an incision is made in the mother's abdomen and uterus so that the baby can be removed.

Complicated Delivery

In some cases, mothers may need assistance with delivery, possibly because labor has proceeded too long with too little to show for it or because of concern about the well-being of the baby or mother. For years, doctors frequently used forceps (an instrument resembling an oversized pair of salad tongs) to assist with a vaginal delivery. However, forceps on the soft skull of the newborn occasionally caused serious problems, including cranial bleeding and brain damage, leading to a sharp decline in use of this instrument over the past 50 years (Laughon et al., 2012). Alternatively, doctors may use vacuum extraction (“suction”) to assist difficult deliveries. This procedure has fewer risks associated with it, although it is not risk free. In a vacuum extraction, a cup is inserted through the opening of the birth canal and attached to the baby's head. Suction is applied to make the cup adhere to the baby's scalp; during each contraction and with the mother bearing down, the doctor uses the traction created by the suction to help deliver the baby.

From the mother's point of view, vacuum extraction is less painful than forceps because the vacuum extractor takes up less space in the birth canal (and therefore is felt less) than forceps (Shekhar, Rana, & Jaswal, 2012). For the baby, however, there is likely to be swelling of the scalp and some marking where the vacuum cup was attached. Bleeding under the scalp is also possible, which may lead to a condition called jaundice. More serious injuries are possible if the vacuum is not properly used (Schot et al., 2013). Thus, relative to forceps, vacuum extraction may be less traumatic for the mother but just as traumatic for the infant. This illustrates the complexity of perinatal issues that need to be considered to ensure a safe outcome for both mother and infant.

Cesarean sections, too, have been controversial. Use of this alternative to normal vaginal delivery has prevented the death of many babies—for example, when the baby is too large or the mother is too small to permit normal delivery, when a fetus out of position cannot be repositioned, when the placenta prematurely separates from the uterus, or when fetal monitoring reveals that a birth complication is likely. Still, overall rates of fetal/neonatal death have not improved with all these Cesareans (Blanchette, 2011). Medical advances have made Cesarean sections about as safe as vaginal deliveries, and few ill effects on mothers and infants have been observed. But mothers who have “C-sections” do take longer to recover from the surgery than from a vaginal delivery, and they are sometimes less positive toward and involved with their babies during the recovery period. The start of breast-feeding may also be delayed in women who have delivered by C-section (Prior et al., 2012; Sakalidis et al., 2013). Nonetheless, the development of babies born by cesarean appears to be perfectly normal and early observed differences in mother–infant interaction disappear by 6 months (Durik, Hyde, & Clark, 2000).

Many observers have questioned why cesarean deliveries have become so much more common—to the point that they

accounted for about one-third of all births in the United States. By one estimate, 11% of first-time cesarean sections are unnecessary and 65% of second-time cesareans are unnecessary (Kabir et al., 2005). Some obstetricians readily opt for C-section deliveries because it may help protect them from the costly malpractice suits that might arise from complications in vaginal deliveries (Childbirth Connection, 2012). C-sections also generate more revenue for physicians and medical practices than vaginal deliveries. Contributing to the high rate of C-sections is the strong likelihood (90%) for women who have had one C-section to deliver subsequent babies by C-section rather than attempting a vaginal delivery (Menacker, MacDorman, & Declercq, 2010). Although there is a very small risk of complications with a vaginal delivery following a C-section, it is safe for the large majority of women and having multiple C-sections carries its own set of risks (Blanchette, 2011). Finally, the high rate of C-section deliveries also reflects the fact that some mothers—and their doctors—prefer having a scheduled birth rather than contending with an unscheduled vaginal delivery (Fuglenes et al., 2012). In one study, 55% of repeat C-sections were elective, not medically necessary (Tita et al., 2009). In some instances, anxiety about a vaginal delivery may lead mothers-to-be to lobby for a C-section delivery (Ramvi & Tangerud, 2011). Women who have planned C-sections, as opposed to those that are emergency and unanticipated, rate their birth experience more positively than any other group, including those who deliver vaginally (Blomquist et al., 2011). There is something to be said for knowing, in advance, when and what is going to happen!

Medications

Some of us were delivered in an era when mothers were routinely drugged into unconsciousness during delivery so that they would not experience any pain, or if they did, they wouldn't remember it. Not surprisingly, concerns have been raised about medications given to mothers during the birth process—analgesics and anesthetics to reduce their pain, sedatives to relax them, and stimulants to induce or intensify uterine contractions. Sedative drugs that act on the entire body cross the placenta and can affect the baby. Babies whose mothers receive large doses of sedative medications during delivery are generally sluggish and irritable, are difficult to feed or cuddle during the first few days of life, and smile infrequently (Elbourne & Wiseman, 2000). In short, they act as though they are drugged. Think about it: Doses of medication large enough to affect mothers can have much greater effects on newborns who weigh only 7 pounds and have immature circulatory and excretory systems that cannot get rid of drugs for days.

Regional analgesics, such as epidurals and spinal blocks, reduce sensation in specific parts of the body. Because they do not cross the placenta, they have fewer ill effects on babies and are preferred by many physicians over sedative drugs that *do* cross the placenta. Use of epidurals has increased from 4% of deliveries in the 1960s to as many as 75% of deliveries to women in the United States (Kjerulff & Zhu, 2014). Mothers rate epidurals as more effective for pain control than other forms of analgesics but despite this advantage, mothers and physicians must weigh disadvantages: Women who have an epidural may obtain some pain relief but in doing so, they tend to lengthen their labor,

and this leads to increased likelihood of needing instrumental assistance—forceps or vacuum extraction (Anim-Soumua et al., 2011; Hasegawa et al., 2013). Alternative methods for controlling pain, such as systematic relaxation techniques, can be successful, but are not regularly offered and require more time from someone trained in these techniques than administering medication for pain control (Smith et al., 2011).

In sum, taking obstetric medications is not as risky a business today as it once was, but it is still a decision that requires the pros and cons to be weighed carefully. The effects depend on which drug is used, how much is taken, when it is taken, and by which mother.

Possible hazards during birth, then, include anoxia; breech presentation; the need for assisted delivery through forceps, vacuum extraction, or cesarean section; and the use of medications for pain relief or to speed up labor. Fortunately, most deliveries, although unique from the parents' perspective, are routine from a clinical perspective. In the next section, we consider the birth experience from a family perspective.

The Mother's Experience

What is it really like to give birth to a child? For every woman who has given birth, you are likely to hear a unique birth story. Most mothers admit that they experienced pain—some quite significant—and a good deal of anxiety, including feelings of outright panic (Waldenström et al., 1996). Yet most also emerged from the delivery room feeling good about their achievement and their ability to cope (“I did it!”). Overall, 77% felt the experience was positive and only 10% said it was negative. And, despite longer labors and more medication, first-time mothers did not perceive labor and delivery much differently than experienced mothers did.

This woman chose to give birth in water, an experience that has been associated with increased feelings of relaxation and decreased pain. Water births can occur at home or in a birth center and even a hospital. While embraced by some, others express concerns about whether this is as safe as a non-water birth for the baby.

Ross Marks Photography/Alamy Stock Photo

What factors influence a mother's experience of birth? Not surprisingly, women who labor longer report more negative feelings about the birth experience (Ulfsdottir et al., 2014). Psychological factors such as the mother's attitude toward her pregnancy, her knowledge and expectations about the birth process, her sense of control over childbirth, and the social support she receives from her partner or someone else are important determinants of her experience of delivery and of her new baby (Waldenström et al., 1996; Wilcock, Kobayashi, & Murray, 1997). Finally, women report a more negative birth experience when their newborn seems to be struggling immediately after birth, even when the infant quickly rebounds (Ulfsdottir et al., 2014). Regardless of whether women experience their infant's delivery as positive or negative, their feelings about motherhood are largely positive 6 months after the experience (DiPietro et al., 2015).

Cultural Factors

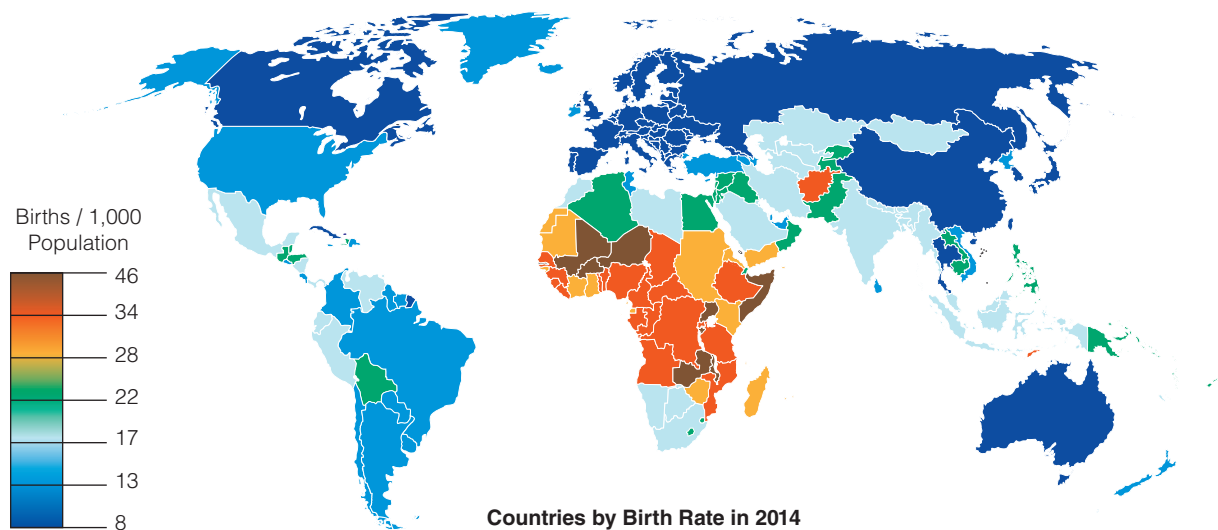

The experience of childbearing is shaped by the cultural context in which it occurs. For example, different cultures have different views of the desirability of having children (■ **Figure 4.14**). Many Islamic cultures favor large families, believing that children are a gift and blessing. In contrast, starting around 1980, the People's Republic of China promoted a "one-child policy" to discourage multiple childbearing in hopes of slowing population growth and raising the standard of living. As a result of this policy, the average number of children per Chinese family dropped from nearly five children to fewer than two. Along with the overall decrease in number of children, the ratio of boys to girls also changed; many parents wanted their one child to be a boy who could support them in old age and therefore aborted female fetuses identified through ultrasound tests or abandoned their female babies after birth (Fitzpatrick, 2009). Following harsh criticism, China's one-child policy relaxed a bit and has recently transitioned to a two-child policy.

This Peruvian woman gives birth in an upright position, which reduces labor and delivery time by allowing gravity to assist with moving the baby down the birth canal. In societies that have medicalized childbirth, women are more likely to be lying horizontal on a bed, which may sound comfortable but is not the optimal laboring or birthing position.

Mariana Bazo/Reuters/Corbis

Practices surrounding birth also differ widely. Consider three different birth scenarios that reflect different cultural beliefs about pregnancy and delivery. Among the Pokot people of Kenya, there is strong social support of the mother-to-be (O'Dempsey, 1988). The community celebrates the coming birth, and the father-to-be stops hunting lest he be killed by animals. As a result, he is available to support his wife. A midwife, aided by female relatives, delivers the baby. The placenta is buried in the goat enclosure, and the baby is washed in cold water and given a mixture of hot ash and boiled herbs so that it will vomit the amniotic fluid it has

■ **Figure 4.14** Birth rates vary considerably around the globe, with the highest rates concentrated in regions of Africa.

Childbirth practices vary across cultures. Here, a woman labors at home with assistance from family or village members.

AF archive/Alamy Stock Photo

swallowed. Mothers are given plenty of time to recover. They go into seclusion for 1 month and devote themselves entirely to their babies for 3 months.

A rather different experience of childbirth is found in rural villages of northern India, where a traditional childbirth attendant called a *dai* assists with the delivery. Most women indicate a preference for a home birth over a hospital birth as they believe that their *dai* will be “hands-on,” literally using her hands to massage and push on the woman’s pregnant belly to help deliver the baby (Iyengar et al., 2008). In contrast, women report that hospital staff are hands-off, preferring to administer “needles and bottles” (injections of drugs and intravenous fluids) and telling mothers-to-be to apply their strength (bear down). Whether at home or in hospital, the pushing can be intense enough to land the newborn on the floor, where it stays until after the placenta is delivered and the umbilical cord has been tied. After 5–15 minutes, the newborn is wrapped and handed to the mother; in many cases, it will be 5–9 days before the baby is washed out of concern that early bathing is associated with death. For the first several days, the baby will be given an herbal concoction rather than milk because it is believed that mother’s milk takes about 3 days to come in.

Finally, among the !Kung San of Namibia, women typically labor by themselves (Cassidy, 2006). Giving birth alone is considered to be a strength. When labor begins, the !Kung woman goes off on her own and is expected to labor quietly. To do otherwise is considered a sign of weakness and possibly shows indifference toward the baby.

In contrast to these examples, childbirth in highly industrialized Western societies is highly “medicalized,” with women hospitalized, hooked up to monitors, and separated from most friends and family members. Should we return to more traditional ways of birthing that view delivery less like a major medical event and more like a natural life event to be managed at home? There are many who would argue that not all “traditional” practices are

in the best interests of parents and babies. Also, Western societies do a far better job than developing countries of preventing mother and infant mortality. In some areas of sub-Saharan Africa, for example, 7–10% of babies die during childbirth or in the first year of life (CIA, 2015). In Western, industrial societies, infant mortality rates have dropped over the past 50 years from 3% (30 infants out of 1,000) to less than 0.5% (4–5 infants out of 1,000) (CIA, 2015). In the United States, infant mortality is more than twice as high for black infants as for white infants, although mortality rates have shown greater improvement over the past 10 years among black infants compared to white infants (Mathews, MacDorman & Thoma, 2015). The secret to a more optimal birth experience may be to blend beneficial traditional practices such as offering emotional support to new mothers with modern medical know-how.

In addition to different cultural influences on childbirth practices, cultural beliefs influence behaviors during the postpartum period. In some cultures, women’s activities and interactions with others are restricted for a period of time following childbirth (Eberhard-Gran et al., 2010). Depending on the culture, this practice may be to protect her and her newborn from “evil forces” or from the wind and cold, or it may be associated with fears that childbirth and the new mother are somehow unclean. Many postnatal differences across cultures have shrunk over the past several decades, although they have not entirely disappeared. In Western countries such as the United States and Canada, new mothers and their newborns might get a few days to a week respite from the hustle and bustle of daily living, but probably do not spend 40 days in isolation while other family or community members cover the typical chores needed to run a household (Eberhard-Gran et al., 2010).

Postpartum Depression

Some new mothers suffer from depression following the birth of their baby. Many new mothers report feeling tearful, irritable, moody, anxious, and depressed within the first few days after birth. This condition—the baby blues—is relatively mild, passes quickly, and is probably linked to the steep drops in levels of female hormones that normally occur after delivery and to the stresses associated with delivering a child and taking on the responsibilities of parenthood (not to mention coping with the lack of sleep experienced by many new mothers). Indeed, it may be difficult to find a new mother who does not experience at least some degree of moodiness or baby blues in the week following delivery.

A second, and far more serious, condition is **postpartum depression**—an episode of clinical depression lasting 2 or more weeks (rather than days) in a woman who has just given birth. It affects approximately 15–20% of new mothers (O’Hara & McCabe, 2013). Only rarely does a woman who has never had significant emotional problems become clinically depressed for the first time after giving birth. Most affected women have histories of depression, and many were depressed during pregnancy. Also, women vulnerable to depression are more likely to become depressed if they are experiencing other life stresses on top of the stresses of becoming a mother (Honey, Bennett, & Morgan,

2003). Lack of social support—especially a poor relationship with a partner—also increases the odds (Webster et al., 2011). Fortunately, the risk of developing postpartum depression can be reduced through various interventions including home visits or telephone conversations with at-risk new mothers during the postpartum period (Dennis & Dowswell, 2013).

Postpartum depression has significant implications for the parent–infant relationship. Compared to children of nondepressed mothers, children whose mothers experienced postpartum depression may become less securely attached to their mothers during infancy and less responsive during interactions with their mothers at age 5 (Murray, Fearon, & Cooper, 2015). These negative patterns of interaction are most likely to occur when the mother’s depression is prolonged and when there are other risk factors in the home. Children of postpartum depressed mothers are also more likely to have experienced depression by age 16 (Murray et al., 2011).

Mothers who had been postnatally depressed report more behavioral problems in their children. At age 11, children of postnatally depressed mothers show more violent behavior even when researchers control for family characteristics and later episodes of maternal depression (Hay et al., 2003). The violence exhibited by these children is associated with anger management problems, attention problems, and hyperactive behavior. Adolescents whose mothers had been postnatally depressed also show elevated levels of cortisol, which is associated with major depression (Halligan et al., 2004). The implication of these results is that early experiences with a depressed mother, prenatally or postnatally, might predispose these children to later depression.

How exactly might maternal depression in the weeks and months following delivery affect children’s behavior and increase their odds of developing depression? Mothers who are depressed tend to be relatively unresponsive to their babies and may even feel hostility toward them. They are tired, distracted, and often lack the energy needed to be fully engaged with their infants. Even though mothers typically recover from postnatal depression, research suggests that their early attitudes about their babies and the resulting pattern of early mother–child interactions set the stage for ongoing interaction problems that affect the child’s behavior (Murray et al., 2015; Weinberg et al., 2006). The contribution of genes inherited from their depression-prone mothers, fetal programming from exposure to the prenatal chemistry of their mothers, and poor quality of the postnatal mother–child relationship can combine to precipitate depression or other problems in the child (Field, 2011). Thus, for their own sakes and for the sakes of their infants, mothers experiencing more than a mild case of the baby blues should seek professional help in overcoming their depression.

The Father’s Experience

When birthing moved into hospitals, the medical establishment aggressively prohibited fathers from participating in their children’s birth on the grounds that they would contaminate the sterile environment needed for a safe birth (Cassidy, 2006). It would take many decades, many lawsuits, and more progressive views about birth support before men were routinely accepted—and

expected—in the delivery room. Today, many men prepare for fatherhood before delivery, attend prenatal classes with their partner, and are present for their child’s birth. Fathers report that they want to be involved with their partner’s pregnancy, although they don’t always know how to make this happen (Draper, 2002).

Like mothers, fathers experience the process of becoming a parent as a significant event in their lives that involves a mix of positive and negative emotions. Also like mothers, fathers tend to be anxious during pregnancy and birth and some even experience some of the same physiological symptoms as their pregnant partner. These symptoms, called **couvade** (from the French word meaning “to hatch”), include bloating, weight gain, fatigue, insomnia, and nausea (Cassidy, 2006). And before you conclude that these symptoms must be “all in their heads,” consider that some research shows hormonal shifts among expectant fathers that are similar to the hormonal shifts experienced by pregnant women (Cassidy, 2006).

As for the labor and delivery period, new fathers report feeling scared, unprepared, helpless, and frustrated (Chandler & Field, 1997; Chapman, 2000; Hallgren et al., 1999). They find labor to be more work than they had expected and sometimes feel excluded as the medical professionals take over. For most men, attending prenatal classes with their partner improves their experience of childbirth, although for a few men the added knowledge that comes with these classes increases their anxiety (Greenhalgh, Slade, & Spiby, 2000). Stress levels among men tend to be highest during their partner’s pregnancy and then decrease after the birth of the baby. Despite the stresses, negative emotions usually give way to relief, pride, and joy when the baby finally arrives (Chandler & Field, 1997). Those fathers present for delivery who cut their newborn’s umbilical cord are found to have greater emotional connection to their infants at 1 month (Brandão & Figueiredo, 2012). This doesn’t mean that all fathers-to-be need to reach for the scissors and cut the umbilical cord, though; there are many other opportunities to develop a strong emotional connection between father and infant.

● Checking Mastery

1. What steps occur during the process of childbirth?
2. What risks does the baby potentially face during the birth process?

● Making Connections

1. Considering the research on birth and the perinatal environment, arrange the perfect birth experience for you and your baby and justify its features. Where would you be, who would be with you, and what would be done?
2. Some experts worry that cesarean sections are overused. What do you think? Should a woman be able to choose whether she delivers vaginally or by cesarean section? Should hospitals be permitted to force a woman to deliver by cesarean if they believe the fetus is in danger?

4.4

The Neonatal Environment

LEARNING OBJECTIVES

- Compare and contrast breast- and bottle-feeding, offering pros and cons of both practices.
- Explain how we can optimize the development of at-risk newborns.

So now that parents have a baby, what do they do? Here we will look at the **neonatal** environment—the events of the first month and how parents might optimize the development of young infants.

There are marked differences in how parents interact with their newborns. As Meredith Small (1999) characterizes it, “Our ideas about parenting and infant care are as culturally constructed as what we wear, what we eat, or how we dance” (p. 41). For example, in societies where infant mortality is high, babies may not even be named or viewed as people until they seem likely to survive (Nsamenang, 1992). The Beng, who are concentrated in small farming towns along the Ivory Coast, believe that newborns are not entirely in this world but exist in the world the babies will eventually inhabit after death (Gottlieb, 2000). Once their umbilical cord stump falls off on the fourth or fifth day of life, they begin to inhabit this world but still vacillate between the two worlds for another 4–5 years. During this time, the Beng regard their children as vulnerable. Spiritual beliefs influence their child care practices, leading, for example, to twice-daily enemas for infants using a chili pepper solution.

In Central Africa, babies born to forager families are carried upright in slings during the day and sleep in the same bed

with their mothers at night. They are touched more than 70% of daytime hours, are breast-fed whenever they want (usually 20–40 times per day), and may not be weaned until the age of 4 (Fouts, Hewlett, & Lamb, 2012). Infants in such societies are indulged considerably, at least until their survival is assured. In contrast, babies born to farming families in Central Africa are touched less often, breast-fed less often, and weaned at an earlier age than the babies in foraging families.

Infant care practices are considerably different in modern, industrialized societies where infant mortality is lower. Infants in industrialized nations like the United States are touched only 12–20% of daytime hours, and they are often trained to breast-feed or bottle-feed on a schedule, usually five to seven times a day (Hewlett, 1996). Babies may sleep in the same bed or room as their parents for just a few weeks before being settled into a crib in their own room, a practice that mothers in many other cultures, who sleep in the same bed with their babies until they are toddlers, find quite bizarre. Parents who do sleep with their babies should be mindful that babies are at increased risk of suffocation when they sleep in adult beds. Adults are obviously much larger and heavier, posing a hazard if they roll onto a baby while sleeping. Adult beds also have more bedding and pillows than an infant crib, and these can suffocate a tiny infant.

Regardless of where they live, new parents are often uncertain about how to relate to their babies and may find the period after birth stressful. Many seek information on what is “normal” behavior from their infant as well as feedback on their own behaviors as parents. To help parents appreciate their baby’s competencies and feel competent themselves as parents, the Neonatal Behavioral Assessment Scale (NBAS), intended for practitioners such as pediatricians, and the Newborn Behavioral Observations (NBO) system, geared toward parents, were developed out of the pioneering work of T. Berry Brazelton (see Brazelton & Nugent, 2011; Nugent, et al., 2007). Both instruments are intended to reveal infants’ capabilities and readiness for the tasks they will need to navigate to survive and thrive. For instance, the NBO evaluates infants’ ability to self-regulate or calm themselves as well as infants’ ability to “tune out” lights and sounds so that they can sleep. The NBO is focused on helping parents form relationships with their infants by revealing the individual characteristics of their infant and profiling areas of strength and areas where greater attention might be needed.

Breast or Bottle?

Breast-feeding is the most natural form of nutrition for newborns and until modern times, it was the sole source of

Welcome to the world, little one! Your journey over the past 9 months has been astonishing. At conception, you received all the genetic material necessary to develop into the baby that we now see. You have already taken your first breaths and the umbilical cord that sustained you in the womb will soon be cut. After being cleaned and wrapped up, you will begin to interact with your family and explore the world around you.

MedicImage/Alamy

Breast milk provides the perfect balance nutrients for the developing infant.

Grant Difford/Greatstock Photographic Library/Alamy Stock Photo

nourishment until solid foods were introduced. For a variety of reasons, breast-feeding in the United States reached an all-time low in the early 1970s, when only 1 in 4 mothers attempted to nurse their newborn infants. Bottle-feeding with formula had become the norm (Eiger and Olds, 1999). Since then, research has shown numerous advantages of breast milk over formula. Breast milk contains several substances that protect nursing infants from infections, and it has the perfect blend of nutrients for a quickly developing little person. In homes where a caregiver smokes cigarettes, breast-feeding offers some protection against the respiratory infections that frequently plague infants exposed to secondhand (passive) smoke (Yilmaz et al., 2009). Children who breast-feed for at least 4 months have stronger lung function, almost certainly because breast-feeding requires infants to suck stronger and longer to obtain the same amount of milk as when bottle-feeding (Ogbuanu et al., 2008). As well, breast-feeding for the first 4–6 months is associated with a handful of cognitive advances

during infancy, especially among preterm babies (Quigley et al., 2012). For premature babies, breast milk has been referred to as “more of a medicine than a food” because of its positive effects on their immune systems and weight gain (Gross-Loh, 2006, p. 38). And mothers who breast-feed lose the weight gained during pregnancy more quickly than those who do not breast-feed following childbirth.

Campaigns to raise awareness of the health benefits of breast-feeding have significantly increased the percentage of new mothers who start breast-feeding their newborns (Breast-feeding Report Card, 2014). But although 79% of new mothers breast-feed, only 49% are still breast-feeding by age 6 months. Women cite a number of reasons for not continuing with breast-feeding, ranging from their own discomfort to concerns that the infant is not getting adequate nutrition. Young women, those from low socioeconomic backgrounds, and those with less education are less likely to breast-feed than other women (Ryan & Zhou, 2006). Being employed outside the home is also associated with lower breast-feeding rates, presumably because of the logistical problems of breast-feeding while at work (Ryan & Zhou, 2006). Finally, fewer black mothers breast-feed than white mothers (Ip et al., 2007). Interestingly, Hispanic mothers have a fairly high rate of breast-feeding until they immigrate to the United States, and then the rate decreases with the amount of time in the United States (Ahluwalia et al., 2012). This likely reflects U.S. cultural values toward breast-feeding, which are more ambivalent than those in many other countries. To improve breast-feeding rates, ambivalent (and in some cases, downright negative) views of breast-feeding need to be addressed so that women view breast-feeding as *the* option, not just *an* option.

Identifying At-Risk Newborns

A few infants will be considered **at risk** for either short-term or long-term problems because of genetic defects, prenatal hazards, or perinatal damage. It is essential to these infants' survival and well-being that they be identified as early as possible. Newborns are routinely screened using the **Apgar test**, which provides a quick assessment of the newborn's heart rate, respiration, color, muscle tone, and reflexes (● **Table 4.7**). The test has been used for more than 60 years and, despite its low-tech nature, is still considered a valuable diagnostic tool. The simple test is given immediately and 5 minutes after birth. It yields scores of 0, 1, or 2 for each of the five factors, which are then added to yield a total score that can range from 0 to 10. Infants who score 7 or higher are in good shape. Infants scoring 4 or lower are at risk—their heartbeats are sluggish or nonexistent, their muscles are limp, and their breathing is shallow and irregular, if they are breathing at all. These babies will immediately experience a different postnatal environment than the normal baby experiences because they require medical intervention in intensive care units to survive, as you will see at the end of the chapter.

One particular group of at-risk babies that should be examined more closely are those with **low birth weight (LBW)**. As

● **Table 4.7** The Apgar Test

Factors	Score		
	0	1	2
Heart Rate	Absent	Slow (<100 beats per minute)	Moderate (>100 beats per minute)
Respiratory Effort	Absent	Slow or irregular	Good; baby is crying
Muscle Tone	Flaccid; limp	Weak; some flexion	Strong; active motion
Color	Blue or pale	Body pink, extremities blue	Completely pink
Reflex Irritability	No response	Frown, grimace, or weak cry	Vigorous cry

● **Table 4.8** illustrates, the younger (and smaller) babies are at birth, the lower their chances of survival. Approximately 8% of babies born in the United States have an LBW (less than 2,500 grams, or 5½ pounds). Some of these babies are born at term and are called “small for gestational age,” but many are born preterm (less than 37 weeks of gestation) and are more at risk as a result. The survival and health of these small infants is a concern, particularly for infants who are very small (less than 1,500 grams or no more than 3.3 pounds).

Although LBW infants account for about 9% of all births, they account for about two-thirds of all infant deaths and nearly 60% of the money spent on pregnancies and deliveries (March of Dimes, 2015; Schmitt, Sneed, & Phibbs, 2006). Very LBW infants are even more costly: They account for less than 1% of all births but 36% of the total hospital costs. Most fragile are the micropreemies—those weighing less than 800 grams or 1.75 pounds at birth. The high emotional and economic costs of LBW have made this an important medical and societal issue, not to mention an intensely personal issue for those families directly affected by a premature delivery. And while aggressive application of medical technology has kept more tiny preemies alive, many experience long-term disabilities (see, e.g., Serenius et al., 2013).

We don’t always know what causes LBW, but research has identified a number of factors regularly associated with it, including:

- age of mother (very young or older)
- low socioeconomic status of mother, linked with poor nutrition and inadequate prenatal care
- race: black women are twice as likely as white women to experience premature delivery
- prior premature deliveries, which may indicate underlying and persistent health conditions
- tobacco or alcohol use

- stress
- pregnancies with more than one fetus (twins, triplets, etc.)
- infections
- high blood pressure

Some of these factors can be controlled: A woman can try to eliminate smoking during pregnancy. Other factors such as high blood pressure can be monitored and treated. But some factors may be outside of a woman’s direct control and, not surprisingly, the more risk factors experienced during pregnancy, the greater the likelihood of delivering a small baby (Rosenberg, 2001).

The good news is that most LBW babies born since the advent of neonatal intensive care in the 1960s function within the normal range of development and experience significant catch-up growth during their first months and years of life (Chyi et al., 2008; Wilson-Costello et al., 2007). However, compared with normal-birth-weight children, LBW children, especially those with extremely LBW are at greater risk for numerous neurobehavioral problems, including blindness, deafness, cerebral palsy, poor academic achievement, autism, and health problems (Costeloe et al., 2012; Serenius et al., 2013). Respiratory difficulties are likely because premature babies have not yet produced enough **surfactant**, a substance that prevents the air sacs of the lungs from sticking together and therefore aids breathing. Surfactant therapy for LBW infants became common practice around 1990 and seems to improve the survival rate among the sickest infants. However, it has not entirely improved health or long-term achievement scores of LBW babies in general, perhaps because small, earlier-born babies, who have the most complications, are now surviving to be among the school-age population of LBW survivors (Hagen et al., 2006; Paul et al., 2006; see also Bode et al., 2009).

● **Table 4.8** Survival and Health of Premature Babies by Gestational Age

Factors	Results (in Weeks and %)				
	22 weeks	23 weeks	24 weeks	25 weeks	26 weeks
Number of completed weeks since last menstruation	22 weeks	23 weeks	24 weeks	25 weeks	26 weeks
Percentage of babies who survived to one year	10%	52%	67%	82%	85%
Percentage of survivors beyond one year with mild or moderate disability	60%	49%	54%	46%	44%
Percentage of survivors beyond one year with a severe disability	40%	21%	13%	10%	7%

Source: Based on data from Serenius et al., 2013.

Although modern technology permits the survival of younger and smaller babies, like this one, many experts believe we have reached the lowest limits of viability around 23 weeks of gestation. What is the long-term prognosis for premature babies?

Steve Lovegrove/Shutterstock.com

In addition to the advances made thanks to the high-tech interventions now available in most neonatal intensive care units (NICUs), research has shown that several low-tech interventions can go far in improving the developmental outcomes of LBW, premature infants. For starters, these vulnerable infants benefit from their mother's breast milk even if they can't effectively nurse when they are hooked up to tubes and machines in the NICU. Mothers can pump their breast milk to provide nutrient-rich nourishment that helps boost their infant's fledgling immune system. Babies with extremely LBW who receive breast milk later score about 5 points higher on the Bayley Scale of Mental Development than similar babies who receive no breast milk (Vohr et al., 2006). And among babies receiving breast milk, there are measurable differences between those who consumed the largest quantities and those who consumed the least.

There is also evidence that skin-to-skin contact is therapeutic for these infants. Sometimes called **kangaroo care**, resting on a parent's chest helps maintain body temperature, heart rate, and oxygen levels in the blood (Conde-Agudelo, Belizán, & Diaz-Rossello, 2011) and the rhythmic sound of the parent's heartbeat calms the infant and may help simulate the environment of the womb. Premature infants who experience kangaroo care settle into more mature patterns of quiet sleep and alert wakefulness than premature infants who do not receive this treatment. And it is not only the infant who benefits: Mothers who participate in kangaroo care of their infants while in neonatal intensive care report positive feelings about the experience as long as they

receive adequate education and support of the practice (Blomqvist & Nyqvist, 2010). One of the nice things about kangaroo care is that both mothers and fathers can participate. Doing so improves parents' sensitivity to their infant and makes the dynamics among the trio more positive (Feldman et al., 2003; Tessier, et al., 2009).

In addition to skin-to-skin contact, Tiffany Field and her colleagues (Diego, Field, & Hernandez-Reif, 2005; Field, Diego, & Hernandez-Reif, 2010) have shown that premature infants benefit from massage therapy. For example, in one study, premature babies received either light or moderate massage three times per day for 5 days (Field et al., 2006). Those who received moderate-pressure massage gained significantly more weight on each of the days of the therapy than the premature babies in the light-massage group. Babies receiving moderate massage seemed to be more relaxed and less aroused, which may have facilitated greater weight gain (Field et al., 2006). In addition, the massage increased the efficiency of the digestive system, which is also associated with greater weight gain (Diego, Field, & Hernandez-Reif, 2005).

Although the long-term health prognosis for LBW babies is now good, many children born with an extremely LBW continue to experience neurosensory impairments and academic problems throughout their childhood and teen years (Doyle & Anderson, 2005; Saigal et al., 2007). These cognitive deficits in childhood can be traced to deficits in attention, speed, and memory evident in preterm infants during their first year (Rose et al., 2005). The fate of premature and LBW babies depends

This 2 pound 10 ounce bundle is enjoying skin-to-skin contact with his mother. Such “kangaroo care” helps babies regulate body temperature and maintain a regular heart rate and oxygen levels in the blood.

Paula Bronstein/Staff/Getty Images

considerably on two factors. The first is their biological condition—their health and neurological status in particular. The second is the quality of the postnatal environment they experience. For instance, in a study of more than 8,000 infants, Dennis Hogan and Jennifer Park (2000) found that the disadvantages of LBW were amplified for children of minority status growing up in poverty with a single parent. In contrast, LBW babies who live with two parents and whose mothers are well educated, although they start out with delays, improve and may even catch up to the average child by age 8 (Ment et al., 2003). And children born with very LBW whose mothers are consistently responsive to them throughout infancy and toddlerhood attain higher levels of cognitive achievement than similar children with less responsive mothers (Landry, Smith, & Swank, 2006). In contrast, premature infants whose mothers are “out of synch” with them exhibit less mature outcomes at age 2 (Feldman & Eidelman, 2006). **Exploration 4.1** describes how we might help parents care for their tiny packages.

Studies such as these raise a larger issue about the importance of early experience. Some developmentalists take seriously the concept of critical (or sensitive) periods in early development. Others stress the resilience of human beings, their ability to rebound from early disadvantages and to respond to environmental influences throughout their lives rather than only during so-called critical periods. Which is it?

Risk and Resilience

To what extent does harm done in the prenatal or perinatal period last, and to what extent can postnatal experiences make up for it? You have encountered many examples in this chapter

of what can go wrong before or during birth. Some damaging effects are clearly irreversible: The thalidomide baby will never grow normal arms or legs, and the child with FAS will always be intellectually disabled. Yet throughout history, many children turned out fine even though their mothers—unaware of many risk factors—smoked and drank during their pregnancies, received heavy doses of medication during delivery, or experienced serious illness. So, although many factors place a fetus at risk and increase the likelihood of problems after birth, not all at-risk infants end up with problems (Fraser, 2004). Is it also possible that some babies exposed to and clearly affected by risks recover from their deficiencies later in life?

Indeed it is, and researchers now have the results of major longitudinal studies that say so. For 40 years, Emmy Werner and her colleague Ruth Smith studied a group of babies

born in 1955 on the island of Kauai in Hawaii (Werner, 1989a, 1989b; Werner & Smith, 1982, 1992, 2001). This was a monumental undertaking. All women of Kauai who were to give birth in 1955 were interviewed in each trimester of pregnancy, and physicians noted any prenatal, perinatal, or postnatal complications. On the basis of this information, each baby was categorized as having been exposed to severe, moderate, mild, or no prenatal or perinatal stress. At ages 1, 2, 10, 18, 32, and 40 years, researchers diligently tracked down their participants and conducted interviews (initially with the mothers and later with the children), administered psychological and cognitive tests, rated the quality of the family environment, and conducted medical examinations. Remarkably, at the 40-year follow-up, 70% (489 of 698) of the original group of babies born in 1955 still participated in the study.

One-third of the children classified as at-risk showed considerable resilience, getting themselves back on a normal course of development. Through this self-righting capacity, they were able to mature into competent, successful adults with no evident learning, social, or vocational problems despite being at risk for poor outcomes. Two major findings emerge from this research:

- The effects of prenatal and perinatal complications decrease over time.
- The outcomes of early risk depend on the quality of the postnatal environment.

The postnatal environments of these successful at-risk children included two types of protective factors, influences that prevent the damaging effects of risk factors or help children overcome disadvantages. These are:

● EXPLORATION 4.1

Skills for Parenting Tiny Babies

Research shows that at-risk infants can benefit from programs that teach their parents how to provide responsive care and appropriate intellectual stimulation to them once they are home. Home visits to advise parents, combined with a stimulating day care program for LBW toddlers, can teach mothers how to be better teachers of their young children and stimulate these children's cognitive development. In an ambitious project called the Infant Health and Development Program, premature and LBW infants at eight sites benefited from such early intervention (McCormick et al., 2006). The program involved weekly home visits during the first year of life and then biweekly home visits and attendance by the infant at a special day care center for half a day every day from age 1 to age 3. Mothers were given child care education and support.

The program appeared to help parents provide a more growth-enhancing home environment—for example, to give their babies appropriate toys and learning materials and

to interact with them in stimulating ways. The intervention also helped these at-risk babies, especially the heavier ones, achieve more cognitive growth by age 3 than they would otherwise have achieved. An impressive 14-point boost in IQ scores at age 3 for heavier LBW children who received the intervention had dropped to a 4-point advantage over control group children at age 8, but this small advantage was still evident at age 18 (McCarton et al., 1997; McCormick et al., 2006). Children who weighed 2,000 grams (4 pounds 6 ounces) or less at birth did not get much benefit from the program.

Other research indicates that early intervention programs for preterm infants should include psychosocial support for their mothers to help them manage the stress of caring for a preterm infant (Benzies et al., 2013). Psychosocial support can have a positive effect on a mother's anxiety and depression as well as her sense of self-efficacy, or confidence in being able to handle the situation. Mothers

who have greater confidence in their ability to care for a preterm infant and who have lower levels of anxiety and depression seem to parent their infants in ways that lead to more positive outcomes.

Researchers have more to learn about what it takes to keep the development of at-risk children on a positive track after the perinatal period comes to a close, but everything we know about life-span environmental forces suggests that supportive parents and programs can do a great deal to optimize every child's development. It seems that premature, LBW babies can achieve normal levels of intellectual functioning during childhood when they live in middle-class homes, when their mothers are relatively educated, and most importantly, when their mothers, rich or poor, are consistently attentive, responsive, and confident when interacting with them (Benzies et al., 2013; Landry et al., 2006).

- *Personal resources.* Possibly because of their genetic makeup, some children have qualities such as intelligence, sociability, and communication skills that help them choose or create more nurturing and stimulating environments and cope with challenges. For example, parents and other observers noted that these children were agreeable, cheerful, and self-confident as infants, which elicited positive caregiving responses. They also believed that they were in control of their own fates—that through their actions, they could bring about positive outcomes.
- *Supportive postnatal environment.* Some at-risk children receive the social support they need within or outside the family. Most importantly, they are able to find at least one person who loves them unconditionally and with whom they feel secure.
- Clearly, hazards during the important prenatal and perinatal periods can leave lasting scars, and yet many children show remarkable resilience. There seem to be some points in the life span, especially early on, in which both positive and negative environmental forces have especially strong effects. Yet *environment matters throughout life*. It would be a mistake to assume that all children who have problems at birth are doomed. In short, early experience by itself can, but rarely does, make or break development; later experience counts, too, sometimes enough to turn around a negative course of development.

● Checking Mastery

1. What are two things you can do during your baby's first weeks and months of life to ensure a healthy start to life?
2. What are two factors that allow some babies to show resilience to negative events of the prenatal or perinatal periods?

● Making Connections

1. Find out if your mother and grandmothers breast-fed their children, including you, and for how long. What are your thoughts on the breast-versus-bottle choice? What factors might make it more or less likely that you or your partner will breast-feed (or have breast-fed if you are already a parent)?
2. Given the high costs of low birth weight, what programs would you make part of a national effort to reduce the number of LBW babies born each year?

Chapter Summary

4.1 Prenatal Development

- Prenatal development begins with conception and proceeds through the germinal, embryonic, and fetal periods.
- Some couples experience difficulties conceiving and turn to assisted reproduction technologies to assist them with having a baby. These include drugs to stimulate the ovaries to release eggs, artificial insemination to inject sperm into a woman's uterus, and in vitro fertilization to fertilize an egg outside the womb and then insert it into a woman's uterus or fallopian tube.
- The germinal period lasts about 2 weeks. During this time, the single-celled zygote created when a sperm penetrates an egg repeatedly multiplies and travels to the uterus where it implants itself.
- The embryonic period lasts through the eighth week after conception. Every major organ takes shape during this time in a process called organogenesis. The placenta forms and connects the embryo to its mother through the umbilical cord. Major developments occur during this time, including formation and beating of the heart and the start of sexual differentiation.
- The fetal period lasts from the ninth week after conception until the end of pregnancy. The body and brain undergo much growth during this time. Neurons multiply, migrate, and differentiate into what they will finally become. The age of viability is reached at around 23–24 weeks' gestation.
- Growth during the prenatal period is faster than during any other period of the life span.

4.2 The Prenatal Environment and Fetal Programming

- The womb is an environment and can affect the embryo/fetus in positive as well as negative ways.
- Through fetal programming, prenatal conditions can alter the architecture of the fetal brain, setting the stage for later vulnerabilities or for later resilience.
- Teratogens include diseases, drugs, or other environmental agents that can harm the developing fetus. Teratogens are most damaging to an organ during the time when the organ is developing most rapidly. In addition, the longer and stronger the exposure to a teratogen, the more likely that damage will occur to the developing child. The genetic makeup of both mother and unborn baby influence the effect of a teratogen, as does the quality of the prenatal and postnatal environments.
- Numerous drugs—prescription, over-the-counter, and recreational—have been found to have teratogenic effects. One of the most widely used drugs—alcohol—results in a cluster of symptoms that have lifelong effects on the children who are exposed prenatally.
- Diseases such as rubella (German measles), syphilis, and AIDS can adversely affect the developing baby, as can environmental hazards such as radiation and pollution.

- Some aspects of the mother can influence the quality of the prenatal environment, including her age, emotional state, and nutritional status. Women in their 20s have the lowest rates of pregnancy and birth complications. Women who experience prolonged and severe emotional stress during pregnancy may give birth to smaller babies. Good nutrition is important throughout pregnancy and is often supplemented with vitamins and fortified foods.
- Characteristics of the father, such as his age, may also affect the baby.

4.3 The Perinatal Environment

- The perinatal environment includes delivery practices and drugs used to assist with delivery. Many births today take place in the medical setting of a hospital or birthing center.
- Childbirth is a three-stage process that begins with regular contractions of the uterus and dilation of the cervix. The second stage of labor is the actual delivery of the baby out of the woman's body. The third stage is the delivery of the placenta.
- Among the possible birth complications is anoxia, or an oxygen shortage, which may occur for a variety of reasons. Anoxia can lead to brain damage or cerebral palsy if the brain is deprived of oxygen for more than a few minutes.
- Some babies must be assisted through the birth canal with vacuum extraction or forceps. Some women undergo a cesarean section, or surgical removal of the baby. Many women in Western cultures are given medications to assist with delivery. Most common are epidural or spinal blocks to reduce pain and oxytocin to promote contractions.
- The experience of pregnancy and childbirth vary widely, across cultures as well as across women within a culture. Some women experience mild to moderate depression following childbirth. Fathers, too, often need time to adjust to the life changes that accompany becoming a parent, as do older siblings.

4.4 The Neonatal Environment

- The neonatal environment refers to the events of the first month or so after delivery. Caring for a newborn varies across cultures. Nearly all cultures promote breast-feeding as the ideal way to nourish the young infant. For a variety of reasons, some mothers bottle-feed their newborns or switch to bottle-feeding after a trial run with breast-feeding.
- Some infants are considered to be at risk for short-term or long-term problems and must receive extra care during the neonatal period. Babies born prematurely and who have low birth weight are at risk for a number of complications.
- Many at-risk babies show remarkable resilience and outgrow their problems, especially if they have personal resources, such as sociability and intelligence, and grow up in stimulating and supportive postnatal environments where someone loves them.

Gary Goldfield and his colleagues from the Healthy Active Living & Obesity Research Group in Canada had 30 obese teenagers engage in light to moderate exercise on stationary bikes (Goldfield et al., 2012). After 10 weeks, perhaps the most important finding was not the expected change in weight or fitness levels. Instead, the intriguing outcome was that the teens showed improved psychosocial functioning; in particular, they experienced a boost in body image, social competence, and even perceived academic performance. Interviewed about the research for *Science Daily*, Goldfield noted, "If you can improve your physical activity and fitness even minimally, it can help improve your mental health. By teaching kids to focus on healthy active lifestyle behaviours, they are focusing on something they can control. . . . This new study is proof positive that even a modest dose of exercise is prescriptive for a mental health boost" (Children's Hospital of Eastern Ontario Research Institute, 2012).

This is just one of many examples illustrating the connections among our physical, cognitive, and socioemotional selves. In this chapter, we consider changes across the life span in body and brain and how these changes influence our physical and mental health. We begin with an overview of the major physical

systems, most notably the brain and nervous system, underlying human functioning. We also look at the reproductive system as it matures during adolescence and then changes during adulthood. Throughout, we consider factors that can interfere with health as well as those that might optimize health.

5.1

Building Blocks of Growth and Lifelong Health

LEARNING OBJECTIVES

- Associate key processes of the endocrine and nervous systems with important aspects of growth and development.
- Describe and provide an example of each of the three major principles of growth.
- Articulate the main components of the life-span developmental model of health and the value of adopting this sort of approach to understanding health.

Our physical selves—brain, body, and all the behaviors that emerge from these—are fundamental to what we are able to do in life. A 5-year-old child is physically able to experience the world in ways markedly different from those available to a 5-month-old infant. Five-year-old Mariah, for example, can stack blocks with her infant brother, throw a ball with her mom, run with her dog, play hopscotch with her friends, feed and dress herself, and enjoy many of the rides at the amusement park. Changes in her brain have increased her memory abilities and capacity to think, and her language skills are astounding compared with those of the 5-month-old. Yet Mariah and other 5-year-olds are also limited by their physical selves. It will be years before their brains are fully developed, allowing greater concentration and more sophisticated thought processes. Their physical skills will continue to

improve, and their bodies will grow taller and heavier and will mature sexually.

Human growth and development is an incredibly complex process, influenced by both genetic and environmental factors. At certain times and for certain developments, genetic influences dominate, whereas at other times, environmental influences are more powerful. But as we have explained in previous chapters, genetic and environmental forces are always working together. Consider height. The average female in the United States is just over 5 feet 4 inches (164 cm) and the average male is about 5 feet 10 inches (178 cm), but there is considerable variability. Until her death in 2012, Yao Defen from China was the tallest woman in the world, her atypical height of 7 feet 8 inches a stark contrast to women with Turner syndrome (see Chapter 3) who are typically 3 feet shorter than this—4 feet 8 inches on average. These are dramatic examples of variability in height, but even among those considered within the average range of height, there is variability. Genes account for some of this: Tall people tend to have tall parents, whereas short people often have “short genes” hanging on their family tree. Heritability studies confirm that, after infancy, there is a strong genetic influence in height (Dubois et al., 2012; Lettre, 2012).

But as noted in Chapter 3, even if you inherit the genetic propensity to be tall (or short), environment can influence the expression of those genes. If you lack adequate nutrition, for example, you may not realize your full growth potential. Especially important to achieving adult height is a childhood diet rich in protein as well as calcium and vitamins A and D (Grasgruber et al., 2014). And consider the case of children with **celiac disease**, an inherited digestive problem in which gluten (the proteins found in all wheat products) triggers an immune response that leads to inflammation and damages the small intestine (see **Figure 5.1**). This leaves affected children unable to absorb

The physical capabilities of this infant have advanced tremendously since birth, but at the ripe old age of 5 years, his sister is able to do many more sophisticated physical tasks.

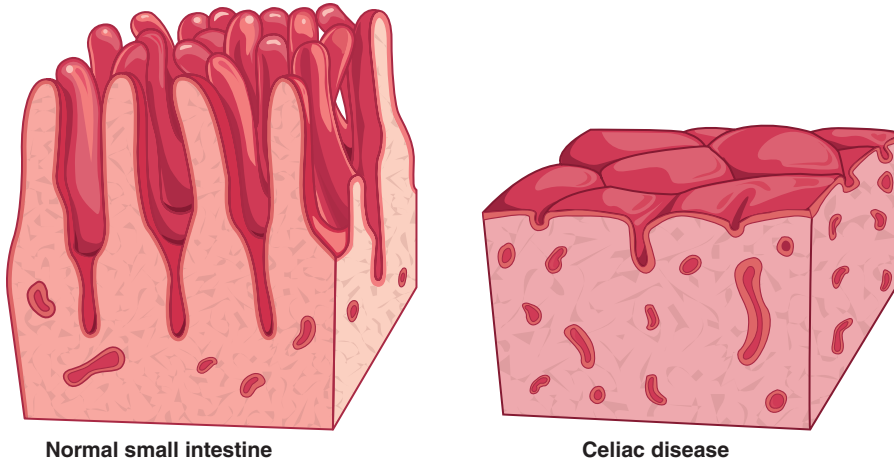

Figure 5.1 A small intestine damaged by celiac disease makes it difficult to absorb nutrients and can lead to malnutrition. Early diagnosis can permit effective treatment before damage becomes permanent.

Mayo Foundation for Medical Education and Research.

nutrients from food despite adequate consumption. Their disease, if untreated, can lead to malnutrition, which stunts growth and delays puberty. Early diagnosis for the estimated 3 million Americans with celiac disease is key to long-term health. Unfortunately, it often takes 10 years before the vague symptoms of bloating,

diarrhea, fatigue, and upset stomach are properly diagnosed. Fortunately, treatment in the form of a gluten-free diet restores absorption of nutrients and can lead to dramatic **catch-up growth**. This catch-up growth after a period of malnutrition or illness reflects the body's struggle to get back on the growth course it is genetically programmed to follow.

To understand more fully how growth can be influenced by genes and environments, we need to consider the workings of the endocrine and nervous systems.

The Endocrine System

The endocrine, or hormonal, system consists of a group of **endocrine glands**, illustrated in

Figure 5.2, that secrete chemicals called *hormones* directly into the bloodstream. Perhaps the most critical of the endocrine glands

is the **pituitary gland**, the so-called master gland located at the base of the brain. Directly controlled by the hypothalamus of the brain, it triggers the release of hormones from all other endocrine glands by sending hormonal messages to those glands. Moreover, the pituitary produces **growth hormone**, which triggers

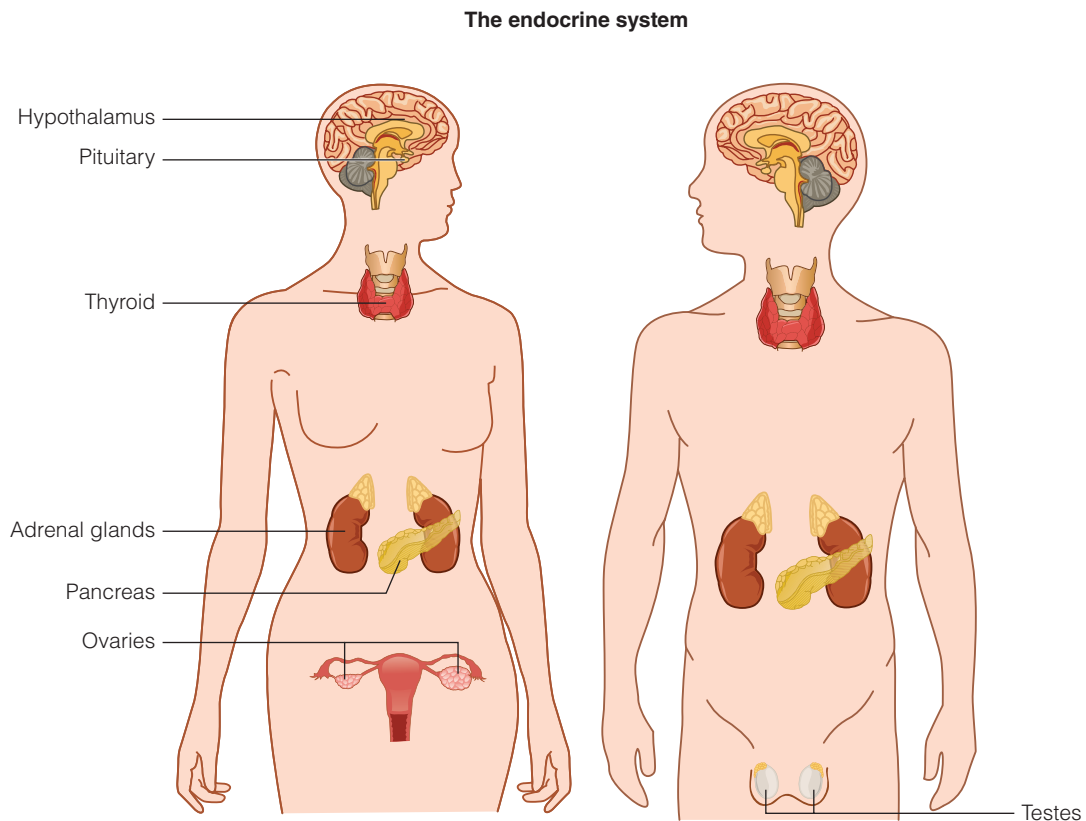

Figure 5.2 The glands of the endocrine system secrete their chemicals, called hormones, directly into the bloodstream.

the production of specialized hormones that directly regulate growth. Yao Defen’s unusual height of 7 feet 8 inches resulted from unchecked release of growth hormone due to a tumor on her pituitary gland. In contrast, children who lack adequate growth hormone are unlikely to exceed 4 feet (or 130 cm) in height as adults if left untreated. Treatment with synthetic growth hormones can lead to near-expected adult height if administered early—well before the start of puberty (Ross et al., 2015).

Children born small for their gestational age are often shorter as adults. Some of these children may also benefit from growth hormone therapy, but results with this group have been variable and controversial. The physical gains from taking the medication are around 2 inches of height and it is not clear whether these small gains add significantly to quality of life (Sandberg & Gardner, 2015; Sommer et al., 2015). Adults who use human growth hormone in an attempt to enhance their athletic performance are at risk for a variety of health conditions, including cardiac problems and insulin resistance (Holt & Sönksen, 2008). Despite widespread beliefs about its potential performance-enhancing benefits, the actual gains in performance are inconsistent and are accompanied by considerable health risks (Birzniece, 2015).

The thyroid gland also plays a key role in physical growth and development and in the development of the nervous system. Children whose mothers had a thyroid deficiency during pregnancy can experience intellectual problems (LaFranchi, Haddow, & Hollowell, 2005; Moog et al., 2015). Thyroid deficiency during infancy can also lead to intellectual disability and slow growth if unnoticed and untreated (see Zimmerman, 2007). Children who develop a thyroid deficiency later in life will not suffer brain damage, because most of their brain growth will have already occurred, but their physical growth will slow drastically.

In Chapter 4 you learned about another critical role of the endocrine system. A male fetus will not develop male reproductive organs unless (1) a gene on his Y chromosome triggers the development of the testes (which are endocrine glands), and (2) the testes secrete the most important of the male hormones, testosterone. Male sex hormones become highly important again during adolescence. When people speak of adolescence as a time of “raging hormones,” they are quite right. The testes of a male

secrete large quantities of testosterone and other male hormones (called **androgens**). These hormones stimulate the production of growth hormone, which in turn triggers the adolescent growth spurt. Androgens are also responsible for the development of the male sex organs and contribute to sexual motivation during adulthood.

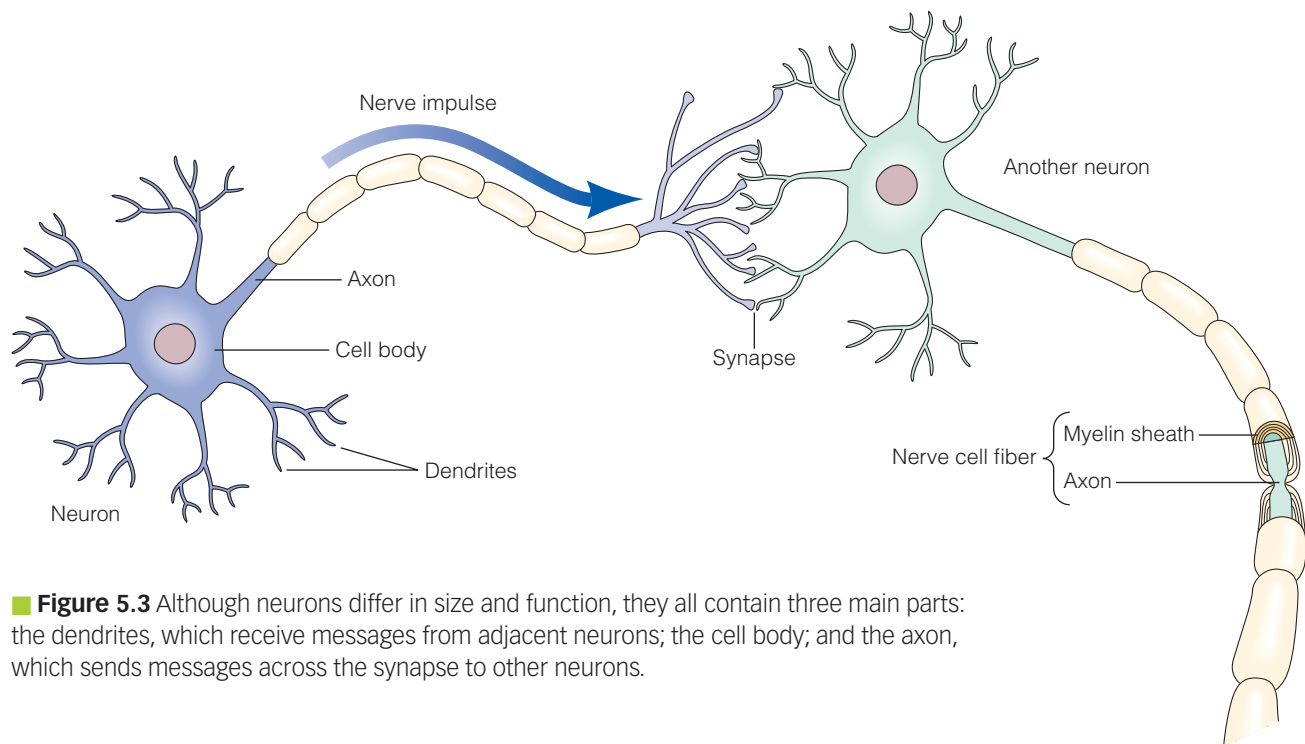

Meanwhile, in adolescent girls, the ovaries (also endocrine glands) produce larger quantities of the primary female hormone, **estrogen**, and of progesterone. Estrogen increases dramatically at puberty, stimulating the production of growth hormone and the adolescent growth spurt, much as testosterone does in males. It is also responsible for the development of the breasts, pubic hair, and female sex organs and for the control of menstrual cycles throughout a woman’s reproductive years. Progesterone is sometimes called the “pregnancy hormone” because it orchestrates bodily changes that allow conception and then support a pregnancy. Finally, the adrenal glands secrete androgen-like hormones that contribute to the maturation of the bones and muscles in both sexes. The maturation of the adrenal glands during middle childhood results in sexual attraction well before puberty in both boys and girls and relates to sexual orientation in adulthood (Herdt & McClintock, 2000; McClintock & Herdt, 1996). The roles of different endocrine glands in physical growth and development are summarized in ● **Table 5.1**.

In adulthood, endocrine glands continue to secrete hormones, under the direction of the hypothalamus and the pituitary gland, to regulate bodily processes. For example, thyroid hormones help the body’s cells metabolize (break down) foods into usable nutrients, and the adrenal glands help the body cope with stress. Throughout the life span, then, the endocrine system works with the nervous system to keep the body on an even keel. Yet changes occur; for example, declines in levels of sex hormones are associated with menopause. And, as you will see later in this chapter, some theorists believe that changes in the functioning of the endocrine glands late in life help bring about aging and death.

In short, the endocrine system, in collaboration with the nervous system, is centrally involved in growth during childhood, physical and sexual maturation during adolescence, functioning over the life span, and aging later in life.

● **Table 5.1** Hormonal Influences on Growth and Development

Endocrine Gland	Hormones Produced	Effects on Growth and Development
Pituitary	Growth hormone	Regulates growth from birth through adolescence; triggers adolescent growth spurt
	Activating hormones	Signal other endocrine glands (such as ovaries and testes) to secrete their hormones
Thyroid	Thyroxine	Affects growth and development of the brain and helps regulate growth of the body during childhood
Testes	Testosterone	Develops the male reproductive system during the prenatal period; directs male sexual development during adolescence
Ovaries	Estrogen and progesterone	Regulate the menstrual cycle; estrogen directs female sexual development during adolescence; progesterone allows conception and supports pregnancy
Adrenal glands	Adrenal androgens	Support the development of muscle and bones; contribute to sexual motivation

■ **Figure 5.3** Although neurons differ in size and function, they all contain three main parts: the dendrites, which receive messages from adjacent neurons; the cell body; and the axon, which sends messages across the synapse to other neurons.

The Brain and Nervous System

None of the physical or mental achievements that we regard as human would be possible without a functioning nervous system. The nervous system consists of the brain and spinal cord (central nervous system) and the neural tissue that extends into all parts of the body (peripheral nervous system). Its basic unit is a **neuron** (■ Figure 5.3). Although neurons come in many shapes and sizes, they have some common features. Branching, bushy dendrites receive signals from other neurons, and the long axon of a neuron transmits electrical signals to other neurons or, in some cases, directly to a muscle cell. The axon of one neuron makes a connection with another neuron at a tiny gap called a **synapse**. By releasing neurotransmitters stored at the ends of its axons, one neuron can either stimulate or inhibit the action of another neuron.

The axons of many neurons become covered by a fatty sheath called *myelin*, which acts like insulation to speed the transmission of neural impulses. The process of **myelination**—neurons becoming encased in this protective substance that speeds transmission—begins prenatally but continues for many years after birth, proceeding from the spinal cord to the hindbrain, midbrain, and forebrain. Myelination has numerous implications for developmental changes observed across the life span. Myelination in the visual cortex is largely complete by age 1, consistent with advances in visual skills over the first year (Deoni et al., 2015). Toddlers experience a vocabulary spurt following a period of rapid myelination of those parts of the brain involved in language development (Su et al., 2008). And teenagers are more likely than children to ask hypothetical “what if” questions and to reason about weighty abstractions, such as truth and justice, owing to myelination within the prefrontal lobes during adolescence. Progressive myelination of the pathways involved in attention and concentration helps explain why infants, toddlers,

school-age children, and even young adolescents have shorter attention spans than do older adolescents and adults. Finally, continued myelination into adulthood may account for adults being better able than teenagers to integrate thoughts and emotions, allowing them to think more clearly in situations where emotions are running high (Araim et al., 2013). We will further explore these changes as we move through the life span in the following sections of this chapter.

These nerve fibers are covered with myelin, shown here in pink. What role does myelin play in neural activity?

Principles of Growth

Now that you know something about the endocrine and nervous systems, and how they contribute to growth early in life, is it possible to make general predictions about growth patterns? To do so, researchers often apply three general principles that underlie growth. It is easiest to see these principles in action during infancy when growth is fast. For instance, you have probably noticed that young infants seem to be all head compared with older children and adults. That is because growth follows the **cephalocaudal principle**, according to which growth occurs in a head-to-tail direction. This pattern is clear in **Figure 5.4**: The head is far ahead of the rest of the body during the prenatal period and accounts for about 25% of the newborn's length and 13% of total body weight. But the head accounts for only 12% of an adult's height and 2% of an adult's weight (Zemel, 2002). During the first year after birth, the trunk grows the fastest; in the second year, the legs are the fastest growing part of the body.

While infants are growing from the head downward, they are also growing and developing muscles from the center outward to the extremities. This **proximodistal principle** of growth can be seen during the prenatal period, when the chest and internal organs form before the arms, hands, and fingers. During the first year of life, the trunk is rapidly filling out but the arms remain short and stubby until they undergo their own period of rapid development.

A third important principle of growth and development is the **orthogenetic principle**. This means that development starts globally and undifferentiated and moves toward increasing differentiation and hierarchical integration (Werner, 1957). Consider a human who starts as a single, undifferentiated cell

at conception. As growth proceeds, that single cell becomes billions of highly specialized cells (neurons, blood cells, liver cells, and so on). These differentiated cells become organized, or integrated, into functioning systems such as the brain or the digestive system.

Having looked at the building blocks of body and brain, you are ready to examine the development, health, and aging of the physical self. We concentrate on changes in the body and brain that will help us understand the contributions of each to many other areas of development that will be covered in subsequent chapters. We also consider factors that are important to health at different ages. In doing so, we turn once again to a life-span model.

A Life-Span Developmental Model of Health

The life-span developmental perspective introduced in Chapter 1 can be applied to our consideration of health and wellness as follows:

- Health is a lifelong process. It is influenced by personal choices over the life span and is constantly changing in response to these choices. For instance, whether you are 18, 48, or 78 years old when you begin an exercise program or stop smoking, these sorts of changes to your lifestyle can alter the path of your health.
- Health is determined by both genetic and environmental influences. According to the biodevelopmental framework from Harvard's Center on the Developing Child (see Shonkoff,

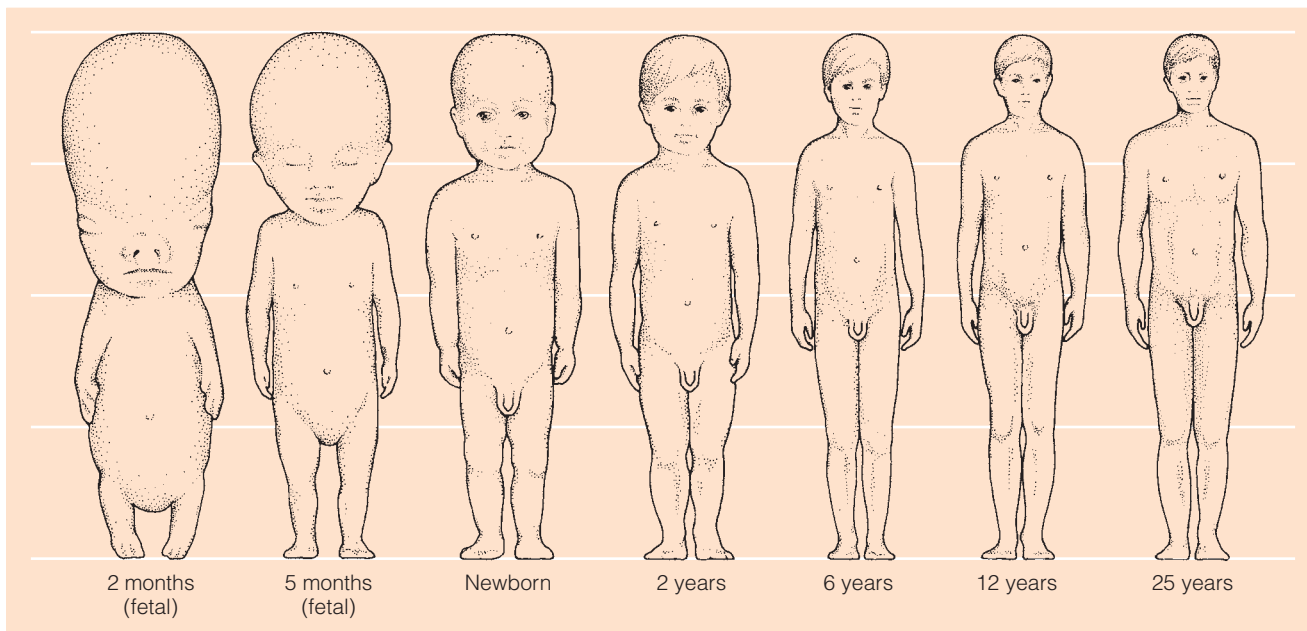

Figure 5.4 The cephalocaudal (“head-to-tail”) principle of growth is illustrated in our body proportions from the fetal period through adulthood. At 2 months after conception, your head made up half of your total body length, but now, as an adult, your head is a mere 12–13% of your adult height. By contrast, during this same time frame, your legs have gone from being only about 12–13% of your early prenatal length to about half of your adult height.

2010), a person's genetic predispositions interact with their environmental experiences to create adaptive (healthy) outcomes or disruptive (unhealthy) ones. As we learned in Chapter 4, by the time we are old enough to make our own choices, we have already been influenced by choices made by our parents and even our grandparents. As a result of fetal programming, an individual whose mother smoked or drank alcohol during pregnancy, for example, may have different health predispositions than one whose mother did not smoke or drink while pregnant.

- Health—and its study—is multidimensional. As we saw in the chapter opener, physical, mental, and social functioning are intertwined with one another; changes in one area influence other aspects of self.
- Changes in health involve both gains and losses; health both improves and declines over the life span in response to many factors.
- Health occurs in a sociohistorical context and can be enhanced or constrained by the social and historical factors that contribute to it. Especially important is socioeconomic status. Lower socioeconomic status is routinely associated with poorer health and well-being and shorter life expectancy.

Thus, an individual's health is determined by genetic factors, personal choices, and environmental influences working in concert across the life span. The importance of a life-span model of health will be clear as we view health in each of the following sections.

● Checking Mastery

1. How does the endocrine system support development?
2. How does myelination contribute to developmental changes that we can observe?
3. What is one example each of the principles guiding growth: cephalocaudal, proximodistal, and orthogenetic development?

● Making Connections

1. Why is it important to view health from a life-span developmental perspective? Illustrate three aspects or components of this perspective as they apply to you or members of your family.

5.2

The Infant

LEARNING OBJECTIVES

- Discuss typical changes in the brain during infancy.
- Summarize newborn capabilities that promote healthy adaptation to the world outside the womb.

Infancy is characterized by continued brain development, rapid growth, and impressive sensory and reflexive capabilities. Understanding the newborn's capacities and limitations brings a fuller appreciation of the dramatic changes that take place between birth and adulthood.

In Chapter 4 we traced the amazing evolution of the brain during the prenatal period. Here we pick up the story by looking at what goes on in the brain after birth. Although the brain is proportionately the largest and most developed part of the body at birth, much of its development takes place after birth. Postnatally, though, development is not so much about generating new neurons as about connecting existing neurons. Recall our discussion in Chapter 4 of how a new neuron migrates to its home in the nervous system and, like a good neighbor, begins reaching out and communicating with other neurons in the same region. Much of brain development in infancy and childhood consists of forging more and more connections between neurons (Johnson & de Haan, 2015). ■ **Figure 5.5** shows how the complexity of the communication network—the dendrites extending from each neuron—increases over childhood. As we go about our daily business of behaving and thinking, some of the connections among neurons become more numerous. But other connections, seldom used, seem to shrivel up and disappear. In **Figure 5.5**, the network of connections in the far right panel from a teenager is less dense than the network in the middle panel

from a child. This illustrates the **synaptogenesis**, or growth of synapses, during childhood as well as the **synaptic pruning** or removal of unnecessary synapses that is also an important component of brain development.

■ **Figure 5.5** Between birth and 7 years of age, there is a tremendous amount of *synaptogenesis*, or the development of connections between neurons. But between 7 and 15 years of age, there is another process at work: *synaptic pruning* or elimination of unnecessary or unused connections.

The development of the brain early in life is heavily influenced by the unfolding of a genetic program that has evolved over many generations. But genes are not the only influence—an individual’s experiences are also crucial to brain development. As Charles Nelson and colleagues (2006) describe it, “The brain’s circuitry must rely on experience to customize connections to serve the needs of the individual” (p. 3). Assuming that the infant has normal opportunities to explore and experience the world, the result will be a normal brain and normal development. During the early brain development spurt that begins before birth and continues during infancy, the brain is fine-tuned by experience through the dual processes of synaptogenesis and synaptic pruning.

Thus, the brain, especially early in its formation, has great **plasticity**; that is, it is responsive to the individual’s experiences and can develop in a variety of ways (Kolb, Whishaw, & Teskey, 2016). On the negative side, the developing brain is highly vulnerable to damage if it is exposed to drugs or diseases (recall the description of teratogens in Chapter 4) or if it is deprived of sensory and motor experiences. On the positive side, this highly adaptable brain can often recover successfully from injuries. Neurons that are not yet fully committed to their specialized functions can often take over the functions of damaged neurons. Moreover, the immature brain is especially able to benefit from stimulating experiences. Rodents that grow up in enriched environments with plenty of sensory stimulation develop larger, better-functioning brains with more synapses than rodents that grow up in barren cages (Garthe, Roeder, & Kempermann, 2016; Greenough, Black, & Wallace, 1987). With advances in technology, researchers have now uncovered similar findings with humans: Spending the first few years of life in impoverished families and neighborhoods leads to less “gray matter,” the brain tissue believed to be involved in information processing (Hanson et al., 2013). These youngsters start life with the same amount of gray matter as those from wealthier families and neighborhoods, but they experience slower rates of brain growth during infancy and early childhood. By 3 years of age, there are measurable differences in the brain matter of children in high, middle, and low socioeconomic groups. Clearly, environment matters.

Brain plasticity is greatest early in development. However, the organization of synapses within the nervous system continues to change in response to experience throughout the life span. Animals put through their paces in mazes grow bushier dendrites, whereas their brains lose some of their complexity if the animals are then moved to less stimulating quarters (Thompson, 2000). This also holds promise for those children who start life in poverty but then have opportunities to live or learn in more enriched circumstances. We will return to this possibility of catch-up growth in cognitive development in later chapters.

In short, the *critical*, or *sensitive*, *period* for brain development—the time when it proceeds most rapidly—is during the late prenatal period and early infancy. The developing brain is characterized by a good deal of plasticity: Normal genes may provide rough guidelines about how the brain should be configured, but early experience determines the architecture of the brain.

Rapid Growth

Newborns are typically about 20 inches long and weigh 7–7½ pounds. However, weight and length at birth can mislead about eventual weight and height because the growth of some fetuses is stunted by a poor prenatal environment (Özaltın et al., 2010). Size during the first few months of life is related more to prenatal experiences (environment) than to size of parent (genes). This is easy to see in twins and other multiple births, because their prenatal growth is significantly restricted by siblings competing for the limited space in the mother’s womb.

In the first few months of life, infants grow rapidly, gaining nearly an ounce of weight a day and an inch in length each month. By age 2, they have already attained about half of their eventual adult height and weigh 27–30 pounds on average. Although we usually think of growth as a slow and steady process, daily measurements of infant length show that babies grow in fits and starts (Lampl & Thompson, 2007). They may go weeks with no growth and then shoot up half an inch in 24 hours! Not surprisingly, these growth spurts are often accompanied by irritability that many parents, unaware of the phenomenal growth taking place, find puzzling. In the end, 90–95% of an infant’s days are growth free, but their occasional bursts of physical growth add up to substantial increases in size. Infants whose overall weight gain outpaces gains in length (height) are at risk of childhood obesity, particularly when that weight increase occurs early in infancy (Bjerregaard et al., 2014; Salgin et al., 2015). We’ll have more to say about obesity in subsequent sections of this chapter.

Bones and muscles are also developing quickly during infancy. At birth, most bones are soft, pliable, and difficult to break. They are too small and flexible to allow newborns to sit up or balance themselves when pulled to a standing position. The soft cartilage-like tissues of the young infant gradually ossify (harden) into bony material as calcium and other minerals are deposited into them. In addition, more bones develop, and they become more closely interconnected. As for muscles, young infants are relative weaklings. Although they have all the muscle cells they will ever have, their strength will increase only as their muscles grow.

Newborn Capabilities

Newborns used to be viewed as helpless little organisms, ill prepared to cope with the world outside the womb. We now know that they are quite well equipped to begin life. Just what can a newborn do? Among the most important capabilities are reflexes, functioning senses, a capacity to learn, and organized, individualized patterns of waking and sleeping. In this chapter, we’ll examine their reflexes and brain development; in subsequent chapters, we address their sensory abilities (Chapter 6) and their potential to learn from experience (Chapters 7 and 8).

Reflexes

One of the newborn’s greatest resources is a set of useful reflexes. A **reflex** is an unlearned and involuntary response to a stimulus, such as when the eye automatically blinks in response to a puff of air. • **Table 5.2** lists some reflexes that can be readily observed in all normal newborns. These seemingly simple reactions are

● **Table 5.2** Major Reflexes of Full-Term Newborns

Survival Reflexes	Developmental Course	Significance
<i>Breathing reflex</i>	Permanent	Provides oxygen; expels carbon dioxide
<i>Eye-blink reflex</i>	Permanent	Protects eyes from bright light or foreign objects
<i>Pupillary reflex</i> : Constriction of pupils to bright light; dilation to dark or dimly lit surroundings	Permanent	Protects against bright light; adapts visual system to low illumination
<i>Rooting reflex</i> : Turning a cheek toward a tactile (touch) stimulus	Weakens by 2 months; disappears by 5 months	Orients child to breast or bottle
<i>Sucking reflex</i> : Sucking on objects placed (or taken) into mouth	Gradually modified by experience over the first few months after birth; disappears by 7 months	Allows child to take in nutrients
<i>Swallowing reflex</i>	Permanent, but modified by experience	Allows child to take in nutrients; protects against choking
Primitive Reflexes	Developmental Course	Significance
<i>Babinski reflex</i> : Fanning then curling toes when bottom of foot is stroked	Disappears by 12–18 months months	Presence at birth and disappearance in first year indicate normal neurological development
<i>Grasping reflex</i> : Curling fingers around objects (such as a finger) that touch the baby's palm	Disappears in first 3–4 months; is replaced by a voluntary grasp	Presence at birth and later disappearance indicate normal neurological development
<i>Moro reflex</i> : Loud noise or sudden change in position of baby's head will cause baby to throw arms outward, arch back, then bring arms toward each other	Disappears by 4 months; however, child continues to react to unexpected noises or a loss of bodily support by showing startle reflex	Presence at birth and later disappearance (or evolution into startle reflex) indicate normal neurological development (which does not disappear)
<i>Swimming reflex</i> : Infant immersed in water will display active movements of arms and legs and will involuntarily hold breath (thus staying afloat for some time)	Disappears in first 4–6 months	Presence at birth and later disappearance indicate normal neurological development
<i>Stepping reflex</i> : Infants held upright so that their feet touch a flat surface will step as if to walk	Disappears in first 8 weeks unless infant has regular opportunities to practice it	Presence at birth and later disappearance indicate normal neurological development

Preterm infants may show little to no evidence of primitive reflexes at birth, and their survival reflexes are likely to be irregular or immature. However, the missing reflexes will typically appear soon after birth and will disappear a little later than they do among full-term infants.

actually quite varied and complex patterns of behavior that provide infants with a way to begin interacting with their world (von Hofsten, 2007; 2013). The presence of these reflexes is important because it lets us know that the infant's nervous system is working.

Some reflexes are called *survival reflexes* because they have clear adaptive value. Examples include the breathing reflex (useful for obvious reasons), the eye-blink reflex (which protects against bright lights or foreign particles), and the sucking reflex (needed to obtain food). Those called *primitive reflexes* are not clearly useful; many are believed to be remnants of evolutionary history that have outlived their purpose (but see Schott & Rossor, 2003, for another perspective). The Babinski reflex is a good example. Why would it be adaptive for infants to fan their toes when the bottoms of their feet are stroked? Frankly, we don't know. Other primitive reflexes may have some adaptive value, at least in some cultures. For example, the grasping reflex may help infants carried in slings or on their mothers' hips to hang on. Finally, some primitive reflexes—for example, the stepping reflex—are forerunners of useful voluntary behaviors that develop later in infancy. The expression of primitive reflexes at age 6 weeks, however, is not related to the expression of later motor behaviors (Bartlett, 1997). Thus, infants who demonstrate a strong primitive grasping reflex at 6 weeks are not necessarily the infants who demonstrate a strong voluntary grasp later in infancy.

Primitive reflexes typically disappear during the early months of infancy. For instance, the grasping reflex becomes weak by 4 months and is replaced by voluntary grasping. These primitive reflexes are controlled by the lower, subcortical areas of the brain and are lost as the higher centers of the cerebral cortex develop and make voluntary motor behaviors possible. Even though many primitive reflexes are not very useful to infants, they have proven to be useful in diagnosing infants' neurological problems. If such reflexes are not present at birth—or if they last too long in infancy—physicians know that something is wrong with a baby's nervous system. The existence of reflexes at birth tells them that infants are ready to respond to stimulation in adaptive ways. The disappearance of certain reflexes tells them that the nervous system is developing normally and that experience is affecting both brain and behavior. Thus, we see that the presence and then the absence of reflexes can serve as a general indicator of neurological health.

Behavioral States

Much to their tired parents' dismay, newborns have no clear sense of night or day and may wake every 1–4 hours. Infants must move from short sleep–wake cycles distributed throughout the day and night to a pattern that includes longer sleep periods at night with longer wake periods during the day. Settling into an organized sleep–wake pattern is an indication that the baby's nervous system is developing as expected and is beginning to integrate a myriad of external signals with internal states. By 3 months, most infants begin to establish a predictable

sleep–wake cycle, which becomes fairly stable by 6 months of age for most infants. Much to their relief, about two-thirds of mothers report that their 6-month-old infants are sleeping through the night nearly every night (Weinraub et al., 2012). The other one-third of mothers continue to be awakened by their infants more nights than not and report that this pattern persists until their infants are about 24 months of age.

These early sleep patterns are indicative of other behaviors. For instance, among premature infants, those who transition smoothly from one state to another exhibit more mature neurocognitive outcomes than other premature infants (Weisman et al., 2011). And those infants with poor sleep habits at 12 months of age are reported to have problems with attention regulation as well as behavior problems at 3 to 4 years of age (Sadeh et al., 2015). In contrast, infants who get more sleep at night tend to be more easygoing during the day (Spruyt et al., 2008). Are they more easygoing because they are well rested from a good night's sleep, or do they sleep well at night because they are easygoing? We don't know the answer to this question in infants, but we do know that adults who are normally easygoing can be irritable when deprived of sleep, so perhaps this is true for infants as well.

Newborns spend half of their sleeping hours in active sleep, also called **REM sleep** (for the rapid eye movements that occur during it). Infants older than 6 months spend only 25–30% of their total sleep in REM sleep, which more closely resembles the 20% that adults spend in REM sleep. Why do young infants sleep so much and spend so much more time in REM sleep than adults? Sleep patterns in infancy are associated with brain maturation and plasticity (Tarullo, Balsam, & Fifer, 2011). REM sleep, in particular, may be important for learning and memory processes (Diekelmann, Wilhelm, & Born, 2009). This may help explain why infants, who have so much to learn, spend more time in this sleep. Think about it: Infants are taking in vast amounts of new

Establishing an organized sleep–wake pattern is an important accomplishment of infancy. It can sometimes take several months before infants sleep through the night.

Andersen Ross/Getty Images

information during the times they are awake. These periods are invariably followed by sleep, which may help their brains learn and remember the new information. If deprived of sleep, infants may become “overloaded” with too much new information that their immature nervous systems cannot fully process. This may explain why infants are notoriously fussy at the end of a busy day—often at dinnertime when parents are tired and hoping for some peace. The infant’s nervous system can be overstimulated by the flood of stimulation received during the day. Somehow, the arousal needs to be reduced—perhaps by crying and then sleeping. Adults sometimes marvel at how infants can sleep through the loudest noises and the brightest lights, but being able to do so may serve a valuable function.

Health and Wellness

What health issues must infants—and their parents—navigate? As noted in the previous chapter, modern medicine has made it possible for smaller and smaller babies to survive premature delivery, but sadly, most of the smallest babies—those weighing less than 1 pound 10½ ounces (750 grams)—die within the first year (MacDorman & Mathews, 2008). The health problems associated with premature delivery and low birth weight often continue to challenge infants throughout their first year and beyond, illustrating one of the principles of the life-span model of health: Some events can have lifelong effects on health. Only about 12% of babies in the United States are premature, but complications of premature birth account for 35% of infant deaths. Complications related to labor and delivery account for about one-quarter of deaths, and various types of infections together account for another one-quarter of deaths (Liu et al., 2015). **Congenital malformations**—defects that are present at birth, either from genetic factors or prenatal events—account for 1 out of 10 deaths during the first year. Such malformations include heart defects, spina bifida, Down syndrome, cleft palates, and more.

Infant health has been dramatically improved in recent decades by administering vaccinations aimed at protecting infants

from a variety of diseases (such as diphtheria, pertussis, polio, and measles). The approximately 20% of infants who do not receive the recommended immunizations are more likely than immunized babies to contract illnesses that can compromise their health (CDC, 2013). Socioeconomic status in the United States often determines who has access to health care services that cover immunizations. Yet the parents who deliberately avoid or delay immunization of their infants are more likely to be white and above-average socioeconomic status. They cite concerns about side effects as reasons to delay or not get their little one immunized, and they are less likely to believe that vaccinations are necessary to protect their child’s health (Smith et al., 2011). As the life-span model maintains, one’s sociohistorical context influences health.

Thus, health during infancy starts well before birth with prenatal care that helps prevent and/or treat potential congenital anomalies and preterm birth. Health after birth is enhanced by well-baby visits to the doctor to ensure that development is proceeding normally and by following recommendations for prevention of illness. Quality and pattern of sleep is an important indicator of nervous system development and is associated with behaviors in childhood.

● Checking Mastery

1. What are the most significant brain changes that occur during infancy?
2. What are two infant reflexes that may help ensure survival in the early months of life?
3. What can an infant’s sleep–wake cycle indicate about her development?

● Making Connections

1. In what ways is brain plasticity an advantage and in what ways might it be a disadvantage to the developing human?

5.3

The Child

LEARNING OBJECTIVES

- Discuss the implications of brain lateralization for behavior and functioning.
- Outline the major physical accomplishments and health challenges of childhood.

Slow and steady is probably the best way to describe the growth that occurs throughout much of childhood. From age 2 until puberty, children gain about 2–3 inches and 5–6 pounds every year. This growth is often tracked on a chart that plots an individual’s height and weight against normative data. This allows physicians and families to see how a particular child is progressing relative to other children of the same age and gender and to graph the pattern of growth over time. Children who are markedly different—higher, lower, or more erratic in their growth rate—may warrant additional investigation.

During middle childhood (ages 6–11), children may seem to grow little, probably because the gains are small in proportion to the child’s size (4–4½ feet and 60–80 pounds on average) and therefore harder to detect. The cephalocaudal and proximodistal principles of growth continue to operate. As the lower parts of the body and the extremities fill out, the child takes on more adultlike body proportions. The bones continue to grow and harden, and the muscles strengthen.

As we’ll see in the next section, there are also steady changes going on within the brain. The brain becomes further organized

to support the behaviors, both mental and physical, in which its “owner” is regularly engaged.

Brain Lateralization

One important feature of the developing organization of the brain is the **lateralization**, or asymmetry and specialization of functions, of the two hemispheres of the cerebral cortex. Instead of developing identically, the functions controlled by the two hemispheres diverge (see ■ **Figure 5.6**). In most people, the left cerebral hemisphere controls the right side of the body and is adept at the *sequential* (that is, step-by-step) processing needed for analytic reasoning and language processing. The right hemisphere generally controls the left side of the body and is skilled at the *simultaneous* processing of information needed for understanding spatial information and processing visual–motor information as well as the emotional content of information (Kensinger & Choi, 2009). Although it is an oversimplification, the left hemisphere is often called the *thinking* side of the brain, whereas the right hemisphere is called the *emotional* brain.

Having two hemispheres of the brain is not the same as having two brains. The hemispheres “communicate” and work together through the corpus callosum, “the super-highway of neurons connecting the halves of the brain” (Gazzaniga, 1998, p. 50). Even though one hemisphere might be more active than the other during certain tasks, they both play a role in all activities. For example, the left hemisphere is considered the seat of language because it controls word content, grammar, and syntax, but the right hemisphere processes melody, pitch, sound intensity, and the affective content of language.

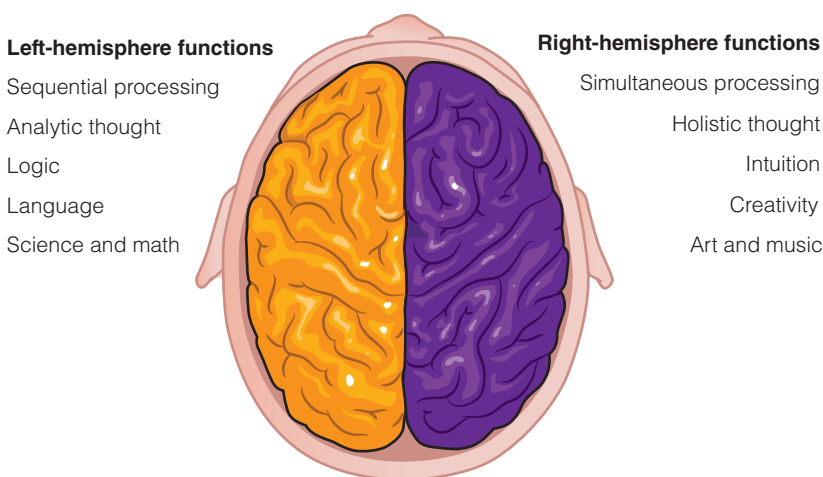

If one hemisphere is damaged, it may be possible for the other hemisphere to “take over” the functions lost. For example, most children who have one hemisphere removed to try to reduce or eliminate severe seizures regain normal language function (Liégeois et al., 2008; Vining et al., 1997). It does not matter whether the remaining hemisphere is the left or the right. Thus,

although the left hemisphere processes language in most people (perhaps 92%), the right hemisphere may also be able to fill this function, although it is not yet known how this possibility might be limited—or enhanced—by age or other characteristics of the individual (Gazzaniga, 1998; Knecht et al., 2000).

When does the brain become lateralized? Signs of brain lateralization are clearly evident at birth. Newborns are more likely to turn their heads to the right than to the left and some clearly prefer the right hand in their grasp reflex (Johnson & de Haan, 2015). Newborns may also show more left hemispheric response to speech sounds (Kotilahti et al., 2010), although this response becomes stronger and more reliable in the second half of the first year (Holowka & Petitto, 2002).

Signs of lateralization so early in life suggest that it has a genetic basis. Further support for the role of genes comes from family studies of handedness. Overall, about 9 in 10 people rely on their right hands (or left hemispheres) to write and perform other motor activities with males somewhat more likely to be left-handed than females (Vuoksimaa et al., 2009). In families where both parents are right-handed, the odds of having a left-handed child are only 2 in 100. These odds increase to 17 in 100 when one parent is left-handed and to 46 in 100 when both parents are left-handed (Springer & Deutsch, 2001). Although this suggests a genetic basis to handedness, it could also indicate that children become left-handed because of experiences provided by left-handed parents. However, experience would not account for head-turning preferences in young infants or for the differential activation of the left and right hemispheres observed in newborns when listening to speech sounds.

Overall, then, the brain appears to be structured very early so that the two hemispheres of the cortex will be capable of specialized functioning. As we develop, most of us come to rely more on the left hemisphere to carry out language processing and more on the right hemisphere to do such things as perceive spatial relationships and emotions. We also come to rely more consistently on one hemisphere, usually the left, to control many of our physical activities.

■ **Figure 5.6** The brain consists of two hemispheres that specialize in different functions. Functions such as logic, analytic reasoning, and language are typically associated with the left hemisphere, whereas such functions as creativity, intuition, and holistic thinking are associated with the right hemisphere.

Physical Behavior

Children’s physical behaviors are noticeably advanced compared to those of infants and toddlers. For instance, although toddlers are capable of controlling their movements in relation to a *stationary* world, children master the ability to move capably in a *changing* environment (Haywood & Getchell, 2014). They must learn to modify their movements to adapt to changes in environment as well as changes in their own bodies as they grow bigger (Adolph & Robinson, 2015). These adaptations allow them to bring their hands together at just the right time to catch a ball and to avoid bumping into moving people when walking through a crowded mall. They also refine many motor skills. For example, young children throw a ball only with the arm, but older children learn to step forward as they throw. Their accuracy throwing a ball increases around age 7, as does their speed of throwing (Favilla, 2006). Thus,

older children can throw a ball farther than younger ones can, not just because they are bigger and stronger but also because they can integrate multiple body movements—raising their arm, turning their body, stepping forward with one foot, and pushing their body forward with the other foot (Haywood & Getchell, 2014).

As a child, one of your textbook authors was teased by an older brother for apparent lack of skill on the ball field. A regular taunt was “you throw like a girl!” It turns out there is a well-established gender difference in both throwing speed and distance: Girls do, indeed, throw like girls and not like boys (Thomas et al., 2010). A typical 13-year-old girl can throw a ball an average of 38.5 miles per hour, which sounds fast until you learn that the typical 13-year-old boy averages 53.5 miles per hour. Some of this difference seems to be nurture: Boys are given more things to throw, start earlier in sports that involve throwing, and spend more time practicing throwing. But practice and the environment do not explain all of the gender difference in throwing. Boys may also be able to throw faster and farther because of their greater upper body muscle mass and their shoulder width.

We should note that girls are somewhat ahead of boys in hopping and tasks that require manual dexterity (Junaid & Fellowes, 2006; Van Beurden et al., 2002). But again, these differences seem to arise, at least in part, from practice and different expectations for males and females.

Apparently, even Olympic gold medal winner in gymnastics Gabby Douglas “throws like a girl.” There are some physical skills where males and females, on average, perform differently from one another.

Jim McIsaac/Getty Images Sport/Getty Images

the childhood years (National Vital Statistics System, 2015). As ● **Table 5.3** shows, drownings top the list of accidental causes of death for 1 to 4 year olds, and crashes involving motor vehicles cause the largest number of fatal injuries throughout the remainder of childhood. Parents can reduce the possibility of accidental drownings by adding fences and coverings to swimming pools and hot tubs and closely monitoring their toddlers around all sources of water, including the bath tub. As well, motor vehicle fatalities may be reduced by properly strapping their infants and young children into car seats, or as they get older, insisting that they sit in the backseat with a shoulder-strap seat belt.

Of course, not all accidents are fatal. Falls and being struck by something cause the largest number of nonfatal injuries during childhood, followed by such things as bee stings, bites, cuts, and overexertion. Most of these injuries are minor and do not constitute a major developmental obstacle. But some injuries for some children can have lasting effects on their physical or mental well-being.

Nutrition

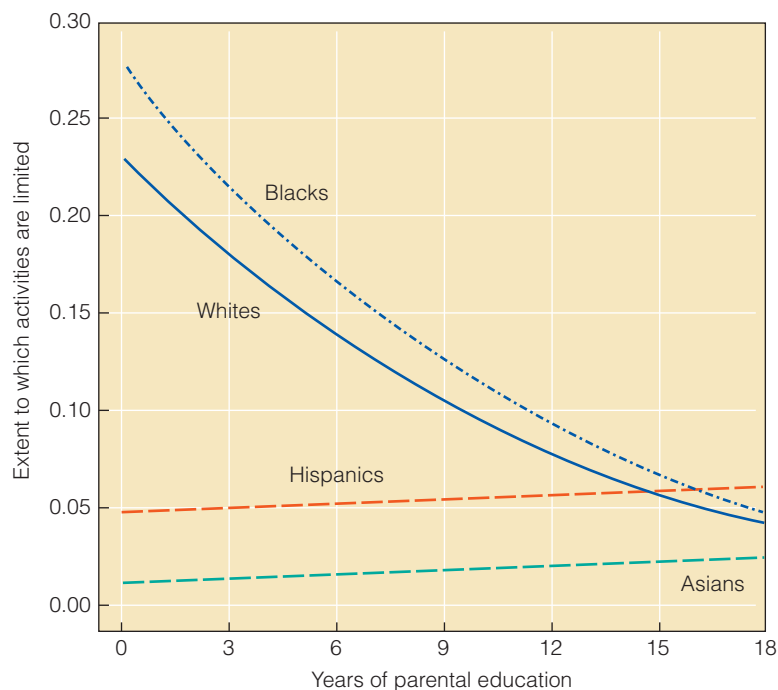

Nutrition continues to be an important contributor to health throughout childhood, as it

Health and Wellness

There are many factors that can influence children’s health and wellness, but three big areas of concern during this period of life are accidents, nutrition, and physical activity levels. All three factors are influenced by the child’s home environment, in particular, the socioeconomic status and education level of parents (Matthews & Gallo, 2011). Children whose parents are less educated are more likely to experience poor or fair health than children with more educated parents. This is particularly true for black children and white children, but less true for Hispanic children and Asian children, whose health outcomes may be buffered by strong social networks that cut across educational and socioeconomic levels (■ **Figure 5.7**). This is another example of how the sociohistorical context of development plays a role in children’s health and well-being.

Accidents

Accidents constitute a major category of negative influences on children’s health and well-being. Childhood is unfortunately marked by numerous unintentional injuries, making accidents the leading cause of death throughout

■ **Figure 5.7** Among white families and black families, parents’ education levels influence the extent to which children’s activities are limited by poor or fair health: Children have more limitations when their parents are less educated. This is not true among Hispanic families and Asian families.

was during infancy. It is probably not surprising to learn that most children do not eat the recommended daily amount of fruits and vegetables (Attorp et al., 2014). Of the total calories consumed by children every day, 27% come from snacks (Kenney et al., 2014). That might be fine if the snacks were healthy, but they tend to be sugary, salty, fatty, and low in nutrients. A determined group of researchers staked out local convenience stores that were located near urban schools (Borradaile et al., 2009). These were small stores within four blocks of the schools that were frequented by children on their way to and from school. For months, the researchers tracked everything the children purchased, briefly surveyed them regarding their purchases, and later analyzed the nutritional content of the food and beverages purchased. The most frequently purchased item was chips, followed by candy, and then sugar-sweetened artificially flavored drinks. In other words, the children were buying fatty, sugary foods and beverages with little nutritional value but high caloric value. Amazingly, these children spent an average of just \$1 dollar to ingest an average of 356 empty calories. What a bargain!

Similar findings emerged from a survey of fluid intake across childhood, which found that sodas and artificially flavored drinks made up a large portion of the fluids that children consume (Borradaile et al., 2009; He, Marrero, & MacGregor, 2008). Sodas not only contribute to weight gain and obesity, they are also associated with lower consumption of milk and intake of calcium, an important nutrient for bone health (Keller et al., 2009; Lim et al., 2009). So what can parents do?

Parents can help children to become healthy eaters by regularly offering a variety of healthy foods and beverages and by modeling healthy eating habits. Education level of mothers is a good predictor of whether children adopt healthy eating patterns and consume fewer sugar-laden beverages (Northstone et al., 2013; van Ansem et al., 2014). More education may translate into greater awareness of healthy habits. These parents, for example, may be more aware of the recommendations for healthy eating and steer

children away from the sugary sodas and other sugar-sweetened beverages that have become so very popular. Higher education levels may also provide parents with additional strategies for managing their children’s behavior, without having to resort to bribing their children with candy and soda to get them to behave (Fisher et al., 2015). Finally, there is also evidence that children may eat more at home and gain more weight if they are living in a stressful home situation, which is often associated with living in poverty. Craig Gundersen and his colleagues (2008) found that young children eat more “comfort foods” when their mothers are stressed, but only if these foods are available to them. These findings illustrate Bronfenbrenner’s exosystem (see Chapter 2): A child is influenced by things going on in the mother’s life that may relate to her work, finances, and other factors that do not directly involve the child but still affect the child.

Also important is the larger environment—the neighborhood and school—of the child. Neighborhoods with higher levels of poverty and lower education levels are associated with higher rates of obesity (Kimbrow & Denney, 2013). And when fast foods and junk foods are available in the neighborhood, in the form of fast-food restaurants and convenience stores, children and their parents are more likely to partake of these often unhealthy eating options (He et al., 2012; Rummo et al., 2015). Children and their families who do not live within easy access of junk food consume less of it. Thus, where you live can influence how you eat. But that’s not all.

The schools that children attend are also important influences on children’s eating habits and health. Students who attend schools with breakfast programs have healthier weights than students in schools without breakfast programs, as indicated by **body mass index (BMI)**, a marker of

A typical fast-food meal: lots of calories, little nutrition.

Brand X Pictures/Getty Images

The U.S. Department of Agriculture introduced its new recommendations for healthy eating in 2011 with a food plate, replacing the food pyramid that reigned for several decades. According to the new recommendations, fruits and vegetables should make up half of your meal.

USDA

body fat calculated from a person's height and weight (Gleason & Dodd, 2009). Children who participate in their school's meal programs consume more milk, vegetables, and 100% fruit juice than children not participating; it turns out that those lunches packed at home and brought to school are not as healthy as school lunches (Caruso & Cullen, 2015; Johnston et al., 2012).

School lunches, though, are far from perfect nutrition. School lunches tend to have higher levels of fat than recommended by nutrition experts, as well as higher than recommended levels of sodium and lower amounts of fiber (Clark & Fox, 2009; Crepinsek et al., 2009). With the Healthy, Hunger-Free Kids Act of 2010, schools in the United States were put on notice that they would need to roll out healthier lunches by 2012. Has nutrition improved since the new guidelines were adopted? High school students were less impressed than elementary students by the changes to their lunches. And while the presence of a fruit and/or vegetable on the lunch tray has increased, there is also a great deal of waste, with many pounds of fruits and vegetables being wasted every day.

Physical Activity

Health during childhood can be fostered not only by a good diet but also by regular physical activity. Children should do at least 60 minutes of moderate or vigorous physical activity every day. Do they get this much activity? One group of researchers tracked older elementary school children with electronic monitors for a week to determine their activity levels (Trost et al., 2013). The children were

sedentary (think, sitting around), on average, for 63% of the time, somewhat active for 31%, and moderately to vigorously active just 6% of the time. Unfortunately, our contemporary lifestyles may inadvertently promote physical inactivity, which may explain why the fitness levels of children have shown a measurable decline in recent years. Across children of all ages, the average amount of TV viewing is 25 hours per week, and this does not include other screen time from computers and other devices (Statistic Brain Research Institute, 2015). Children who watch more than 5 hours of television a day are about five times more likely to be overweight than children who watch 2 hours a day or less, perhaps because they get little exercise and eat the junk foods that they see advertised on TV (see Shifrin et al., 2015). At the same time, some schools have reduced recess time and physical education requirements. Most kids get chauffeured everywhere they need to go in the family car, further decreasing their opportunities for walking and physical activity.

Children who live in neighborhoods that provide opportunities for safe outdoor activities are less likely to be overweight than their peers who live in settings that offer few such opportunities (Committee on Environmental Health, 2009). Particularly for families in urban neighborhoods, if parents do not believe that it is safe for their children to play outdoors, children tend to replace outdoor activity with sedentary indoor activity such as watching television (Cecil-Karb & Grogan-Kaylor, 2009). But indoor activity does not have to be completely sedentary. Children who play *active* sports or fitness video games—those that require fairly rigorous movement—benefit in comparison to children who play only the traditional, inactive video games, although they do not benefit as much as they would from physically participating in the actual sport (LeBlanc et al., 2013; Sween et al., 2014). Further, children who attend preschools with more portable equipment (for example, balls and bikes) engage in more physical activity over the course of the day than children who attend preschools

Children get more exercise if their playgrounds provide open space and portable equipment such as balls.

AP Images/Alexander Zemlianichenko

with more fixed equipment such as swing sets (Dowda et al., 2009). But even the environments that encourage the most activity cannot turn every couch potato into an athletic powerhouse. Some children are predisposed by temperament to lead more sedentary lifestyles and resist even the most engaging playground equipment and incentives to be physically engaged (Saudino, 2012; Saudino & Zapfe, 2008). Thus, characteristics of the environment in combination with characteristics of the child affect activity levels.

Children who achieve the recommended level of physical activity are, not surprisingly, more physically fit than children who lead a more sedentary lifestyle. What is especially important to consider, though, is that the benefits of exercise go beyond physical fitness: Physical activity enhances cognitive and psychological functioning. One researcher has referred to exercise as “brain food” (Ploughman, 2008). Regular physical activity seems to support effective executive functions, those important cognitive activities involved in planning and executing goal-directed behaviors (Tomprowski et al., 2008). Not surprisingly, then, children engaged in regular physical activity also show higher levels of academic achievement (Michael et al., 2015).

As Charles Basch (2011) phrased it in an introduction to a special issue of *The Journal of School Health*, “healthier students are better learners” (p. 593).

● Checking Mastery

1. How are brain functions of the two hemispheres typically organized?
2. What are three major factors that contribute to health during childhood?
3. What are two things that schools or parents can do to influence children’s eating behaviors in order to help them maintain or achieve a healthy weight?

● Making Connections

1. Design an intervention to increase children’s fitness levels and indicate how you will assess the effectiveness of your intervention.

5.4

The Adolescent

LEARNING OBJECTIVES

- Explain how brain changes during adolescence influence teens’ behavior.
- Compare and contrast the experience of puberty for males and females, including both physical and psychological correlates of puberty.

Adolescents are intensely focused on their physical self, and rightly so—dramatic physical changes are taking place during this period, both inside and out. Consider your own transformation from child to adult. You rapidly grew taller and took on the body size and proportions of an adult during your growth spurt. Moreover, you experienced **puberty**—the processes of biological change that result in an individual’s attaining sexual maturity and becoming capable of producing a child. And although you could not see them, there were changes taking place in your brain that would contribute to your transition from child to adult. We look at all these processes, starting with the brain.

The Adolescent Brain: What’s Going On in There?

The brain undergoes much change during adolescence. Magnetic resonance imaging (MRI) studies show that the brain’s “gray matter,” made up primarily of cell bodies and dendrites, undergoes change in an inverted-U pattern across adolescence. That is, the volume of gray matter increases, peaks, and then decreases throughout the teen years (Blakemore, Burnett, & Dahl, 2010). This pattern is believed to be associated with increased synaptogenesis just before puberty, followed by a period of heightened pruning of synapses (Johnson & de Haan, 2015). In contrast to

this inverted U-pattern, the brain’s “white matter,” consisting of clusters of axons, increases in linear fashion throughout adolescence, a likely result of the steady progression of myelination of axons (Blakemore et al., 2010).

Adolescents are notorious for taking chances that most adults would not take. Can brain changes explain why adolescents take more risks than adults? They often display poor judgment and decision making when it comes to alcohol, drug, and cigarette use; sexual activities; and driving (see ● **Table 5.4**). These choices have important implications for their health, both in the short term and the long term. Consider the high school students who report occasional heavy or binge drinking. Teens under the influence of alcohol are more likely to make additional risky choices:

1. They are more likely to smoke cigarettes, and the more they smoke, the more likely they are to become addicted to nicotine.
2. They are more likely to engage in risky sexual behaviors, including sex with multiple partners and unprotected sex. In turn, these behaviors are associated with unintended pregnancies and sexually transmitted diseases.
3. They are more likely to get into a car where the driver has been drinking, which greatly increases the risk of an accident.
4. They are more likely to get into physical fights, experience academic problems, and engage in illegal behaviors.

● **Table 5.4** Risky Behaviors During Adolescence

Drinking alcohol (45%)
Having sex without a condom (39%)
Getting into a physical fight (35%)
Riding with a driver who has been drinking (29%)
Using alcohol or drugs before sexual intercourse (23%)
Using marijuana (20%)
Smoking cigarettes (reported by 20% of adolescents)
Carrying weapons (18% overall but 30% among males)
Drinking and driving (10%)

Source: Department of Health and Human Services, Youth Risk Behavior Survey, 2009.

These behaviors, or the predisposition to these behaviors, may have been present before the alcohol use, but alcohol use can still exacerbate the problems. By some analyses, making the decision not to drink during adolescence may be one of the teen’s most important health decisions.

How might brain changes during adolescence relate to risky behavior? There are two things to consider. One is that the part of the brain involved in regulating self-control has not yet matured (Casey, 2015; Casey & Caudle, 2013). At some point, there may have been evolutionary advantages to this, but at this point, it seems to make teens vulnerable to potentially harmful behaviors (see Casey, 2015). The second thing to consider is that adolescence ushers in a period of increased responsiveness to rewards. Indeed, the reward system of the brain is hyper-responsive: The adolescent brain has greater need for reward, which leads to more reward-seeking behaviors. Adriana Galvan and her colleagues (2007) measured activity in a part of the brain called the *nucleus accumbens* (thought to be associated with reward, pleasure, and addiction) as participants worked on a task with varying rewards for correct answers. They found that adolescents, relative to children and adults, exhibited higher levels of activity—hyper-responsiveness—in the nucleus accumbens in anticipation of both negative and positive consequences of risk taking. In terms of timing, teens experience this higher threshold for reward prior to attaining adult levels of decision making. In particular, the neurons serving the frontal lobes are among the last areas of the brain to become myelinated. The frontal lobes are essential to many higher-order mental activities of thinking, planning, and decision making. Thus, brain changes may leave adolescents in a vulnerable position: Their desire for reward increases before their ability to think through all the consequences of their actions (Geier, 2013). The area of the brain involved in inhibiting risky behavior is not fully developed until around age 25 (Giedd, 2004).

As with all behaviors, there are individual differences. Although adolescents as a group may be more prone to risk-taking behaviors, it is certainly not the case that all adolescents engage in the same level of risk taking. Teens with stronger working memory skills, for instance, are less likely to take risks than their peers with weaker working memory skills (Khurara et al., 2015). In addition, a positive relationship between teens and their parents can help protect them during this period of development (Qu, Fuligni,

Galvan, & Telzer, 2015). On the other hand, teens tend to be more prone to risk taking when hanging out with their peers, again, thanks to what’s going on in the brain at this time of development (Somerville, 2013).

The adolescent brain, then, is still a work in progress, and some risk taking by teenagers may be par for the course until further brain developments, such as maturation of the prefrontal cortex, refine their good judgment and decision making. Laurence Steinberg (2015), who has extensively studied adolescent brain development, makes the interesting observation that educational programs aimed at getting teenagers to change their behaviors have been largely ineffective. Instead of trying to change how teenagers think, Steinberg (2015) argues that we should restructure their environments to reduce their exposure to risky situations until their brains have a chance to more fully mature. Their restructured worlds would include, for example, reduced opportunities to obtain alcohol, drugs, and cigarettes, less unstructured time (perhaps by having longer school days), and later start times for their school days to enable them to get adequate sleep, which is important to being mentally sharp throughout the day. **Exploration 5.1** considers another serious threat to brain health during adolescence—concussions.

The Growth Spurt

As noted earlier in the chapter, the **adolescent growth spurt** is triggered by an increase in the level of growth hormones circulating through the body during adolescence. Boys and girls grow at different rates, as do different body parts. Girls’ peak rate of growth for height is just under 12 years; for boys it is 13.4 years (Geithner et al., 1999). The peak rate of growth for weight is 12.5 years for girls and 13.9 years for boys. Thus, boys lag behind girls by 1–2 years. Both sexes return to a slower rate of growth after the peak of their growth spurts. Like infants, adolescents may grow in spurts rather than continuously. Girls achieve their adult height by around 16 years; boys are still growing at 18, 19, or even 20 years (Fryar, Gu, & Ogden, 2012).

Muscles also develop rapidly in both sexes, with boys normally gaining a greater proportion of muscle mass than girls do. Total body weight increases in both sexes, but it is distributed differently: Girls gain extra fat, primarily in the breasts, hips, and buttocks; boys develop broader shoulders.

Sexual Maturation

Long before the physical signs of puberty are evident, the body is changing to prepare for sexual maturity. The adrenal glands increase production of adrenal androgens sometime between the ages of 6 and 8 in both boys and girls. Known as **adrenarche**, this circulation of adrenal hormones contributes partly to such secondary sex characteristics as pubic and axillary (underarm) hair. But the more obvious signs of sexual maturity emerge with increased production of gonadal hormones (those produced by the testes or ovaries): androgens in males and estrogen and progesterone in females. The gonadal hormones are primarily responsible for the development of secondary sexual characteristics and sexual maturity. This increased hormone production will also trigger sexual thoughts, feelings, and maturation. Yes, teenagers

● EXPLORATION 5.1

Sports and Brain Damage

There are many benefits of participating in sports, but for some participants, injuries can leave an unwanted lasting impact. Considerable concern has been raised about head injuries, namely, **concussion**, which is a brief loss of brain function in response to a hit or blow to the head. Most concussions are classified as mild and symptoms resolve within weeks (Daneshvar et al., 2011). It is a fairly common sports injury, with high school football incidents accounting for nearly half of all sports-related concussions, followed by ice hockey and soccer. The number of teens treated in emergency rooms for concussion has dramatically increased over the past decade, likely from increased awareness of the serious consequences of concussion but perhaps also from the increased intensity of competitions.

Immediate symptoms of concussion include headache, sensitivity to light and sound, feeling dizzy or foggy, and slowed reaction time. But perhaps more concerning are the longer-term effects of concussions (see Bramlett & Dietrich, 2015). Researchers at Johns Hopkins University compared nine retired players from the National Football League (NFL) to a group of men who had not played football (Coughlin et al., 2015). The football players ranged in age from mid-50s to mid-70s and self-reported anywhere from zero to forty concussions during their football careers. Participants underwent PET scans and MRIs to uncover possible structural abnormalities as well as the presence of a protein that is linked to damage and repair in the brain. They also completed various memory tests. The findings were fairly dramatic, showing clear evidence of damage in the former football players' brains decades after they had retired from the sport. In particular, there was damage to the parts of the brain associated with memory and regulation of mood.

As a result of sports-related injuries, at least 25% of retired football players are expected to develop **chronic traumatic encephalopathy (CTE)**, a degenerative brain disease with symptoms of memory loss, poor impulse control, depression, and eventually dementia. One such player was Dave Duerson, who played for the Chicago Bears and New York Giants. Duerson

retired from the NFL in 1993 and eventually killed himself in 2011 at the age of 50. In a note to his family, Duerson described "having trouble with spelling, blurred vision, short-term memory problems, issues with putting full concepts and sentences together" (Martin, 2015). Duerson asked that scientists conduct a post-mortem exam of his brain. It showed damage to his frontal and temporal lobes and advanced CTE.

What about "regular" or nonprofessional players? Another group of researchers scanned the brains of 50 patients 4 months after they had experienced a mild concussion and compared these to healthy (nonconcussive) patients (Ling et al., 2013). The brains of those who had experienced a concussion showed abnormalities in the frontal cortex. It's important to note that these patients had experienced mild concussions and outward symptoms of the injury were largely or completely absent at the time of the scans. Still, there was evidence of damage to their brains.

And it's not just male athletes. Female soccer and basketball players are more likely than their male counterparts to experience a concussion in these sports, and they take longer to recover. The reasons for this gender difference are not clear, but it could be that female players report injuries more often than do males. It's also possible that anatomical differences, such as head, spine, and neck muscles, are different and place females at greater risk than males. A review of 21 studies that examined concussion symptoms among males and females, aged 12 to 26 years, found that females had more symptoms, but the researchers were not able to conclude that the male-female difference was truly meaningful

Jonathan Daniel/Getty Images

in terms of the injury (Brown et al., 2015). Women's menstrual cycles may interact with symptoms of concussion, leading to what seems like a gender difference in concussive symptoms.

The American Academy of Neurology (AAN) has issued recommendations aimed at avoiding further damage following an initial traumatic brain injury. In the past, it was common for players to 'tough it out' and continue to play in a game following an injury or to return to practice and play within days of an injury. We now know that insufficient time to recover from a traumatic brain injury can leave the brain more vulnerable to subsequent trauma. Thus, the AAN recommends that players with any symptoms of altered consciousness, regardless of whether they fainted or 'blacked out,' should not be permitted to return to playing until they have been examined and cleared to play by a medical professional trained in head trauma.

Coaches, parents, and medical professionals need to carefully train their players to reduce the sorts of moves and mindsets that increase the risk of head injuries during sports. Doing so will help ensure that athletes get the benefits of sports without the dangers.

Why are boys generally more positive than girls about the physical changes in their bodies during adolescence

Kmiragaya | Dreamstime.com

think a lot about sex and, as we will discuss in Chapter 12, some (many?) teens begin to act on these thoughts. Here, we focus on the physical changes of puberty and the psychological implications of these changes.

Progression through puberty and attainment of sexual maturity is often measured using the “Tanner Scale,” named for the British pediatrician who developed it (see Marshall & Tanner, 1969, 1970). The Tanner Scale includes five stages ranging from prepubertal—no evidence of secondary sexual characteristics—to

adult secondary sexual characteristics (● Table 5.5). For girls, the most dramatic event in the sexual maturation process is **menarche**—the first menstruation—normally between ages 11 and 15, with an average of about 12.5 years. Menstruation is the process of shedding the lining of a uterus prepared to support a fertilized egg. However, some girls begin to menstruate before they have begun to ovulate, so they may not be capable of reproducing for a year or more after menarche (Spear, 2000a). But other girls *do* ovulate—release a mature egg capable of being fertilized—when they begin to menstruate and should know that sexual activity can lead to a pregnancy.

There is a great deal of variability in when secondary sex characteristics (such as breast buds and pubic hair) appear. Sexual maturation also proceeds at different rates in different ethnic groups. Several studies have found that African American and Mexican American girls begin to experience pubertal changes earlier than European American girls (Chumlea et al., 2003; Jean et al., 2011). At age 9, for example, 49% of African American girls have begun to develop breasts compared with only 16% of European American girls and 25% of Mexican American girls (Wu, Mendola, & Buck, 2002). A few girls (1% of European Americans and 3% of African Americans) show signs of breast or pubic hair development at age 3, and a few have not begun to mature even at age 12 (Herman-Giddens et al., 1997).

For the average boy, the sexual maturation process begins around age 11 to age 11½ with an initial enlargement of the testes and scrotum (the saclike structure that encloses the testes). Unpigmented, straight pubic hair appears soon thereafter, and about 6 months later, the penis grows rapidly about the same time that the adolescent growth spurt begins (refer again to Table 5.5). The marker of sexual maturation most like menarche in girls is

● **Table 5.5** Tanner’s Stages of Secondary Sexual Characteristics and Annual Growth (in inches) for Boys and Girls

Stage	Boys	Girls
I	Prepubertal AG: 2–2.5 inches	Prepubertal AG: 2–2.5 inches
II Boys: ages 12.5–14.5 Girls: ages 10–12	Testes: a bit larger (first sign in boys) Scrotum: red Penis: still childlike but erections common AG: 2.75–3.25 inches	Breasts: small bud, widened areola AG: 2.8–3.2 inches
III Boys: ages 13–15 Girls: ages 11–13	Testes: larger Scrotum: darker Penis: increases in length AG: 3.25 inches	Breasts: larger and more elevated AG: 3.2 inches
IV Boys: ages 13.5–15.5 Girls: ages 12–14	Testes: more enlargement Scrotum: more darkening Penis: becomes thicker AG: 4 inches	Breasts: secondary mound of areola from body AG: 2.8 inches
V Boys: ages 14–18 Girls: ages 14–18	Testes, scrotum, and penis all adult Final height by 18–19 years	Breasts: adult shape and size Final height by 16 years

AG=annual growth

Source: Adapted from O’Keeffe, Gwenn (2009, December). Puberty resource page. Retrieved (2016, November) from www.pediatricsnow.com/2009/12/puberty-resource-page/.

semenarche, or a boy’s first ejaculation—the emission of seminal fluid in a “wet dream” or while masturbating. It typically occurs around age 13 (Herman-Giddens et al., 2012). Just as girls often do not ovulate until sometime after menarche, boys often do not produce viable sperm until sometime after their first ejaculation.

Somewhat later, boys begin to sprout facial hair, first at the corners of the upper lip and finally on the chin and jawline. As the voice lowers, many boys have the embarrassing experience of hearing their voices “crack” uncontrollably up and down between a squeaky soprano and a deep baritone, sometimes within a single sentence. Boys may not see the first signs of a hairy chest until their late teens or early 20s, if at all.

What determines an adolescent’s rate of development? Genes are part of the answer: Identical twins typically begin and end their growth spurts at very similar times, and early or late maturation tends to run in families (Silventoinen et al., 2008). In both sexes, the changes involved in physical and sexual maturation are triggered when the hypothalamus of the brain stimulates activity in the endocrine system. Boys and girls have similar levels of both male and female sex hormones during childhood. By the time sexual maturation is complete, however, males have larger quantities of male hormones (androgens, including testosterone) circulating in their blood than females do, whereas females have larger quantities of female hormones (estrogen, progesterone, and others).

Physical and sexual maturation, then, are processes set in motion by the genes and executed by hormones. But environment also plays its part in the timing of maturation. This is dramatically illustrated by the **secular trend**—the historical trend in industrialized societies toward earlier maturation and greater body size. In 1840, for example, the average age of menarche was 16½ years, a full 4 years later than it is today (Rees, 1993).

What explains the secular trend? Better nutrition, advances in medical care, higher rates of obesity, and exposure to a wide array of chemicals that may alter hormone production are the major contributing factors (Gluckman & Hanson, 2006; Herman-Giddens et al., 2012). As ● **Table 5.6** shows, the age

of menarche varies across countries and tends to be earlier in countries with good nutrition, long life expectancies, and high literacy rates, reflecting the effect of both biological and environmental factors (Thomas et al., 2001). In industrialized nations, today’s children are more likely than their parents or grandparents to reach their genetic potential for maturation and growth because they are better fed and less likely to experience growth-retarding illnesses. Even within the relatively affluent U.S. society, poorly nourished adolescents—both boys and girls—mature later than well-nourished ones do. Girls who are taller and heavier as children tend to mature earlier than other girls (Lee et al., 2007). In particular, being overweight during early childhood (birth to 2 years) is associated with early puberty among girls (Wan, Deng, Archer, & Sun, 2012). By contrast, girls who engage regularly in strenuous physical activity and girls who suffer from anorexia nervosa (the life-threatening eating disorder that involves dieting to the point of starvation, discussed in Chapter 16) may begin menstruating late or stop menstruating after they have begun. These variations seem to be tied not to overall weight but to skeletal development, particularly maturation of the pelvic bones necessary for delivering a baby (Ellison, 2002).

Family situations can also affect the timing of puberty, at least for girls. For instance, girls experience earlier puberty when their family is disrupted by a separation or divorce that removes their biological father from the home at an early age (Culpin et al., 2014). Early absence of the father is associated with adolescent depression as well as with economic disadvantage. These factors, and not the father’s absence per se, may be the real reason for early menarche (Culpin et al., 2014; Culpin, Heron, Araya, & Joinson, 2015). The common thread in all this research is stress in the girls’ lives, starting at a relatively young age (James, Ellis, Schlomer & Garber, 2012; Simpson et al., 2012). Over time, stress can affect many bodily systems and functions and early menarche may be one by-product of these changes. Truly, then, physical and sexual maturation are the products of an interaction between heredity and environment, with some environments delaying maturation and others hastening it.

● **Table 5.6** Median Age of Menarche and Emergence of Secondary Sexual Characteristics (if available) in Select Countries

	Stage 2 Breast	Stage 2 Pubic Hair	Menarche

Psychological Implications

As noted previously, there are large individual differences in the timing of physical and sexual maturation. An early-maturing girl may develop breast buds at age 8 and reach menarche at age 10, whereas a late-developing boy may not begin to experience a growth of his penis until age 14½ or a height spurt until age 16. Within a middle school, then, there is a wide assortment of bodies, ranging from entirely childlike to fully adultlike. It is no wonder adolescents are self-conscious about their appearance!

What psychological effects do the many changes associated with puberty have on adolescents? Girls approaching or experiencing puberty tend to become self-conscious about their appearance and worry about how others will respond to them. One adolescent girl may think she is too tall, another that she is too short (Oldehinkel, Verhulst, & Ormel, 2011). One may try to pad her breasts; another may hunch her shoulders to hide hers.

Some girls develop poor body images, possibly because they are bothered by the weight gains that typically accompany menarche (McCabe & Ricciardelli, 2004). These weight gains, though, are not driven solely by pubertal changes. Girls going through puberty report lack of energy and lower levels of activity, perhaps as a result of the hormonal changes but possibly also a result of their increased feelings of self-consciousness (Oldehinkel et al., 2011). Many girls exhibit mood changes, which seem to escalate as they proceed through puberty.

What about boys? Their body images are more positive than those of girls, and they are more likely to welcome their weight gain and voice changes. But they hope to be tall, hairy, and handsome, and they may become preoccupied with their physical and athletic prowess. Boys who experience slow growth and/or short stature can experience a rocky emotional road during adolescence as the smallest kid in the class, the last picked for sports, and the one least likely to be noticed in a romantic way by peers who are more developed. Their smaller size often means that others perceive them as younger and less mature. As they proceed through puberty, though, boys show a decrease in anxiousness and feelings of worthlessness (Oldehinkel et al., 2011).

Whereas menarche is a memorable event for girls, boys are often unaware of some of the physical changes they are experiencing. They notice their first ejaculation, but they rarely tell anyone about it and often were not prepared for it (Stein & Reiser, 1994). Although males express a mix of positive and negative reactions to becoming sexually mature, they generally react more positively to semenarche than girls do to menarche; 62% of boys regard semenarche positively, whereas only 23% of girls view menarche positively (Oldehinkel et al., 2011; Seiffge-Krenke, 1998).

Pubertal changes may prompt changes in family relations. Adolescents physically distance themselves from their parents

by engaging in less body contact, especially with fathers, and they go to great lengths to avoid being seen naked by their parents (Schulz, 1991, in Seiffge-Krenke, 1998). Likewise, parents seem to restructure the parent–child relationship, placing greater distance between themselves and their children. Perhaps as a result of the barriers erected between adolescents and their parents, teens become more independent and less close to their parents (Steinberg, 1989). They are also more likely to experience conflicts with their parents, especially with their mothers—mostly about minor issues such as unmade beds, late hours, and loud music rather than about core values. Hormone changes in early adolescence may contribute to this increased conflict with parents and to moodiness, bouts of depression, lower or more variable energy levels, and restlessness (Buchanan, Eccles, & Becker, 1992). However, cultural beliefs about family relations and about the significance of becoming an adult also influence parent–child interactions during adolescence. For example, many Mexican American boys and their parents appear to become closer rather than more distant during the peak of pubertal changes (Molina & Chassin, 1996).

Even when parent–child relationships are disrupted during early adolescence, they become warmer once the pubertal transition is completed. Parents—mothers and fathers alike—can help adolescents adjust successfully to puberty by maintaining close relationships and helping adolescents accept themselves (Swarr & Richards, 1996). Overall, you should not imagine that the physical and hormonal changes of puberty cause direct and straightforward psychological changes in the individual. Instead, biological changes interact with psychological characteristics of the person and with changes in the social environment to influence how adolescence is experienced (Graber, Nichols, & Brooks-Gunn, 2010).

Early versus Late Development

If “timely” maturation has psychological implications, what is it like to be out of synch with your peers—to be an early or late developer? The answer depends on whether we are talking about males or females and also on whether we examine their adjustment during adolescence or later on.

Consider the short-term effects of being an early-developing or late-developing boy. Early-developing boys are judged to be socially competent, attractive, and self-assured, and they enjoy greater social acceptance by their peers (Mendle et al., 2010; Mensah et al., 2013). There are some negative aspects of being an early-maturing boy, namely increased risk of earlier involvement in substance use and other problem behaviors such as bullying, aggression, and delinquency (Kaltiala-Heino et al., 2003; Lynne et al., 2007). By comparison, late maturation in boys has more negative effects. Late-maturing boys tend to be more anxious and less sure of themselves, and they experience more behavior and adjustment problems (Dorn, Susman, & Ponirakis, 2003; Graber et al., 2004). As a group, they even score lower than other students do, at least in early adolescence, on school achievement tests (Dubas, Graber, & Petersen, 1991). However, on the positive side, late-maturing boys are less likely to drink alcohol during adolescence (Bratberg et al., 2005).

Early-maturing girls may find themselves hanging out with older peers and engaging in risky behaviors at an earlier age than their on-time or late-maturing age-mates.

Dean Pictures/Getty Images

Now consider early-maturing and late-maturing girls. Traditionally, physical prowess has not been as important in girls' peer groups as in boys', so an early-developing girl may not gain much status from being larger and more muscled. In addition, because girls develop about two years earlier than boys do, an early-developing girl may be subjected to teasing or bullying for being the only one in her grade who is developed. Perhaps for some of these reasons, early maturation appears to be more of a disadvantage than an advantage for girls. The early-maturing girl expresses higher levels of body dissatisfaction than her prepubertal classmates and may engage in unsafe dieting and exercising as a result of this discomfort. In addition, early maturity seems to alter girls' social environments, thrusting them into socializing with older peers, at least when they are outside of the highly age-organized setting of their classrooms (Allison & Hyde, 2011; Skoog & Stattin, 2014). As a result, they are likely to become involved in dating, smoking, drinking, having sex, and engaging in minor troublemaking at an early age.

Girls who experience puberty earlier than their peers report higher levels of depression at least for the period of time that they are out of synch (Reynolds & Juvonen, 2012). But which comes first: Does being depressed ignite biochemical changes in the body, triggering early puberty and sexual activity? Or does experiencing early puberty and sexual activity lead to being depressed?

Fiona Mensah and her colleagues (2013) used data from approximately 3,500 children in the Longitudinal Study of Australian Children to try to tease apart these two pathways. Multiple measures were collected from children and their parents from age 4–5 through age 10–11. It turns out that both boys and girls who experienced early puberty had also displayed signs of behavior and adjustment problems as early as preschool age. The authors concluded that there are “pre-existing and persistent early childhood differences in mental health-related indicators among children who experience early puberty” (p. 124). Thus, teens are not becoming depressed or engaging in problem behaviors because they have experienced early puberty, but they experienced early puberty because of underlying conditions present long before the first observable signs of puberty.

Late-maturing girls (like late-maturing boys) may experience some anxiety as they wait to mature, but they do not seem to be as disadvantaged as late-maturing boys. Indeed, whereas later-developing boys tend to perform poorly on school achievement tests, later-developing girls outperform other students (Dubas et al., 1991). Perhaps late-developing girls focus on academic skills when other girls have shifted some of their focus to extracurricular activities.

Do differences between early and late developers persist into later adolescence and adulthood? Typically, the effects of being out of synch are greatest during the time when the adolescent is most noticeably different from others. In other words, early-maturing girls experience negative feelings during early adolescence when their early maturation is most noticeable relative to peers. Late-maturing girls are more likely to experience negative feelings in mid- to late-adolescence, again when

their late maturation is most noticeable (Reynolds & Juvonen, 2012). By the end of high school, though, most of the negative effects of being out of synch have disappeared because there are few observable differences by this time. Still, when tracked into adulthood, early-maturing girls have not always attained as much education as girls who were not early maturing (Johansson & Ritzén, 2005). And there may be lasting effects of some of the risky behaviors engaged in by early-maturing girls (such as sex and drinking). Early-maturing girls have a greater likelihood than all other groups of experiencing long-term adjustment problems, including anxiety and depression (Graber, 2013). Some of the advantages of being an early-maturing boy may carry over into adulthood, but early-maturing boys also seem to experience greater anxiety than late-maturing ones, who may learn some lessons about coping in creative ways from their struggles as adolescents (Zehr et al., 2007).

Overall, then, late-maturing boys and early-maturing girls are especially likely to find the adolescent period disruptive. However, psychological differences between early-maturing and late-maturing adolescents become smaller and more mixed in quality by adulthood. It is also important to note that differences between early and late maturers are relatively small and that many factors besides the timing of maturation influence whether this period goes smoothly or not. For example, girls who make the transition from elementary to middle school at the same time they experience puberty exhibit greater adjustment problems than girls who do not experience a school transition and pubertal changes simultaneously (Simmons & Blyth, 1987).

Finally, and perhaps most important, the effects of the timing of puberty depend on the adolescent's perception of whether pubertal events are experienced early, on time, or late (Seiffge-Krenke, 1998). Thus, one girl may believe she is a “late bloomer” when she does not menstruate until age 14; but another girl, who exercises strenuously, may believe that menarche at age 14 is normal because delayed menarche is typical of serious athletes. Peer and family-member reactions to an adolescent's pubertal changes are also instrumental in determining the adolescent's adjustment. This may help explain the difference in adjustment between early-maturing boys and early-maturing girls. Parents may be more concerned and negative about their daughter's emerging sexuality than they are about their son's. These attitudes may be inadvertently conveyed to teens, affecting their experience of puberty and their self-concept.

Health and Wellness

Adolescents should be reaching their peak of physical fitness and health and, indeed, many adolescents are strong, fit, and energetic. Unfortunately, the sedentary lifestyle of modern society may be undermining the health and fitness of an increasing number of teens. Fitness tests of American teenagers show that an alarming number of them have poor physical fitness. Only 25% of teenagers do the recommended 60 minutes of daily physical activity (CDCP, 2015). Barely 15% of students walk or bicycle to school and, once at school, only a small percentage of high schools have *daily* physical activity factored

into the school schedule (CDCP, 2015). Girls tend to become less active than boys in adolescence, although this gender gap has certainly narrowed in recent years with federally mandated gender equality in athletics (Yan et al., 2009). Teens may be doing well in school, but they are flunking treadmill tests that measure heart and lung function. Today’s teens are showing up with high blood pressure, high cholesterol, and high blood sugar, putting them at risk for heart disease at earlier ages than previous generations.

Weight

As with children, the number of teens who meet the criteria for **obesity**—being 20% or more above the “ideal” weight for height, age, and sex—is increasing. As **Figure 5.8** shows, close to one-third of teenagers are either overweight or obese and these rates have been creeping up over the past 15 years. They are especially higher among certain ethnic minority groups, with, for example, 35% of non-Hispanic blacks meeting the definition for obesity compared to 24% of non-Hispanic whites (Flegal et al., 2012). Some of the same issues that we discussed earlier regarding children’s weight also apply to adolescents. Adolescents have more sedentary lifestyles and consume more empty calories than they need, often in the form of beverages. Adolescents who drink more calorie-dense, nutrient-poor beverages not only gain weight, they have higher systolic blood pressure (Nguyen et al., 2009). The weight and the blood pressure put them at risk for later health problems, including heart and kidney disease, diabetes, liver problems, and arthritis. Rates of **diabetes**—high levels of sugar in the blood leading to various health problems—have significantly increased in recent years among adolescents, with more and more teens now taking antidiabetic drugs (Hsia et al., 2009).

Obesity may also affect brain function through **metabolic syndrome (MeTS)**, which is a combination of risk factors typically associated with obesity and includes high blood pressure, unhealthy cholesterol

levels, and diabetes (Kassi, Pervanidou, Kaltsas, & Chrousos, 2011). Researchers from New York University compared adolescents with MeTS to adolescents without MeTS (Yau et al., 2012). The two groups were matched on multiple factors that might otherwise influence the results: age, gender, ethnicity, and socioeconomic status. The adolescents underwent endocrine testing, were evaluated with MRIs, and were assessed for cognitive and intellectual functioning.

The findings showed that adolescents with MeTS scored slightly lower—4 points—on overall IQ, but nearly 10 points lower on measures of math achievement. They also demonstrated some issues with attention and mental flexibility. While all scores were in the normal or average ranges, it is concerning that adolescents with MeTS are not operating at the same level of cognitive functioning as their non-MeTS peers. And the more MeTS risk factors that these teens had, the lower their cognitive functioning. Further research is needed to better understand how obesity and MeTS relate to brain function. Nonetheless, the cognitive deficits, whether they are permanent or temporary, add to the larger picture of childhood and adolescent obesity, and collectively, the findings indicate this is a serious health concern that cannot be ignored.

Children and adolescents whose parents are overweight have twin risk factors for becoming overweight themselves: the genes that their parents have passed along to them that may predispose them to be overweight, and the environment that

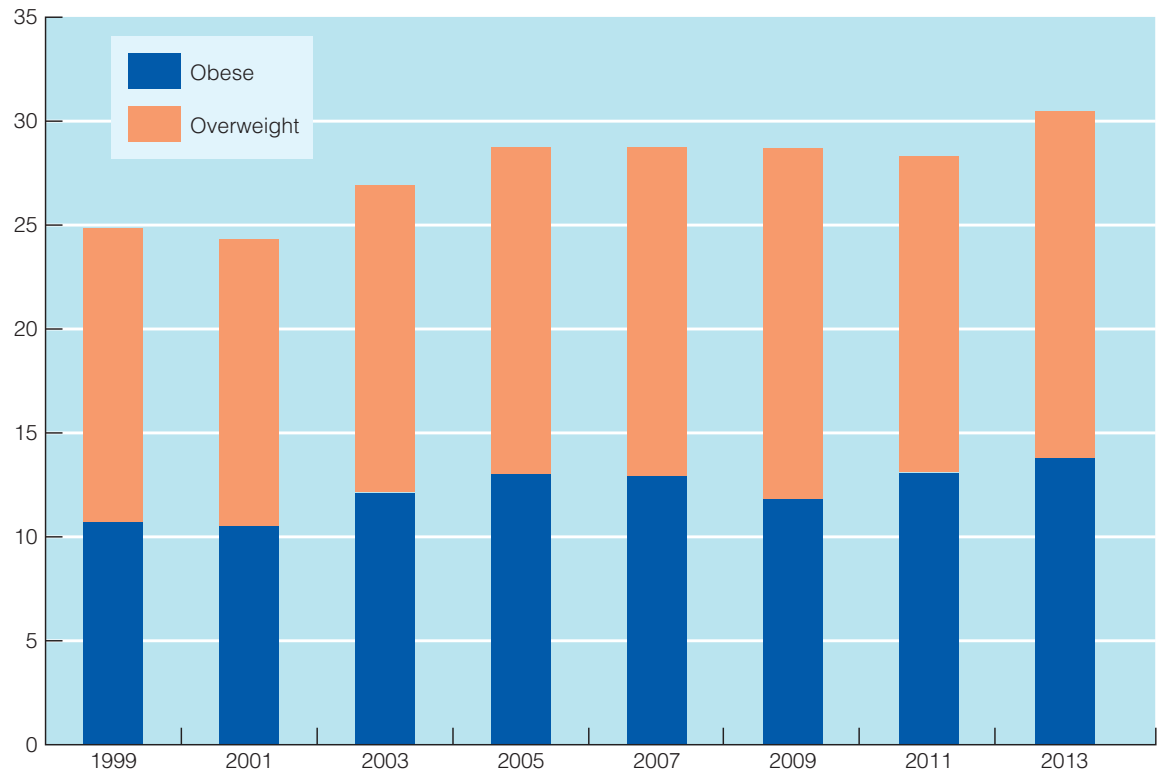

Figure 5.8 Percentage of overweight and obese high school students, 1999–2013.

Source: Centers for Disease Control and Prevention, National Center for Chronic Disease Prevention and Health Promotion, Youth Risk Behavior Surveillance System (YRBSS), various years, 1999–2013.

is created for them by overweight parents (Steffen et al., 2009; Thibault et al., 2010). For instance, overweight parents are less likely to engage their children in vigorous physical activity and they are more likely to model sedentary behaviors, such as watching television. Overweight parents are also more likely to be economically disadvantaged, so they purchase less expensive foods that are often high in calories and low in nutritional value. Adolescents who are overweight tend to gravitate toward other overweight teens (Valente et al., 2009). Being friends with other teens who are overweight may be comfortable in that it reduces the stigma of being overweight. Further, it establishes an unhealthy pattern of behavior—inactivity coupled with poor eating habits—as normative and acceptable. There is little incentive to be different from the peers with whom you spend your time, so if they are sitting around eating junk food and drinking sugary drinks, then it is easy to do the same.

Obesity is usually the product of both nature and nurture: Heredity is certainly important, but poor eating habits, inactivity, and parental behaviors contribute (Steffen et al., 2009).

● **Table 5.7** summarizes some of the environmental factors that contribute to obesity, in particular, the rise in rates of obesity in recent decades.

Sleep

Another health issue that seems to plague many teenagers is insufficient sleep. Puberty ushers in changes in the sleep–wake cycle, melatonin production, and circadian rhythms, which can shift the “natural” time for falling asleep later and later. Research shows that the level of melatonin (a sleep-promoting hormone) rises later at night for teens than for children or adults (Crowley et al., 2015). Teens report later bedtimes from age 12 to age 18, and only 20% of them get the optimal amount of sleep on school nights. Although psychosocial factors may also contribute to later bedtimes than in childhood (for example, doing homework or text messaging with friends late into the night), biological factors—puberty in particular—seem primarily responsible. Teens who go to bed at midnight P.M. should not wake up until around 8 or 9 A.M. if they are to get the recommended 8–9 hours of sleep. However, most teens find themselves getting out of bed around 6:30 A.M. to get to school on time. High schools typically start earlier than elementary schools, often by 7:30 A.M. to accommodate bus schedules. Thus, just when their biological clocks are pushing back sleep times at night, schools are getting teens up earlier in the morning.

What are the consequences for teens who do not get enough sleep? Teens report greater sleepiness during the day, which is associated with decreased motivation, especially for “boring” tasks (Carskadon, 2011b). Tired teens may be able to successfully navigate a favorite class or read a particularly good book, but these same teens may have trouble completing an assignment in their least favorite subject or studying for an exam. Teens who have had their sleep restricted display increased sleepiness in proportion to the number of nights that their sleep is reduced. But surprisingly—at least to many adults—these same teens “perk up” in the evenings and show high levels of energy that discourage them from going to bed early (Carskadon, 2011a).

● **Table 5.7** Environmental Factors Contributing to the Obesity Epidemic

Inactive lifestyles	Among adults, occupations have become more sedentary (think, sitting at computer all day) and, as a result, adults burn 100–150 fewer calories every day. Over a person’s work life, this can add nearly 30 pounds of weight.
Portion sizes	In just 20 years, the average soda size has increased from 6.5 to 20 ounces. Burgers at fast food restaurants increased from 4.5 to 8 ounces. The original McDonald’s hamburger, in 1955, weighed just 1.6 ounces.
Fat content	In 2000, average fat consumption was 75 pounds per year, up nearly 30 pounds from 1950.
Sugar	In 1822, each person consumed approximately 6 pounds per year; today, each person consumes nearly 108 pounds per year. This figure rises even higher—as much as 150 pounds per year—if all forms of sweeteners are combined. The American Heart Association recommends no more than 9.5 teaspoons per day.
Stress	Prenatal exposure to a mother’s stress can craft a neural architecture that is associated with later obesity. And stress in one’s own life is associated with accumulation of belly fat. Unhealthy snacking is a common response to stress. Although research has uncovered these connections between stress and obesity, it does not address whether stress has contributed to the rise in obesity.
Poverty	A large proportion of children who live in poverty are obese or overweight relative to children in households not affected by poverty. The number of households meeting the U.S. criteria for poverty has increased in recent years. Among adults, <i>higher</i> income tends to be associated with higher obesity rates for men, but with lower obesity rates for women.

Sources: CDC, NCCDPHP, 2012b; CDC, 2012a; Church et al., 2011; Guyenet & Landen, 2012; Molteni et al., 2002; USDA Factbook, 2012; Young & Nestle, 2002.

Teens who sleep less at night or who stay up later on the weekends than their peers report higher levels of depression, irritability, and lack of tolerance for frustration (Carskadon, 2011b; Wolfson & Carskadon, 1998). They may also have difficulty controlling their emotional responses, which leads to greater expression of aggression or anger. As with younger children, teens who do not get enough sleep have trouble concentrating in school, experience short-term memory problems, and may doze off in class (National Sleep Foundation, 2015). In an attempt to counterbalance their lack of sleep, many teens begin consuming higher quantities of caffeine,

which in turn, can further disrupt their sleep cycles (Carskadon & Tarokh, 2014).

Some teens report that, with their busy schedules, cutting back on sleep is unavoidable. Consider teens who have a big test scheduled for the next day but also have after-school obligations that will push back the start of their study time. Should they stay up late and study or should they go to bed with less study time? If you answered that they should go to bed and get a good night's sleep instead of studying, then you are correct according to research by Cari Gillen-O'Neel, Virginia Huynh, and Andrew Fuligni (2013). The researchers had students keep diaries of their sleep and study times for blocks of time in ninth, tenth, and twelfth grades. They found that the amount of study time throughout the week did not matter if students ended up cutting short their sleep time. Students who got a good night's sleep the night before a test did better than students who sacrificed a good night's sleep to get in more study time. There is an important message here for you: Manage your time so that you get all the study time you need *without sacrificing your sleep time*. Maintaining a consistent sleep-wake cycle with sufficient sleep time is an essential part of optimizing cognitive skills, not to mention physical health.

For all ages, learning more about sleep needs and the effects of sleep deprivation can lead to healthy lifestyle changes. Adhering to a regular bedtime and wake time on the weekends and on school and work days can help

Adolescents seem to be especially likely to doze off during the day as puberty alters their sleep-wake cycles and leaves them short on sleep

F. JIMENEZ MECA/Shutterstock.com

maintain healthy sleep habits. Unfortunately, “sleeping in” on the weekends alters the sleep-wake cycle and makes it more difficult to get up early for work or school Monday morning. So, next time you find yourself dozing off in class or at work, do not jump to the conclusion that the work you are doing is boring. It may be that your sleep-wake cycle is out of sync with the schedule imposed on you by school or work.

● Checking Mastery

1. How do the typical brain changes throughout adolescence correlate with teen behavior?
2. Which group of teens is likely to have the “best” experience of puberty and which group is likely to experience more problems with the process of puberty?
3. What factors affect timing of menarche in girls?

● Making Connections

1. What are the most significant health concerns during adolescence? If you could get adolescents to change two behaviors to improve their health, what would they be and why?
2. How would you counsel the parents of an early-maturing girl so that they understand the risks she may face and what they can do to help her adjust successfully?

5.5

The Adult

LEARNING OBJECTIVES

- Integrate the findings of both gains and losses in the adult brain.
- Summarize changes in the reproductive system throughout adulthood, with attention to how the physical changes may influence psychological well-being.
- Classify the typical changes of adulthood according to their likely impact on daily functioning.
- Compare the major theories of aging and evaluate their contributions to our understanding of why we age and die.

The body of the young adult is at its prime in many ways. It is strong and fit; its organs are functioning efficiently; it is considered to be in peak health. But it is aging, as it has been all along. Physical aging occurs slowly and steadily over the life span. Physical and health changes begin to have noticeable effects on appearance and functioning in middle age and have an even more significant effect by the time old age is reached, although more so in some people than in others.

But don't equate aging with only loss and decline: There are also gains and increases in some areas. This will be evident when we look at the brain in this chapter and then follow up in greater depth in Chapter 8 with the cognitive abilities of adults. In the next sections, we discuss typical changes that occur as we progress

through middle adulthood and old age. We also look at health issues that can challenge us and consider what it takes to age successfully. You will learn that lifestyle choices play a key role in your overall health and longevity.

The Changing Brain

When does the brain complete its development? In the past, we might have answered that the brain is fully developed by the end of infancy, or even by the end of pregnancy. Today, however, the answer is that *brain development is never truly complete*. The brain is responsive to experience and is capable of **neurogenesis**, the process of generating new neurons, across

the life span. Consider first some research with mice. Mice that regularly work out on their treadmills (that is, running wheels) learn more quickly to navigate through a maze than their couch potato counterparts (mice without running wheels) (Pereira et al., 2007). By examining the brain tissue of the active mice, researchers found evidence of neurogenesis—new neurons were being created in response to the mouse’s activity. And it turns out that adult songbirds can learn new songs with the help of new neurons (Goldman, 2008).

Neurogenesis in adult humans was once considered impossible, but there is now evidence suggesting it may be possible (Jessberger & Gage, 2014; Kempermann, Song, & Gage, 2015). Consider Terry Wallis who, injured at age 19 in a serious car accident, suffered severe brain damage and existed in a minimally conscious state for nearly 20 years (Hopkins, 2006). Doctors had assumed that recovery was not possible, but one day Terry “woke up” and began to talk. Although he remains disabled from injuries sustained during the accident, he has regained some functions and can communicate. Doctors attribute his miracle awakening to generation of new neurons and connections in the brain. But does what happened with this one individual hold true for other adults?

Fred Gage and his colleagues studied the effects of exercise on brain activity in a small group of adults (Pereira et al., 2007; and see Kempermann, Song, & Gage, 2015). The adults were given a learning task, completed a 3-month aerobic exercise program, and were then given another learning task. Learning improved following the exercise program. The researchers could not examine actual brain tissue after exercise as they do with mice. However, they did study blood volume in the brain and found that it was almost twice as high after the exercise program in the hippocampus, a part of the brain involved in learning and memory. This increased blood volume seems to be associated with production of new neurons. Other researchers have uncovered evidence that certain health conditions such as stroke and epilepsy may increase neurogenesis, whereas other conditions such as depression may decrease it (Balu & Lucki, 2009).

Denise Park and Chih-Mao Huang (2010) reviewed whether culture—growing up surrounded by Eastern Asian versus Western cultural values and experiences—has an effect on the organization of the brain. When asked to view pictures of an individual object, a background, and the object embedded in the background, East Asians and Westerners demonstrated different patterns of brain activity with each type of picture, as illustrated by images of blood flow captured by functional magnetic resonance imaging (fMRI) (see Goh et al., 2007). Over various studies like this one, the findings suggest that different patterns of brain activity are associated with different cultural experiences reflecting the collectivist focus of East Asian and the individualistic focus of Western cultures. In other words, your cultural experiences shape your brain function and possibly also brain structure (Park & Huang, 2010). Your brain continues to be responsive to the environment; it is not “done” or set in stone at birth or even in infancy or childhood.

Thus, the brain displays plasticity early in life and signs of neurogenesis and synaptogenesis throughout life. It can change in response to physical and mental exercise. It may be able to regenerate some functions following injury, which holds great promise for future therapies for patients with a wide range of conditions

such as stroke, epilepsy, and degenerative diseases such as Parkinson’s and Alzheimer’s (see Ernst & Frisén, 2015). But although the adult brain can generate new neurons, it does so at a much lower rate than the young brain (Lee, Clemenson, & Gage, 2012). What does this mean for the average person? What happens to the typical brain as it ages?

Many people fear that aging means losing brain cells and ultimately becoming “senile.” As you will see in Chapter 16, Alzheimer’s disease and other conditions that cause serious brain damage and dementia are *not* part of normal aging; they do not affect most older people. Normal aging is associated with gradual and relatively mild degeneration within the nervous system—some loss of neurons, diminished functioning of many remaining neurons, and potentially harmful changes in the tissues surrounding and supporting the neurons, such as the protective myelin covering (Scheibel, 2009). Just as brain weight and volume increase over the childhood years, they decrease over the adult years, especially after age 50 (Bartzokis & Lu, 2009; Taki et al., 2013). As people age, more of their neurons atrophy or shrivel, transmit signals less effectively, and ultimately die (Scheibel, 2009). Elderly adults may end up with 5–30% fewer neurons, depending on the brain site studied, than they had in early adulthood. Neuron loss is greater in the areas of the brain that control sensory and motor activities than in either the association areas of the cortex (involved in thought) or the brain stem and lower brain (involved in basic life functions such as breathing).

Other signs of brain degeneration besides neuron loss include declines in the levels of important neurotransmitters; the formation of “senile plaques,” hard areas in the tissue surrounding neurons that may interfere with neuronal functioning and are seen in abundance in people with Alzheimer’s disease; and reduced blood flow to the brain, which may starve neurons of the oxygen and nutrients they need to function (Aanerud et al., 2012). One of the main implications of such degeneration, as you will see later, is that older brains typically process information more slowly than younger brains do.

Your brain on exercise. Using magnetic resonance imaging (MRI) technology that maps cerebral blood volume, researchers have found evidence of increased blood volume in a region of the hippocampus after exercise. This suggests the brain is capable of neurogenesis and could pave the way for developing new treatments for various conditions.

Source: Pereira et al. (2007). An in vivo correlate of exercise-induced neurogenesis in the adult dentate gyrus. *Proceedings of the National Academy of Sciences*, 104, 5638–5643.

On the positive side, research shows that middle age brings greater integration of the left and right hemispheres, which may help increase creativity and cognitive functioning. And the brain can remain healthy with exercise—both mental puzzles and physical aerobic workouts. Older adults who engage in high levels of aerobic activity show enhanced mental performance and corresponding increases in activity in certain regions of the brain (Barcelos et al., 2015; Gill et al., 2015). Some intriguing new research suggests that physical aerobic activity may be responsible for the number of new neurons generated in the brain, whereas mental activity influences the number of these new neurons that survive (Curlik & Shors, 2013). And not just any mental activity, but activity that is “new, effortful, and successful” (Shors, 2014, p. 311). Thus, if you want to grow your brain, you are going to have to put in some hard work.

What does it mean for older adults that both degeneration and plasticity—both losses and gains—characterize the aging brain? In some people, degeneration may win and declines in intellectual performance will occur. In other people, plasticity may prevail; their brains may form new and adaptive neural connections faster than they are lost so that performance on some tasks may actually improve with age (at least until very old age). Denise Park and Patricia Reuter-Lorenz (2009; Reuter-Lorenz & Park, 2014) make a compelling case that the aging brain may compensate for losses by increased activity in the prefrontal cortex. In particular, they propose the scaffolding theory of aging and compensation (STAC) to explain how the brain may adapt to losses by revving up in other areas. Thus, where a young adult’s brain would use only the area that specializes in a particular kind of task to perform it, an older adult’s brain might recruit other brain areas to help out. This kind of compensation may not always be possible due to health issues or genetic predispositions or adverse life experiences, but when it is, older adults may be able to maintain useful cognitive functioning for a longer period of time.

Just as physical activity helps to keep the body healthy, mental activity helps to keep the brain healthy.

Compuinfo / Dreamstime.com

In a revised version of the STAC model, the researchers acknowledge that life events can have both a negative effect on the brain, depleting neural resources, and a positive effect, conserving and even enriching neural resources (Reuter-Lorenz & Park, 2014). It is important to consider a person’s current level of cognitive functioning as well as the *rate* at which cognitive change occurs. Thus, you can reject the view that aging involves nothing but a slow death of neural tissue. Old brains *can* learn new tricks (it may just take some work).

The Changing Reproductive System

During most of adulthood, the sex hormones that prompted puberty and all of its changes continue to be produced, helping to ensure interest in sexual behavior and the ability to have children. These hormones also have psychological implications and effect the experience of aging. In men, testosterone levels fluctuate annually, with peak levels detected in spring and lower levels in fall, and daily, with peak levels in the morning (Moskovic, Eisenberg, & Lipshultz, 2012; van Anders, 2012). Men with high levels of testosterone tend to be more sexually active and aggressive than other men, although this relationship is influenced by other factors (see Trainor & Nelson, 2012). Otherwise, it is not clear that changes in men’s hormone levels are tied to changes in their moods and behavior.

By contrast, hormone levels in women shift drastically each month as they progress through their menstrual cycles. For some women, these shifts may be accompanied by symptoms such as bloating, moodiness, breast tenderness, and headaches during the days just before the menstrual flow, symptoms collectively referred to as **premenstrual syndrome (PMS)**. Estimates of how many women experience PMS vary substantially. Roughly half of young women report that they experience PMS and a majority—as high as 90%—report at least some symptoms before menstruation and usually regard these as a normal accompaniment to the menstrual cycle (Delara et al., 2012; Wong, 2011). As many as 10% of women experience symptoms severe enough to interfere with their ability to perform daily activities and a few of these, perhaps 2–3%, may be diagnosed with a severe form of PMS called **premenstrual dysphoric disorder (PDD)**. PDD differs from PMS in that it includes affective symptoms in addition to physical symptoms associated with the menstrual cycle, and it can be disabling—disrupting work and relationships (American Psychiatric Association, 2013). Women with PDD report poorer health-related quality of life than those without PDD (Delara et al., 2012).

In recent decades, there has been some debate about the validity of PMS. In research where women are simply asked to complete mood surveys every day and do not know that their menstrual cycles are being studied, most report little premenstrual mood change. This suggests that expectations and not hormones play a role in at least some cases of PMS. Still, symptoms consistent with PMS are reported across many cultures, including those that generally do not label or acknowledge the syndrome (see Yonkers & Casper, 2012). Changes in estrogen and progesterone levels are the likely causes of the symptoms associated with PMS. Various treatments are available for PMS, depending on the

severity and type of symptoms experienced. For instance, some women with severe PMS may find relief when treated with antidepressant drugs such as Prozac (Maharaj & Trevino, 2015). For women with milder forms of PMS, treatment with minerals and vitamins such as calcium, potassium, iron, and vitamin D may alleviate symptoms because the low estrogen levels experienced prior to menstruation can interfere with the absorption of these substances by the body (Chocano-Bedoya et al., 2013; Saeedian Kia, Amani, & Cheraghian, 2015). There is considerable variability in how women experience their menstrual cycles and, as we'll see in the next section, how they navigate through the years when their menstrual cycles end.

Female Menopause

Like other systems of the body, the reproductive system ages. The ending of a woman's menstrual periods in midlife is called **menopause**. Levels of estrogen and other female hormones decline so that the woman who has been through menopause has a hormone mix that is less "feminine" and more "masculine" than that of the premenopausal woman. When menopause is completed, a woman is no longer ovulating, no longer menstruating, and no longer capable of conceiving a child.

The average woman experiences menopause at age 51, and the usual age range is from 45 to 54 (National Institute on Aging, 2013). The process takes place gradually over 5–10 years as periods become either more or less frequent as well as less regular. Although life expectancy has increased and the age of menarche has decreased over history as part of the secular trend, the age of menopause does not appear to have changed much and is similar from culture to culture (Brody et al., 2000). What has changed is that women are now living long enough to experience a considerable period of postmenopausal life. The age at which a woman reaches menopause is somewhat related to both the age at which she reached menarche and the age at which her mother reached menopause (Varea et al., 2000). Researchers have discovered that menopause can be predicted by a hormone called anti-Müllerian hormone (Mishra & Dobson, 2012; Mishra & Kuh, 2012). Anti-Müllerian hormone peaks around age 16, remains stable until about age 25, and then begins a slow decline (Fong et al., 2012).

Society holds rather stereotypic views of menopausal women. They are regarded as irritable, emotional, depressed, and unstable. How much truth is there to this stereotype? Not much. About two-thirds of women in U.S. society experience **hot flashes**—sudden experiences of warmth and sweating, usually centered around the face and upper body, that occur at unpredictable times, last for a few seconds or minutes, and are often followed by a cold shiver (Whitbourne & Whitbourne, 2014). Many also experience vaginal dryness and irritation or pain during intercourse. Still other women experience no symptoms.

For years, **hormone replacement therapy (HRT)** (taking estrogen and progesterin to compensate for hormone loss at menopause), was considered an effective cure for the symptoms that some women experience with menopause. For many women, HRT helps relieve physical symptoms of menopause, such as hot flashes and vaginal dryness, and also prevents or slows osteoporosis.

Unfortunately, trust in HRT was shattered in 2002 by a large government study that found that HRT increases women's chances of developing breast cancer and experiencing heart attacks and strokes (Women's Health Initiative, 2004). For most women, these risks outweigh the benefits of HRT, particularly if the hormones estrogen and progesterin are taken over a long period. Still, for women with severe menopausal symptoms associated with decreasing production of hormones, short-term HRT (for example, up to 2 years) may be warranted. Lifestyle changes such as exercising and getting adequate sleep may be the best options for menopausal women because they alleviate some complaints and are safe.

What about the psychological symptoms—irritability and depression? Again, researchers have discovered wide variation among menopausal women—and not much truth to the negative stereotypes. In a particularly well-designed study, Karen Matthews and her associates (Matthews, 1992; Matthews et al., 1990) studied 541 initially premenopausal women over a 3-year period, comparing those who subsequently experienced menopause with women of similar ages who did not become menopausal. The typical woman entering menopause initially experienced some physical symptoms such as hot flashes. Some women also reported mild depression and temporary emotional distress, probably in reaction to their physical symptoms, but only about 10% could be said to have become seriously depressed in response to menopause. Typically, menopause had no effect on the women's levels of anxiety, anger, perceived stress, or job dissatisfaction. When women do experience severe psychological problems during the menopausal transition, they often had those problems well before the age of menopause (Greene, 1984).

Why do some women experience more severe menopausal symptoms than others do? Again, part of the answer may lie with biology. Women who have a history of menstrual problems (such as PMS) report more menopausal symptoms, both physical and psychological (Morse et al., 1998). Thus, some women may experience greater biological changes or be more sensitive to them. But psychological and social factors of the sort that influence women's reactions to sexual maturation and to their menstrual cycles also influence the severity of menopausal symptoms. For example, women who expect menopause to be a negative experience are likely to get what they expect (Matthews, 1992). There is also a good deal of variation across cultures in how menopause is experienced. In a recent study, women from the United States, United Kingdom, and Canada reported more symptoms than women from Sweden and Italy (Minkin et al., 2015). Portuguese women report primarily neutral symptoms and feelings about menopause (Pimenta et al., 2011). The effect of menopause is colored by the meaning it has for the woman, as influenced by her society's prevailing views of menopause and by her own personal characteristics.

Women who have been through menopause generally say it had little effect on them or that it even improved their lives; they are usually more positive about it than women who have not been through it yet (Morrison et al., 2014). Of course, this is not true of all women: Some report that the whole thing was worse than expected (Minkin, Reiter, & Maamari, 2015). Perceptions may vary depending on when women are asked and how fresh the experience

is for them. In short, despite all the negative stereotypes, menopause seems to be “no big deal” for most women. Indeed, many women find the end of monthly periods to be quite liberating.

Male Andropause

Obviously, men cannot experience menopause because they do not menstruate. They also do not experience the sharp drop in hormones that accompanies menopause in women. But some research has pointed to the possibility that men experience andropause as they age. **Andropause**, also called *age-associated hypogonadism*, is characterized by slowly decreasing levels of testosterone and a variety of symptoms including low libido, fatigue and lack of energy, erection problems, memory problems, and loss of pubic hair (Samaras, 2015). By age 80, men have between 20% and 50% of the testosterone that they had at age 20. Pharmaceutical companies that manufacture synthetic testosterone would like us to believe that the low testosterone (“Low-T”) levels associated with aging represent a disease in need of a treatment (Perls & Handelsman, 2015). This change in hormone levels, though, is a natural part of the aging process.

Some research reports that testosterone levels are markedly lower among men over age 50 with symptoms of andropause than among men without symptoms (Wu, Yu, & Chen, 2000). But other research does not show a clear connection between andropause symptoms and testosterone levels (see, for example, Vermeulen, 2000). In one study, for example, half of 50- to 70-year-old men complained of **erectile dysfunction**—inability to achieve or sustain an erection for intercourse—despite having sufficient levels of testosterone (Gould, Petty, & Jacobs, 2000). Most cases of erectile dysfunction are caused by medical conditions such as diabetes and not by lower hormone production. Erectile dysfunction among older men is often treatable with *sildenafil*, no doubt more familiar to you by the name Viagra.

In sum, the changes associated with andropause in men are more gradual, more variable, and less complete than those associated with menopause in women. As a result, men experience fewer psychological effects. Frequency of sexual activity does decline as men age. However, this trend cannot be blamed entirely on decreased hormone levels, because sexual activity often declines even when testosterone levels remain high (Gould et al., 2000; see also Chapter 12 on sexuality).

Health and Wellness

There are minor changes in physical appearance during our 20s and 30s and more noticeable signs of aging in our 40s and 50s. Skin becomes wrinkled, dry, and loose, especially among people who have spent more time in the sun. Hair thins and often turns gray from loss of pigment-producing cells. And to most people’s dismay, they put on extra weight throughout much of adulthood as their metabolism rate slows but their eating and exercise habits do not adjust accordingly. Only 30% of adults engage in regular physical activity during their leisure time, less than 20% do strength training, and few engage in the level of aerobic exercise needed to maintain, let alone improve, their fitness (Schoenborn & Adams, 2010). Consequently, many middle-aged adults are overweight or even obese.

We discussed many of the health concerns associated with obesity in an earlier section. To impress upon you the magnitude of this issue, consider that obesity is a multi-billion dollar “business,” accounting for 20% of the total health care costs in the United States (Cawley & Meyerhoefer, 2012). The U.S. Department of Health and Human Services has identified obesity as one of the most significant health care concerns facing Americans and has issued a number of recommended strategies for combating obesity. Many of these are the same ones recommended for children and adolescents: promoting healthy foods and beverages, discouraging consumption of those foods and beverages that add calories but not nutrition, and increasing physical activity through a variety of community programs. The upward trend in obesity rates must be curbed or future generations will face the unsettling prospect of shorter life spans than their parents or grandparents.

Challenges to Health

By the time people are 65 or older, it is hard to find many who do not have something wrong with their bodies. Acute illnesses such as colds and infections become less frequent from childhood on, but chronic diseases and disorders become more common. National health surveys indicate that many of the 70-and-older age group have at least one chronic impairment—whether a sensory loss, arthritis, hypertension, or a degenerative disease (Federal Interagency Forum, 2012). Arthritis alone affects 43% of elderly men and 54% of elderly women. **Osteoarthritis** is a common joint problem that results from gradual deterioration of the cartilage that cushions the bones from rubbing against one another. For some older adults, joint disease is deforming and painful and limits their activities. The older person who can no longer fasten buttons, stoop to pick up dropped items, or even get into and out of the bathtub may easily feel incompetent and dependent (Whitbourne & Whitbourne, 2014).

Another common affliction in old age is **osteoporosis** (meaning “porous bone”), a disease in which a serious loss of minerals leaves the bones fragile and easily fractured. It involves pain and can result in death if the victim falls and fractures a hip. Nearly one-third of elderly adults who fracture a hip die within one year; hip fractures are also a leading cause of nursing home admissions (Whitbourne & Whitbourne, 2014). One fall can change an older person’s entire lifestyle, requiring a shift from independent living to assisted living. Not surprisingly, adults who have experienced a fall often begin to restrict their activities out of fear of falling again. Unfortunately, less activity can make them more vulnerable because it can lead to further decreases of muscle and bone mass (Whitbourne & Whitbourne, 2014). Osteoporosis is a special problem for older women, who never had as much bone mass as men and whose bones tend to thin rapidly after menopause. European and Asian women with light frames, those who smoke, and those with a family history of osteoporosis are especially at risk.

What can be done to prevent osteoporosis? For starters, dietary habits can influence a person’s risk for osteoporosis. Many individuals do not get enough calcium to develop strong bones when they are young or to maintain bone health as they age (National Osteoporosis Foundation, 2013). Weight-bearing exercises such

as walking or jogging can help prevent osteoporosis, as can the HRT that some women take following menopause (but see this chapter's earlier section, "Female Menopause," for a discussion of concerns about HRT). Good bone health starts in childhood and adolescence: Girls and young women who are physically active and eat a healthy diet develop higher bone density that protects them from bone loss in later life (Krucoff, 2000).

Aging also involves a gradual decline in the efficiency of most bodily systems from the 20s on. Most systems increase to a peak sometime between childhood and early adulthood and decline slowly thereafter. No matter what physical function you look at—the capacity of the heart or lungs to meet the demands of exercise, the ability of the body to control its temperature, the ability of the immune system to fight disease, or strength—the gradual effects of aging are evident. For example, we lose nearly 10% of our strength capacity with each passing decade (Katzel & Steinbrenner, 2012). In terms of handgrip strength, both men and women show declines from early to late adulthood, with men's losses fairly evenly distributed over adulthood and women's losses starting out slow but then escalating after age 55 (Samson et al., 2000). Why consider handgrip strength? It turns out that handgrip strength in middle age is a good predictor of disability and ability to function in later life: Those with weaker handgrip in middle age are more likely to report greater difficulty with such everyday activities as housework, walking, dressing, and bathing 25 years later (Rantanen et al., 1999). Those with stronger handgrip at midlife are more likely to beat the odds and live to age 100 (Rantanen et al., 2012). Why would handgrip be associated with health and longevity? Likely because it is an external indication of internal health and wellness. Someone with a strong handgrip is likely more active and healthy than someone with a weak handgrip.

Another fact of physical aging is a decline in the **reserve capacity** of many organ systems—that is, their ability to respond to demands for extraordinary output, such as in emergencies (Goldberg & Hagberg, 1990). For example, old and young people do not differ much in resting heart rates, but older adults, even if they are disease-free, will have lower maximal heart rates (Lakatta, 1990). This means that older adults who do not feel very old as they go about their normal routines may feel very old indeed if they try to run up mountains.

Finally, if you have ever taken a walk with a grandparent or another older adult, you likely found yourself slowing down so as to not leave your older companion behind. Older adults walk more slowly than the average of 4 feet per second clocked by most of their younger counterparts. In many situations, the older adult may simply need to allow additional time for getting places. In other situations, though, their slow speed may pose a safety concern, such as crossing a busy street where stoplights are programmed for the average adult's walking speed and not the average *older* adult's walking speed (Lobjois & Cavallo, 2009). In addition, research has revealed that walking speed can be a useful predictor of survival among older adults. Stephanie Studenski and her colleagues (2011) examined the relationship between the walking speed of more than 34,000 adults over the age of 65 and their 5-year and 10-year survival rates. The findings showed that an older adult's walking speed can effectively predict survival, especially among

those 75 years and older. Thus, the fast-walking 75-year-old is more likely to be alive 5 and 10 years later than her slow-walking companions. This makes sense when you consider that walking speed, like handgrip strength, gives us a window into the functioning of multiple internal organ systems. When one or more of the organ systems that contribute to walking (for example, lungs, heart, musculature, nervous system, and so on) is damaged or begins to deteriorate, this will be reflected externally in a slower gait.

There is tremendous variability in the health, wellness, and functioning of older adults. Some are limited by health problems, but others enjoy active, healthy lives. A highly fit 75-year-old can outperform a sedentary 40-year-old couch potato. Indeed, some older adults are far more active than younger ones. For instance, Fauja Singh ran a full marathon (26.2 miles) at age 100! Doctors had conducted tests on Singh when he was 94 years old and concluded that his one leg had the bone density of a 35-year-old, while the other leg had the bone density of a 25-year-old. Upon hearing these test results, Singh quipped that he knew his one leg was weak (Morley, 2013). Although Singh is an extreme example, there is little doubt that exercise is an important component of health and wellness.

Exercise: Enhancing Health

Exercise is important mentally and physically across the entire life span. Exercise can improve cardiovascular and respiratory functioning, slow bone loss, and strengthen muscles. In one

A remarkable centenarian and great-great-grandfather, Fauja Singh retired from competing in marathons at age 101. He has attributed his health and longevity to careful food choices, avoidance of smoking and alcohol, and of course, regular exercise.

REUTERS/Bobby Yip

study, older athletes (average age 69 years) were compared with older non-athletes on several physiological measures following exercise. The athletes showed better oxygen uptake capacity and greater cardiovascular stamina than the non-athletes (Jungblut et al., 2000). Our brains need oxygen to function properly, so exercising your body also helps boost your brain power (Ratey, 2013). Exercise can make aging adults feel less stressed and happier, and it can enhance their cognitive functioning (Barnes et al., 2003; Rowe & Kahn, 1998; Yaffe et al., 2001). Physical activity is also associated with a lower incidence of depression among older adults (Lampinen, Heikkinen, & Ruoppila, 2000). Overall, it is estimated that regular exercise by older adults can delay the onset of physical disabilities by up to 7 years (Vita et al., 1998).

Unfortunately, adults decrease their involvement in vigorous physical activity as they get older—females earlier than males (Katzel & Steinbrenner, 2012). Older adults who are socially isolated and lonely reduce their physical activity even more than those who maintain strong social connections (Hawkey, Thisted, & Cacioppo, 2009). By late adulthood, older adults may find that they get tired just climbing stairs or carrying groceries; running a marathon is out of the question. The average older person tires more quickly and needs more time to recover after vigorous activity than the average younger person.

Theories of Aging: Why Do We Age and Die?

No matter what we do to stay fit and healthy and avoid the diseases associated with aging, we all eventually die. There is no simple answer to the question of why we age and die. However, several theories have been proposed, and each of them says something important about the aging process. These theories can be organized into two main categories: **Programmed theories of aging** propose that aging follows a predictable genetic timetable; **damage or error theories of aging** call attention to more haphazard processes that cause damage or errors in cells to accumulate and organ systems to deteriorate (Arking, 2006; Campisi & Robert, 2014; Hayflick, 2004). The question, really, is whether aging and death are the result of a biological master plan or of accumulation of random insults to the body while we live.

Programmed Theories

Programmed theories assume that aging will unfold according to a species-specific genetic program. There is no doubt that **maximum life span**—a ceiling on the number of years that anyone lives—varies by species. The fruit fly is lucky to live for 2–3 months, whereas the mighty Galapagos tortoise can reach an astonishing 190 years. Among mammals, humans have the longest maximum life span, estimated at around 125 years (Weon & Je, 2009). To date, the longest documented and verified human life is that of Jeanne Louise Calment, a French woman who died in 1997 at age 122 (Willcox et al., 2009). She lived on her own until age 110 when she could no longer see well enough to safely cook or light her daily cigarette (Cruikshank, 2009). Nearly blind and deaf and confined to a wheelchair, she maintained her sense of humor to the end, attributing her longevity to everything from having a stomach “like an ostrich’s” to being forgotten by God (Trueheart, 1997). Calment and others who live almost as long are the basis for setting the maximum human life span around 125 years. Despite the fact that the *average* life expectancy increased 30 plus years during the 20th century and that more and more people today are living to be 100, the *maximum* life span has changed very little (Kinsella, 2005).

Beyond the species-specific maximum life span, an individual’s genetic makeup, combined with environmental factors, influences how rapidly he ages and how long he lives compared with other humans. For example, genetic differences among us account for more than 50% of differences in the ability to stay free of major chronic diseases at age 70 or older (Reed & Dick, 2003) and for up to about a third of the variation in longevity (Melzer, Hurst, & Frayling, 2007). Among the oldest of the old, genetic factors may play an even greater role (Sebastiani et al., 2012). Perhaps, then, it is not surprising that a fairly good way to estimate how long you will live is to average the longevity of your parents and grandparents. For more tips on what it might take to live to be 100, check out **Exploration 5.2**.

It is not clear yet exactly how genes influence aging and longevity, though. The most promising programmed aging theory is based on the work of Leonard Hayflick (1976, 1994; 2004; 2007), who discovered that cells from human embryos could divide only

Want to Live to Be 100?

An increasing number of people are **centenarians**—people who live to be 100 or older. Dan Buettner (2008) identified five communities around the world with unusually high proportions of centenarians. These so-called “Blue Zones” are located in Ikaria Greece; Loma Linda, California; Sardinia, Italy; Okinawa, Japan; and Nicoya, Costa Rica. By studying these communities and other centenarians, what can we learn about the secrets to a long, and importantly, a healthy life? Consider Don Pellmann, who set five world records in track and field at the 2015 Senior Olympics after reaching the century mark. Although Pellmann had run track as a teenager, he didn’t return to the sport until age 70, when a son suggested that he give it a try. Feeling exhausted after that first competition, Pellmann realized he needed to start exercising if he wanted to continue competing. For the next 30 years, Pellmann walked or jogged, threw the shot put and discus, participated in competition after competition, and earned more awards (somewhere in the range of 900) than he could keep in his assisted living apartment (Almond, 2015).

Asked about his secret to a long life, Pellmann provided these pearls of wisdom: “I guess I have pretty good genes” and “I take care of what I got” (Almond, 2015; Crouse, 2015). Genetics does play a role in longevity: If you have long-lived relatives, then you are more likely to live a long life than someone without this family history (Gavrilov & Gavrilova, 2015). Research with a large sample of Danish twins found that genes accounted for about 25% of the differences in longevity (Herskind et al., 1996). The precise nature of this genetic contribution to longevity is still being studied, although several intriguing findings have

emerged to date. For instance, there is some indication that a mother’s longevity may contribute to longevity of her sons and daughters, whereas a father’s longevity may influence only his son’s longevity (Deluty et al., 2015). Genes may also influence longevity by offering protection from disease. Those from ‘sturdy stock’ with no major health conditions may pass along these ‘sturdy’ genes to their offspring. After all, part of what helps us live a long life is avoiding those diseases and illnesses that can do us in before we reach a ripe old age.

Interestingly, birth month also shows some relation to longevity, with those born in the fall months enjoying better odds of living to be 100 than those born at other times of the year (Gavrilov & Gavrilova, 2011). How could birth month possibly effect longevity? Researchers believe that birth month correlates with a mother’s exposure to infections, sunshine and its vitamin D benefits, and nutrition during the prenatal and early postnatal period. These events may exert an epigenetic influence on the developing fetus and newborn, setting the stage for lifelong health (Gavrilov & Gavrilova, 2011).

Genes are important, but they alone are not going to get you to age 100. Gwen Weiss-Numeroff interviewed 30 centenarians for her book, *Extraordinary Centenarians in America: Their Secrets to Living a Long Vibrant Life*, and found that a common thread emerging from these interviews was adaptability. Centenarians had a positive outlook on life and were able to easily adapt to change. In addition, many of the centenarians reported fairly healthy eating habits and avoidance—for the most part—of unhealthy habits such as smoking. This takes us back to Don Pellmann’s second piece of wisdom—taking care of what you have. A diet high in fruits, vegetables, nuts, and legumes

and low in carbohydrates and fats can reduce the risk of heart disease, diabetes, and various cancers (Davinelli, Willcox, & Scapagnini, 2012).

In their book, *The Longevity Project*, Howard Friedman and Leslie Martin (2011) describe the life outcomes for 1,500 folks who were originally recruited in 1921 by Lewis Terman for a study of giftedness (see Chapter 9). By analyzing the health records and death dates of these Terman study participants, Friedman and Martin found that the trait of conscientiousness in both childhood and adulthood predicted longevity. People who are conscientious likely make decisions that enhance their health rather than detract from it. Conscientious folks are the ones who follow the recommendations for regular checkups and diagnostic tests to detect potential health problems as early as possible. They probably floss their teeth and wear their seatbelts, all of which contributes to a long and healthy life.

So the key to longevity is likely a combination of good genes and a healthy lifestyle. If you would like to calculate how long you can be expected to live based on information about your lifestyle, stress level, eating habits, and health status, try completing “The Living to 100 Life Expectancy Calculator” developed by Dr. Thomas Perls and available at www.livingto100.com. Another interesting tool is the Vitality Compass™ on the bluezones.com website, which will give you an estimate of your biological age and life expectancy as well as information on how your personal habits and life choices might raise or lower your estimated longevity. You do not have to live in one of the “Blue Zones” or have super-centenarian genes to add years to your life.

a certain number of times—50 times, plus or minus 10—an estimate referred to as the **Hayflick limit**. Hayflick also demonstrated that cells taken from human adults divide even fewer times, presumably because they have already used up some of their capacity for reproducing themselves. Moreover, the maximum life span of a species is related to the Hayflick limit for that species: The long-lived Galapagos tortoise’s cells can divide 90–125 times whereas the cells of the short-lived fruit fly can divide far less than this.

The mechanism behind the cellular aging clock suggested by Hayflick’s limit on cell division has turned out to be **telomeres**—stretches of DNA that form the tips of chromosomes and that shorten with every cell division (see ■ **Figure 5.9**). This progressive shortening of telomeres eventually makes cells unable to replicate and causes them to malfunction and die. Thus telomere length is a yardstick of biological aging (see Mather, Jorm, Parslow, & Christensen, 2011).

■ **Figure 5.9** As cells divide over time, telomeres shorten until, eventually, cells can no longer divide.

But what determines how fast telomeres shorten? Fascinating research is revealing that chronic stress, such as that involved in caring for an ill child or a parent with dementia, is linked to shorter than normal white-blood-cell telomeres, which in turn are associated with heightened risk for cardiovascular disease and death (Epel, 2009; Epel et al., 2004, 2006). Other research has found shortened telomeres among war veterans suffering from post-traumatic stress disorder (Jergović et al., 2014). Many of us believe that stress ages people; now there is concrete evidence that stress speeds cellular aging. Moreover, lack of exercise, smoking, obesity, and low socioeconomic status—all risk factors for age-related diseases—are also associated with short telomeres (Cherkas et al., 2006, 2008). According to programmed theories of aging, what might we do to extend life? It is possible that researchers might devise ways of manipulating genes to increase longevity or even the maximum life span (Arking, 2006). Life spans of 200–600 years are probably not possible, but some think researchers could raise the average age of death to around 112 years and enable 112-year-olds to function more like 78-year-olds (Miller, 2004). For example, researchers have established that the enzyme telomerase can be used to prevent the telomeres from shortening and thus keep cells replicating and working longer; telomerase treatments could backfire, however, if they also make cancerous cells multiply more rapidly (Wang, 2010; Wright & Shay, 2005).

Damage or Error Theories

In contrast to programmed theories of aging, damage or error theories generally propose that wear and tear—an accumulation of random damage to cells and organs over the years—ultimately causes death (Hayflick, 2004; 2007; Maynard et al., 2015). Like cars, we may have a limited warranty and simply give out after a certain number of years of use and abuse (Olshansky & Carnes, 2004). Early in life, DNA strands and cells replicate themselves faithfully; later in life this fidelity is lost and cells become

increasingly damaged. Random error theorists believe that biological aging is about random damage rather than genetically programmed change.

According to one leading error theory, damage to cells that compromises their functioning is done by **free radicals**, which are toxic and chemically unstable by-products of metabolism, or the everyday chemical reactions in cells such as those involved in the breakdown of food (Maynard et al., 2015; Shringarpure & Davies, 2009). Free radicals are produced when oxygen reacts with certain molecules in the cells. They have an unpaired, or “free,” electron and are highly reactive with and damaging to other molecules in the body, including DNA. Over time the genetic code contained in the DNA of more and more cells becomes scrambled, and the body’s mechanisms for repairing such genetic damage simply cannot keep up with the chaos. More cells then function improperly or cease to function, and the organism eventually dies.

“Age spots” on the skin of older people are a visible sign of the damage free radicals can cause. Free radicals have also been implicated in some of the major diseases that become more common with age—most notably, cardiovascular diseases, cancer, and Alzheimer’s disease (Maynard et al., 2015). Moreover, they are implicated in the aging of the brain (Poon et al., 2004). However, the damage of most concern is damage to DNA, because the result is more defective cells replicating themselves. Unfortunately, we cannot live and breathe without manufacturing free radicals.

Many researchers adopting an error perspective have focused on preventing the damage caused by free radicals. **Antioxidants** such as vitamins E and C (or foods high in them such as raisins, spinach, and blueberries) can donate one of their electrons to unstable free radicals, thereby neutralizing their damage to your body (see ■ **Figure 5.10**). At least when they are produced by the body or consumed in foods rather than taken in pill form, antioxidants may increase longevity, although not for long, by inhibiting free radical activity and in turn helping prevent

Figure 5.10 Free radicals have an unpaired electron, which can cause damage as these free radicals can indiscriminately absorb or steal electrons from other cells throughout the body. Antioxidants are molecules that can safely donate an electron to free radicals, thereby neutralizing their potential for damage.

age-related diseases (Meydani, 2001). One potential antioxidant receiving a great deal of interest is resveratrol, a natural substance in grapes, red wine, and peanuts (Ferro & DeSouza, 2011; Ungvari et al., 2011). More research is needed to fully understand how resveratrol works and the conditions under which it might be effective in ameliorating age-related damage.

One theory is that resveratrol's effects are similar to those that result from **caloric restriction**—a highly nutritious but severely restricted diet representing a 30–40% or more cut in normal total caloric intake (Anderson & Weindruch, 2012; Omodei & Fontana, 2011). Laboratory studies involving rats and primates suggest that caloric restriction extends both the average longevity and the maximum life span of a species and that it delays or slows the progression of many age-related diseases (Bodkin et al., 2003; Lane et al., 2001). By one estimate, a 40% reduction in daily calories results in a 40% decrease in body weight, a 40% increase in average longevity, and a 49% increase in the maximum life span of diet-restricted rats (Harman, 2001).

How does caloric restriction achieve these results? It clearly reduces the number of free radicals and other toxic products of metabolism. A restricted diet appears to alter gene activity and trigger the release of hormones that slow metabolism and protect cells against oxidative damage (Antebi, 2007; Arking, 2006). These changes help the half-starved organism hang on to life as long as possible. However, we do not know whether caloric restriction works as well for humans as it apparently has for rats, what calorie counts and combinations of nutrients are optimal, or whether humans who have a choice would put up with being half-starved for most of their lives. We do know that exceptionally long-lived people are rarely obese (Willcox et al., 2009).

Nature and Nurture Conspiring

The theories just described are some of the most promising explanations of why we age and die. Programmed theories of aging generally say that aging and dying are as much a part of nature's plan as sprouting teeth or uttering first words and may be the

by-products of a genetic makeup that also contributed to early growth, development, and reproduction. Evidence for the genetic control of aging and dying comes from various sources: the maximum life span, the role of individual genetic makeup in longevity, the Hayflick limit on cell replication timed by telomeres, changes in the activity of certain genes as we age, and systematic changes in several bodily systems. By contrast, error theories of aging hold that we eventually succumb to haphazard destructive processes, such as those caused by free radicals—processes that result in increasingly faulty DNA and abnormal cell functioning and ultimately a breakdown in bodily functioning.

Neither of these broad theories of aging has proved to be *the* explanation; instead, many interacting mechanisms involving both aging processes and disease processes are at work (Arking, 2006; Knight, 2000). For example, genes influence the capacity of cells to repair environmentally caused damage, and the random damage caused by free radicals alters genetic material. John Medina (1996) put it this way: “Toxic waste products accumulate because genes shut off. Genes shut off because toxic waste products accumulate” (p. 291). In short, nature and nurture, biological and environmental factors, interact to bring about aging and dying—just as they interact to produce development.

Successful Aging

Aging is inevitable, so how can we do it successfully and what do we even mean by “successful” aging? To some, this may mean living a long life, without necessarily considering the *quality* of life. Others may focus on quality and associate successful aging with being free of diseases that limit physical and mental skills and the ability to actively participate in desired daily activities. In their scaffolding theory of aging and cognition, discussed earlier in this chapter, Reuter-Lorenz & Park (2014) note that successful aging is “simply the absence of age-related pathology” (p. 356). But most older people have at least some chronic disease or impairment, making it hard to know how an elderly person might function if he was disease-free. To explore this, James Birren and his colleagues (1963) conducted extensive medical examinations of men aged 65–91, which allowed them to identify two groups of elderly men: (1) those who were almost perfectly healthy and had no signs of disease and (2) those who had slight traces of some disease in the making but no clinically diagnosable diseases. Several aspects of physical and intellectual functioning were assessed in these men, and the participants were compared with young men.

The most remarkable finding was that the healthier group of older men hardly differed from the younger men. They were equal in their capacity for physical exercise, and they beat the younger men on measures of intelligence that required general information or knowledge of vocabulary words. Their main limitations were the slower brain activity and reaction times that seem to be so basic to the aging process. Overall, aging in the absence of disease had little effect on physical and psychological

Sister Esther, shown here at age 106, enjoys interacting with Nun Study researcher Dr. David Snowdon. What have we learned from the Nun Study?

Steve Liss//Time Life Pictures/Getty Images

functioning. However, the men with slight traces of impending disease were deficient on several measures. Diseases that have progressed to the point of symptoms have even more serious consequences for performance.

In another extraordinary study, David Snowdon (2002) studied 678 nuns ranging in age from 75 to 106 years. Snowdon, an epidemiologist, chose to study the nuns because they were very similar with respect to socioeconomic status, housing, health care, and diet. In this remarkable longitudinal study, participants underwent annual mental and physical testing, provided complete access to a lifetime of health records, and agreed to donate their brains for examination following their deaths.

The first finding to emerge from the so-called Nun Study was that level of education affected longevity and health. Those with a college degree lived longer and were more likely to remain independent. The risk of death among the college-educated nuns was lower at every age. Another major finding was that the nuns who were active, both physically and mentally, lived longer and healthier than nuns who were not as active.

A unique aspect of the Nun Study was that each nun had written an autobiography prior to taking her vows (average age of 22 years) and, decades later, these autobiographies became part of the data analyzed for the study. This analysis revealed that older nuns who were healthy had used more complex vocabulary in their autobiographies decades earlier (on average, 60 years earlier). They used words such as “particularly, privileged, and quarantined” as opposed to simple words such

as “girls, boys, and sick” that were used by nuns who later developed symptoms of Alzheimer’s disease (Snowdon, 2002, p. 107). In particular, idea density, a measure of language-processing ability, measured in early adulthood predicted mental functioning in later adulthood. In addition, nuns whose autobiographies expressed more positive emotions lived longer than nuns whose autobiographies expressed fewer positive emotions.

The message to take away from such research is that both physical and mental activity, along with a positive attitude, can help slow the effects of aging on both the body and brain. Muscles atrophy if they are not used, and the heart functions less well if a person leads a sedentary life (Rosenbloom & Bahns, 2006). The brain also needs “mental exercise” to display plasticity and to continue to function effectively in old age (Black, Isaacs, & Greenough, 1991; Shors, 2014). So while we can’t avoid the biological reality of aging, we

can make choices across the life span that will increase the odds of living a long life and aging successfully. Clearly, then, our health and well-being are influenced by an interaction of environmental and genetic factors.

● Checking Mastery

1. What physical changes, including those in the brain, can we expect as we age?
2. What is the major difference between a programmed theory of aging and an error theory of aging?
3. What have we learned about successful aging from the “Nun Study” and other research on centenarians?

● Making Connections

1. Many (indeed, most) stereotypes of the physical aging process are negative and depressing. What in this chapter gives you reason to be more optimistic about aging, and why? Cite specific concepts and research findings.
2. Suppose you set as your goal reaching age 100 in superb physical condition. Describe and justify a plan for achieving your goal, then indicate why you might not make it despite your best efforts.

Chapter Summary

5.1 Building Blocks of Growth and Lifelong Health

- Growth is influenced by genes and environments, through the working of the endocrine and nervous systems. The nervous system consists of the brain, the spinal cord, and peripheral neurons. Endocrine glands such as the pituitary, thyroid, testes, and ovaries regulate behavior by secreting hormones directly into the bloodstream. The workings of the endocrine and nervous systems can be hindered or enhanced by environmental forces.
- Physical growth proceeds according to the cephalocaudal (head-to-tail), proximodistal (center outward), and orthogenetic (global and undifferentiated to differentiated and integrated) principles.
- Health is best viewed from a life-span developmental perspective emphasizing genes, personal choice, and environmental factors in interaction.

5.2 The Infant

- The infant's brain undergoes synaptogenesis (growth of synapses) as well as synaptic pruning (loss of unused synapses). It is capable of responding to experiences, both positive and negative.
- Infants come into the world equipped with reflexes and organized states that allow them to adapt to their environments.
- Congenital malformations and complications of preterm birth are the leading causes of infant mortality. Preventative medicine such as well-baby visits to the doctor and vaccinations can improve infant health.

5.3 The Child

- During childhood, neural transmission speeds up and lateralization of various brain functions, although present at birth, becomes more evident in behavior.
- There is steady and marked improvement in all aspects of physical growth over the childhood years.
- Physical activity is an important component of health during childhood. Children's health is also influenced by their parents' socioeconomic status and lifestyle choices.
- Health is enhanced with proper nutrition and regular physical activity. Current lifestyles have decreased physical activity and increased sedentary media time, resulting in increased weight among today's children.

5.4 The Adolescent

- During adolescence, the brain (especially the prefrontal cortex) continues to develop, permitting sustained attention and strategic planning. Brain changes may place adolescents at greater risk for making unsafe decisions.
- The adolescent period is marked by physical growth—the adolescent growth spurt—and attainment of puberty or sexual maturity. Girls experience their growth spurt at a younger age

than do boys. The major milestone of sexual maturity for girls is menarche—their first menstruation. For boys, it is the less-noted experience of semenarche, or first ejaculation. A combination of genes, hormones, and environmental factors determine the timing and rate of growth and puberty.

- The physical changes of adolescence are significant and have psychological implications. Girls' experience is often on the negative side, whereas boys tend to report a more positive reaction to growth and puberty. Boys who mature early experience largely positive benefits, whereas late-maturing boys have a more negative experience. In contrast, girls who mature early are sometimes disadvantaged by teasing from their peers and the influence of the older peers with whom they often socialize. Late-maturing girls seem to benefit academically, possibly because they continue to spend more time on schoolwork than their early-maturing peers.
- Adolescents are a relatively healthy bunch, but the fitness level of some teens is poor because of a lack of physical activity and insufficient sleep.

5.5 The Adult

- The adult brain is capable of some degree of neurogenesis, or generating new neurons.
- The aging brain exhibits both degeneration and plasticity. Neurons atrophy and die, and blood flow to the brain decreases; but the aging brain forms new synapses to compensate for neural loss and reorganizes itself in response to learning experiences.
- Changes in health and physical functioning start to become evident during middle adulthood, and declines are noticeable in most older adults. There are large individual differences in physical functioning of older adults.
- For both sexes, changes in the reproductive system are a normal part of aging. Women experience menopause, a cessation of menstruation, and an end of child-bearing years. Men experience andropause, a more gradual change in their reproductive system. The experience of menopause is variable and a variety of treatments are available to alleviate the symptoms.
- Health and well-being during adulthood are influenced by genetic predispositions acting in concert with the environment and lifestyle choices. Exercise can enhance both physical and mental functioning. Common diseases among older adults include osteoporosis, which leads to fragile bones, and osteoarthritis, or joint inflammation.
- Two theories of aging and death include those that emphasize the genetic control of aging—the programmed theories—and those that emphasize haphazard loss—the damage or error theories.
- Physical and mental activity, as well as a positive attitude, improve the odds of successful aging.

The Adult in Perspective

When asked to speculate on which of their senses would be most problematic to lose, many students say vision or hearing, as these senses seem to take center stage in so many daily activities. Some believe losing their visual sense would be a devastating loss as they would need to give up such activities as driving, a major source of independence. Others, though, conclude that losing their auditory sense would be most challenging, perhaps because many aspects of social relationships hinge on hearing what others have to say. A survey of adults conducted by www.healthyhearing.com found that most ranked the ability to see as the most valuable sense, followed by the ability to hear. About one in four adults ranked the ability to touch as most valuable, but only one in ten voted for the ability to smell or to taste. Which sense do you believe is the most valuable? After you have read this chapter, consider this question once again because your thoughts might shift after you learn about the remarkable contributions of all the senses to the quality of our lives.

In this chapter, we examine how our senses provide us with the building blocks for understanding the world around us. We discuss the tremendous flood of sensations bombarding the infant and how infants come to “make sense” of this information. We trace major changes in sensation and perception through childhood, adolescence, and early adulthood, and then look at some of the inevitable declines that occur in middle and later adulthood. We also examine how perception is coupled with action in a *synergistic* fashion. As you changed from a largely immobile infant to an on-the-move toddler, for example, you coupled your burgeoning perceptual skills with advances in your nervous system and your body’s growing physical capabilities to engage in goal-oriented actions. Finally, we look at the important role that attention plays in our awareness of the world around us and why some information is noticed and other information seems to drop off our “radar screens.”

What do we mean by these terms *sensation*, *perception*, and *action*? Psychologists have long distinguished between sensation

and perception. **Sensation** is the process by which sensory receptor neurons detect information and transmit it to the brain. From birth, infants sense their environment. They detect light, sound, odor-bearing molecules in the air, and other stimuli. But do they *understand* the patterns of stimulation coming in from the various sense organs? This is where **perception**, or the interpretation of sensory input, comes into play: recognizing what you see, understanding what is said to you, knowing that the odor you have detected is a sizzling steak, and so on. But let’s be clear about something: The sense organs are not passive receptacles that detect and merely pass along information to the brain. Your eyes, nose, tongue, ears, and skin actually help shape the brain (see, for example, Schreuder, 2014). Sensation and perception are at the heart of human functioning. *Everything you do—all of your physical and mental actions—depends on your ability to sense and perceive the world around you.* To begin our journey, we consider perspectives on how we perceive the world and gain knowledge of reality, exploring again the nature–nurture issue.

6.1

Perspectives on Perception

LEARNING OBJECTIVES

- Distinguish between the nativist and constructivist positions on perception.
- Summarize Gibson’s ecological approach to perception and how it differs from approaches that are primarily constructivist or nativist.

Does the ability to perceive the world around us depend solely on innate biological factors, or is this ability acquired through experience and learning? **Constructivists**, including Jean Piaget who was introduced in Chapter 2 and will be further discussed in Chapter 7, come down on the side of nurture (Johnson & Hannon, 2015). They argue that perceptions of the world are constructed over time through learning. Yes, we come equipped at birth with functioning sensory systems, but understanding the input coming in through our senses requires interacting with the environment and figuring out what those sensations mean (Johnson & Hannon, 2015). For instance, the retinal image of an object located 50 feet from an observer is different from the retinal image of the same object located just 10 feet from the observer. According to the constructivists, we need experience with viewing objects at various distances to learn how to interpret the different retinal images that they project. With experience, we create an association between the retinal image (for example, small) and its meaning (for example, distant object).

Although the constructivist view of perception has long been very popular, more sophisticated methods of assessing infants’ capabilities have yielded new findings about their perceptual abilities. This includes evidence of object understanding at a very early age (see Johnson & Hannon, 2015). As a result, some researchers have shifted toward a more nativist perspective on the origins of some aspects of perception. The **nativists** argue that perception is *not* created by interpreting external input; instead, innate capabilities and maturational programs are the driving forces in perceptual development. Infants come equipped with basic sensory capabilities, which are further refined according to an innate plan. Nativists would argue that the

infant does not need experience to learn how to interpret different retinal images cast by the same object at different distances. The brain automatically understands the meaning of different retinal images created as we move about our world (for example, a small image is automatically “read” by the brain as distant object). Thus, from the nativist perspective, perception is direct—it does not require interpretation based on previous experience (Johnson & Hannon, 2015).

Falling somewhere in the middle of the nurture-based constructivists and the nature-focused nativists is Gibson’s ecological theory of perception developed by Eleanor Gibson (2001) and her husband James Gibson (1966, 1979). In Chapter 2, we introduced Bronfenbrenner’s ecological (later, bioecological) theory that described how the environment is organized and affects development. Similarly, Gibson’s ecological approach also considers the organization of the environment. In particular, Gibson’s theory proposes that information important for perception is readily and directly available in the environment: in the to-be-perceived objects. As we move around in our world, our position relative to all other objects in the environment is constantly changing and altering the flow of information and the images projected to our retina. For example, suppose we look at a round object that gradually projects a larger image on our retina; how do we know what this is and how we might interact with it? The constructivists might say that we need to take all the pieces of information coming in from our senses and construct an understanding of what this object is and what it can do. It may take multiple interactions with the object before we put together all the pieces of the puzzle and learn its properties and figure out that a ball is moving toward us. In contrast, the ecological approach argues that we do not

What do you see when you look at this object? According to the constructivist theory of perception, you use past experiences to construct an understanding of what this object might be.

Steve Rosenberg/Getty Images

need to construct how we might interact with this object. Instead, features of the object directly reveal its **affordances**: what it has to offer us and how it might be used by us. Thus, as the round object moves toward us, the pattern of light reaching our eyes provides all the information we need to know what this object *affords*: the prospect of getting hit in the face if we do not take some action.

In the ecological view, perception drives action. Perception provides us with valuable information about what objects in the environment afford, or can offer us: surfaces to sit on, pots and pans that can serve as musical instruments, sticks that can poke things, and so on. As James Gibson (1979) noted, “we must perceive in order to move, but we must also move in order to perceive” (p. 223). This is an important difference between how the Gibson ecologists and the constructivists view the role of the environment and past experience: The constructivists would argue that past learning experiences are

needed to interpret the current perceptual situation, whereas the Gibson ecologists would say that all the information needed to interpret the current perceptual situation is available in the current situation.

Note that what an object or the environment affords depends on each individual’s capabilities, including their genetic predispositions and current goals and motivations (Miller, 2016). A pencil may offer an 8-year-old the possibility of writing something on a piece of paper because the 8-year-old has the capacity to write and therefore perceives this affordance of this object. For a 12-month-old infant who has not yet developed this capability, the pencil may afford something quite different, such as a stick for poking or something else to chew. Thus, Gibson ecologists view nature and nurture as inseparable (Miller, 2016).

In this chapter, we will use the constructivist, nativist, and ecological perspectives to help us gain a better understanding of perception and action across the life span. As we begin our journey in infancy, we will look closely at sensation and perception because most fundamental capacities emerge and quickly develop during the first months of life. Later, you will see how much more “intelligent” perceptual abilities become during childhood and adolescence and will question the image of old age as a time of little more than sensory and perceptual decline.

● Checking Mastery

1. How is perception different from sensation?
2. What is the difference between how constructivists and nativists view sensation and perception?
3. In what way is Gibson’s ecological theory of perception distinct from the constructivist and the nativist views of perception?

● Making Connections

1. How could you demonstrate that perception of an object’s distance is innate rather than constructed through experience?

6.2

The Infant

LEARNING OBJECTIVES

- Describe the changes in visual capabilities from birth through the first year, and note the visual preferences exhibited by infants.
- Explain how infants come to “make sense” of the visual world.
- Outline the auditory capabilities of the pre- and early postnatal period, including a description of how researchers evaluate these capabilities.
- Summarize the infant’s chemical senses as well as the functioning of their somaesthetic senses.
- Explain the early experiences needed for development of normal perceptual skills and the influence of early experience on the brain.

The pioneering American psychologist William James (1890) claimed that sights, sounds, and other sensory inputs formed a “blooming, buzzing confusion” to the young infant. James was actually noting that impressions from the several senses are fused rather

than separable, but his statement has since been quoted to represent the view that the world of the young infant is hopelessly confusing.

Today the accepted view is that young infants have far greater perceptual abilities than anyone suspected. Their senses

are functioning even before birth, and in the first few months of life they show many signs that they are perceiving a coherent rather than a chaotic world. Why the change in views? It is not that babies have become smarter. It is that researchers have become smarter. They have developed more sophisticated methods of studying what infants can and cannot do. Infants, after all, cannot tell researchers directly what they perceive, so the trick has been to develop ways to let their behavior speak for them. The main methods used to study infant perception are summarized in • Table 6.1 and include habituation, preferential looking, evoked potentials, and operant conditioning techniques. These techniques have revealed a good deal about what infants perceive and what they do not, as you will now see.

Vision

As noted in the chapter opener, many of us tend to think of vision as our most indispensable sense. Because vision is indeed important, we examine its early development in some detail before turning to the other major senses.

Basic Capacities

How does something as complicated as vision work? The eye functions by taking in stimulation in the form of light and converting it to electrochemical signals to the brain. Even before birth, the fetus responds to bright lights it detects from the outside world, such as a flashlight directed at the mother's belly (see Johnson & Hannon, 2015). And after birth, the newborn can visually track a slow-moving picture or object. Failure to follow an object when the object is presented within normal viewing range is often an early indicator of a visual problem. Even among sighted newborns, though, visual capabilities are lacking compared with those of a child or an adult. At birth, newborns' **visual acuity**, or the ability to perceive detail, is 40 times worse than an adult's, but improves across the first month of life to roughly the equivalent of 20/120 vision on the standard eye chart—being able to see only the big E at the top of the chart (Hamer, 2016). Objects are blurry to young infants unless they are within about 12 inches (30 cm) from the face or are bold

patterns with sharp light–dark contrasts—the face of a parent, for example. The young infant's world is also blurred because of limitations in **visual accommodation**—the ability of the lens of the eye to change shape to bring objects at different distances into focus. It is likely to take 6 months to 1 year before the infant can see as well as an adult (Hofsten et al., 2014).

To some extent, very young infants also see the world in color, not in black and white as some early observers thought (Zemach, Chang, & Teller, 2006). How do researchers know this? Suppose they accustom an infant to a blue disk using the **habituation** technique described in • Table 6.1. What will happen if they then present either a blue disk of a different shade or a green disk? Infants 4 months old will show little interest in a disk of a different blue but will be attentive to a green disk—even when the light reflected from these two stimuli differs in wavelength from the original blue stimulus by the same amount (Peeples & Teller, 1975). Thus, 4-month-olds appear to discriminate colors and categorize portions of the continuum of wavelengths of light

A physician checks a young infant's vision. What is this infant likely to be able to see?

UniversalImagesGroup/Getty Images

• Table 6.1 Methods for Assessing Infant Perception

Habituation	The same stimulus is repeatedly presented until the infant grows bored with what has become familiar and disengages (e.g., looks away). Researchers can measure how long (e.g., how many trials) until an infant becomes bored. They can also measure how distinct a second, new stimulus needs to be in order to recapture the infant's attention.
Preferential looking	Two stimuli are simultaneously shown to an infant to determine which one they prefer, which is inferred to be the one they look at longer. Adding head-mounted, eye-tracking cameras has allowed researchers to more precisely measure preferential looking.
Evoked potentials	Electrical activity in different parts of the brain is measured while the infant watches, listens to, or is otherwise exposed to stimulation. Electrodes are attached to the surface of the skull and a computer records the pattern of electrical activity corresponding to various stimuli.
Operant conditioning	Infants are conditioned to reliably respond a certain way to a certain stimulus (e.g., they are rewarded for turning their head every time they hear a sound). Once this response is well-established, the researcher can examine the conditions under which the infants will, or will not, continue to produce the behavior. Presumably, continued head turning suggests that infants do not detect a noticeable difference between the original and new stimuli, whereas lack of the conditioned response is evidence that they <i>do</i> distinguish between the two stimuli.

into the same basic color categories (red, blue, green, and yellow) that adults do. Color vision is present at birth, but newborns cannot discriminate some color differences well because their receptors are not yet mature. By 3 months, however, color vision seems comparable to that of an adult (Adams, 1987; Zemach et al., 2007). Like adults, 4-month-old infants can detect a colored stimulus on a background that is a different shade of the same color (Franklin, Pilling, & Davies, 2005). However, also like adults, they are *faster* at detecting the stimulus on a background of a different color.

In short, the eyes of the young infant are not working at peak levels, but they are working. As one researcher (Hainline, 1998) summarizes it: Infants are able to see what they need to see, a conclusion consistent with Gibson’s ecological approach. Even newborns can perceive light and dark, focus on nearby objects, distinguish colors, and see simple patterns. But does all this visual stimulation make any sense?

Organizing the World of Objects

Alan Slater and his colleagues (2010b) note that, above all else, perception is organized. In what ways do infants organize their perceptions? One of the first challenges for the infant is to separate the visual field into distinct objects, even when parts of objects are hidden behind other objects or are adjacent to one another. In other words, where does one object end and another object begin? From an early age, infants show remarkable abilities to organize and impose order on visual scenes in much the same way that adults do. Research suggests an important breakthrough in **form perception**, or recognition of the patterns that constitute an object, starting around 3 months (Courage, Reynolds, & Richards, 2006). One-month-olds focus on the outer contours of forms such as faces, as if they are finding the boundaries of the object; see **Figure 6.1** (Johnson & de Haan, 2015).

But starting around 2 months, infants no longer focus on some external boundary or contour; instead, they explore the interiors of figures thoroughly (for example, looking at a person’s eyes rather than just at the chin, hairline, and top of the head). It is as though they are no longer content to locate where an object starts and where it ends, as 1-month-olds tend to do; they seem to want to know what it is. During this time, infants also become better at shifting their attention or disengaging from a stimulus. Initially, their gaze seems to become “stuck” on the fixated object, and they have difficulty shifting it to another object (Johnson & de Haan, 2015). As you might imagine, this difficulty with shifting gaze limits what young infants can take in from their environment.

How exactly do infants determine where one object ends and another begins? Elizabeth Spelke and her colleagues (Kellman & Spelke, 1983; Spelke, 1990) have concluded that young infants are sensitive to several cues about the wholeness of objects, especially cues available when an object moves. For example, 4-month-olds seem to expect all parts of an object to move in the same direction at the same time, and they therefore use *common motion* as an important cue in determining what is or is not part of the same object (Kellman & Spelke, 1983). It takes infants longer, until about 6 months of age, to determine the boundaries or edges of *stationary* objects (Gibson & Pick, 2000). Thus, babies

Visual scanning of the human face by 1- and 2-month-old infants

Figure 6.1 Visual scanning by young infants. The 1-month-old spends more time at the edges of the face, as if trying to figure out where it begins and ends. The 2-month-old spends more time exploring the interior features of the face.

Source: Adapted from Salapatek, 1975.

appear to have an innate ability to organize a visual scene into distinct objects, and they are better able to make sense of a world in motion—a world like the one they live in—than to make sense of a stationary world.

It’s clear that infants try to impose order on the complex world of objects. In doing so, they demonstrate preferences for certain patterns over others. What are the properties of patterns that capture the young infant’s attention?

- Young infants pay attention to patterns that have a large amount of light–dark transition, or **contour**; they are responsive to sharp boundaries between light and dark areas (Banks & Shannon, 1993; Farroni et al., 2005). The soft pastel colors often presented to young infants may not have enough contrast to be detected by them (Brown & Lindsey, 2009).
- Infants are interested in displays that are dynamic (as opposed to static) or contain *movement* (Courage et al., 2006; Kavsek & Yonas, 2006). Newborns can and do track a moving target with their eyes, although their tracking at first is imprecise and likely to falter unless the target is moving slowly (Slater et al., 2010b).
- Young infants seem to be attracted to patterns that are *moderately complex*: not too simple, which would be boring, and not too complex, which would be overwhelming. Thus, they prefer a clear pattern (for example, a bold checkerboard pattern) to either a blank stimulus or an elaborate one such as a page from the *New York Times* (Fantz & Fagan, 1975). As infants mature, they prefer more complex stimuli.

This young infant is attracted to the mobile's well-defined contours (or light–dark contrasts) and bold patterns, which are neither too simple nor too complex.

Ruth Jenkinson/Getty Images

To recap, researchers know that infants younger than 2 months have visual preferences, and they also know something about the physical properties of stimuli that attract infants' attention. Martin Banks and his colleagues have offered a simple explanation for these early visual preferences: *Young infants prefer to look at whatever they can see well* (Banks & Ginsburg, 1985). Because the young infant's eye is small and its neural receptors are immature, it has poor visual acuity and sees a highly complex visual display as a big, dark blob. However, the pattern in a moderately complex display can be seen. Less-than-perfect vision would therefore explain why young infants prefer moderate complexity to high complexity. Indeed, limited vision can account for several of the infant's visual preferences. Young infants seem to actively seek the visual input they can see well—input that will stimulate the development of the visual centers of their brains (Banks & Shannon, 1993; Hainline, 1998).

Face Perception

One special pattern that has garnered much attention from researchers is the human face. Detecting faces from nonfaces and discriminating familiar from nonfamiliar faces are critical skills in successfully navigating the social world. Imagine the possible

consequences, for example, if an infant was unable to detect the difference between a face and a balloon, or was unable to identify his mother's face from among the many faces that appear in his visual field each day.

Soon after birth, young infants prefer to look at schematic drawings of faces rather than other patterned stimuli, and faces elicit more visual tracking by young infants than other targets (Gamé, Carchon, & Vital-Durand, 2003). Newborns can distinguish a human face from a monkey face, although they don't show a preference for the human face (Di Giorgio et al., 2012). They can also distinguish their mother's face from that of a stranger's, at least in static and simplified displays (for example, Bushnell, 2001). Such findings seem to suggest an inborn tendency to discriminate faces from non-faces. More challenging is being able to discriminate among faces in real settings, where the faces are dynamic (moving) and embedded in an ever-changing environment. Lorraine Bahrack and her colleagues (for example, Bahrack, Gogate, & Ruiz, 2002; Bahrack & Newell, 2008) presented 5-month-olds with displays of women's faces as the women engaged in such tasks as brushing their teeth and blowing bubbles. Weeks later, they tested the infants for recognition of the action as well as the faces. The infants remembered the actions but did not remember or discriminate among the faces until the researchers either increased the infant's exposure time to the faces or removed the action and made the faces static. Bahrack, Lickliter, and Castellanos (2013) conclude that "actions are more salient than faces" (p. 2). Infants do not yet have sufficient attention resources: They can attend to the action or to the face, but not to both, and the action is more salient to their young attentional system.

Much remains to be learned about early perception of faces, including whether this is an innate ability or something that emerges only after having some experience looking at faces. Some scholars believe there is an innate preference for faces. But as we have learned, infants prefer contour, movement, and moderate complexity. Human faces have all of these physical properties. In addition, research shows that newborns have a preference for patterns that have more information in their upper visual field—that is, patterns that are "top heavy" (Cassia, Turati, & Simion, 2004; Cassia et al., 2006; Turati, 2004). Again, faces fit the bill: They are top heavy. Thus, what appears to be a preference for faces may be a preference for the features that happen to be connected with faces.

Nonetheless, we can conclude that infants truly perceive a meaningful face, not merely an appealing pattern, by 2–3 months of age. At this time, infants smile when they see faces as though they recognize them as familiar and appreciate their significance. So it goes with form perception more generally: As infants gain experience with different objects, their attention is drawn to certain objects not only because they have certain physical properties, but also because their forms are recognized as familiar. With experience comes greater expertise. One final note about face perception: Although infants "have" face recognition, there are further refinements in both the accuracy and speed of face recognition throughout childhood (de Heering, Rossion, & Maurer, 2012).

Depth Perception

Another very important aspect of visual perception involves perceiving depth and knowing when objects are near or far. Although it can take years to learn to judge the size of objects in the distance, very

Is face perception innate or does it emerge with experience? This infant is likely attracted to what features of his mother's face?

Ashley Gill/Alamy Stock Photo

young infants have some intriguing abilities to interpret spatial cues involving nearby objects. For example, they react defensively when objects move toward their faces; blinking in response to looming objects first appears around 1 month and becomes more consistent over the next few months (Kayed & van der Meer, 2007; Nanez & Yonas, 1994). By 4 months of age, infants demonstrate understanding of **size constancy**: They recognize that an object is of the same size despite changes in its distance from the eyes, which would project different images on the retina. Carl Granrud (2006) came to this conclusion using the habituation technique. Infants were initially habituated to either a small- or a medium-sized disk presented at different distances. They were then tested to see whether they preferred to look at a disk that was the same physical size but cast a different retinal image or one that was a different (that is, novel) physical size but cast the same retinal image. Keep in mind that once habituated to a stimulus, infants are bored with it and no longer attend to it. To recapture their attention, they need to be presented with a new stimulus that they can recognize as different from the original. Granrud found that the infants responded on the basis of actual object size, not size of the retinal image cast by the object. They preferred to look at the disk that was a novel physical size even though it cast the same retinal image as during the habituation phase. This indicates that infants recognize the size of an object even when the object is presented at different distances and thus produces different images on the retina.

Does this evidence of early spatial perception mean that infants who have begun to crawl know enough about space to avoid crawling off the edges of beds or staircases? The first attempt to examine depth perception in infants was carried out in classic research by Eleanor Gibson and Richard Walk (1960) using an apparatus called the **visual cliff**. This cliff consists of an elevated glass platform divided into two sections by a center board. On the “shallow” side a checkerboard pattern is placed directly under the glass. On the “deep” side the pattern is several feet below the glass, creating the illusion of a drop-off or “cliff.” Infants are placed on the center board and coaxed by their mothers to cross both the

shallow and the deep sides. Testing infants 6½ months of age and older, Gibson and Walk found that 27 of 36 infants would cross the shallow side to reach Mom, but only 3 of 36 would cross the deep side. Most infants of crawling age (typically 7 months or older) clearly perceive depth and are afraid of drop-offs.

The testing procedure used by Gibson and Walk depended on the ability of infants to crawl. Would younger infants who cannot yet crawl be able to perceive a drop-off? Joseph Campos and his colleagues (Campos, Langer, & Krowitz, 1970) found that when they slowly lowered babies over the shallow and deep sides of the visual cliff, babies as young as 2 months had a slower heart rate on the deep side than on the shallow side. Why slower? When we are afraid, our hearts beat faster, not slower. A slow heart rate is a sign of interest. So, researchers concluded that 2-month-old infants *perceive a difference* between the deep and the shallow sides of the visual cliff, but they have not yet learned to *fear* drop-offs.

But do infants really avoid drop-offs out of fear? Perhaps not. Karen Adolph and her colleagues (2014) point out several flaws with this conclusion, including the rather circular logic that infants avoid the cliff out of fear and we “know” they are afraid because they avoid the cliff. Further, Adolph points out that these allegedly fearful infants spend time exploring the edge of the cliff, often with no visible signs of distress such as crying. Rather than being a product of fear, avoidance of drop-offs appears to be learned through crawling—and falling now and then, or at least coming close to it (Campos, Bertenthal, & Kermoian, 1992). Some beginning crawlers will shuffle right off the ends of beds or the tops of stairwells if they are not watched carefully. However, avoidance of drop-offs is stronger in infants who have logged a few weeks of crawling than in infants of the same age who do not yet crawl. Alas, infants who have learned the lesson that crawling over drop-offs is risky do not transfer the lesson to similarly risky situations they encounter once they begin walking. They must again learn what they can and cannot do when faced with, for example, a stair step or an open space in the floor that a foot could fall through (Adolph, Berger, & Leo, 2011; Kretch & Adolph, 2013).

Infants’ behavior around drop-offs is consistent with Gibson’s theory of affordances, described in the previous section. Features of a cliff provide infants with the necessary information to know how to interact (or not interact) with the cliff. Infants who have some experience with drop-offs, slopes, and the like will have gleaned more information about whether they can safely cross and whether they need to make any adjustments, such as crouching or adjusting their gait, to do so (Adolph, Kretch, & LoBue, 2014).

The Infant as an Intuitive Theorist

The infant’s visual perceptual abilities are impressive. But that’s not all that is remarkable about the infant’s growing perception and knowledge of the world. Researchers have been exploring infants’ understandings of the physical laws that govern objects. For example, Elizabeth Spelke and her colleagues have been testing infants to determine what they know of Newtonian physics and the basic laws of object motion (Spelke & Hermer, 1996). Do babies know that a falling object will move downward along a continuous path until it encounters an obstruction? Spelke’s studies suggest that infants only 4 months of age seem surprised when a

Mark Richards/PhotoEdit

ball dropped behind a screen is later revealed below a shelf rather than resting on it. They look longer at this “impossible” event than at the comparison event in which the ball’s motion stops when it reaches a barrier. By 6 months, infants also seem surprised when a ball drops behind a screen and then, when the screen is lifted, appears to be suspended in midair rather than lying at the bottom of the display unit (Kim & Spelke, 1992; Spelke et al., 1992). This hints that they know something about the laws of gravity.

Do infants understand any other simple principles of physics? Yes; 4-month-olds watching a moving object disappear behind the left side of a screen seem to expect to see the object reappear from the right side of the screen (Bremner et al., 2005). And 4-month-olds are also surprised when a wide object disappears into a narrow container (Wang, Baillargeon, & Brueckner, 2004).

Such findings have led some developmentalists to conclude that young infants do more than just sense the world—they come equipped with organized systems of knowledge, called **intuitive theories**, which allow them to make sense of the world (Gelman, 1996; Wellman & Gelman, 1992). From an early age, children distinguish between the domains of knowledge adults know as physics, biology, and psychology. They organize their knowledge in each domain around causal principles and seem to understand that different causal forces operate in different domains (for example, that desires influence the behavior of humans but not of rocks). According to this intuitive theories perspective, young infants have innate knowledge of the world, and they perceive and even reason about it much as adults do. Coming to know

the physical world is then a matter of fleshing-out understandings they have had all along rather than constructing entirely new ones as they get older (Spelke, 1994). All in all, it is clear that young infants know a good deal more about the world around them than anyone imagined, although they learn more every year.

Hearing

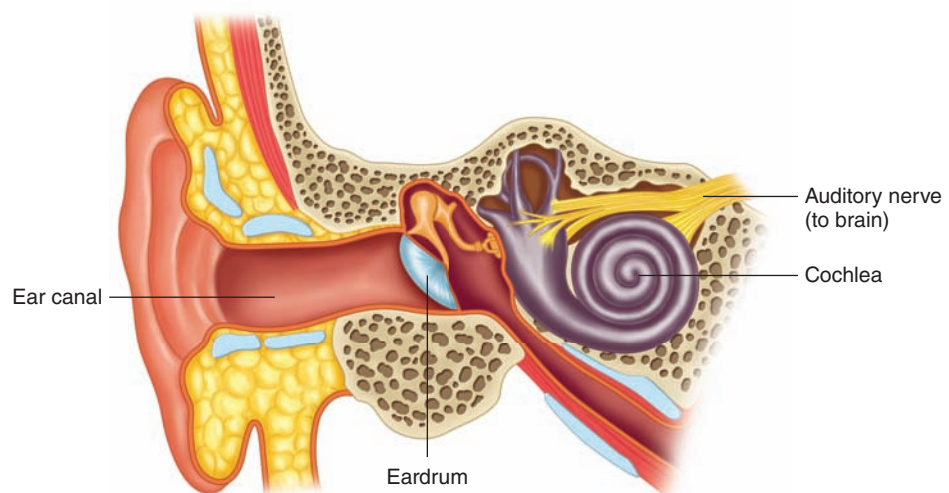

Hearing is at least as important to us as vision, especially because we depend on it to communicate with others through spoken language. As Anne Fernald (2001) notes, “while vision may be primary in enabling infants to learn about the physical world, audition plays a powerful role in initiating infants into a social world” (p. 37).

The process of hearing begins when moving air molecules enter the ear and vibrate the eardrum. These vibrations are transmitted to the cochlea in the inner ear and are converted to signals that the brain interprets as sounds (see ■ Figure 6.2).

Basic Capacities

Newborns can hear well—better than they can see. They can also localize sounds: They are startled by loud noises and will turn from them, but they will turn toward softer sounds (see Burnham & Mattock, 2010). Even fetuses can hear some of what is going on in the world outside the womb as early as the fourth month of pregnancy. Researchers have detected changes in fetal heart rates that correspond to changes in sounds they are exposed to while in their mother’s womb (Fifer, Monk, & Grose-Fifer, 2004; Saffran, Werker, & Werner, 2006).

But, wait, there’s even more: Fetuses exposed to music in the womb show behaviors that seem to suggest they are trying to sing and dance along! Researchers in Barcelona, Spain, used ultrasound to observe fetal activity as the fetuses were exposed to music from a ‘Babypod,’ a device inserted into the mother’s vagina (López-Teijón, García-Faura, & Prats-Galino, 2015). When the

■ **Figure 6.2** Sound waves enter the outer ear and are transmitted through the middle ear to the cochlea in the inner ear.

music was played, fetuses showed increased head and limb movements as well as more mouth and tongue movements. When the music stopped, these movements decreased. Not everyone is impressed with the caliber of the research involving the Babypod (the lead researcher, for example, is also involved in marketing the product for profit), but other research has shown that prenatal exposure to music has a lasting effect on brain activity. Eino Partanen and his colleagues (2013) had mothers-to-be play ‘Twinkle, twinkle, little star’ repeatedly during the last trimester of their pregnancies. At birth and again at 4 months of age, the infants exposed prenatally to the music, as well as a control group of infants who had not been exposed to the music, were tested to see whether there were any differences in the brain activity of the two groups. Indeed, there were. The infants who had been exposed to the music showed greater response, as measured by the brain’s electrical activity, than nonexposed infants, and the responses varied with how often they had been exposed to the tune in the womb. Thus, not only is the auditory system operational prior to birth, but prenatal auditory experiences can shape the neural architecture of the brain.

Under typical conditions, the environment of the womb exposes fetuses to low-frequency sounds, which can be a stark contrast to the high-frequency sounds of the postnatal environment. This may be especially problematic for premature babies whose auditory systems are not as fully developed as those of full-term infants (Graven & Browne, 2008). Researchers are beginning to examine whether this assault on the developing auditory system might place premature infants at risk for later attention, hearing, or language problems (Lahav & Skoe, 2014; McMahon, Wintermark, & Lahav, 2012). Interestingly, preterm infants who are exposed to ‘womb-like’ sounds (e.g., maternal voice, heartbeat, and intestinal gurgles) in the neonatal intensive care unit (NICU)

develop a larger auditory cortex than preterm infants who listen to the standard sounds of the NICU (Webb, Heller, Benson, & Lahav, 2015). This is further evidence that the environment of the womb provides the ideal conditions for development. But what if fetuses or infants have hearing problems? This would place them at risk for later language and communication problems. **Application 6.1** examines the importance of early identification and treatment of hearing problems.

Speech Perception

Young infants seem to be especially responsive to human speech and show a preference for speech over nonspeech sounds (Vouloumanos & Werker, 2007). In many ways, it seems as though the human brain was designed to produce and understand language (Fernald, 2009). We can discriminate basic speech sounds—called **phonemes**—very early in life. Peter Eimas (1975b, 1985) pioneered research in this area by demonstrating that infants 2–3 months old could discriminate between similar consonant sounds (for example, *ha* and *pa*). And newborns just hours old, recognize vowel sounds from their native language that they were exposed to in the womb. Researchers determined this by measuring how much newborns sucked on a special pacifier when exposed to a variety of vowel sounds from their native language as well as those from a nonnative language that they would not have been exposed to in the womb. The difference in their sucking rates showed that these newborns could discriminate between the native and nonnative sounds. Such results demonstrate that infants are not a blank slate at birth: They have already been learning in their prenatal environments (Moon, Lagercrantz, & Kuhl, 2013).

Infants can actually make some speech sound discriminations better than adults (Kuhl et al., 2014). They begin life biologically prepared to learn any language humans anywhere speak. As they mature, they become especially sensitive to the sound differences significant in their own language and less sensitive to sound differences irrelevant to that language. Patricia Kuhl and her colleagues (2014) demonstrated this with their research measuring brain activity in response to various linguistic sounds. They found that, at 7 months of age, there was no difference in brain activity in response to sounds from infants’ native language versus sounds from a nonnative language. By 11–12 months of age, though, the brain response was greater for native language sounds than for nonnative sounds. Again, this is evidence that early auditory experiences can shape the formation of neural connections, or synapses, in the auditory areas of infants’ brains so that they are optimally sensitive to the sound contrasts that they have been listening to and that are important in the language they are acquiring (see Chapter 10). In short, experience shapes the brain.

Newborns are especially attentive to female voices (Ecklund-Flores & Turkewitz, 1996), but can they recognize their mother’s voice? Indeed they can. Even unborn fetuses can distinguish their mother’s voice from a stranger’s voice. How do we know this? Canadian researchers measured fetal heart rate in response to a tape recording (played over the mother’s stomach) of either

Identifying hearing problems as early as possible allows caregivers to provide early intervention and ensure that development proceeds along a typical path.

● APPLICATION 6.1

Aiding Infants and Children with Hearing Impairments

Although sensory impairments have the potential to derail normal development, much can be done to help even those individuals who are born totally deaf or blind develop in positive directions and function effectively in everyday life. Here, we examine interventions for infants and children who have hearing impairments; in a later box, we examine interventions for hearing loss at the other end of the age spectrum.

For the 2 to 3 in 1,000 infants born deaf or hearing impaired, early identification and treatment are essential if they are to master spoken language. We know that children who receive no special intervention before age 2 usually have lasting difficulties with speech and language (for example, Vohr et al., 2011). As a result, most states have now mandated that all newborns be screened for hearing loss before they leave the hospital. How do you test the hearing of newborns? By using auditory **evoked potentials** (refer to **Table 6.1**) doctors can determine whether sounds trigger normal activity in the brain. Infants' behaviors also give physicians clues about their hearing. Does she turn her head when spoken to? Does he react to loud noises? Is she soothed by your voice? If the answers to these questions are no, a more thorough examination is warranted.

Once hearing-impaired infants are identified, interventions can be planned. Many programs attempt to capitalize on whatever residual hearing these children have by equipping them with hearing aids and providing them with an enriched language environment. Children whose hearing loss is identified soon after birth and who are raised in an environment that exposes them to a rich array of language opportunities develop better language skills than children raised without as rich a linguistic environment (Vohr et al., 2014).

Today, even profoundly deaf children can be helped to hear through an advanced amplification device called the **cochlear implant** (see the photo in this box). The device is implanted in the inner ear through surgery and connected to a microphone worn outside the ear. It works by bypassing damaged hair cells (sensory receptors located in the inner ear) and directly stimulating the auditory nerve with electrical impulses. The younger children are when they

John Robertson/Barcroft Media/Getty Images

receive the implant, the better the outcome. For example, deaf children who received implants in their first year of life perform better on a variety of vocabulary and speech measures compared to those who received implants in their second or third years (Colletti et al., 2011). In addition, speech production and speech perception are improved in deaf children who have cochlear implants compared with deaf children who have traditional hearing aids, with language development of those with the implants nearly equivalent to that of children with normal hearing (Levine et al., 2016). Children with two cochlear implants—one in each ear—show additional benefits, particularly for localizing sounds (Godar, Grieco, & Litovsky, 2007). For some, cochlear implants have truly opened up new opportunities that were not thought possible before the implant (see, for example, Denworth, 2006; Mishori, 2006).

Close to 80% of congenitally deaf infants and preschoolers now undergo surgery for cochlear implants. But despite their benefits, cochlear implants do not have the full support of the deaf community (see, for example, Humphries et al., 2014; Napoli et al., 2015). Deaf children who use them, some say, will be given the message that they should be ashamed of being deaf. They will be

deprived of participation in the unique culture that has developed in communities of deaf people who share a common language and identity. They may feel that they do not belong to either the deaf or the hearing world, because their hearing will still be far from normal.

The correct amplification device and auditory training have proven effective in improving the ability of hearing-impaired infants and preschoolers to hear speech and learn to speak. Yet for other deaf and severely hearing-impaired children, the most important thing may be early exposure to sign language. Early intervention programs for parents of deaf infants can teach them strategies for getting their infants' attention and involving them in conversations using sign language (Chen, 1996). The earlier in life deaf children acquire some language system, whether spoken or signed, the better their command of language is likely to be later in life (Humphries et al., 2016). Using MRIs, researchers have found that delay in acquiring a language leads to structural changes in the organization of the brain (Pénicaud et al., 2013). Deaf children whose parents are deaf and use sign language with them, as well as deaf children of hearing parents who participate in early intervention programs, generally show normal patterns of development, whereas children who are not exposed to any language system early in life suffer for it (Marschark, 1993).

By talking, singing, and otherwise making sounds during her pregnancy, this mother-to-be is familiarizing her unborn child to the sound of her voice.

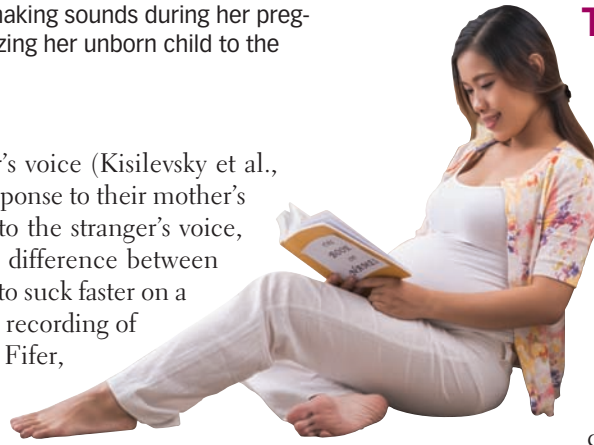

Dragon Images/Shutterstock.com

their mother's voice or a stranger's voice (Kisilevsky et al., 2003). Heart rates increased in response to their mother's voice and decreased in response to the stranger's voice, indicating that fetuses detected a difference between the two. Newborns will also learn to suck faster on a special pacifier when it activates a recording of the mother's voice (DeCasper & Fifer, 1980).

Does this early recognition extend to fathers' voices? Not so much. Newborns who had listened to either their father or their mother read a story prior to birth preferred to listen to their mother's voice (Lee & Kisilevsky, 2014). Even by 4 months, infants show no preference for their father's voice over the voice of a strange man (Ward & Cooper, 1999). They can detect differences between various male voices, however, indicating that the lack of preference for the father's voice is not because of a failure to distinguish it.

Why would infants prefer their mother's but not their father's voice? Again, we need to look at what is happening before birth to answer this question. In a now-classic study, Anthony DeCasper and Melanie Spence (1986) had mothers recite a portion of Dr. Seuss's *The Cat in the Hat* many times during the last 6 weeks of their pregnancies. At birth, the infants were tested to see if they would suck more to hear the story they had heard before birth or to hear a different story. Remarkably, they preferred the familiar story. Somehow these infants were able to recognize the distinctive sound pattern of the story they had heard in the womb. Auditory learning before birth could also explain why newborns prefer to hear their mother's voice to those of unfamiliar women but do not show a preference for their father's voice. They are literally bombarded with their mother's voice for months before birth, giving them ample opportunity to learn its auditory qualities. Even when fathers are explicitly asked to read to the fetus prior to birth (e.g., Lee & Kisilevsky, 2014), the exposure to the mother's voice is still likely to be greater. Researcher Eino Partanen (in Kim, 2013) summed this up well: "the voice of the mother is the most salient sound in the womb" (A6). And truth be told, many women might argue that this advantage is well-deserved for all the other issues they may experience over the course of a pregnancy.

So hearing is more developed than vision at birth. Infants can distinguish among speech sounds and recognize familiar sound patterns such as their mother's voice soon after birth. Within the first year, they lose sensitivity to sound contrasts insignificant in the language they are starting to learn, and they further refine their auditory perception skills. Although the speech recognition ability of infants is quite impressive, there will be further refinements during childhood. For instance, when listening to speech that is not clear, children will try to clarify it by using visual cues (e.g., mouth and tongue movements) to augment the auditory information (Jerger, Damain, Tye-Murray, & Abdi, 2014).

The Chemical Senses: Taste and Smell

Can newborns detect different tastes and smells? Both of these senses rely on the detection of chemical molecules; thus, the characterization of them as the "chemical senses." The sensory receptors for taste—taste buds—are located mainly on the tongue. In ways not fully understood, taste buds respond to chemical molecules and produce perceptions of sweet, salty, bitter, or sour tastes. At birth, babies can clearly distinguish sweet, bitter, and sour tastes and show a preference for sweets (Mennella & Bobowski, 2015). Indeed, sugar water—but not plain water—may help calm babies who are experiencing mildly stressful events.

Different taste sensations also produce distinct facial expressions in the newborn (Rotstein et al., 2015). For instance, newborns lick their lips and sometimes smile when they are tasting a sugar solution but purse their lips and even drool to get rid of the foul taste when they are given a bitter solution. Their facial expressions become increasingly pronounced as a solution becomes sweeter or more bitter, suggesting that newborns can discriminate different concentrations of a substance. Even before birth, babies show a preference for sweets when they swallow more amniotic fluid that contains higher concentrations of sugar than amniotic fluid with lower concentrations of sugar (Bakalar, 2012; Fifer, Monk, & Grose-Fifer, 2004).

Although we may have a general—and innate—preference for sweets and avoidance of bitters, flavor preferences are highly responsive to learning. Neuroscientist Gordon Shepherd (2012) studies the sense of smell and its relationship to taste and flavor. He argues that the basic tastes are hardwired and present at birth, whereas more sophisticated perception of flavors is learned. Appreciating the flavor of food comes from having the food in our mouths and not just in front of our noses. Chewing food or swishing fluids around in our mouths releases molecules that are breathed out and travel to the receptors in our nasal passages. From there, the signals are sent to the brain, which processes this information and constructs meaning. In Shepherd's (2012) words, "flavor does not reside in a flavorful food any more than color resides in a colorful object" (p. 5). Like our perception of color, our perception of flavor is highly dependent on how our brains assign meaning to the signals received from our sensory apparatus.

Our early experience with foods may leave us with lasting taste preferences. In one study, for example, infants were fed one of two formulas for 7 months, starting at 2 weeks of age (Mennella, Griffin, & Beauchamp, 2004). One formula was bland, and the other was bitter and tasted sour, at least to most adults. After this period, the babies who had been fed the sour formula continued to consume it, but the other infants refused when it was offered to them. By 4–5 years, children fed the unpleasant-tasting

From birth, infants respond to tastes. In response to a sugar solution, newborns part their lips, lick their upper lips, make sucking movements, and sometimes smile. From this infant's expression, we can infer that she is not getting a spoonful of something sweet.

thislife pictures/Alamy Stock Photo

formula were more likely to consume other sour-tasting foods (for example, a sour-flavored apple juice) than children exposed to only bland-tasting formula. Later research uncovered a sensitive period, during the first 4–6 months after birth, when exposure to certain tastes or flavors seems to influence later acceptance of these flavors (Mennella & Castor, 2012). Further, infants need more than a short-term exposure to a flavor. Those fed the rather foul-tasting formula for just 1 month did not later show any greater acceptance of the flavor than those who had not been fed the formula. Only those infants who had been fed the formula for 3 or more months showed later acceptance (Mennella & Castor, 2012).

Such research may be key to helping researchers understand why some people are picky eaters, whereas others are open to a wide variety of tastes. Greater exposure to a variety of flavors during infancy—what a breast-fed baby with a mother who eats many different foods might experience—may lead to a more

adventuresome eater later on. These early experiences with different flavors also extend to the prenatal period and exposure to different chemicals in the amniotic fluid. The foods eaten by pregnant women flavor the amniotic fluid that fetuses live in for 9 months (Mennella, 2014). Although learning plays a role in taste preferences, we cannot discount genetic predispositions. Discovery of several “taste genes” has shown that genetic differences can account for a lot of the disparity in children and adults’ perception of bitterness and some of the variation in children’s perception of sweetness (Knaapila et al., 2012; Mennella, Reiter, & Daniels, 2016).

Like taste, the sense of smell, or **olfaction**, is working well at birth. Even premature babies (born at 28 weeks of gestation) are capable of detecting various odors via sensory receptors located in the nasal passage. Newborns react vigorously to unpleasant smells such as vinegar or ammonia and turn their heads away (Rieser, Yonas, & Wilkner, 1976). Newborns also reliably prefer the scent of their own amniotic fluid over that of other amniotic fluid, suggesting that olfactory cues are detectable prenatally (Schaal, Marlier, & Soussignan, 1998). Exposure to a familiar odor—their own amniotic fluid or their mother’s breast milk—can also calm newborns, resulting in less crying when their mothers are absent or when the newborns undergo a painful procedure (Nishitani et al., 2009; Rattaz, Goubet, & Bullinger, 2005). All babies also show a preference for the smell of human milk over formula, even if they have consumed only formula (Delaunay-El Mam, Marlier, & Schaal, 2006; Marlier & Schaal, 2005). Furthermore, babies who are breast-fed can recognize their mothers solely by the smell of their breasts or underarms within 1 or 2 weeks of birth (Cernoch & Porter, 1985; Porter et al., 1992; Vaglio, 2009). Babies who are bottle-fed cannot, probably because they have less contact with their mothers’ skin. On the flip side, mothers can identify their newborns by smell, and they are less repulsed by the odor of their own infant’s dirty diaper than by one from an unfamiliar infant (Case, Repacholi, & Stevenson, 2006; Porter, 1999). Thus, the sense of smell we often take for granted may help babies and their parents get to know each other.

The Somaesthetic Senses

The **somaesthetic senses** are your “body” senses, including your sense of touch, temperature, and pain, as well as your *kinesthetic sense* of knowing where your body is in relation to other body parts and to the environment. Whether you realize it or not, you use your kinesthetic sense throughout your waking hours. For example, you know when you are upright as opposed to lying down. And when walking along a crowded sidewalk, you constantly make adjustments to your body to avoid bumping into others. At what point are these somaesthetic senses operational?

The sense of touch seems to be operating nicely before birth and, with the body senses that detect motion, may be among the first senses to develop (Hollins, 2010). You saw in Chapter 5 that newborns respond with reflexes if they are touched in appropriate areas. For example, when touched on the cheek, a newborn will turn her head and open her mouth. Even in their sleep,

newborns will habituate to strokes of the same spot on the skin but respond again if the tactile stimulation is shifted to a new spot—from the ear to the lips, for example (Kisilevsky & Muir, 1984). Sensitivity to tactile stimulation develops in the cephalocaudal (head-to-toe) direction described in Chapter 5, so the face and mouth are more sensitive than lower parts of the body. No wonder babies like to put everything in their mouths—the tactile sensors in and around the mouth allow babies to collect a great deal of information about the world. Most parents quickly recognize the power of touch for soothing a fussy baby. Touch has even greater benefits: Premature babies who are systematically stroked over their entire body gain more weight and exhibit more relaxed behavior and more regular sleep patterns than premature babies who are not massaged (Field, Diego, & Hernandez-Reif, 2010).

Newborns are also sensitive to warmth and cold; they can tell the difference between something cold and something warm placed on their cheeks. Finally, young babies clearly respond to painful stimuli such as needle pricks. For obvious ethical reasons, researchers have not exposed infants to severely painful stimuli. However, analyses of babies' cries and facial movements as they receive injections and have blood drawn leave no doubt that these procedures are painful. Even premature babies show cortical responses to pain (Slater et al., 2006). And pain is responsive to learning. For example, researchers have compared infants born to diabetic mothers, who have their heels pricked every few hours after birth to test their blood sugar levels, with infants born to nondiabetic mothers (Taddio, 2002). Both groups of infants have blood drawn from the back of their hands before they leave the hospital so several routine tests can be conducted. The infants who have already had their heels pricked show a larger response to having blood drawn than the infants who have never experienced presumably painful needle pricks in their feet. Indeed, some infants who had already experienced the heel pricks began to grimace when the nurse prepared their skin for the needle prick, indicating that they had learned from their prior experiences that a painful moment was coming.

Such research challenges the medical wisdom of giving babies who must undergo major surgery little or no anesthesia. It turns out that infants are more likely to survive heart surgery if they receive deep anesthesia that keeps them unconscious during the operation and for a day afterward than if they receive light anesthesia that does not entirely protect them from the stressful experience of pain (Anand & Hickey, 1992). And the American Academy of Pediatrics recommends that local anesthesia be given to newborn males undergoing circumcision (AAP Task Force on Circumcision, 2012). Finally, swaddling and/or breast-feeding during painful events such as getting a vaccination or having blood drawn has been shown to reduce the behavioral signs that infants are experiencing pain (Codipietro, Ceccarelli, & Ponzone, 2008; Ho et al., 2016).

You have now seen that each of the major senses is operating in some form at birth and that perceptual abilities improve dramatically during infancy. Are any special experiences necessary to develop normal perceptual abilities?

Influences on Early Perceptual Development

The perceptual competencies of even very young infants are remarkable, as is the progress made within the first few months of life. All major senses begin working before birth and are clearly functioning at birth; parents would be making a huge mistake to assume that their newborn is not taking in the sensory world. Many perceptual abilities—for example, the ability to perceive depth or to distinguish melodies—emerge within just a few months of birth. Gradually, basic perceptual capacities are fine-tuned, and infants become more able to interpret their sensory experiences—to recognize a pattern of light as a face, for example. By the end of the second year, the most important aspects of perceptual development are complete. The senses and the mind are working to create a meaningful world of recognized objects, sounds, tastes, smells, and bodily sensations.

The fact that perceptual development takes place so quickly can be viewed as support for the “nature” side of the nature–nurture debate. Many basic perceptual capacities appear to be innate or to develop rapidly in all normal infants. What, then, is the role of early sensory experience in perceptual development?

Early Experience and the Brain

Classic studies that would ultimately lead to a Nobel Prize for David Hubel and Torsten Wiesel showed that depriving newborn kittens of normal visual experience by suturing one eye closed for 8 weeks resulted in a lack of normal connections between that eye and the visual cortex—and blindness even after the eye had been reopened (Hubel & Wiesel, 1970). Even as little as 1 week of deprivation during the critical period of the first 8 weeks of life can lead to permanent vision loss in a kitten (Kandel & Jessell, 1991). By contrast, depriving an adult cat's eye of light does not lead to permanent damage.

From other classic research with kittens, we know that kittens need to actively experience their environments to develop normal visual perception (Held & Hein, 1963). In an ingenious study, kittens were able to see their environment but from the vantage point of a passive rider in a cart pulled by another cat (picture a horse pulling a wagon with a passenger in it and then substitute kittens for the horse and passenger). Despite being able to see the world pass by, the passenger kittens did not have the opportunity to learn how their own movement influenced the incoming flow of visual images. They needed to have this active feedback loop between their actions, the visual stimulation, and their perception of this information. For cats, anyway, there seems to be a critical period of time when normal visual experiences are needed in order to develop normal visual perception.

Some clever researchers came up with the idea of using ‘sticky mittens’ (i.e., mittens with Velcro) to test whether action would similarly benefit human infants who were too young to reach and grasp objects (Libertus & Needham, 2010). Infants in the passive condition could watch as their parents manipulated objects, whereas infants in the active condition could themselves manipulate the objects, which were covered with material that

would allow them to stick to their mittens. The Velcro offered an opportunity for young infants to hang on to the objects and manipulate them. Following this experience, infants in the active condition showed more visual searching and more reaching behaviors than infants in the passive condition. The differences between the two groups of infants, though, were not as dramatic as those found by other researchers who studied kittens.

In humans, it is probably more accurate to characterize the effects of early experience on vision in terms of **sensitive periods** rather than critical periods (Armstrong et al., 2006). A sensitive period is “a window of time during which an individual is *more* affected by experience, and thus has a higher level of plasticity than at other times throughout life” (Armstrong et al., 2006p. 326). Terri Lewis and Daphne Maurer (2005, 2009) provide evidence for multiple sensitive periods during which vision can be influenced by experience. First, there is the period they call visually driven normal development. This is when expected developmental changes in vision will occur with exposure to “normal” visual input; these changes will not occur if visual input is absent. Second, there is a sensitive period for damage; that is, there is a period when abnormal or absent visual input is likely to lead to permanent deficits in some aspect of vision. Third, there is a sensitive period for recovery when the visual system has the potential to recover from damage (Lewis & Maurer, 2005).

Sensory experience is vital in determining the organization of the developing brain. Imagine what visual perception would be like in an infant who was blind at birth but later had surgery to permit vision. This is the scenario for perhaps 3 of every 5,000 infants with congenital **cataracts**, a clouding of the lens that leaves these infants nearly blind from birth if it is not corrected. In the past, surgery to remove cataracts was often delayed until infants were older. But such delays meant that infants had weeks, months, or even years with little or no visual input. Consequently, some never developed normal vision even after the lens defect was removed.

It turns out that the visual system requires stimulation early in life, including patterned stimulation, to develop normally. Although the visual system has some plasticity throughout childhood, the first 3 months of life are considered critical (Lambert & Drack, 1996). During this time, the brain must receive clear visual information from both eyes. Unfortunately, not all infants with cataracts are identified early enough to benefit from surgery. Identification and removal of cataracts by 10 weeks of age is associated with better long-term outcomes than identification and removal after this age (Chan et al., 2012). Even after surgery restores their sight, these infants have difficulty, at least initially, perceiving their visual world clearly (Maurer, Mondloch, & Lewis, 2007). Although acuity immediately after surgery is what you might find in a newborn without cataracts—in other words, rather poor—it improves significantly during the month following surgery (Maurer et al., 1999).

Years after corrective surgery, individuals who missed out on early visual experience because of congenital cataracts show normal visual abilities in some areas, such as sensitivity to low spatial frequencies (for example, wide stripes) and recognition of faces based on the *shape* of facial features. However, adults who

Congenital cataracts can interfere with visual input that is needed to develop normal vision.

Public Health Image Library/Centers for Disease Control and Prevention (CDC)

had cataract surgery as infants are not as adept as other adults at reading emotions from facial expressions (Gao, Maurer, & Nishimura, 2013). In addition, they struggle with certain other visual tasks, including the ability to distinguish between mid- and high-spatial frequencies (for example, medium and narrow stripes) and holistic face processing and recognizing faces based on *spacing* of facial features. What might account for these findings?

Daphne Maurer and her colleagues (2007) argue that the lingering deficits reflect **sleeper effects**—delayed outcomes—of early visual deficits. Thus, patterned visual input early in life is critical to developing later sensitivity to detail and holistic face processing. Even though these abilities do not normally develop until after early infancy—and after corrective surgery has been done—early visual deprivation likely affects the brain in a way that prevents infants from developing these abilities even when normal visual input is restored (Maurer et al., 2007). Clearly, then, early visual experiences influence later visual perception.

The same message about the importance of early experience applies to the sense of hearing: Exposure to auditory stimulation early in life affects the architecture of the developing brain, which in turn influences auditory perception skills (Finitzo, Gunnarson, & Clark, 1990). Children with hearing impairments who undergo a cochlear implant, which bypasses damaged nerve cells in their inner ear, may struggle to understand the meaning of signals reaching their brain through the implant before they derive benefits. Although the brain is being fed information, it must learn how to interpret these signals. Within 2–4 months after a cochlear implant, infants and young children show brain activity patterns indicating differentiation of long and short vowel sounds, a building block of more advanced language skills (Vavatzanidis et al., 2015; see also **Application 6.1**). The conclusion is clear: Maturation alone is not enough; normal perceptual development also requires normal perceptual experience. The practical implication is also clear: Visual and hearing problems in children should be detected and corrected as early in life as possible.

What Do Infants Need?

Fortunately, parents need not worry about arranging the right sensory environment for their children because young humans actively seek the stimulation they need to develop properly. Infants are active explorers and stimulus seekers; they orchestrate their own perceptual, motor, and cognitive development by exploring their environment and learning what it will *afford*, or allow, them to do (Gibson, 1988; Gibson & Pick, 2000).

According to Eleanor Gibson's (1988) ecological perspective, infants proceed through three phases of exploratory behavior:

1. From birth to 4 months, infants explore their immediate surroundings, especially their caregivers, by looking and listening, and they learn a bit about objects by mouthing them and watching them move.
2. From 5 to 7 months, once the ability to voluntarily grasp objects has developed, babies pay far closer attention to objects, exploring objects with their eyes as well as with their hands.
3. By 8 or 9 months, after most have begun to crawl, infants extend their explorations into the larger environment and carefully examine the objects they encounter on their journeys, learning all about their properties.

By combining perception and action in their exploratory behavior, infants actively create sensory environments that meet their needs and contribute to their own development (Eppler, 1995). As

children become more able to attend selectively to the world around them, they become even more able to choose the forms and levels of stimulation that suit them best. Again, we see a coupling of perception and action.

● Checking Mastery

1. Describe two procedures used by researchers to assess perceptual abilities of infants.
2. During their first few months of life, what can infants see best?
3. What sorts of experiences are necessary to develop normal visual perception?

● Making Connections

1. Drawing on your knowledge of the sensory and perceptual capacities of newborns, put yourself in the place of a newborn just emerging from the womb and describe your perceptual experiences. What do you see, feel, hear, and so on? What, if anything, do you make of all this information?
2. How would you design a nursery for an infant to make the best use of his sensory and perceptual abilities?

6.3

The Child

LEARNING OBJECTIVES

- Explain how perception and action work together in the development and refinement of locomotor skills.
- Provide an example of both fine motor and gross motor skills and note the typical order in which these skills develop.
- Discuss the dynamic systems theory of motor development and summarize the research findings supporting this theory.
- Describe and provide two examples of cross-modal perception. Explain how researchers demonstrate that someone has cross-modal perception.

There are some refinements of the sensory systems during childhood. For example, visual acuity improves to adult levels sometime between 4 and 6 years, and sensitivity to visual contrasts develops completely by about 7 years of age (Maurer et al., 2007). Ability to identify odors improves across childhood, although this may reflect improved language skills more than any real change in sensory sensitivity (Bastos et al., 2015). For the most part, sensory and perceptual development is largely complete by the end of infancy. Does anything remain to be accomplished during childhood? Yes, indeed. We will cover two important accomplishments with the transition from infancy to childhood: (1) the coupling of perception and action leading to purposeful movement; and (2) integration of multiple sources of sensory information.

Locomotion: The Coupling of Perception and Action

Locomotion, or movement from one place to another, is a vital aspect of development. One of young children's most impressive accomplishments is getting up off of their bellies, backs, or bottoms and moving with purpose throughout their environment on two legs. This shift from crawling to walking offers toddlers the opportunity to engage differently with their environments. They are no longer restricted to objects that are close by and close to the ground. They can now cross the room to get objects, access higher objects, and use their hands to share and interact with objects in new ways (see Adolph & Robinson, 2014). In Gibson's ecological framework, walking opens up new environments and new affordances, or ways

of interacting with objects in the environment. To make this transition, the young child must learn to integrate perception with action (Smitsman & Corbetta, 2010). This coupling occurs gradually and becomes more refined with experience.

The groundwork for walking is laid during infancy. Infants generally acquire **gross motor skills** (skills such as kicking the legs or drawing large circles that involve large muscles and whole-body or limb movements) before mastering **fine motor skills** (skills such as picking Cheerios off the breakfast table or writing letters of the alphabet that involve precise movements of the hands and fingers or feet and toes). If you examine the progression of these motor skills, you will notice the workings of the cephalocaudal and proximodistal principles of development (see Chapter 5). Early motor development follows the *cephalocaudal principle* because the neurons between the brain and the muscles acquire myelin sheaths in a head-to-tail manner. Thus, infants can lift their heads before they can control their trunks enough to sit, and they can sit before they can control their legs to walk. The *proximodistal principle* of development is also evident in early motor development. Activities involving the trunk are mastered before activities involving the arms and legs, and activities involving the arms and legs are mastered before activities involving the hands and fingers or feet and toes. Therefore, infants can roll over before they can walk or bring their arms together to grasp a bottle. As the nerves and muscles mature downward and outward, infants gradually gain control over the lower and the peripheral parts of their bodies. When this happens, infants are ready for the next step, literally.

Although parents must be on their toes when their toddlers begin walking, they take great delight in witnessing this new milestone in motor development, which occurs around age 1. By collecting an enormous number of observations of infants' and toddlers' daily movements, Karen Adolph and her colleagues (2008, 2013) have found that it takes an average of 13 starts and stops over a period of days and sometimes weeks before toddlers show consistent performance of a motor skill. During the transition period of acquiring a new motor skill, they are truly taking “one step forward, two steps backward.” They may appear to have started walking, only to revert to crawling, much to the chagrin of their proud parents. From the toddler's perspective, the apparent regression in skills is quite logical. They have mastered crawling and are quite fast at it, whereas walking on two legs is hard work and can slow them down (Adolph & Tamis-LeMonda, 2014). So if they have important things to do, they might find it more efficient to use their reliable crawling skills than to labor at walking. With a little bit of practice, walking will soon become routine. Indeed, by 14 months of age, the average toddler is taking 2,300 steps an hour, which is equivalent to traveling a distance of nearly seven football fields (see Adolph et al., 2012). No

wonder parents feel as though they can barely keep up with their toddlers at times. And there's more: Not only are toddlers traveling all over the house, but walking frees up their arms and hands. **Exploration 6.1** considers the remarkable changes taking place with the use of hands and fingers.

Motor Skills as Dynamic Action Systems

How do motor skills emerge? Esther Thelen (1995, 1996) observed infants throughout their first year and discovered that they spent a great deal of time engaged in **rhythmic stereotypies**. That is, they moved their bodies in repetitive ways—rocking, swaying, bouncing, mouthing objects, and banging their arms up and down. Thelen found that infants and toddlers performed these rhythmic stereotypies shortly before a new skill emerged but not after the skill had become established. Thus, infants might rock back and forth while on their hands and knees, but once they were crawling, they no longer rocked.

Esther Thelen's work has culminated in the development of the **dynamic systems theory** to explain such motor developments (Thelen & Smith, 1994; see also Spencer et al., 2006). According to the dynamic systems theory, developments take place over time through a “self-organizing” process in which children use the sensory feedback they receive when they try different movements to modify their motor behavior in adaptive ways (Smith & Thelen, 1993; von Hofsten, 2007). Behaviors that seem to emerge in a moment of time are actually the cumulative effects of motor decisions that the infant makes over a much longer time (Spencer et al., 2006). In this view, motor milestones such as crawling and walking are the learned outcomes of a process of interaction with the environment in which infants do the best they can with what they have in order to achieve their goals (Thelen, 1995). Thus, development is highly individualistic: “[I]nfants must explore a

According to Gibson's ecological theory, this toddler may find that this plank bridge affords, or offers, a sturdy enough surface to walk safely on his own.

INSADCO Photography/Alamy Stock Photo

wide range of behaviors to discover and select their own unique solutions in the context of their intrinsic dynamics and movement history” (Spencer et al., 2006, p. 1528). Neural maturation, physical growth, muscle strength, balance, and other characteristics of the child interact with gravity, floor surfaces, and characteristics of the specific task to influence what children can and cannot learn to do with their bodies. You can probably think of times when you have been through this dynamic self-organizing process: when you were learning to serve a tennis ball, dance a new dance, or drive a car.

Consistent with the dynamic systems approach, Karen Adolph and Anthony Avolio (2000) found that young toddlers could adjust their walking to changes in both their body dimensions and the slope of a walkway. The researchers had toddlers walk on slopes of different degrees while wearing a vest with removable “saddlebags” that could be weighted to simulate changes in their body dimensions (■ **Figure 6.3**). The weights added mass and shifted the toddlers’ center of gravity, akin to what happens when toddlers grow. Would toddlers be able to compensate for the changes in their body and their environment? Yes—they adjusted their motor skills to adapt to rapid “growth” of their bodies and to changes in their environment (Adolph & Berger, 2006). Like adults carrying a heavy load on their shoulders, toddlers bent their knees and kept

■ **Figure 6.3** Adolph and Avolio’s walkway with adjustable slope. Infants are outfitted with weighted saddlebags to alter their body mass and center of gravity. While an experimenter stays beside infants to ensure safety, parents stand at the end of the walkway and encourage their child to walk toward them.

From Adolph, K. E., & Avolio, A. M. (2000). Walking infants adapt locomotion to changing body dimensions. *Journal of Experimental Psychology: Human Perception and Performance*, 26, 1148–1166. their upper bodies stiffly upright to maintain their balance with heavier loads. Toddlers with greater walking experience did better than those with less experience (Garciguire, Adolph, & Shrout, 2007). Toddlers also seemed to recognize when the walkway was too steep for safe travel—they either avoided it or scooted down on their bottoms or on their hands and knees. Young walkers (16 months) are also clever enough to figure out that they can use handrails to help maintain their balance while walking across bridges (Berger & Adolph, 2003). Further, they quickly discover that a sturdy handrail offers more support than a “wobbly” handrail and they are more adventuresome when they can use a sturdy handrail for support (Berger, Adolph, & Lobo, 2005). If they are not sure how to proceed across a potentially unstable surface, they look to their mothers for advice. With mother’s encouragement, 75% of infants will try to navigate a questionable slope; only 25% of infants are brave enough to give it a shot when mothers express discouragement (Karasik et al., 2008; Tamis-LeMonda et al., 2008).

As every parent knows, toddlers do not become proficient walkers without experiencing more than a few falls—as many as 17 per hour and 100 per day by one estimate (Adolph et al., 2012). As it turns out, these tumbles help walkers learn which surfaces are safe and which ones may be problematic (Joh & Adolph, 2006). With age, toddlers become increasingly adept at figuring out how to avoid falls, but they still appear awkward compared with the older child, who takes steps in more fluid and rhythmic strides and is better able to avoid obstacles. And children quickly become able to do more than just walk. By age 3, they can walk or run in a straight line, although they cannot easily turn or stop while running. Kindergarten children can integrate two motor skills hopping on one foot with walking or running—into mature skipping (Loovis & Butterfield, 2000). With each passing year, school-age children can run a little faster, jump a little higher, and throw a ball a little farther.

What does the dynamic systems perspective say about the contribution of nature and nurture to development, then? According to Thelen (1995), toddlers walk not because their genetic code programs them to do so but because they learn that walking works well given their biomechanical properties and the characteristics of the environments they must navigate. In the dynamic systems approach, nature (maturation of the central nervous system) and nurture (sensory and motor experience) are both essential and largely inseparable. Feedback from the senses and from motor actions is integrated with the ever-changing abilities of the infant. Having learned how to adjust one motor skill (such as crawling) to successfully navigate varied environmental conditions, however, does not mean that toddlers will generalize this knowledge to other motor skills (such as walking; see Adolph & Berger, 2006). Different motor skills present different challenges. Crawling toddlers, for instance, must learn to avoid such dangers as bumping their heads on table legs. Walking toddlers face other challenges, such as not toppling over when turning around. To master these challenges, children need opportunities to gather feedback from each motor activity.

Finally, an important contribution of the dynamic systems approach to motor development is its integration of action with thought (von Hofsten, 2007). The motor behaviors we have been describing are not separate and distinct from the child’s knowledge.

● EXPLORATION 6.1

Grasping and Reaching

If you look at what children can do with their hands, you will find it progresses from reflexive activity of early infancy to more voluntary, coordinated behavior. By the middle of the first year, infants grasp objects well, although they use a rather clumsy, clamplike grasp in which they press the palm and outer fingers together—the **ulnar grasp**. Initially, they reach for objects using jerky movements and a locked elbow (Berthier & Keen, 2006). Over the next few months, their reaching movements become increasingly smooth and they anticipate how they need to adjust their hand so that it can effectively grasp an approaching object (Barrett & Needham, 2008; von Hofsten, 2007). We can again see the workings of the proximodistal principle of development as we watch infants progress from controlling their arms, then their hands, and finally

their individual fingers enough to use a **pincer grasp**, involving only the thumb and the forefinger (or another finger). The pincer grasp, which is very useful for picking up food and getting it to your mouth, appears as early as 5 months and is reliable by the child's first birthday (Sacre, Karl, & Whishaw, 2012; Wallace & Whishaw, 2003).

By 16 months, toddlers can scribble with a crayon, and by the end of the second year they can copy a simple horizontal or vertical line and even build towers of five or more blocks. They are rapidly gaining control of specific, *differentiated* movements, then *integrating* those movements into whole, coordinated actions. They use their new locomotor and manipulation skills to learn about and adapt to the world around them. By cornering bugs and stacking Cheerios, they develop their minds.

This toddler uses the pincer grasp to pick up a crayon.

Mark Wallis/Alamy Stock Photo

Children have to think about how to organize their movements to optimize what they are able to get from their ever-changing environment. Thus, there is far more to motor development than implied by norms indicating when we might expect infants to sit up, stand alone, or walk independently. The emergence of motor skills is complex and is closely connected to perceptual-cognitive developments.

Integrating Sensory Information

Moving around the world opens up the floodgates of sensory information. In most situations, multiple senses provide the brain with different information and, ideally, the brain integrates these pieces of information into a single coherent understanding. Without such integration, our understanding of the world would be fragmented and rather chaotic. At what point are we able to put together information gained from viewing, fingering, sniffing, and otherwise exploring objects?

To some extent, the senses function in an integrated way at birth. For instance, newborns will look in the direction of a sound they hear, suggesting that vision and hearing are linked. They also expect to feel objects that they can see and are frustrated by a visual illusion that looks like a graspable object but proves to be nothing but air when they reach for it (Bower, Broughton, & Moore, 1970).

Thus, vision and touch, as well as vision and hearing, seem to be interrelated early in life. This integration of the senses helps babies perceive and respond appropriately to the objects and people they encounter (Hainline & Abramov, 1992; Walker-Andrews, 1997).

Although present in a rudimentary form in early infancy, fully and meaningfully integrating the senses develops fairly late relative to the development of the individual senses (Burr & Gori, 2012). Thus, it is not enough for each individual sense to be operational for multisensory integration to occur. This more advanced skill requires ongoing “conversation” among the various sensory systems and the brain. As the brain develops, so does the ability to consider multiple pieces of information and draw on memory of past experiences to better understand the meaning of multiple sources of input (Burr & Gori, 2012). With each new encounter of the nearly continuous flow of multisensory information, children refine their understanding of the rich sensory world.

An even more difficult task is to recognize through one sense an object familiar through another, a type of multisensory integration called **cross-modal perception**. This capacity is required in children's games that involve feeling objects hidden in a bag and identifying what they are by touch alone. Although some researchers (for example, Streri, 2003; Streri & Gentaz, 2004)

Intersensory perception. The ability to recognize through one sense (here, touch) what has been learned through another (vision) increases with age during infancy and childhood. Here, the birthday girl must identify prizes in the bag by touch alone.

Mary Kate Denny/PhotoEdit

report that newborns can recognize an object by sight that they had previously touched with their hand, others have had trouble demonstrating cross-modal perception in such young infants (for example, Maurer, Stager, & Mondloch, 1999). Apparently, early cross-modal perception is a fragile ability dependent on various task variables such as which hand is used to manipulate the object (Steri & Gentaz, 2004). Performance on complex cross-modal perception tasks that require matching patterns of sounds with patterns of visual stimuli continues to improve throughout childhood and even adolescence (Bushnell & Baxt, 1999).

Researchers now conclude that impressions from the different senses are “fused” or integrated early in life, making it easier for infants to perceive and use information that comes to them through multiple channels simultaneously (Walker-Andrews, 1997). Then, as the separate senses continue to develop and each becomes a more effective means of exploring objects, toddlers become more skilled at cross-modal perception and are able to coordinate information gained through one sense with information gained through another.

Advances in Attention

We have talked about perception without much focus on an important costar: attention. At least some of the advances in perceptual development across childhood and adolescence reflect the development of **attention**—the focusing of perception and cognition on something in particular. Youngsters become better

able to use their senses deliberately and strategically to gather the information most relevant to a task at hand.

Infants actively use their senses to explore their environment, and they prefer some sensory stimuli to others. Selective as they are, though, young infants do not deliberately choose to attend to faces and other engaging stimuli. Instead, a novel stimulus attracts their attention and, once their attention is “caught,” they sometimes seem unable to turn away (Butcher, Kalverboer, & Geuze, 2000; Ruff & Rothbart, 1996). Thus, there is some truth to the idea that the attention of the infant or very young child is “captured by” something and that of the older child is “directed toward” something. This difference has been described as the difference between having an **orienting system**, one that reacts to events in the environment, and having a **focusing system**, one that deliberately seeks out and maintains attention to events (Ruff & Rothbart, 1996). As children get older, three things change: their attention spans become longer, they become more selective in what they attend to, and they are better able to plan and carry out systematic strategies for using their senses to achieve goals.

Longer Attention Span

If you have spent any time in the company of young children, then you are probably aware that they have short attention spans. Researchers know that they should limit their experimental sessions with young children to a few minutes, and nursery-school teachers often switch classroom activities every 15–20 minutes. Even when they are doing things they like, such as watching a television program or playing with a toy, 2- and 3-year-olds spend far less time concentrating on the program or the toy than older children do (Ruff & Capozzoli, 2003; Ruff & Lawson, 1990). In one study of sustained attention, children were asked to put strips of colored paper in appropriately colored boxes (Yendovitskaya, 1971). Children aged 2–3 worked for an average of 18 minutes and were easily distracted, whereas children aged 5–6 often persisted for 1 hour or more. Further improvements in sustained attention occur from ages 5 to 10 as those parts of the brain involved with attention become further myelinated (Betts et al., 2006). Beyond ages 10 to 12 there is not much increase in length of sustained attention, but children do become more accurate on tasks requiring sustained attention over the next few years (Betts et al., 2006; Vakil et al., 2008).

More Selective Attention

Although infants clearly deploy their senses in a selective manner, they are not good at controlling their attention—deliberately concentrating on one thing while ignoring something else, or what is known as **selective attention**. With age, attention becomes more selective and less susceptible to distraction. As infants approach 2 years, they become able to form plans of action, which then guide what they focus on and what they ignore (Ruff & Rothbart, 1996).

Research suggests that preschool children have an adult-like orienting system but an immature focusing system of attention (Ristic & Kingstone, 2009). Between approximately 3½ and 4 years, there is a significant increase in focused attention. Kathleen Kannass and John Colombo (2007) tested 3½- and 4-year-olds while they worked on a task under one of three conditions: no distraction, constant distraction (a TV program in an

unfamiliar language played continuously in the background), or intermittent distraction (the same TV program played in the background but it was frequently turned on and off as the children worked). Among the 3½-year-olds, the two groups working with any distraction had more trouble completing their task than the group working without distraction. Among the 4-year-olds, only the group working with constant distraction had trouble finishing the task. Those working with intermittent distraction were able to stay as focused on the task as children working without distraction. Finally, the researchers found that when a distractor was present, looking away from the task led to worse performance, whereas looking away when there was no distraction did not impair performance. Selective attention continues to improve throughout childhood, with 8- to 11-year-olds better able to ignore irrelevant information and focus on what's important during an auditory task than 4- to 7-year-olds (Jones, Moore, & Amitay, 2015). Similarly, on a visual task, 8- to 10-year-olds show greater selective attention than 6-year-olds (Kovshoff et al., 2015).

These findings should suggest to parents and teachers of young children that performance will be better if distractions in task materials and in the room are kept to a minimum. In particular, the presence of a continuous distractor will lead to trouble completing tasks (Kannass & Colombo, 2007). If distractions

cannot be avoided, children can benefit from regular reminders to stay on task (Kannass, Colombo, & Wyss, 2010).

More Systematic Attention

Finally, as they age, children become more able to plan and carry out systematic perceptual searches. You have already seen that older infants are more likely than younger ones to thoroughly explore a pattern. Research with children in the former Soviet Union reveals that visual scanning becomes considerably more detailed and exhaustive over the first 6 years of life (Zaporozhets, 1965). But the most revealing findings come from studies of how children go about a visual search. In general, children search more slowly than adults (Donnelly et al., 2007) but they are also less efficient. Elaine Vurpillot (1968) recorded the eye movements of 4- to 10-year-olds trying to decide whether two houses, each with several windows containing various objects, were identical or different. As **Figure 6.4** illustrates, children ages 4 and 5 were not systematic. They often looked at only a few windows and, as a result, came to wrong conclusions. In contrast, most children older than 6 were very systematic; they typically checked each window in one house with the corresponding window in the other house, pair by pair. For most, improvements in visual search continue to be made throughout childhood and into early adulthood (Burack et al., 2000).

Figure 6.4 Are the houses in each pair identical or different? As indicated by the lines, 8-year-olds are more likely than 5-year-olds to answer correctly because they systematically scan the visual features of the two pictures.

Adapted from Vurpillot, 1968, The development of scanning strategies and their relation to visual differentiation. *Journal of Experimental Child Psychology*, 6, 632–650.

● Checking Mastery

1. How do children master the important skill of walking and, once they do so, how does this new skill affect their development in general?
2. Why is cross-modal perception important?
3. What are three ways that attention improves during childhood?

● Making Connections

1. You have an unlimited budget for redesigning a local child care center that serves children 6 weeks to 6 years old. Given what you know about sensory and perceptual capabilities of infants and young children, what equipment and toys will you purchase, and how will you remodel and redecorate the rooms?
2. You are commissioned by a local pediatrician to write a brochure on “locomotor skills of the infant and young child.” Begin this assignment by developing a bulleted list of the skills that support the development of walking and order these by when or in what order they typically emerge.

6.4

The Adolescent

LEARNING OBJECTIVES

- Document the changes in attention during the adolescent period and discuss the implications of today's multitasking lifestyle of many teens.
- Discuss the challenges to the auditory system during adolescence.
- Outline changes in the chemical senses of adolescents and indicate the likely contributing factors to these changes.

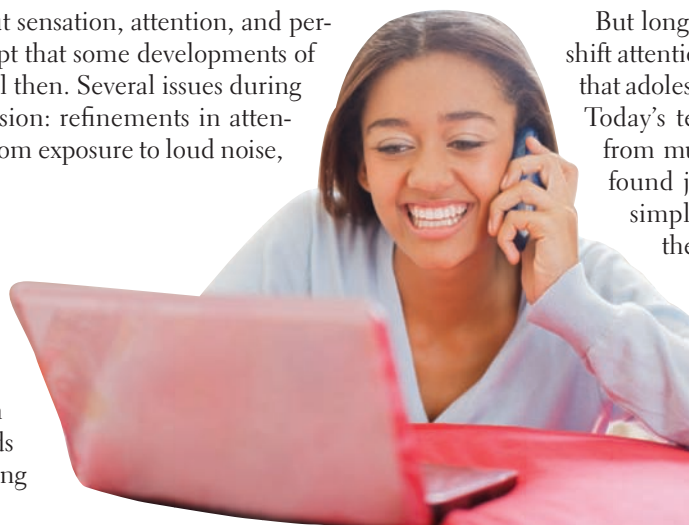

There is little news to report about sensation, attention, and perception during adolescence, except that some developments of childhood are not completed until then. Several issues during this time, though, warrant discussion: refinements in attention, potential insults to hearing from exposure to loud noise, and expanding taste horizons.

Attention

It is fairly clear that adolescents have longer attention spans than children. They can, for example, sit through longer classes, work on papers or study for lengthier periods of time, and take tests that last as long as 3–4 hours (for example, the SAT). This improved ability to sustain attention seems to be tied to increased myelination of those portions of the brain that help regulate attention (Tanner, 1990). As we noted in Chapter 5, a myelin coating on neurons helps insulate them to speed up transmission of neural impulses.

In addition, adolescents are better able to switch attention from one task to another (Crone et al., 2006). They become more efficient at ignoring irrelevant information so that they can concentrate on the task at hand. Not only do they learn more than children do about material they are supposed to master, but they also learn *less* about distracting information that could potentially interfere with their performance (Miller & Weiss, 1981). Children have the rudimentary skills to adapt to distractions, but compared with adolescents and adults, they are slowed down and more likely to be thrown off track by distractors.

Similarly, adolescents can divide their attention more systematically between two tasks. For instance, Andrew Schiff and Irwin Knopf (1985) watched the eye movements of 9-year-olds and 13-year-olds during a two-part visual search task. Children were to push a response key when particular symbols appeared at the center of a screen and to remember letters flashed at the corners of the screen. The adolescents developed efficient strategies for switching their eyes from the center to the corners and back at the right times. The 9-year-olds had an unfortunate tendency to look at blank areas of the screen or to focus too much attention on the letters in the corners of the screen, thereby failing to detect the symbols in the center.

Adolescents seem to be skilled at dividing their attention among several tasks, but what does the research show about multitasking?

Paul Bradbury/OJO Images/Getty Images

But longer attention spans and being able to shift attention between two tasks does not mean that adolescents' attention spans are unlimited. Today's teens are flooded with information from multiple sources and are increasingly found juggling multiple tasks: They don't simply talk with a friend on the phone; they talk with one friend on their cell phone while watching YouTube videos and messaging local friends about what happened at school that day as well as messaging online acquaintances about the latest changes in their shared Internet game world. According to StatisticBrain.com, the vast amount of information available to us 24/7 in the blink of an eye, or the touch of a button, has reduced our attention span to below that of a goldfish! What are the consequences of this

constant flow of information and the accompanying **multitasking**, attending to two or more tasks at the same time?

Among college students, about half of their time on the Internet is spent multitasking (Judd, 2013; Moreno et al., 2012). Terry Judd (2013) monitored computer sessions of students in an open computer laboratory and found that only 10% of the sessions were focused on a single task. When students are required to bring a laptop to class, presumably for course-related educational reasons, the majority of students use email and access unrelated material through the browser, and some spend time instant messaging (Kraushaar & Novak, 2010). Students surveyed about their multitasking during class report engaging in a wide range of additional behaviors, including texting (50% of students), working on other course work (18%), eating (26%), posting to Facebook (25%), instant messaging (13%), and listening to music (7%). These percentages are significantly higher when students are asked to report on their multitasking during an online class (Burak, 2012). And we suspect that if students report this much multitasking during class time, they are likely engaged in at least as much multitasking when studying outside of the class.

When college students text during a class lecture, they don't perform as well when tested on the lecture material as students who did not text (Ellis, Daniels, & Jauregui, 2010). The same

pattern occurs when students are on a laptop during a class lecture—they do not perform as well when tested on the material (Sana, Weston, & Cepeda, 2013). What’s more, students who were close by and could also see their classmate’s screen during the lecture also did not do as well on the test.

The relationship here is fairly clear: As multitasking increases, students’ grade point averages decrease (Burak, 2012). Students who multitask while reading or studying for a class take longer to complete their assignments. Their perceived study time, therefore, may be longer than their actual study time, deceiving them into thinking they have spent a sufficient amount of time studying. Dividing up our attentional resources can be risky to the learning enterprise. While we may be able to multitask two activities that are familiar and well-learned, our success at multitasking quickly disappears when the tasks are less familiar and relatively new to us (Schumacker et al., 2001). When faced with multiple pieces of information coming in for processing, our brains are forced to make some decisions about what to attend to first and what to “put on the back burner” (Dux et al., 2006).

Many people overestimate their abilities to multitask, believing that they can successfully juggle more than one task at a time. However, those folks who regularly multitask are more distracted by irrelevant information than those who focus on one thing at a time (Ophir, Nass, & Wagner, 2009; Sanbonmatsu et al., 2013). It turns out that the very folks who think they are good at multitasking and engage in this juggling act on a regular basis are less capable of it than are their peers who typically stick to a single task.

Perhaps the lesson here is that the next time you prepare to study for a test, consider whether it would be more beneficial to spend time on this one task rather than allowing yourself to be interrupted and distracted by texting, tweeting, messaging, and more. You may find that focused attention to one task at a time is more efficient than attending to multiple tasks, but not effectively mastering any of them.

Hearing

Adolescence should be a period of optimal acuity of all the senses, but in today’s world of concerts, power equipment, and headphones attached to a multitude of sound-producing personal devices, auditory acuity can become compromised in some adolescents (e.g., Jiang et al., 2016). As ● Table 6.2 shows, loud sounds—those above 75 decibels—may leave the listener with a loss of hearing. Fans of loud music, beware: The noise at rock concerts and nightclubs is often in the 120- to 130-decibel range, well above the level where damage may occur. And if you can hear the music coming from the earbuds or headphones connected to your friend’s smartphone, your friend may be damaging her hearing.

The most common outcome of noise exposure is **tinnitus**, or ringing sounds in one or both ears that can last for days, weeks, or indefinitely. Tinnitus is a common complaint among military veterans, and as many as 85% of concert attendees report experiencing tinnitus (Kochkin, Tyler, & Born, 2011; Tunkel et al., 2014). Hearing problems associated with short periods of exposure to loud sounds may be temporary, but damage from regular

● **Table 6.2** Noise Levels

The healthy ear can detect sounds starting at 0 decibels. Damage to hearing can start between 75 and 80 decibels and is more likely with long-term exposure to loud sounds. Using in-ear earphones to listen to music from an iPod at full volume can begin to cause damage after just 5 minutes.

Noise	Number of Decibels
Whisper	30
Normal speech	60
City traffic	80
Lawnmower	90
Rock concerts	110–140
iPod at full volume	110
Jet plane takeoff	120
Jackhammer	130
Firearm discharge	140

Source: The National Institute on Deafness and Other Communication Disorders (NIDCD), 2016b, *It’s a Noisy Planet*. www.noisyplanet.nidcd.nih.gov/Pages/Default.aspx

exposure to these same sounds can accumulate over time, leading to moderate or even severe hearing loss by adulthood.

Many teens report that they are aware of the potential for hearing loss from exposure to loud sounds, but they do not believe that hearing loss is a serious health concern for them (Chung et al., 2005). Thus, despite their awareness that noise exposure can lead to hearing loss, and regardless of warnings from parents and health officials that noise can be hazardous, many teens do little to protect their hearing because hearing loss is not perceived as an important issue. Few wear earplugs at concerts or ear protectors when operating power equipment (Bogoch et al., 2005; Chung et al., 2005). Young adults who downplay the risk of hearing loss are less likely to wear protection than those who acknowledge the risk from exposure to loud sounds (Keppler, Dhooge, & Vinck, 2015).

Part of the problem is the perception that ear protection is not “cool.” Teens who are more open to behavioral change and those who are less concerned about appearance are more willing to use ear protection (Bogoch et al., 2005). In addition, teens from higher socioeconomic backgrounds tend to rate noise exposure as more negative, and therefore are more open to ear protection, than teens from lower socioeconomic backgrounds (Widén & Erlandsson, 2004; Widén et al., 2009).

Educational programs to improve hearing protection among teens need to focus on several issues to be effective (see, for example, Keppler et al., 2015). They need to help teens recognize that there may be long-term consequences of noise exposure; damage to the auditory system can accumulate over time. Second, they need to address teens’ perception that hearing loss is not an important health issue. Until hearing is perceived as a priority, teens and others will have little motivation to protect this sensory system. And finally, education programs need to reduce the stigma associated with wearing hearing protection so teens feel comfortable making the decision to protect their hearing when they are in settings with loud noise.

Another Look at the Chemical Senses

Taste

Earlier, we introduced four basic tastes (sweet, sour, bitter, and salty) and discussed how smell contributes to the taste of foods. Are there any noticeable changes in taste during adolescence? There is a slight decline in preference for sweets and an increased sensitivity to—and liking of—sour tastes (University of Copenhagen, 2008). A preference for sour tastes, or at least a tolerance for sour tastes, is associated with willingness to try new foods and expand food horizons. This slight shift in an adolescent's taste palette leads to another difference between the child and adolescent: Adolescents are more likely to have developed an *acquired taste* for previously disliked or avoided foods. Most children may not enjoy, for example, eating snails (escargot) or fried squid (calamari), but many adolescents and adults have learned that these items can be quite tasty! Teenagers are more likely to enjoy foods with strong or strange tastes because they have had more opportunity to “acquire” these tastes through multiple exposures. Teenagers loosen up on the childhood tendency to reject new foods, and they are more open to experimenting with foods that may have odd textures or odors (Segovia et al., 2002). Of course, there are large individual differences in taste, with some teenagers enjoying very hot, spicy foods and others rejecting anything that has just a tiny amount of spice. Take the test in **Engagement 6.1** to see if you might be a supertaster who is more sensitive to low levels of chemicals hitting your taste receptors.

In addition, it turns out that your sense of taste is mediated by more than smell and taste receptors on the tongue. It is also determined by something called “chemosensory irritation,” which is the reaction of your skin—in your mouth and nose—to certain chemical compounds of foods (Beauchamp & Mennella, 2009). When you feel the burn from hot peppers, the cooling sensation from menthol, or the tingle from a carbonated beverage, you are

With their maturing taste buds, adolescents may be more open to trying new foods.

Kablonk! RM/Golden Pixels/Alamy Stock Photo

experiencing chemosensory irritation. This irritation of your skin contributes to your experience of a food, with, for example, some people reporting that they love to “feel the burn” of hot peppers and others completely turned off by it.

Taste is also influenced by cognition: You taste what you expect to taste. From past experience, we learn to associate certain features of food with certain tastes. For instance, brightly colored juices are thought to be tastier than pale ones, even when the juices are identical other than the addition of a few drops of artificial coloring to some (Hoegg & Alba, 2007). Thus, we see a bright orange liquid in a cup and we believe that this will be more flavorful than a pale orange liquid.

Smell

Interestingly, gender plays a role in the sense of smell during adolescence and adulthood, with women generally demonstrating greater sensitivity than men to a variety of odors (Doty & Cameron, 2009; Ferdenzi et al., 2013). This may reflect hormonal differences between men and women and the effect of different hormonal levels on detection and interpretation of the chemicals that comprise odors. Among women, hormonal changes influence sensitivity—both discrimination and identification—to different smells (Derntl et al., 2013). Women who are fertile may use odor as part of their criteria for selecting a desirable mate, judging the body odor of some men—those who have symmetrical or balanced physical features—as more desirable than the body odor of other men during the time they are ovulating (Foster, 2008; Yamazaki & Beauchamp, 2007). Symmetry (having balanced features) may be a biological marker of better health.

Men, too, may use differences in women's body odors as a component of mate selection; they rate odor during ovulation as more pleasant than odor at other times of women's menstrual cycles (Havlicek et al., 2006; Singh & Bronstad, 2001). Evolutionary theory would predict that men and women want to select a mate who is healthy and capable of reproduction, and odor may provide some clues in this regard. Both men and women report that odor is an important consideration in choosing romantic partners, even though most cannot clearly articulate what constitutes a “good” or a “bad” smelling person (Sergeant et al., 2005). But be forewarned: Women are more sensitive to body odor than men, and it is more difficult to cover up body odor so that women do not detect it, whereas perfumes and other cover-ups often fool men (Wysocki et al., 2009). We learned earlier that babies and their mothers can recognize one another through smell. Now we see that odor is also important in later relationships, perhaps serving as a filter to allow some people to get close and discourage others.

Cultural Variation

Do people who grow up in different cultural environments encounter different sensory stimulation and perceive the world in different ways? Perceptual preferences obviously differ from culture to culture. In some cultures, people think heavier women are more beautiful than slim ones or relish eating sheep's eyeballs or chicken heads. Are more basic perceptual competencies also affected by socialization?

● ENGAGEMENT 6.1

Are You a Supertaster?

Some folks seem to experience certain tastes with much greater intensity than others. These “supertasters” have more taste buds than the average person and their taste buds are genetically inclined to be more sensitive (Mennella, Pepino, & Reed, 2005; Negri et al., 2012). Although the prevalence of supertasters varies across different regions of the world, on average, about 25% of the adult population has substantially more taste receptors than the other 75%, making them super sensitive to tastes (Bartoshuk, Duffy, & Miller, 1994; Robino et al., 2014). The definitive supertaster test consists of a small paper filter that is infused with a special chemical. When placed on the tongue of a supertaster, it is perceived as incredibly bitter, but tastes bland or mildly bitter to those without the supertaster gene. Your answers to the following questions will give you an estimate of whether you might be a supertaster.

1. Do you enjoy or despise grapefruit juice?
2. Do you like milk chocolate or dark chocolate?
3. Do you hate raw broccoli or Brussels sprouts or think these veggies are okay or even good?
4. As a child, did you eat lots of vegetables?
5. Do you often think that desserts or cookies are too sweet, while others report that the same foods taste just right?

Supertasters are likely to have a strong dislike for the bitter tastes of grapefruit juice, dark chocolate, or raw broccoli/Brussels sprouts. As children, supertasters avoided vegetables because they tasted “too strong.” Supertasters are likely to think that too much sweetener has been used in foods and would prefer less sugar. To follow up, you can perform this relatively simple test using a drop of blue food coloring and a small piece of wax paper that you have punched with a single hole-puncher. Place a few drops of the blue food coloring on your tongue. Place the wax paper that has the hole punched in it over the blue patch on your tongue. Now carefully count the little pink circles that are within the circle. If you have a lot (25 or more) of little pink circles, then you have more than the average number of papillae and are a supertaster (each papillae contains 6–15 taste

This tongue has an average number of papillae, or bumps containing taste buds. The tongue of a “supertaster” would have as many as twice the papillae seen here.

Koval Image Creation/WorkbookStock/Getty Images

buds). If you have very few pink circles (less than 6), then you are a nontaster and are probably insensitive to bitter and other strong tastes. Anything between these two extremes

is where most of us (50%) fall. With our average number of papillae, we enjoy most foods and don’t find them too bitter or too sweet, but also don’t find them bland.

People from different cultures differ little in basic sensory capacities, such as the ability to discriminate degrees of brightness or loudness (Berry et al., 1992). There is some evidence that the threshold for detecting odors may vary between folks in industrialized settings and those in nonindustrialized locations (Sorokowska et al., 2013). Researchers found that people of the nonindustrialized rainforest could detect lower concentrations of an odor compared with people from an industrialized area of Germany. The difference may reflect compromised olfactory systems due to pollution and chemicals in the industrialized group, or it could be that the nonindustrialized group relies more on the sense of smell, fostering greater sensitivity.

Although there may be some differences in sensory thresholds, the bigger difference seems to be in people's perceptions and interpretations of sensory input. For example, you have already seen that children become insensitive, starting at the end of the first year of life, to speech sound contrasts that they do not hear regularly because they are not important in their primary language. Michael Lynch and his associates (1990) have shown that the same is true for perceptions of music. Infants from the United States, they found, noticed equally notes that violated either Western musical scales or the Javanese pelog scale. This suggests that humans are born with the potential to perceive music from a variety of cultures. However, American adults were less sensitive to bad notes in the unfamiliar Javanese musical system than to mistuned notes in their native Western scale, suggesting that their years of experience with Western music had shaped their perceptual skills.

Another example of cultural influence concerns the ability to translate perceptions of the human form into a drawing. In Papua New Guinea, where there is no cultural tradition of drawing and painting, children aged 10–15 who have had no schooling do not have much luck drawing the human body; they draw scribbles or tadpole-like forms far more often than children in the same society who have attended school and have been exposed many times to drawings of people (Martlew & Connolly, 1996; ■ Figure 6.5). We all have the capacity to create two-dimensional representations, but we apparently develop that capacity more rapidly if our culture provides us with relevant experiences.

Interesting research by Asifa Majid and Niclas Burenhult (2014) suggests that perception of odors is also influenced by culture. Westerners often have a hard time naming an odor, but Majid and Burenhult's research shows that this is not universally true. They studied Jahai, one of the hunter-gatherer subgroups of the Malay Peninsula. It turns out that the Jahai have many more words to describe odors, allowing them to name odors more readily than Westerners whose language does not include such rich descriptors.

Other research compared Japanese and German women's ratings of three groups of odors, including one set of odors that would likely be familiar to Japanese women, a second set likely familiar to German women, and a third set that would likely be familiar to both groups. Consistent with the researcher's hypotheses, Japanese women were better able to

describe the 'Japanese smells' and rated these as more pleasant, whereas the German women were better at describing the 'German smells' and thought these were more pleasant (Ayabe-Kanamura et al., 1998).

Cultural factors may not necessarily affect our sensory receptors, but they do play a role throughout infancy, childhood, and adolescence in how we learn to perceive or interpret many of the sensory signals we receive throughout our day.

■ **Figure 6.5** These human figures were drawn by children between the ages of 10 and 15. On the left, the drawings were made by children in Papua New Guinea, who often lack experience with drawing the human form and produce figures much like those done by far younger children (such as 4-year-olds) in the United States. The drawing on the right was made by a 12-year-old child in the United States. The contrast between the drawings on the left and the one on the right illustrates how cultural experience influences the ability to translate visual perceptions into representations on the page.

● Checking Mastery

1. What concerns might we have regarding hearing during the adolescent years?
2. What are two observations regarding the chemical senses during adolescence?

● Making Connections

1. You are a tutor and want a 5-year-old and a 15-year-old to systematically compare pairs of maps to determine whether they are similar or different. What can you expect of each child, and what can you do to optimize the performance of the younger child?
2. Design an educational unit for a high school health class that is aimed at reducing the incidence of noise-induced hearing loss.

6.5

The Adult

LEARNING OBJECTIVES

- Describe typical changes in vision and hearing that occur over adulthood and indicate how these changes may affect daily activities.
- Summarize changes of the chemical and somesthetic sensory systems that occur in the aging individual.
- Provide a balanced summary of the gains and losses that are typical of older adulthood.

What becomes of sensory and perceptual capacities during adulthood? There is good news and bad news, and we might as well dispense with the bad news first: Sensory and perceptual capacities decline gradually with age in the typical person. Whispers become harder to hear, seeing in the dark becomes difficult, food may not taste as good, and so on. Often these declines begin in early adulthood and become noticeable in the 40s, sometimes giving middle-aged people a feeling that they are getting old. Further declines take place in later life, to the point that you would have a hard time finding a person age 65 or older who does not have at least a mild sensory or perceptual impairment. The good news is that these changes are gradual and usually minor. As a result, we can usually compensate for them, making small adjustments such as turning up the volume on the TV set or adding a little extra seasoning to food. Because the losses are usually not severe and because of the process of compensation, only a minority of old people develop serious problems such as blindness and deafness.

The losses we are describing take two general forms. First, sensation is affected, as indicated by raised **sensory thresholds**.

The threshold for a sense is the point at which low levels of stimulation can be detected—a dim light can be seen, a faint tone can be heard, a slight odor can be detected, and so on. Stimulation below the

threshold cannot be detected, so the rise of the threshold with age means that sensitivity to very low levels of stimulation is lost. (You saw that the very young infant is also insensitive to some very low levels of stimulation.)

Second, perceptual abilities decline in some aging adults. Even when stimulation is intense enough to be well above the detection threshold, older people sometimes have difficulty processing or interpreting sensory information. As you will see, they may have trouble searching a visual scene, understanding rapid speech in a noisy room, or recognizing the foods they are tasting.

So, sensory and perceptual declines are typical during adulthood, although they are far steeper in some individuals than in others and can often be compensated for. These declines involve both a rise of thresholds for detecting stimulation and a weakening of some perceptual abilities.

Vision

Fortunately, few adults experience complete loss of vision, but many adults face some sort of vision problems as they get older. Why do these changes in the visual system occur, and is there anything you can do to prevent losses? Before we answer these questions, we need to briefly review the basic workings of the visual system.

As **Figure 6.6** shows, light enters the eye through the cornea and passes through the pupil and lens before being projected (upside down) on the retina. From here, images are relayed to the brain by the optic nerve at the back of each eye. The pupil of the eye automatically becomes larger or smaller depending on the lighting conditions, and the lens changes shape, or accommodates, to keep images focused on the retina. In

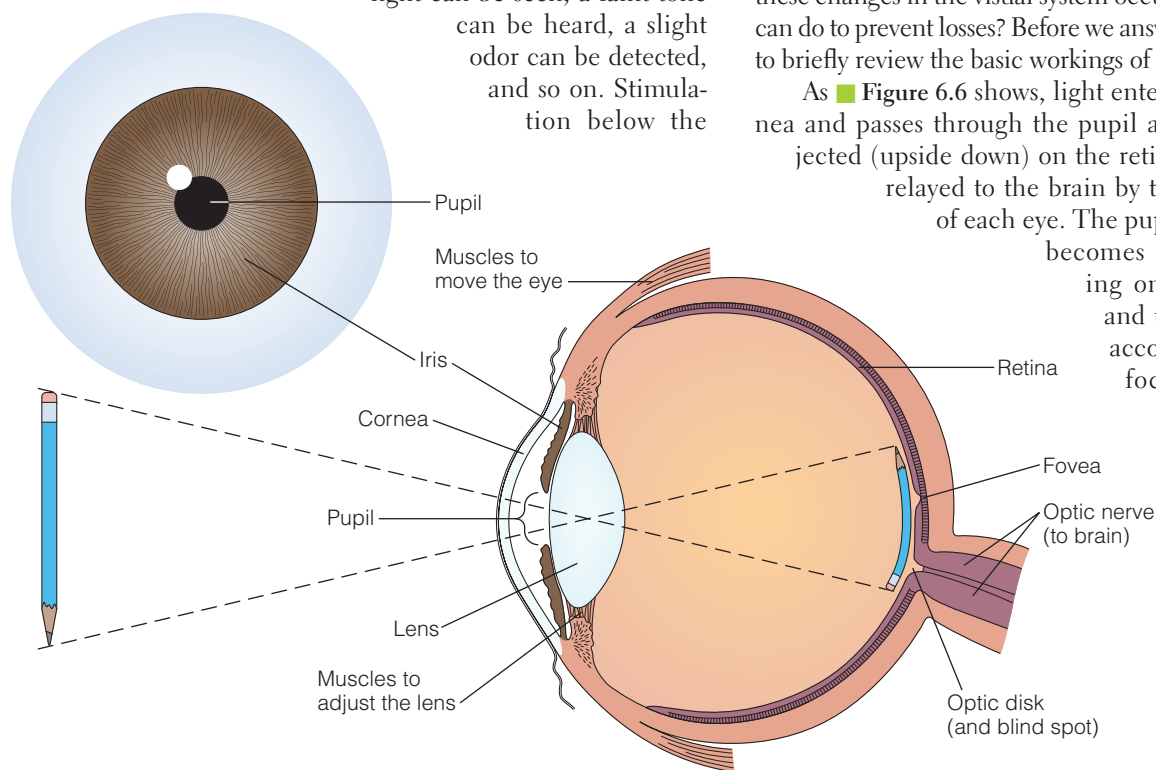

Figure 6.6 The human eye and retina. Light passes through the cornea, pupil, and lens and falls on the light-sensitive surface of the retina, where images of objects are projected upside down. The information is relayed to the brain by the optic nerve.

● **Table 6.3** Age-Related Changes in the Visual System

Part of Eye	Age-Related Changes or Disease	Resulting Limitation(s)
Pupil	Less responsive to changes in lighting conditions and to dim light	Difficulty reading menus in dimly lit restaurants; trouble with night driving; unable to adjust quickly enough to oncoming lights at night or exiting a movie theatre into daylight
Lens	Cataract: Cloudiness of the lens Presbyopia: Thickening or hardening of the lens	Blurred or distorted vision Decreased ability to see close objects; need for “reading” glasses
Retina	Age-related macular degeneration (AMD): Photoreceptors in the middle of the retina, the <i>macula</i> , deteriorate Retinitis pigmentosa (RP): Deterioration of light-sensitive cells outside the macula	Loss of central vision, an important contributor to reading, driving, watching TV, and other daily activities Loss of peripheral vision
Eyeball	Glaucoma: Increased fluid pressure in the eyeball	Loss of peripheral vision and eventual loss of all vision

adolescents and young adults, the visual system is normally at peak performance. Aging brings changes to all components of the visual system. We summarize the most common vision problems in ● **Table 6.3**.

Some of these changes have important implications for everyday functioning. For example, changes in the pupil lead to difficulty with reading in dim lighting conditions, such as those found in many restaurants. Approximately one in three adults over the age of 85 years exhibits a tenfold loss of the ability to read low-contrast words in dim lighting, as in trying to read certain menus in restaurants with ‘mood lighting’ (Owsley, 2011). But as **Figure 6.7** shows, older adults may continue to read well under ideal conditions of high contrast and bright light. Older adults may also struggle with night driving, as the pupil of the eye requires more time to adapt to the bright lights of oncoming cars and trucks, and then back again to the dark road.

■ **Figure 6.7** Visual acuity of older adults under optimal (high contrast and bright light), average (low contrast and bright light), and poor (low contrast and low light) stimulus conditions.

Adapted from Haegerstrom-Portnoy, G., Schneck, M. E., & Brabyn, J. A. (2000). Seeing into old age: Vision function beyond acuity. *Optometry and Vision Science*, 76, 141–158. Reprinted by permission of Lippincott, Williams, and Wilkins.

The thickening and increasing rigidity of the lens of the eye make it difficult to focus on close objects. You may notice that many middle-aged and older adults use reading glasses or they may gradually move newspapers and books farther from their eyes to make them clearer—both are methods of compensating for the decline of near vision that is associated with hardening of the eye’s lens and is the most noticeable feature of **presbyopia**, or aging of the eye.

As for distance vision, visual acuity as measured by standard eye charts increases in childhood, peaks in the 20s, remains steady through middle age, and steadily declines in old age. The implications for the average adult are fairly minor. For example, in one major study, three out of four older adults (75 years and older) had good corrected vision (Evans et al., 2002). At worst, most of them could see at 20 feet what a person with standard acuity can see at 25 feet—not a big problem. Among the oldest adults—those in their 90s—only 7% have lost all functional vision (Evans et al., 2002). Several studies show that women experience greater declines in visual acuity than men (see, for example, Zetterberg, 2016). Older women with declining vision are more susceptible to falling and fracturing a bone, which is a serious threat to their independence (Ambrose, Paul, & Hausdorff, 2013; Marks, 2014). Fracturing a hip often triggers a shift from independent to assisted living and can even be fatal. And poor vision that is not correctable can seriously decrease older adults’ quality of life. According to one estimate, older adults with poor visual acuity (20/40 or worse) are as impaired as those with a major medical problem such as stroke (Chia et al., 2004).

For those with the serious retinal problem **age-related macular degeneration (AMD)**, vision becomes blurry and begins to fade from the center of the visual field, leading to blank or dark space in the center of the image. Because cataracts are now often successfully corrected with surgery, AMD has become the leading cause of blindness in older adults. The causes of macular degeneration are largely unknown, but some research points to a genetic contribution; other research

As adults age, they often find themselves more bothered by glare from bright lights or sun. What is the likely cause of this increased sensitivity?

iStockphoto.com/Lisay

shows a connection with cigarette smoking (Rasoulinejad et al., 2015). Currently, there is no cure for AMD, but several researchers are working to develop retinal implants that would stimulate the remaining cells of the retina and restore some useful vision (Boston Retinal Implant Project, 2016). In addition, some doctors prescribe vitamin and mineral supplements that have had some success in slowing the progression of AMD, preserving useful vision for as long as possible.

Changes in the retina also lead to decreased visual field, or a loss of peripheral (side) vision. Looking straight ahead, an older adult may see only half of what a young adult sees to the left and the right of center. Can you think of activities that might be hindered by a decreased visual field? Driving a car comes to mind. For example, when approaching an intersection, you need to be able to see what is coming toward you as well as what is coming from the side roads. **Exploration 6.2** describes some other sensory changes that might make driving more hazardous for older people.

To recap, you can expect some changes in vision as you age. (See **Figure 6.8** for a view of how the world looks through aging eyes affected by the conditions discussed here.) Sensory thresholds increase with age so that you need higher levels of stimulation than when you were young. Acuity, or sharpness of vision, decreases, near vision is negatively affected by hardening of the lens (presbyopia), and it takes longer for eyes to adapt to changes. Fortunately, it is possible to correct or compensate for most of these “normal” changes. And older adults who have good family support systems and personal coping mechanisms that focus on

acceptance rather than wishful thinking adapt more successfully to visual impairment (Reinhardt, Boerner, & Horowitz, 2009). Some older adults will experience serious visual problems, but others will retain good vision and healthy eyes until well into old age, illustrating the wide range of variability in vision among older adults (Dagnelie, 2013).

Attention and Visual Search

As you learned earlier in this chapter, perception is more than just seeing. It is using the senses intelligently and allocating attention efficiently. Francesca Fortenbaugh and her colleagues (2015) cleverly used data from over 10,000 visitors who completed a “continuous concentration” task on the website TestMyBrain.org. Participants ranged in age from 10 to 70 years. Consistent with what we learned in the previous section, sustained attention improved throughout the adolescent years. It was then relatively stable throughout early adulthood, peaked at age 43, and then slowly declined. Most adults are in the prime of their careers at age 43; how is it that their attention peaks 20–25 years before most people retire? Part of the answer is that the researchers measured

reaction time, which generally slows across the life span. But by examining the patterns of correct and incorrect responses, as well as response times, the researchers concluded that older adults—wisely—began to use a more cautious strategy than young adults. For example, after a trial with an error, older adults strategically slowed down on the next trial, presumably to increase their accuracy.

Now consider a different type of task, one that requires dividing attention between two tasks (divided attention) or selectively attending to certain stimuli while ignoring others (selective attention; see Juola et al., 2000; Madden & Langley, 2003). The more distractors a task involves, the more the performance of elderly adults falls short of the performance of young adults. In everyday life, this may translate into difficulty carrying on a conversation while driving or problems locating the asparagus amid all the frozen vegetables at the supermarket.

In one test of visual search skills, Charles Scialfa and his colleagues (Scialfa, Esau, & Joffe, 1998) asked young adults and elderly adults to locate a target (for example, a blue horizontal line) in a display where the distractor items were clearly different (for example, red vertical lines) or in a more difficult display where the distractors shared a common feature with the target (for example, blue vertical and red horizontal lines). Older adults were slower and less accurate on the more challenging search task. They were also more distracted by irrelevant information; they were especially slow compared with young adults when the number of distractor items in the display was high.

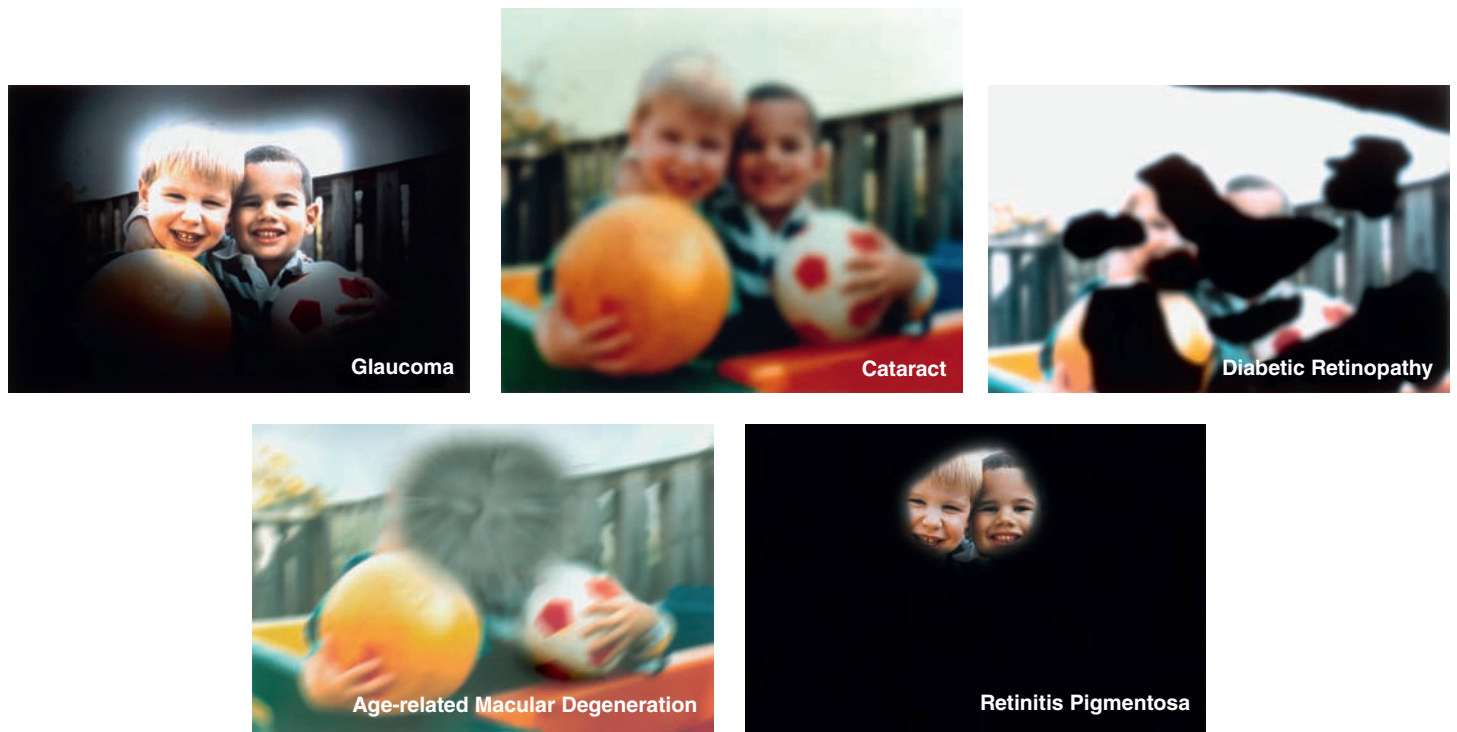

Figure 6.8 These photos illustrate how a scene might be viewed by someone with various eye conditions: (A) glaucoma; (B) cataracts; (C) diabetic retinopathy; (D) age-related macular degeneration; (E) retinitis pigmentosa.

National Eye Institute, National Institutes of Health

In some situations, elderly people appear to have difficulty inhibiting responses to irrelevant stimuli so that they can focus their attention more squarely on relevant stimuli. Jennifer Weeks and her colleagues (2016) demonstrated that older adults' propensity to encode irrelevant with relevant information could be used to their advantage. In one task, they showed adults a series of faces with names superimposed on the photo of the face and instructed them to pay attention only to the face. Later, they asked the adults to learn a set of faces with names, some of which were the same face-name combinations that had been presented in the earlier task. Older, but not younger, adults had an easier time remembering the names paired with faces in the earlier task, even though they had been told to ignore the names and focus only on the faces in that task.

In short, older adults have their greatest difficulties in processing visual information when the situation is *novel* (when they are not sure exactly what to look for or where to look) and when it is *complex* (when there is a great deal of distracting information to search through or when two tasks must be performed at once). By contrast, they have fewer problems when they have clear expectations about what they are to do and when the task is not overly complicated (Madden, 2007). Thus, an older factory worker who has inspected televisions for years may be just as speedy and accurate as a younger worker at this well-practiced, familiar task, but he might perform relatively poorly if suddenly asked to inspect pocket calculators and look for a much larger number of possible defects—a novel and complex task.

Hearing

There is some truth to the stereotype of the hard-of-hearing older person. Hearing impairment is approximately three times as prevalent as visual impairment among older adults (Davila et al., 2009). About one-third of adults in their 60s have some hearing loss and the majority (80%) of adults 85 years and older have impaired hearing (Walling & Dickson, 2012). According to one estimate, the typical 65-year-old adult can expect to live about 10 years (males) to 13 years (females) with a hearing impairment (Kiely et al., 2015). How might we improve hearing, or maintain good quality of life for those who experience hearing loss? Before we attempt to answer these questions, let's review changes with age in basic hearing capacities.

Basic Capacities

Sources of hearing problems range from excess wax buildup in the ears to infections to a sluggish nervous system. Most age-related hearing problems seem to originate in the inner ear, however (National Institute on Deafness and Other Communication Disorders, 2016a). The cochlear hair cells that serve as auditory receptors, their surrounding structures, and the neurons leading from them to the brain degenerate gradually over the adult years. The most noticeable result is a loss of sensitivity to high-frequency or high-pitched sounds, the most common form of **presbycusis**, or problems of the aging ear. Thus, an older person may have difficulty hearing a child's high voice, the flutes in an orchestra, and high-frequency consonant sounds such as *s*, *z*, and *ch*.

EXPLORATION 6.2

Aging Drivers

Older drivers are perceived by many as more accident prone and slower than other drivers. Perhaps you have had the experience of zipping down the interstate when a slow-moving car driven by an elderly adult pulls into your path, forcing you to brake quickly. Is this experience representative, and is the stereotype of older drivers accurate? This is an important question, because 20% of all drivers will be older than 65 years by 2030 (U.S. Census Bureau, 2014).

It is true that older adults (70 years and older) are involved in more automobile fatalities than middle-aged adults (see the graph in this box). But the most accident-prone group is young drivers between ages 16 and 24 (Insurance Institute for Highway Safety, 2016). When you take into account that young people drive more than elderly people, it turns out that both elderly drivers and young drivers have more accidents per mile driven than middle-aged drivers (Insurance Institute for Highway Safety, 2016).

Why is driving hazardous for elderly adults? Clearly, vision is essential to driving; vision accounts for approximately 90% of the information necessary to operate and navigate a car (National Safety Commission, 2008). Limited visual acuity or clarity is one component of problematic driving, but as noted in the main text, poor acuity is fairly easy to correct and is, therefore, unlikely to account for all the problems older drivers have.

Diminished peripheral vision may be an issue because good drivers must be able to see vehicles and pedestrians approaching from the side. Half the fatal automobile accidents involving older drivers occur at intersections, and older drivers are more than twice as likely as young drivers to have problems making left turns (Cicchino & McGartt, 2015). Why? Poor surveillance is the most common reason. They look, but they do not necessarily see or do not interpret the information in the most effective manner. And, you learned in Chapter 5 that older adults typically have slower response times than younger adults; thus, they need more time to react to the same stimulus.

Older adults may also struggle to simultaneously process multiple pieces of information. Thus, older drivers have trouble reading street signs while driving (Dewar, Kline, & Swanson, 1995), and they are less able than younger adults to quickly change their focus from the dashboard to the rearview mirror to the road ahead. When another vehicle is approaching, they must be able to evaluate the speed and trajectory of this vehicle and integrate this information with their own speed and trajectory to determine a course of action. For example, is the car approaching from the left going to hit my car, or will I be through the intersection before it reaches me? Finally, after understanding the dynamics of a potentially dangerous situation, the driver must be able to react quickly to threats (for example, a child chasing a ball into the street).

However, the driving records of older adults are not as bad as might be expected, because many of them compensate for visual and other perceptual difficulties and slower reactions by

driving less frequently, especially in conditions believed to be more hazardous—at night, during rush hour, and when the weather is poor (Messinger-Rapport, 2003). Older adults with visual problems such as cataracts and those with cognitive problems are more likely to limit their driving than older adults without these problems (Messinger-Rapport, 2003). To give up driving is to give up a big chunk of independence, something anyone would be loath to do. Most people want to find ways to drive safely as long as possible.

There is good news: Today's older drivers are healthier than those of earlier generations. Those who return to the classroom for a refresher course on safe driving and get behind-the-wheel training can improve their driving (Marottoli, 2007). By understanding the strengths and limitations of their sensory-perceptual abilities, older adults will be in a good position to keep driving safely, which is good to remember the next time you are stuck behind a slow driver.

Motor vehicle crash deaths per 100,000 people by age and gender, 2014.

These older adults are unlikely to experience problems locating items at their usual supermarket. But in an unfamiliar context, the same visual search of shelves for items may prove challenging.

LdF/Vetta/Getty images

(Whitbourne & Whitbourne, 2014) but may have less trouble with deep voices, tubas, and sounds such as b. After age 50, lower-frequency sounds also become increasingly difficult to hear (Kline & Scialfa, 1996). Thus, to be heard by the average older adult, a sound—especially a high-pitched sound but ultimately any sound—must be louder than it needs to be to exceed the auditory threshold of a younger adult.

Is this loss of hearing with age the inevitable result of basic aging processes, or is it caused by other factors? Researchers know that the loss is more noticeable among men than among women, that men are more likely to work in noisy industrial jobs, and that those who hold such jobs experience more hearing loss than other men (Masterson et al., 2015). But even when adults who have held relatively quiet jobs are studied, men show detectable hearing losses earlier in life (in their 30s) and lose hearing sensitivity at a faster rate than women do (Pearson et al., 1995). It seems, then,

that most people, men more than women, will experience some loss of sensitivity to high-frequency sounds as part of the basic aging process, but that certain people will experience more severe losses because of their experiences. There are both personal and societal consequences associated with hearing loss as individuals with hearing loss often become more socially isolated, experience lower levels of emotional well-being, and retire earlier than their peers without hearing loss (Contrera et al., 2016; Helvik, Krokstad, & Tambs, 2013).

Speech Perception

Perhaps the most important thing we do with our ears in everyday life is listen to other people during conversations. The ability to hear is one requisite for understanding speech, but this complex auditory perception task also depends on cognitive processes such as attention and memory. How well do aging adults do?

Older adults typically have more difficulty understanding conversation than younger adults do, even under ideal listening conditions. This age difference becomes smaller when differences in hearing are controlled, but it does not entirely disappear. Under poor listening conditions—for example, loud background noise—group differences between older and young adults are larger, even when individual differences in hearing are accounted for (see Wingfield & Lash, 2016). Thus, older adults may recall less information from a conversation that takes place in a crowded, noisy restaurant.

Age-related declines in auditory sensitivity (that is, acuity) are partly responsible, but cognitive declines also seem to contribute to declines in speech perception among older adults (Wingfield & Lash, 2016). Patricia Tun and her colleagues (Tun, McCoy, & Wingfield, 2009) compared two groups of older and younger adults: those with good and poor hearing. Participants listened to words and then recalled as many of these words as possible. On half the trials, they did this while also performing a simple visual tracking task. Older adults with good hearing performed significantly worse than young adults with good hearing, so there is more to the recall of spoken words than having good auditory acuity. Moreover, the additional attentional demands of the second task had no significant effect on the younger adults, regardless of whether they had good or poor hearing, but older adults were disadvantaged by increased attentional demands and recalled few spoken words when they had to divide their attention.

In addition, auditory perception tasks, like visual perception tasks, are more difficult for older people when they are novel and complex. In familiar, everyday situations, older adults are able to use contextual cues to interpret what they hear. In one study, for example, elderly adults were about as able as young adults to recall meaningful sentences they had just heard (Wingfield et al., 1985). However, they had serious difficulty repeating back grammatical sentences that made no sense or random strings of words, especially when these meaningless stimuli were spoken rapidly. So an older person may be able to follow an ordinary conversation but not a technical presentation on an unfamiliar topic—especially if the speaker makes the task harder by talking too fast.

Overall, then, most older adults have only mild hearing losses, especially for high-frequency sounds, and only minor

problems understanding everyday speech, at least under good listening conditions. In addition, they can compensate for their difficulties successfully—for example, by reading lips and relying on contextual cues. Novel and complex speech heard under poor listening conditions is likely to cause more trouble. Returning to the questions we asked at the beginning of this section, **Application 6.2** describes how we might help older people to improve their hearing or compensate for its loss and maintain good quality of life.

Aging of the Chemical Senses

Does the aging of sensory systems also mean that older people become less able to appreciate tastes and aromas? On average, yes: There is a general decline in sensitivity to taste, with older men showing somewhat greater decline than older women (Wehling et al., 2016). But keep in mind that there is great variability: Some older adults will continue to have keen senses of smell and taste, while others experience sharp declines in these chemical senses. Thus, some older adults may report that food tastes bland and use larger amounts of salt, sugar, and other seasonings than they used when they were younger. In addition,

both middle-aged and older adults sometimes have difficulty discriminating among tastes that differ in intensity (Nordin et al., 2003). In one study, older adults were less able than young adults to reliably recognize a food on the basis of smell and taste (see ● **Table 6.4**). Older adults tend to produce less saliva than younger adults, and saliva facilitates distribution of the chemical molecules carrying information about taste around the mouth (Brynie, 2009). Interestingly, though, older adults do not have difficulty distinguishing degrees of sweetness; people apparently do not lose the sweet tooth they are born with!

The ability to perceive odors also typically declines with age. Sensitivity to odors increases from childhood to early adulthood. At peak levels, humans can detect somewhere around a trillion different odors (Bushdid et al., 2014). Declines in olfaction occur during adulthood, more so with increasing age, but differences among age groups are usually small, and many older people retain their sensitivity to odors. The age decline depends on the type of odor: Older adults can identify and remember unpleasant odors just as well as younger adults, although they show some decline in their ability to detect and remember pleasant odors (Larsson, Öberg-Blåvarg, & Jönsson, 2009). Women are more likely than men to maintain their ability to label odors in scratch-and-sniff

● APPLICATION 6.2

Aiding Adults with Hearing Impairments

In **Application 6.1**, we examined ways to help infants and children who have hearing impairments, often from birth. Here we consider the other end of the life span. What can be done to assist hearing-impaired adults, most of whom were born with normal hearing? Unfortunately, many older adults are reluctant to admit that they have a hearing problem and do not seek assistance, or they may not even realize they have hearing loss as it occurs gradually and they have learned to compensate. Among those who acknowledge having a hearing problem, many refuse to wear a hearing aid because they feel it stigmatizes them as old, or they report that hearing aids do not work or do not help them to hear better (Lupsakko, Kautiainen, & Sulkava, 2005).

Those who do not have their hearing corrected may suffer depression, decreased independence, and strained relationships (Appollonio et al., 1996). Imagine how hard social interaction can become if you cannot understand what is being said, misinterpret what is said, or have to keep asking people to repeat what they said. One 89-year-old woman became extremely depressed and isolated: “There is an *awfulness* about silence. . . . I am

days without speaking a word. It is affecting my voice. I fear for my mind. I cannot hear the alarm clock, telephone ring, door bell, radio, television—or the human voice” (Meadows-Orlans & Orlans, 1990, pp. 424–425). In contrast, among those older adults who do use hearing aids, quality of life improves (Vuorialho, Karinen, & Sorri, 2006). We tend to think of vision as our most important sense, but hearing impairments may be more disruptive than visual impairments to cognitive and social functioning.

Hearing aids, although beneficial, cannot restore normal hearing; they tend to distort sounds and to magnify background noise as well as what the wearer is trying to hear. In addition, many older people are ill-served by hearing aids that are of poor quality or that are poorly matched to their specific hearing problems. Because cochlear implants work best for individuals exposed to spoken language before they lost their hearing, elderly people are ideal candidates for them. They tolerate the surgical procedure required for implantation well, and their hearing-test scores increase significantly (Kelsall, Shallop, & Burnelli, 1995). In addition, adults who receive cochlear implants report

that their quality of life improves significantly (Faber & Grontved, 2000). Cochlear implants, however, cannot work overnight miracles; it can take months, even years, to learn how to interpret the messages relayed by the implant to the brain (Colburn, 2000).

Finally, the physical and social environment can be modified to help people of all ages with hearing losses. For example, furniture can be arranged to permit face-to-face contact; lights can be turned on to permit use of visual cues such as gestures and lip movements. Then there are the simple guidelines we can follow to make ourselves understood by hearing-impaired people. One of the most important is to avoid shouting. Shouting not only distorts speech but also raises the pitch of the voice (therefore making it more difficult for elderly people to hear); it also makes it harder for the individual to read lips. It is best to speak at a normal rate, clearly but without overarticulating, with your face fully visible at a distance of about 3–6 feet.

With modern technology, appropriate education, effective coping strategies, and help from those who hear, hearing-impaired and deaf individuals of all ages can thrive.

● **Table 6.4** Age Differences in Recognition of Fruits and Veggies

Elderly adults have more difficulty than young college students in identifying most blended foods by taste and smell alone. Percentages of those recognizing food include reasonable guesses such as “orange” in response to “apple.”

Percentage Recognizing Food		
Pureed Food Substance	College Students (ages 18–22)	Elderly People (ages 67–93)
Fruits		
Apple	93	79
Banana	93	59
Pineapple	93	86
Vegetables		
Broccoli	81	62
Carrot	79	55
Cucumber	44	28

tests, partly because they are less likely than men to have worked in factories and been exposed to chemicals that could damage the chemical receptors involved in odor perception (Ship & Weiffenbach, 1993). Also, healthy adults of both sexes retain their sense of smell better than do those who have diseases, smoke, or take medications (Wilson et al., 2006). Again, then, perceptual losses in later life are part of the basic aging process but vary from person to person depending on environmental factors.

Are declines in the sense of smell truly significant? Yes. Researchers Johannes Attems, Lauren Walker, and Kurt Jellinger (2015) note that a diminished ability to smell “significantly impairs physical well-being, quality of life, enjoyment of food, everyday safety, and is associated with increased mortality in older adults” (p. 486). If foods do not have much flavor, an older person may lose interest in eating and may not get proper nourishment. Alternatively, an older person may overuse seasonings such as salt or may eat spoiled food, which can threaten health in other ways. Clearly, a diminished sense of smell is more than an inconvenience associated only with minor decreases in flavor perception. As you will learn in Chapter 16, a decreased sense of smell may be a harbinger of serious cognitive impairments (Roberts et al., 2016).

Conclusions about changes in taste and smell must be put in perspective. These sensory and perceptual abilities are highly variable across the entire life span, not just in older adulthood. Taste and smell receptors are replaced throughout the life span and are influenced by such environmental factors as smoke, medications, and extreme temperatures. This means that, under optimal environmental conditions, many older adults will not experience deficits: They can continue to smell the roses and enjoy their food.

Changes in the Somaesthetic Senses

By now you have seen numerous indications that older adults are often less able than younger adults to detect weak sensory stimulation. This holds true for the sense of touch. The detection threshold for touch increases and sensitivity is gradually lost from middle childhood on. It is not clear that minor losses in touch sensitivity have many implications for daily life, however.

Similarly, older people may be less sensitive to changes in temperature than younger adults are (Frank et al., 2000). Some keep their homes too cool because they are unaware of being cold; others may fail to notice that it is too hot. Because older bodies are less able than younger ones to maintain an even temperature, elderly people face an increased risk of death in heat waves or cold spells (Worfolk, 2000).

It seems only fair that older people should also be less sensitive to painful stimulation, but are they? They are indeed less likely than younger adults to report weak levels of stimulation as painful, although the age differences in pain thresholds are not large or consistent (Wickremaratchi & Llewelyn, 2006). Yet older people seem to be no less sensitive to stronger pain stimuli. Unfortunately, older adults are more likely to experience chronic pain than younger adults but are less likely to obtain adequate pain relief (Gloth, 2001). Adults with arthritis, osteoporosis, cancer, and other diseases who also experience depression and anxiety are especially likely to perceive pain (Hall, 2016). Treating these secondary conditions and administering effective pain relief can improve the daily functioning and psychological well-being of older adults.

The Adult in Perspective

Of all the changes in sensation and perception during adulthood that we have considered, those involving vision and hearing appear to be the most important and the most universal. Not only do these senses become less keen, but older people also use them less effectively in such complex perceptual tasks as searching a cluttered room for a missing book or following rapid conversation in a noisy room. Declines in the other senses are less serious and do not affect as many people.

Although people compensate for many sensory declines, their effects cannot be entirely eliminated. At some point, aging adults find that changes in sensory abilities affect their activities. As ● **Table 6.5** shows, older adults with one or two sensory impairments are more likely to experience difficulty with basic tasks of living—walking, getting outside, getting in or out of bed or a chair, taking medicines, or preparing meals. Notice, however, that even older adults without sensory impairments report some difficulty with these tasks. People who are limited by sensory impairments usually have physical or intellectual impairments as well, most likely because of general declines in neural functioning that affect both perception and cognition (Baltes & Lindenberger, 1997; Vallet, 2015). Most older adults, even those with sensory impairments, are engaged in a range of activities and are living full lives. Thus, although most adults will experience some declines in sensory abilities with age, these changes do not need to detract from their quality of life.

● **Table 6.5** Percentage of Older Adults with Various Impairments Who Report Limits on Activities

Activity	With Visual Impairments	With Hearing Impairments	With Both Visual and Hearing Impairments	Without Visual or Hearing Impairments
Difficulty walking	43.3	30.7	48.3	22.2
Difficulty getting outside	28.6	17.3	32.8	11.9
Difficulty getting in or out of a bed or chair	22.1	15.1	25.0	10.4
Difficulty taking medicines	11.8	7.7	13.4	5.0
Difficulty preparing meals	18.7	11.6	20.7	7.8

● Checking Mastery

1. What are the most common eye problems experienced by older adults?
2. What is the greatest functional difficulty with hearing loss among older adults?
3. Which taste is best perceived across the life span (that is, there is little loss of acuity)?

● Making Connections

1. You have been hired to teach a cooking course to elderly adults. First, analyze the perceptual strengths and

weaknesses of your students: What perceptual tasks might be easy for them, and what tasks might be difficult? Second, considering at least three senses, think of five strategies you can use to help your students compensate for the declines in perceptual capacities that some of them may be experiencing.

2. You are the coordinator for social and educational activities at your community center, which means you work with people of all ages, ranging from the youngest infants to the oldest adults. In planning activities, what should you consider in trying to capture and hold the attention of different age groups?

Chapter Summary

6.1 Perspectives on Perception

- Sensation is the detection of sensory stimulation, and perception is the interpretation of what is sensed.
- Constructivists argue that the newborn is a “blank slate” and must acquire an understanding of the world through experience with sensory inputs. Thus, according to the constructivist perspective, nurture drives the development of perception.
- Nativists believe that each person is born with some innate understanding of how to interpret sensory information. Thus, according to the nativists, the origin of perception is largely nature.
- Gibson’s ecological theory proposes that everything we need to understand the world around us is available in the environment itself. We are able to directly detect the affordances of objects—what they offer us in terms of how we might interact with them. In the ecological view, nature and nurture are integrally related.

6.2 The Infant

- Methods of studying infant perception include habituation, evoked potentials, preferential looking, and operant conditioning techniques.
- The visual system is fairly well developed at birth. Infants younger than 2 months old discriminate brightness and colors and are attracted to contour, moderate complexity, and movement. Starting at 2 or 3 months, infants more clearly perceive

whole patterns such as faces and seem to understand a good deal about objects and their properties, guided by intuitive theories of the physical world.

- Spatial perception develops rapidly, and by about 7 months, after they begin to crawl, infants not only perceive drop-offs but also show fear or concern about them.
- The auditory sense is well developed at birth. Young infants can recognize their mother’s voice and distinguish speech sounds that adults cannot discriminate.
- The senses of taste and smell are also well developed at birth. In addition, newborns are sensitive to touch, temperature, and pain.
- The early presence of sensory and perceptual abilities suggests that they are innate, but they are also clearly influenced by early experiences. Certain experiences may be necessary for normal visual perception to develop, suggesting a sensitive period for the visual system.
- Infants actively seek out stimulation by exploring their environments, which typically provides them with the stimulation they need to develop normal sensory and perceptual skills.

6.3 The Child

- Sensory skills undergo little change during childhood, although children learn better how to use the information coming in through their senses.

- Coupling perception with action to develop locomotion skills—the ability to navigate one’s body around the environment—is a major accomplishment of childhood made understandable by the dynamic systems theory.
- Cross-modal perception, the ability to recognize through one sense what was learned by a different sense, originates in infancy but becomes more fully developed in childhood.
- Learning to control attention is an important part of perceptual development during childhood. Infants and young children are selectively attentive to the world around them, but they have not fully taken charge of their attentional processes.
- With age, children become more able to concentrate on a task for a long period, to focus on relevant information and ignore distractions, and to use their senses in purposeful and systematic ways to achieve goals.

6.4 The Adolescent

- Basic perceptual and attentional skills are perfected during adolescence. Adolescents are better than children at sustaining their attention and using it selectively and strategically to solve the problem at hand.
- Teens often multitask, which can lead to less efficient learning of new information.
- Exposure to loud noise can cause tinnitus or ringing sounds in the ear that can be temporary or permanent. Damage to the auditory system from exposure to loud noise can accumulate over time, leading eventually to hearing impairment.

- The chemical senses operate at adult levels and may contribute to mate selection.

6.5 The Adult

- During adulthood, sensory and perceptual capacities gradually decline in most individuals, although many changes are minor and can be compensated for. Sensory thresholds—the amount of stimulation required for detection—rise, and perceptual processing of sensory information often declines. Moderate to severe declines that are not corrected can lead to declines in activities and quality of life among older adults.
- Visual changes include cataracts (clouding of the lens), reduced ability of the pupil to change in response to changes in light, thickening of the lens leading to decreased acuity (presbyopia), and retinal changes such as age-related macular degeneration.
- Presbycusis—changes in hearing associated with aging—affects many older adults and most commonly leads to trouble detecting high-pitched sounds. Older adults have more difficulty with speech perception, especially under noisy conditions, than younger adults. Hearing aids can significantly improve older adults’ abilities to detect sounds.
- Many older people have difficulty recognizing or enjoying foods, largely because of declines in the sense of smell and memory; touch, temperature, and pain sensitivity also decrease slightly, but intense pain stimuli still hurt.

“Consider what would happen if children of various ages were given a horseshoe-shaped metal magnet for the first time. Six-month-olds might accommodate to the unfamiliar metallic taste, the peculiar (horseshoe) shape, and the sound of the magnet being dropped. . . . Three-year-olds, if given an assortment of objects, might accommodate to the fact that some of the objects cling to the magnet and might entertain explanations such as ‘stickiness’ and ‘wanting to stay together’. Nine-year-old children might construct the concept that only metal objects are pulled to the magnet and might notice the conditions in which this occurs—through glass, water, and certain distances. Only adolescents could accommodate by formulating an abstract theory of magnetism and simultaneously consider all of the variables involved, such as the size and shape of the magnet and the distance from the object” (Miller, 2016, pp. 59–60).

In this example, four children—an infant, a 3-year-old, a 9-year-old, and an adolescent—interact with the same object, a magnet, but their interactions are influenced by their current level of development and lead to very different understandings. The infant is competent at getting objects into her mouth and so goes the magnet. The 3-year-old is probably amused by how some objects stick to the magnet without having any clue why this occurs. The 9-year-old may do some trial-and-error testing to see which objects stick to the magnet, and from this develops a fairly logical understanding of magnetism. The adolescent may generate hypotheses about magnetism, systematically test these hypotheses, and create an abstract understanding of the properties of magnetism.

At least this is how Piaget’s prominent theory of cognitive development would interpret the situation.

According to Piaget’s theory, by actively exploring the physical world and seeing how their actions bring about changes, children like these two construct cognitive structures that help them organize and understand their world.

Henglein & Steets/Cultura/Jupiter Images

Psychology was significantly altered by Piaget’s curiosity and desire to figure out what children were thinking and why their responses changed with age. The theory dominated the field for many decades and generated a tremendous amount of useful research. Some findings emerging from this research support Piaget’s general description of the development of **cognition**—the activity of knowing and the processes through which knowledge is acquired and problems are solved. Other findings, though, have led to the emergence of alternative theories. Perhaps the most influential of these is Lev Vygotsky’s sociocultural perspective on cognitive development. After gaining an understanding of these two theories, we consider a contemporary theory that incorporates some ideas from both Piaget and Vygotsky before turning our attention to changes in cognitive development across the life span.

Piaget’s Constructivist Approach

LEARNING OBJECTIVES

- Describe the processes of developmental change in Piaget’s theory and give an example of each process.
- Discuss the strengths of Piaget’s theory, noting features that remain fairly well supported by the research in this field.
- Explain the challenges to Piaget’s theory that have emerged as scientists have conducted research to test hypotheses generated from the theory.

In their book on theories of development, John Flavell and his colleagues (2001, p. 8) captured the tremendous influence of Jean Piaget with this summation: “[T]heories of cognitive development can be divided into B.P. (Before Piaget), and A.P. (After Piaget).” Our understanding of cognitive development has been forever altered by the theory that emerged from Piaget’s careful observations of children. As a young man, Piaget was working at the Alfred Binet laboratories in Paris on the first standardized IQ test. In constructing the IQ test, Binet was interested in estimating an individual’s intelligence based on the number of questions they correctly answered. Piaget, though, soon became intrigued by children’s *wrong* answers and noticed that children of about the same age gave the same kinds of wrong answers. By questioning them to find out how they were thinking about the problems presented to them, he began to realize that young children do not simply know less than older children; instead, they think differently.

The flexible question-and-answer technique that Piaget used to discover how children think about problems has become

known as the **clinical method**. Consider the following exchange between Piaget and 6-year-old Van (Piaget, 1926, p. 293):

Piaget: Why is it dark at night?

Van: Because we sleep better, and so that it shall be dark in the rooms.

Piaget: Where does the darkness come from?

Van: Because the sky becomes grey.

Piaget: What makes the sky become grey?

Van: The clouds become dark.

Piaget: How is that?

Van: God makes the clouds become dark.

In the clinical method, the initial question may be consistent across children, but subsequent questions to children would vary. Many contemporary researchers consider this method imprecise because it does not involve asking standardized questions of all children tested. But Piaget (1926) believed that the investigator should have the flexibility to pursue an individual child’s line of reasoning to fully understand that child’s mind. Using his

naturalistic observations of his own children and the clinical method to explore how children understand everything from the rules of games to the concepts of space and time, Piaget formulated his view of the development of intelligence.

What Is Intelligence?

Piaget's definition of intelligence reflects his background in biology: *Intelligence is a basic life function that helps an organism adapt to its environment.* You can see adaptation when you watch a toddler attempting to get chunks of food from plate to mouth, a school-age child figuring out how to divide treats among friends, or an adolescent trying to set up a new computer. The newborn enters an unfamiliar world with few means of adapting to it other than working senses and reflexes. But Piaget viewed infants as active agents in their own development, learning about the world of people and things by observing, investigating, and experimenting.

As infants and children explore their world, their brains respond by creating schemes (sometimes called *schema* in the singular and *schemata* in the plural). **Schemes** are cognitive structures—organized patterns of action or thought that people construct to interpret their experiences (Piaget, 1952, 1977). Schemes are like having a set of rules or procedures that can be repeated and generalized across various situations (Miller, 2016). For example, the infant's grasping actions and sucking responses are early behavioral schemes, patterns of action used to adapt to different objects. During their second year, children develop symbolic schemes, or concepts. They use internal mental symbols such as images and words to represent objects and events, such as when a young child sees a funny dance and carries away a mental model of how it was done (Miller, 2016). Older children become able to manipulate symbols in their heads to help them solve problems, such as when they add two numbers together mentally rather than on paper or with the aid of their fingers.

Using Piaget's clinical method, this interviewer might present a simple problem to solve or ask a question and see where the child's answer leads their conversation.

Masterfile

As children develop more sophisticated schemes, or cognitive structures, they become increasingly able to adapt to their environments. Because they gain new schemes as they develop, children of different ages will respond differently to the same objects and events. The infant may get to know a juice box mainly as something to chew, the preschooler may decide to let the juice box symbolize or represent a cell phone and put it to her ear, and the school-age child may read the writing on the box.

How Does Intelligence Develop?

Recall from Chapter 2 that Piaget took an interactionist position on the nature–nurture issue: Children actively create knowledge by building schemes from their experiences (nurture), using two inborn (nature) intellectual functions, which he called organization and adaptation. These processes operate throughout the life span. Through **organization**, children systematically combine existing schemes into new and more complex ones. Thus, their minds are not cluttered with an endless number of independent facts; they contain instead logically ordered and interrelated actions and ideas. For example, the infant who gazes, reaches, and grasps will organize these simple schemes into the complex structure of visually directed reaching. Complex cognitive structures in older children grow out of reorganizations of simpler structures.

Adaptation is the process of adjusting to the demands of environment (Piaget, 1971). It occurs through two complementary processes, assimilation and accommodation. Imagine that you are a 2-year-old, that the world is still new, and that you see your first skunk in the backyard. What will you make of it? You likely will try to relate it to something familiar. **Assimilation** is the process by which we interpret new experiences in terms of existing schemes or cognitive structures. Thus, if you already have a scheme that mentally represents your knowledge of cats, you may label this new beast “kitty.” Through assimilation, we deal with our environment in our own terms, sometimes bending the world to squeeze it into our existing categories. Throughout the life span, we rely on our existing cognitive structures to understand new events.

But if you notice that this new “kitty” moves differently than most cats and that it has a bushier tail, a pointier nose and an awful odor, you may be prompted to change your understanding of the world of four-legged animals. **Accommodation** is the process of modifying existing schemes to better fit new experiences. Perhaps you will need to invent a new name for this animal or ask what it is and revise your concept of four-legged animals accordingly.

If we always assimilated new experiences, our understandings would never advance. Piaget believed that all new experiences are greeted with a mix of assimilation and accommodation. Once we have schemes, we apply them to make sense of the world, but we also encounter puzzles that force us to modify our understandings through accommodation. According to Piaget, when new events seriously challenge old schemes, or prove our existing understandings to be inadequate, we experience cognitive conflict. This cognitive conflict, or disequilibrium, then stimulates cognitive growth and the formation of more adequate understandings (Piaget, 1985; ■ **Figure 7.1**). This occurs because mental conflict is not pleasant; we are motivated to reduce conflict through what Piaget called **equilibration**, the process of achieving mental stability where our

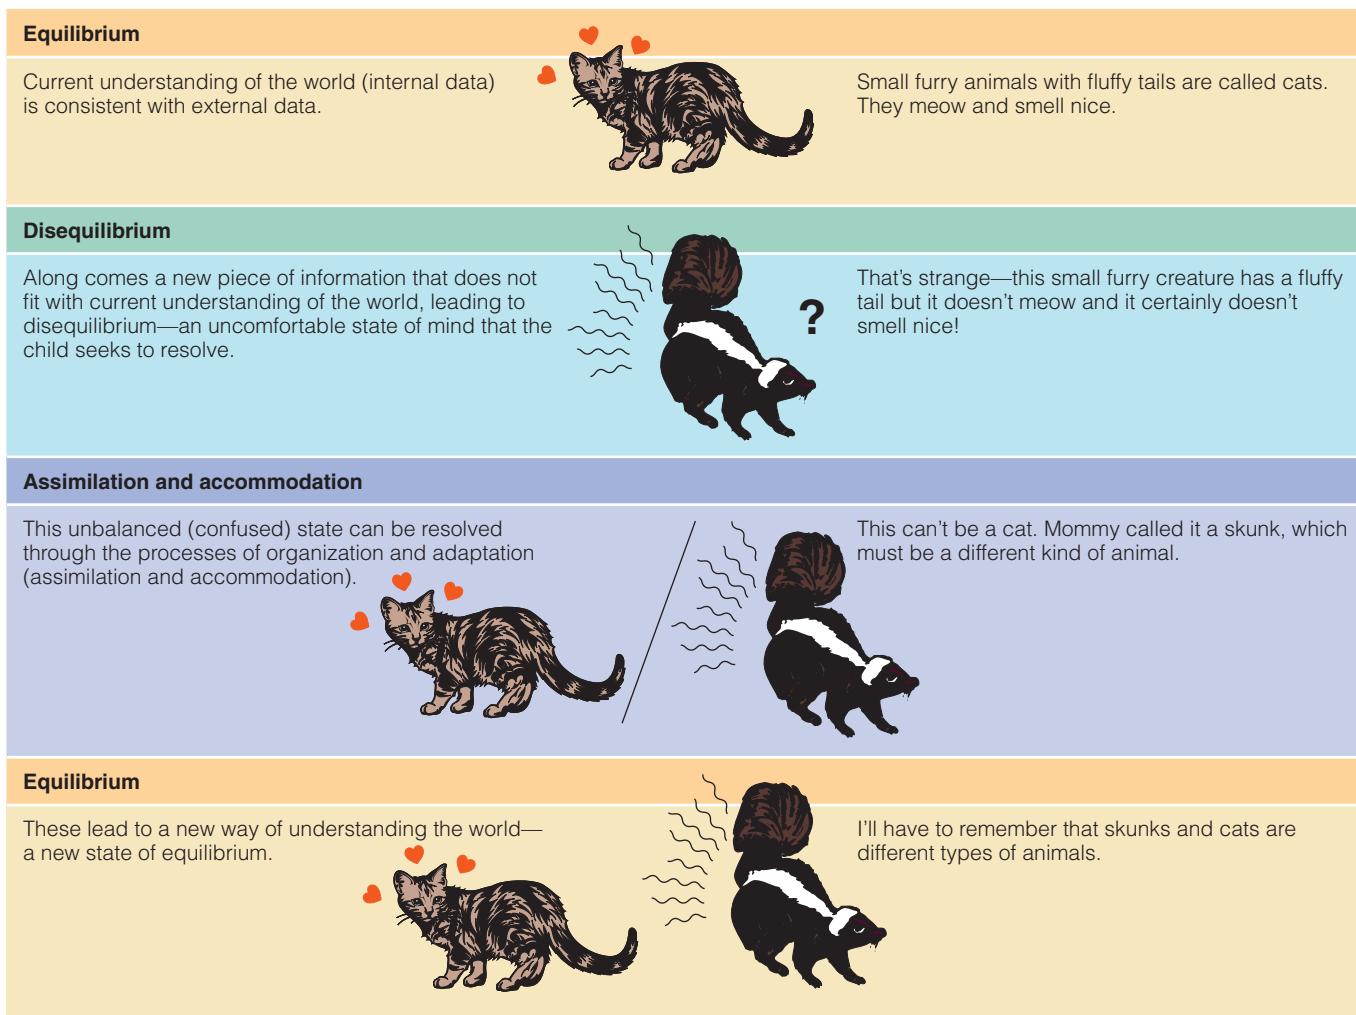

Figure 7.1 Process of change in Jean Piaget's theory

internal thoughts are consistent with the evidence we are receiving from the external world (Piaget, 1978).

Intelligence, then, in Piaget's view, develops through the interaction of the individual with the environment. Nature provides the complementary processes of assimilation and accommodation that make adaptation to environments possible. The processes of adaptation and organization are driven by an innate tendency to maintain equilibration. As a result of the interaction of biological maturation and experience, humans progress through four distinct stages of cognitive development:

1. The sensorimotor stage (birth to roughly 2 years)
2. The preoperational stage (roughly 2–7 years)
3. The concrete operations stage (roughly 7–11 years)
4. The formal operations stage (roughly 11 years and beyond)

These stages represent qualitatively different ways of thinking and occur in an invariant sequence—that is, in the same order in all children. However, depending on their experiences, children may progress through the stages at different rates, with some moving more rapidly or more slowly than others. Thus, the age ranges associated with the stages are only guidelines. A child's stage of development is determined by his reasoning processes, not his age. We'll describe each of the stages more fully as we move through this chapter.

Piaget's Contributions

Piaget is a giant in the field of human development. As one scholar quoted by Harry Beilin (1992) put it, “[A]ssessing the impact of Piaget on developmental psychology is like assessing the impact of Shakespeare on English literature or Aristotle on philosophy—impossible” (p. 191). It is hard to imagine that researchers would know even a fraction of what they know about intellectual development without Piaget's groundbreaking work.

One sign of a good theory is that it stimulates research. Piaget asked fundamentally important questions about how humans come to know the world and showed that we can answer them “by paying attention to the small details of the daily lives of our children” (Gopnik, 1996, p. 225). His cognitive developmental perspective has been applied to almost every aspect of human development, and the important questions he raised continue to guide the study of cognitive development. Thus, his theory has undoubtedly stimulated much research in the decades following its creation.

We can credit Piaget with some lasting insights, including ones that have become so deeply entrenched in our way of thinking as to be taken for granted (Flavell, 1996). For example, Piaget showed us that infants and children are active in their own development—that from the start they seek to master problems

Piaget's theory makes the claim that this toddler and his teenage cousin think differently. They have different cognitive structures for guiding their actions and interpreting the world around them.

Septemberlegs/Alamy Stock Photo

and to understand the incomprehensible by using the processes of assimilation and accommodation to resolve their cognitive disequilibrium. And as you will see as you proceed through this chapter, Piaget taught us that young people think differently than older people do—and often in ways we never would have suspected.

In addition, many scholars today agree that Piaget was largely right in his basic *description* of cognitive development. The sequence he proposed—sensorimotor to preoperational to concrete operations to formal operations—seems to describe the general course and content of intellectual development for children and adolescents from the many cultures and subcultures that have been studied (Miller, 2016). Although cultural factors influence the rate of cognitive growth, the direction of development is always from sensorimotor thinking to preoperational thinking to concrete operations to, for many, formal operations (or even postformal operations).

Challenges to Piaget

Partly because Piaget's theory has been so enormously influential, it has had more than its share of criticism: Some of this has been mild—suggesting the need for minor tweaking of the theory—whereas other criticism has been more severe. John Broughton (1984), for example, concluded that Piaget's theory is fundamentally flawed and should be thrown out. We are not ready to throw out what has been a blockbuster theory, but we need to point out four common criticisms (see Lourenco & Machado, 1996; Miller, 2016):

1. **Underestimating young minds.** Piaget seems to have underestimated the cognitive abilities of infants and young children, although he emphasized that he was more interested in understanding the sequences of changes than the specific ages at which they occur (Lourenco & Machado, 1996). When researchers use more familiar problems than Piaget's and simplify the tasks to their essentials, hidden competencies

of young children—and of adolescents and adults—are sometimes revealed. What should we make of these earlier competencies when task demands are reduced? It may be that Piaget failed to distinguish between *competence* and *performance*. There is an important difference between understanding a concept (competence) and passing a test designed to measure it (performance). Piaget may have been too quick to assume that children who failed one of his tests lacked competence; they may only have failed to demonstrate their competence in a particular situation. Perhaps more importantly, Piaget may have overemphasized the idea that knowledge is an all-or-nothing concept (Schwitzgebel, 1999). Instead of having or not having a particular competence, children probably gain competence gradually and experience long periods between not understanding and understanding. Indeed, many of the seemingly contradictory results of studies using Piagetian tasks can be accounted for with this idea of gradual change in understanding (Miller, 2016).

2. **Wrongly claiming that broad stages of development exist.** According to Piaget, each new stage of cognitive development is a coherent mode of thinking applied across a range of problems. Piaget emphasized the consistency of thinking *within* a stage and the difference *between* stages. Yet individuals are often inconsistent in their performance on different tasks that presumably measure the abilities defining a given stage. This may occur because cognitive development is domain specific—that is, it is a matter of building skills in particular content areas—and growth in one domain may proceed much faster than growth in another (Fischer, Kenny, & Pipp, 1990). In addition, the transitions between stages are not swift and abrupt, as most of Piaget's writings suggest, but are often lengthy (over several years) and subtle. It is not always clear when a child has made the shift from one set of cognitive structures to a more advanced set of structures. Thus, research findings have cast serious doubts on the idea that stages can adequately describe development (Barrouillet, 2015).
3. **Failing to adequately explain development.** Many critics have noted that Piaget did a better job of describing development than of explaining how it comes about (Bruner, 1997; Miller, 2016). To be sure, Piaget wrote extensively about his interactionist position on the nature–nurture issue and did as much as any developmental theorist to tackle the question of how development comes about. Presumably, humans are always assimilating new experiences in ways that their level of maturation allows, accommodating their thinking to those experiences, and reorganizing their cognitive structures into increasingly complex modes of thought. Yet this explanation is vague. Researchers need to know far more about how specific maturational changes in the brain and specific kinds of experiences contribute to important cognitive advances. A good theory needs to be able to explain and predict the course of cognitive development, something that Piaget's theory struggles to accomplish.
4. **Giving limited attention to social influences on cognitive development.** Some critics say Piaget paid too little attention to how children's minds develop through their social interactions with more competent individuals and how they develop

differently in different cultures (Karpov, 2005). Piaget's child often resembles an isolated scientist exploring the world alone, but children develop their minds through interactions with parents, teachers, peers, and siblings. True, Piaget had interesting ideas about the role of *peers* in helping children adopt other perspectives and reach new conclusions (see Chapter 13 on moral development). But he did not believe that children learned much from their interactions with *adults*. This may seem counterintuitive, but Piaget believed that children see other children, but not adults, as “like themselves.” Hearing a different perspective from someone like oneself can trigger internal conflict, but hearing a perspective from someone different from oneself may not be viewed as a challenge to one's current way of thinking because the person—and their views—are simply too different. Thus, in Piaget's model, no notable cognitive disequilibrium, and therefore little cognitive growth, occurs from children interacting with adults. As you will see shortly, the significance of social interaction and culture for cognitive development is the basis of the perspective on cognitive development offered by one of Piaget's early critics, Lev Vygotsky.

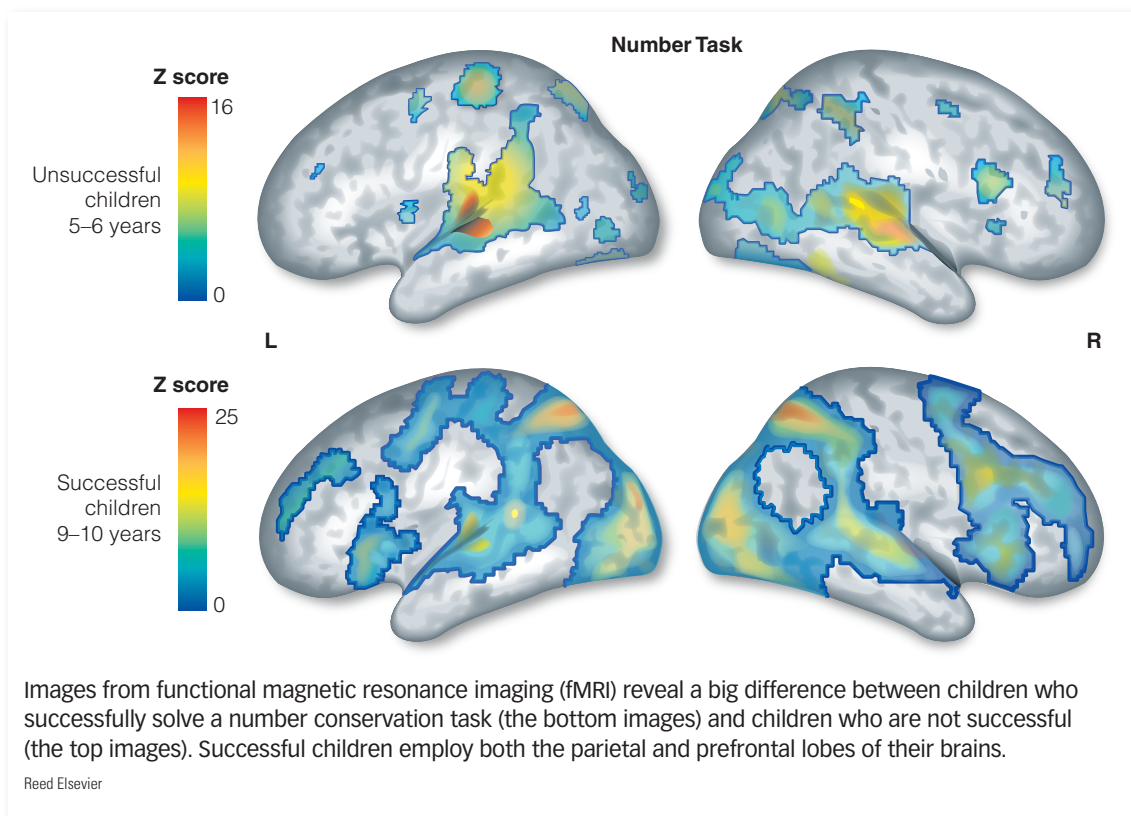

A Modern Take on Constructivism

By now, you should know that Piaget adopted a position called *constructivism*, maintaining that children actively create or build their own understandings of the world based on their experiences. Some scholars have attempted to be more precise on the specific mechanisms of *how* development occurs, that is, just how do children construct knowledge? One promising approach to this issue comes from work by Denis Mareschal, Gert Westermann, and Annette Karmiloff-Smith (see, for example, Karmiloff-Smith, 2006, 2009, 2015; Mareschal, 2011; Mareschal et al., 2007; Westermann, Thomas, & Karmiloff-Smith, 2010). They propose a model of cognitive development that builds on this central tenet of Piaget's theory, namely, that we construct increasingly complex mental representations of the world.

According to the **neuroconstructivism theory**, new knowledge is constructed through changes in the neural structures of the brain in response to experiences (Westermann et al., 2010). Piaget had a

background in biology and certainly believed that biological factors played a role in cognitive development. Consider, though, that Piaget developed his theory in an era devoid of modern tests for measuring electrical activity and blood flow in the brain, before precise **reaction time** and eye tracking measures, and before genetic analyses could be performed. Thus, theories such as neuroconstructivism are not necessarily an indication that Piaget was incorrect. Instead, they are taking our understanding of cognitive development to a level not possible when Piaget developed his theory. Where Piaget noted that cognitive structures become more sophisticated and others have argued that mental representations become more complex, the neuroconstructivists believe that the neural structures in the brain underlying these cognitive phenomena develop and change in response to experience. As Annette Karmiloff-Smith (2009) states, “human intelligence is a process [that emerges from] dynamic multidirectional interactions between genes, brain, cognition, behavior, and environment” (p. 61). Development of cognition is not static but reflects a complex and ongoing interplay of factors that change across the life span and across different contexts. The manner in which an environmental factor interacts with genetic factors to influence an aspect of cognition may be quite different at different periods of the life span (Karmiloff-Smith, 2006).

Consider some research by Olivier Houdé and colleagues (2011). Children aged 5 to 10 years were given a classic Piagetian cognitive task in which they need to compare two rows of objects and determine whether the rows contain the same number of objects. As they were solving the task, researchers used functional magnetic resonance imaging (fMRI) to monitor brain activity. Children who successfully solved the task showed increased activity in parts of their brains that were not activated in children

who did not solve the task. Both groups of children, solvers and nonsolvers, showed activity in a part of the brain associated with processing numbers; thus both groups understood the task to be about numbers. Obviously, though, this is not enough for success on the task. Those who were successful also showed activity in an area of their prefrontal lobes associated with working memory control. Thus, the neuroconstructivist theory attempts to modernize Piaget by connecting the patterns of thought he described with patterns of neural activity.

We leave this section by concluding that, although there have been challenges to Piaget's theory, it continues to offer a useful framework for any discussion of cognitive development. Throughout this chapter, we describe advances in cognitive development using research from Piaget and other like-minded scholars in the field. First, though, we consider another influential theorist, Lev Vygotsky, who drew our attention to the role of culture in cognition.

7.2

Vygotsky's Sociocultural Perspective

LEARNING OBJECTIVES

- Indicate how culture and social interaction affect thought in Vygotsky's theory.
- Explain how tools, especially language, influence thought.

Lev Vygotsky was born in 1896, the same year as Piaget, and was an active scholar in the 1920s and 1930s when Piaget was formulating his theory. For many years, Vygotsky's work was banned for political reasons in his homeland, the former Soviet Union, and North American scholars lacked English translations of his work, which limited consideration of Vygotsky's ideas until recent decades. In addition, Vygotsky died of tuberculosis at age 38, before his theory was fully developed. However, his main theme is clear: Cognitive growth occurs in a sociocultural context and evolves out of the child's social interactions.

Culture and Thought

Culture and society play a pivotal role in Vygotsky's theory. Indeed, intelligence in the Vygotskian model is held by the group, not the individual, and is closely tied to the language system and other tools of thinking the group has developed over time (Case, 1998). Culture and social experiences affect how we think, not just what we think.

Consider some research by Vygotsky's colleague, Alexander Luria (1974/1976), who tested groups of 9- to 12-year-old children growing up in different social environments. Children were given target words and asked to name the first thing that came to mind when they heard each word. Luria found that children growing up in a remote rural village with limited social experiences gave remarkably similar responses, whereas children growing up in a large city gave more distinctly individual answers. Vygotsky and Luria believed that this difference reflected the city children's broader exposure to various aspects of culture. On their own, the

Checking Mastery

1. What is a scheme in Piaget's theory?
2. How do assimilation and accommodation operate to bring about cognitive change?
3. What are two of Piaget's major contributions to our understanding of cognitive development?
4. What are three problems with, or challenges to, Piaget's theory of cognitive development?

Making Connections

1. How might Piaget's theory be updated to accommodate some of the major criticisms and research findings that have emerged since he constructed his theory?
2. Using your own experiences, provide an example of how the inborn processes of organization and adaptation operate.

rural children were unable to develop certain types of knowledge. Knowledge, then, depends on social experiences.

Vygotsky would not be surprised to learn that adolescent formal-operational thought is rarely used in some cultures; he expected cognitive development to vary from society to society depending on the mental tools, such as the language, that the

According to Lev Vygotsky's theory, cognitive development is shaped by the culture in which children live and the kinds of problem-solving strategies that adults and other knowledgeable guides pass on to them.

PETE MULLER/National Geographic Creative

culture values and makes available. How do children acquire their society's mental tools? They acquire them by interacting with parents and other more experienced members of the culture and by adopting their language and knowledge (Callaghan & Corbit, 2015).

Social Interaction and Thought

Consider this scenario: Annie, a 4-year-old, receives a jigsaw puzzle, her first, for her birthday. She attempts to work the puzzle but gets nowhere until her father sits down beside her and gives her some tips. He suggests that it would be a good idea to put the corners together first. He points to the pink area at the edge of one corner piece and says, "Let's look for another pink piece." When Annie seems frustrated, he places two interlocking pieces near each other so that she will notice them. And when she succeeds, he offers words of encouragement. As Annie gets the hang of it, he steps back and lets her work more independently. Vygotsky said that this kind of social interaction fosters cognitive growth.

How? First, Annie and her father are operating in what Vygotsky called the **zone of proximal development**—the gap between what a learner can accomplish independently and what she can accomplish with the guidance and encouragement of a more-skilled partner. Skills within the zone are ripe for development and are the skills at which instruction should be aimed. Skills outside the zone are either well mastered already or still too difficult. In this example, Annie obviously becomes a more competent puzzle-solver with her father's help than without it. More importantly, she will internalize the problem-solving techniques that she discovered in collaboration with her father, working together in her zone of proximal development, and will use them on her own, rising to a new level of independent mastery. What began as a social process involving two people becomes a cognitive process within one.

Support for Vygotsky's idea of the zone of proximal development comes from various sources, including research showing that pairing less-skilled readers with more-skilled ones substantially increases reading fluency when the less-skilled readers are provided with a model of good reading and encouragement (Nes, 2003). Other support for Vygotsky's zone comes from applied research conducted by a group of 7th and 8th grade science teachers (Hui & Mohd Salleh, 2015). The teachers first determined their students' scientific understanding by assessing their abilities to identify patterns in data and use of scientific concepts to explain these patterns. After understanding what students could do on their own, the teachers provided "bite-sized" instruction to introduce students to the knowledge and skills they would need to move forward in their scientific thinking. The teachers found that they sometimes needed to make adjustments in their lessons to keep students "in the zone" so that the concepts were not too difficult but remained within reach of students' abilities. After the instruction, students were again asked to explain scientific principles and they critiqued one another's explanations (i.e., did peer review). This careful approach led to improvement in students' scientific reasoning, supporting Vygotsky's concept of the zone of proximal development.

By working with a more knowledgeable partner, this child is able to accomplish more than would be possible on her own. According to Lev Vygotsky, the difference between what a child can accomplish alone and with a partner is the zone of proximal development.

Brand X Pictures/Getty Images

In many cultures, children do not go to school with other children to learn from teachers, nor do their parents explicitly teach tasks such as weaving and hunting. Instead, they learn through **guided participation**—by actively participating in culturally relevant activities with the aid and support of their parents and other knowledgeable guides (Rogoff, 1998). Jerome Bruner (1983) had a similar concept in mind when he wrote of the many ways in which parents provide **scaffolding** for their children's development; that is, the more-skilled person gives structured help to a less-skilled learner but gradually reduces the help as the less-skilled learner becomes more competent. By calling attention to guided participation processes, in the zone of proximal development, Vygotsky was rejecting Piaget's view of children as independent explorers in favor of the view that they learn more sophisticated cognitive strategies through their interactions with more mature thinkers. To Piaget, the child's level of cognitive development determines what he can learn; to Vygotsky, learning in collaboration with more knowledgeable companions drives cognitive development.

Tools of Thought

Vygotsky believed that mental activity, like physical activity, is mediated by tools (Daniels, 2011). If a child wants to start a garden, we wouldn't send her outside empty handed and say, "Go ahead and make a garden." We would, instead, equip her with an array of tools—shovel, rake, gloves, fertilizer, seeds, and so on—that have already been proven useful for accomplishing this task. Further, we would probably show her how to best use these tools to accomplish the desired task. We might show the child how to poke holes in the soil and drop seeds inside, watch while the child attempted this, and perhaps correct her if she pushed the seeds in too deep. As the child practices and masters the use of the tools

presented by the adult, the child adopts the tools as her own. The same process is involved in passing along cultural tools for mental activity.

In Vygotsky's view, adults use a variety of tools to pass culturally valued modes of thinking and problem solving to their children. Spoken language is the most important tool, but writing, using numbers, and applying problem-solving and memory strategies also convey information and enable thinking (Vygotsky, 1978). The type of tool used to perform a task influences performance on the task. Consider a study by Dorothy Faulkner and her colleagues (2000) with

9- and 10-year-old children. Children worked in pairs on a science project, originally developed by Inhelder and Piaget (1964), in which they needed to figure out which chemicals to combine to make a colored liquid. Some pairs worked with the actual physical materials and others used a computer simulation of the task. The children who worked with the computerized version talked more, tested more possible chemical combinations, and completed the task more quickly than children who worked with the physical materials. The computer, then, was a tool that changed the nature of the problem-solving activity and influenced performance, as Vygotsky would have predicted.

Look more closely at Vygotsky's notion of how tools—especially language—influence thought. Whereas Piaget maintained that cognitive development influences language development, Vygotsky argued that language shapes thought in important ways and that thought changes fundamentally once we begin to think in words (Bodrova & Leong, 1996). Piaget and Vygotsky both noticed that preschool children often talk to themselves as they go about their daily activities, almost as if they were play-by-play sports announcers. (“I’m putting the big piece in the corner. I need a pink one. Not that one—this one.”) Two preschool children playing next to each other sometimes carry on separate monologues rather than conversing. Piaget (1926) regarded such speech as egocentric—further evidence that preoperational thinkers cannot yet take the perspectives of other people (in this case, their conversation partners) and therefore have not mastered the art of social speech. He did not believe that egocentric speech played a useful role in cognitive development.

In contrast, Vygotsky called preschool children's recitations **private speech**—speech to oneself that guides one's thought and behavior. Rather than viewing it as a sign of cognitive immaturity, he saw it as a critical step in the development of mature thought and as the forerunner of the silent thinking-in-words that adults engage in every day. Adults guide children's behavior with speech, a tool that children adopt and initially use externally, just as adults did with them. Gradually, this regulatory speech is internalized.

Talking to oneself or a stuffed animal may help youngsters work through problems and advance their cognitive development.

Susan Northcutt/Alamy Stock Photo

Studies conducted by Vygotsky and other researchers support his claim. For example, in one set of studies, Vygotsky (1934/1962) measured children's private speech first as they worked unhindered on a task, then as they worked to overcome an obstacle placed in their path. Their use of private speech increased dramatically when they confronted an interruption of their work—a problem to solve.

Katherine Nelson (2015), who has studied language and its relationship with thought for over 40 years, concurs with Vygotsky when it comes to private speech. In an extensive examination of a toddler's “crib speech,” Nelson concluded that this talking out loud to oneself is a way to externally examine and process what is in one's head. Thus, at least some private speech is the external representation of thought and may help young

children solve complex problems. Children tend to use more private speech when faced with a new task and use less private speech as the task becomes familiar (Duncan & Pratt, 1997). Even adults sometimes think aloud when they are stumped by a problem (Duncan & Cheyne, 2002).

Both the amount of private speech as well as the nature of what is said are related to performance (Chiu & Alexander, 2000). In particular, children who use private speech to talk themselves through a problem (“No, I need to change this. Try it over here. Yes, that's good.”) show greater motivation toward mastery; that is, they are more likely to persist on a task even without adult prodding (Chiu & Alexander, 2000). Thus, private speech not only helps children think their way through challenging problems but also allows them to incorporate into their own thinking the problem-solving strategies they learned during their collaborations with adults. Notice that, as in guided participation, what is at first a social process becomes an individual psychological process. In other words, social speech (for example, the conversation between Annie and her father as they jointly worked a puzzle) gives rise to private speech (Annie talking aloud, much as her father talked to her, as she then tries to work the puzzle on her own), which in turn goes “underground” to become first mutterings and lip movements and then inner speech (Annie's silent verbal thought).

Evaluation of Vygotsky

Although many scholars find Vygotsky's ideas a refreshing addition to Piaget's, some concerns should be noted. Vygotsky died young (age 38), leaving us with many intriguing ideas but without a complete theory of cognitive development. It is, of course, impossible to know how the theory might have evolved had Vygotsky continued to work on it for as long as Piaget worked

on his theory. Whereas Piaget has been criticized for placing too much emphasis on the individual and not enough on the social environment, Vygotsky has been criticized for doing the opposite: placing too much emphasis on social interaction (Feldman & Fowler, 1997). Vygotsky seemed to assume that all knowledge and understanding of the world is transmitted through social interaction. But at least some understanding is individually constructed, as Piaget proposed. Vygotsky and Piaget are often presented as opposites on a continuum representing the extent

to which cognitive development derives from social experience. However, a careful reading of the two theorists reveals that they are not as dissimilar as they are often presented to be (Lourenço, 2012). Both Piaget and Vygotsky acknowledge the importance of the social context of development. Still, there are differences in their emphasis. • **Table 7.1** summarizes some of the differences between Vygotsky's sociocultural perspective and Piaget's cognitive developmental view. **Application 7.1** explains their views on improving cognitive functioning.

● APPLICATION 7.1

Improving Cognitive Functioning

What do the theories of Piaget and Vygotsky have to contribute to the goal of optimizing cognition? Let's start with Piaget. Studies suggest that it is possible to teach many Piagetian concepts to children who are younger than the age at which the concepts would naturally emerge. For instance, 4-year-olds can be trained to recognize the identity of a substance such as a ball of clay before and after its appearance is altered in Piaget's famous conservation task—that is, to understand that although the clay looks different, it is still the same clay and has to be the same amount of clay (Field, 1981). Nearly 75% of the children given this identity training could solve at least three of five conservation problems 2–5 months after training. Despite these sorts of successes, no one has demonstrated that 2-year-olds can be taught formal operations! But at least these studies demonstrate that specific training experiences can somewhat speed a child's progress through Piaget's stages or bring out more advanced capacities in an adult performing at a less advanced level.

In truth, Piaget disapproved of attempts by Americans to speed children's progress through his stages (Piaget, 1970). He believed parents should provide young children with opportunities to explore their world and teachers should use a discovery approach in the classroom that allows children to learn by doing. Given their natural curiosity and normal opportunities to try their hand at solving problems, children would construct ever more complex understandings on their own. Many educators have incorporated Piaget's ideas about discovery-based education into their lesson

plans, especially in science classes. Teachers have also taken seriously Piaget's notion that children understand material best if they can assimilate it into their existing understandings. Finding out what the learner already knows or can do and providing instruction matched to the child's level of development are in the spirit of Piaget.

What would Vygotsky recommend to teachers who want to stimulate cognitive growth? As you might guess, Vygotsky's theoretical orientation leads to a different approach to education than Piaget's does—a more social one. Whereas students in Piaget's classroom would most likely be engaged in independent exploration, students in Vygotsky's classroom would be involved in guided participation, with teachers and more knowledgeable peers providing just enough assistance to allow them to solve a new problem (Wass & Golding, 2014). The roles of teachers and other more skillful collaborators would be to organize the learning activity, break it into steps, provide hints and suggestions carefully tailored to the student's abilities, and gradually turn over more of the mental work to the student. According to Vygotsky's sociocultural perspective, the guidance provided by a skilled partner will then be internalized by the learner, first as private speech and eventually as silent inner speech. Education ends up being a matter of providing children with tools of the mind important in their culture, whether hunting strategies or computer skills (Berk & Winsler, 1995; Bodrova & Leong, 1996).

Is there evidence that one of these theoretical approaches might be superior to the

other? Consider some research that had 3- to 5-year-old children help a puppet with a sorting task in which they had to decide which furnishings (sofas, beds, bathtubs, stoves, and so on) should be placed in each of six rooms of a dollhouse that the puppet was moving into (Freund, 1990). First the children were tested to determine what they already knew about proper furniture placement. Then each child worked at a similar task, either alone (as might be the case in Piaget's discovery-based education, although here children were provided with corrective feedback by the experimenter) or with his or her mother (Vygotsky's guided learning). Finally, to assess what they had learned, children performed a final, rather complex furniture-sorting task. The results were clear: Children who had sorted furniture with help from their mothers showed dramatic improvements in sorting ability, whereas those who had practiced on their own showed little improvement. Moreover, the children who gained the most from guided participation with their mothers were those whose mothers talked the most about how to tackle the task. So children do not always learn the most when they function as solitary scientists, as Piaget's theory would predict. Instead, consistent with Vygotsky's theory, conceptual growth is more likely to occur when children interact with other people—particularly with competent people who provide an optimal amount of guidance. Perhaps the ideal scenario would be to provide the best of both worlds: opportunities to explore on their own and supportive companions to offer help when needed.

● **Table 7.1** A Comparison of Vygotsky and Piaget

Vygotsky's Sociocultural View	Piaget's Cognitive Developmental View
Processes of animal and human development are fundamentally different.	Processes of animal and human development are fundamentally the same.
Cognitive development is different in different social and historical contexts.	Cognitive development is mostly the same universally.
Appropriate unit of analysis is the social, cultural, and historical context in which the individual develops.	Appropriate unit of analysis is the individual.
Cognitive growth results from social interactions (guided participation in the zone of proximal development).	Cognitive growth results from the child's independent explorations of the world.
Children and their partners co-construct knowledge.	Children construct knowledge on their own.
Social processes become individual psychological ones (e.g., social speech becomes inner speech).	Individual, egocentric processes become more social (e.g., egocentric speech becomes social speech).
Adults are especially important because they know the culture's tools of thinking.	Peers are especially important because the cognitive conflict triggered by different perspectives of other children is not so overwhelming that it cannot be resolved.
Learning precedes development (tools learned with adult help become internalized).	Development precedes learning (children cannot master certain things until they have the requisite cognitive structures).
Training can help mediate development.	Training is largely ineffective in "speeding up" development.

● Checking Mastery

1. What theme is stressed in Vygotsky's theory that is largely missing in Piaget's theory?
2. What is the zone of proximal development? Provide an example of this concept.

● Making Connections

1. Create descriptions of a Piagetian preschool and a Vygotskian preschool. What are the main differences in how children will be assessed, what they will be taught, and how they will be taught?
2. Piaget and Vygotsky differed in their views of the importance of the individual versus society. Compare their positions on individual versus society in terms of cognitive development.

7.3

Fischer's Dynamic Skill Framework

LEARNING OBJECTIVES

- Describe Fischer's perspective on context and performance.
- Explain what changes or develops in Fischer's dynamic skill framework.
- Compare Fischer's model of cognitive development to Piaget's theory.
- Indicate where Fischer's concepts of developmental change are similar to Vygotsky's concepts.

Kurt Fischer has devoted his professional career to developing, testing, and revising a dynamic skill framework for understanding cognitive development (1980; Fischer & Bidell, 2006; Fischer & Pipp, 1984). According to this perspective, "it is not possible to analyze behavior outside the context in which it occurs. Behavior is not something that a person 'has'; it emerges from interactions between person and context" (Rose & Fischer, 2011, p. 146). Consider the experience of studying for an exam and having your friend test your understanding with questions the day before the exam as you relax in a coffee shop. You answer the questions successfully and go into the exam feeling confident. But now, in the context of the exam room with the palpable stress in the room, you don't seem to "know" nearly as much as you did the day before.

Or perhaps you can relate to the example of the basketball player who can make shots all day long when practicing in the gym, but then "chokes" and misses the hoop in the context of a game. In contrast, maybe you perform well under pressure and need the increased stress that comes with a testing or game situation to really focus and demonstrate your best performance. Fischer believes that such differences in performance across different contexts are perfectly normal. Indeed, when someone consistently performs at the same level over and over, we often say "he's like a machine." Such consistency across different contexts seems more typical of a machine than of a human. Unlike machines, human performance is **dynamic**, that is, it changes in response to changes in context.

Comparison to Piaget and Vygotsky

Fischer’s dynamic system view is different from Piaget’s view that the cognitive structures underlying each stage are inherent in the person. Piaget, and much of the research sprouting from Piaget’s theory, tested children in rather artificial settings with carefully constructed tasks that may not be typical of tasks encountered in everyday life. Fischer and others, including Bronfenbrenner whom we discussed in Chapter 2, firmly believe that developmental psychologists need to put development back into its natural context and not study it in isolation.

Another difference between Piaget and Fischer is their view of *what* develops. According to Piaget, cognitive structures develop, whereas Fischer proposes that skill levels change and develop. A **skill** is a person’s ability to perform on a particular task in a specific context (Fischer & Bidell, 2006). Someone who wins spelling bee contests is demonstrating skill to perform this task—spelling words—in the context of a competition. This person may or may not exhibit skill on a related task, such as defining words based on how they are used in sentences. A surgeon who has a 99% success rate of repairing retinal tears on eyeballs has a skill for this type of surgical procedure in the context provided by this type of surgical arena. The same surgeon may not be the one you want to have repairing your damaged heart valve. Thus, a skill is both task-specific and context-specific.

Where Piaget proposed distinct stages in which thinking undergoes fairly dramatic qualitative—abrupt—change from one stage to the next, change in Fischer’s model may or may not seem “stage-like.” Under conditions with little support, children’s development may appear to be gradual and linear as they slowly work themselves through the levels of acquiring a skill. But under

According to the dynamic skill framework, skills depend on both the task and the context. This boy may be able to perform this task in this context with his grandfather but not in a different context.

Blend Images—Kidstock/Getty Images

conditions of high support, change may occur swiftly and more closely resemble stages, as children master several levels within a short period of time.

Drawing directly from Vygotsky, Fischer uses the concept of *zone of proximal development* to explain how cognition advances from one level to another. The “zone” represents the opportunity for growth that exists between a person’s optimal ability and their actual performance on a given task in a particular context, that is, their current skill level. With research and further refinement of dynamic skill theory, Fischer and others have adopted the term **developmental range** to better capture their findings that people’s abilities vary with context. With a supportive context, people can perform at an optimal level of skill. Most of the time, though, we perform below our optimal level because the support structure needed to perform optimally is not in place (Rose & Fischer, 1998). Thus, high levels of support can lead to larger jumps in skill acquisition, whereas low levels of support can result in slow linear acquisition of skills.

In sum, the dynamic skill theory that has taken shape over the past 40 years uses some ideas from Piaget and Vygotsky and proposes new concepts to account for the variability observed in actual performance. Piaget was interested in uncovering universal stages of cognitive development. Fischer and other dynamic theorists are especially interested in variability of performance as research has repeatedly shown that people demonstrate inconsistent skills. Once a person “has” a skill, why wouldn’t they always demonstrate optimal use of this skill? As we’ve seen, the dynamic skill theorists believe that skills do not exist in isolation from the task and the context. Seen from this perspective, many seemingly inconsistent performances begin to make much more sense.

We have now examined three major perspectives on cognitive development. In the following sections, we will look at specific aspects of cognitive development in infancy, childhood, adolescence, and adulthood, guided largely by Piaget’s theory. We will also see how Vygotsky’s and Fischer’s perspectives enrich our understanding of cognitive development.

● Checking Mastery

1. Define the terms “dynamic” and “skill” in context of the dynamic skill framework.
2. How is the dynamic skill framework similar to Vygotsky’s sociocultural theory?
3. In what ways is the dynamic skill framework different from Piaget’s theory of cognitive development?

● Making Connections

1. How might a classroom teacher use the concept of Fischer’s developmental range to optimize students’ performance?
2. If you are preparing a team for a competition, whether this is an athletic, academic, musical, or other type of competition, what features of the dynamic skill theory could you apply to your coaching to enhance your team’s performance?

7.4

The Infant

LEARNING OBJECTIVES

- Explain the importance of object permanence and describe the path from lack of object permanence to full understanding of object permanence.
- Note the major cognitive achievements emerging from the period of infancy.

What sort of cognitive activity is possible during infancy? One of the strengths of Piaget’s approach to cognitive development is that he provided a rich description of what he observed infants and young children *doing*. From these observations, he drew inferences about what infants were likely *thinking* and how their minds were working. Piaget proposed that the groundwork for cognitive development occurred during the first 2 years of life as infants learn about the world through their senses and their motoric actions (hence, the name *sensorimotor* for this first stage). The dominant cognitive structures of this stage are behavioral schemes—patterns of action that evolve as infants begin to coordinate sensory input (seeing an object) and motor responses (grasping an object). Because infants solve problems through their actions rather than with their minds, their mode of thought is qualitatively different from that of older children.

The six substages of the sensorimotor stage are outlined in

• **Table 7.2.** At the start of the sensorimotor period, infants may not seem highly intelligent, but they are already active explorers of the world around them. Researchers see increasing signs of intelligent behavior as infants pass through the substages, because they are gradually learning about the world and about cause and effect by observing the effects of their actions. They are transformed from reflexive creatures who adapt to their environment using their innate reflexes to reflective ones who can solve simple problems in their heads. The advances in problem-solving ability captured in the six substages of the sensorimotor period bring many important changes. We can illustrate the impressive advances in thinking across infancy by closely examining

the acquisition of one of Piaget’s most notable concepts—object permanence.

The Development of Object Permanence

According to Piaget, newborns lack an understanding of **object permanence** (also called *object concept*). This is the fundamental understanding that objects continue to exist—they are permanent—when they are no longer visible or otherwise detectable to the senses. It probably does not occur to you to wonder whether your shoes still exist after you place them in the closet and shut the door. But very young infants, because they rely so heavily on their senses, seem to operate as though objects exist only when they are perceived or acted on. According to Piaget and others, infants must construct the notion that reality exists apart from their experience of it.

Piaget believed that the concept of object permanence develops gradually over the sensorimotor period. Up through roughly 4–8 months, it is “out of sight, out of mind”; infants will not search for a toy if it is covered with a cloth or screen. By the end of the first year (substage 4), they master that trick but still rely on their perceptions and actions to “know” an object (Piaget, 1952). After his 10-month-old daughter, Jacqueline, had repeatedly retrieved a toy parrot from one hiding place, Piaget put it in a new spot while she watched him. Amazingly, she looked in the *original* hiding place. She seemed to assume that her behavior determined where the object would appear; she did not treat the object as if it existed apart from her actions or from its initial location. The surprising

• **Table 7.2** The Substages and Intellectual Accomplishments of the Sensorimotor Period

Substage	Description
1. Reflex activity (birth–1 month)	Active exercise and refinement of inborn reflexes (e.g., change sucking patterns to fit the shapes of different objects).
2. Primary circular reactions (1–4 months)	Repetition of interesting acts centered on the child’s own body (e.g., repeatedly suck a thumb, kick legs, or blow bubbles). These typically begin as random acts but are then repeated for pleasure.
3. Secondary circular reactions (4–8 months)	Repetition of interesting acts on objects (e.g., repeatedly shake a rattle to make an interesting noise or bat a mobile to make it wiggle). Thus, circular actions extend beyond one’s self (primary) to objects in the environment (secondary to self).
4. Coordination of secondary schemes (8–12 months)	Combination of actions to solve simple problems or achieve goals (e.g., push aside a barrier to grasp an object, using the scheme as a means to an end); first evidence of intentionality.
5. Tertiary circular reactions (12–18 months)	Experimentation to find new ways to solve problems or produce interesting outcomes (e.g., explore bathwater by gently patting it, then hitting it vigorously and watching the results; or stroke, pinch, squeeze, and pat a cat to see how it responds to varied actions).
6. Beginning of thought (18–24 months)	First evidence of insight; able to solve problems mentally and use symbols to stand for objects and actions; visualize how a stick could be used (e.g., move an out-of-reach toy closer).

tendency of 8- to 12-month-olds to search for an object in the place where they last found it (A) rather than in its new hiding place (B) is called the **A-not-B error**. The likelihood of infants making the A-not-B error increases with lengthier delays between hiding and searching and with the number of trials in which the object is found in spot A (Marcovitch & Zelazo, 1999).

As we suggested earlier in this chapter, task demands and physical limitations of infants may influence performance on tasks like the A-not-B task (Lew et al., 2007). This is one of those areas where simplifying the task leads to the conclusion that infants develop at least some understanding of object permanence far earlier than Piaget claimed. For example, Renee Baillargeon and her colleagues have used a method of testing for object concept that does not require reaching for a hidden object, only looking toward where it should be. In one study, infants as young as 2½ months seemed surprised (as demonstrated by looking longer) when a toy that had disappeared behind one screen (left side of **Figure 7.2**) reappeared from behind a second screen (right side of **Figure 7.2**) *without* appearing in the open space between the two screens (Aguiar & Baillargeon, 1999).

At this young age, however, understanding of hidden objects is still limited. Consider the scenario shown in **Figure 7.3**. In the high-window condition, a toy is hidden as it moves along a track behind a block that has a window located at its top. There is nothing odd about this condition. In the low-window condition, a toy *should* be visible as it moves along a track behind a block that has a window located at its bottom, but it is not. To someone who understands the properties of object permanence, this should strike them as odd. At 2½ months, infants do not show signs that they detect a difference between objects moving along a track under the high-window and low-window conditions. But just 2 weeks later, 3-month-olds look longer at the low-window event compared with the high-window event, as if surprised (Aguiar & Baillargeon, 2002). Thus, by 3 months, infants have gained an understanding that objects should be visible when nothing is obstructing them (see also Bremner, Slater, & Johnson, 2015).

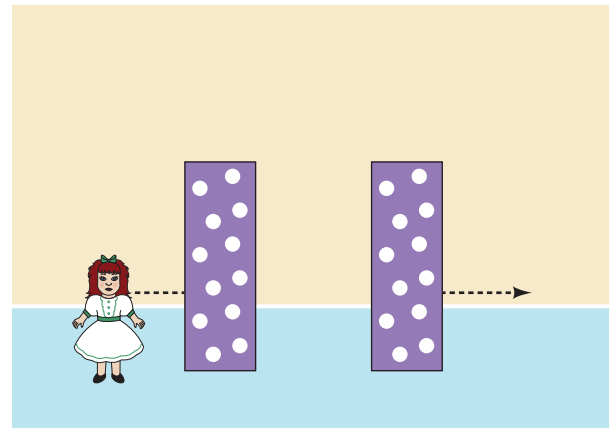

Figure 7.2 Test stimuli used by Aguiar and Baillargeon (1999, 2002). The doll moves behind the screen on the left and reappears on the right side of the second screen without appearing in the space between screens.

Source: From Aguiar, A. & Baillargeon, R. (2002). Developments in young infants' reasoning about occluded objects, *Cognitive Psychology*, 45, pp. 267–336, Figure 1. Reprinted by permission of Elsevier.

In general, then, it seems that babies sometimes know a good deal more about object permanence than they reveal through their actions when they are given the kinds of search tasks originally devised by Piaget (Baillargeon, 2002). This illustrates Fischer's notion that skill depends on the task demands and the context. When tested using the task demands specified by Piaget, infants demonstrate less skill. But changing the task demands, by peeling away some of the complexity and providing a supportive context, gives infants the opportunity to demonstrate optimal skill levels (Fischer & Bidell, 1991). In addition to characteristics of the task, characteristics of the infant can influence performance. For instance, researchers at the Uppsala Child and Baby Lab in Sweden have found that infants' activity levels affected their performance on object permanence tasks (Johansson, Forssman, & Bohlin, 2014). Those with lower activity levels performed better, perhaps because their lower activity allowed for greater focus on the cognitive task.

To be fair to Piaget, we should note that he contended that looking behaviors were developmental precursors to the reaching behaviors that he assessed. He did not believe, however, that looking represented complete understanding of object permanence. An analysis of infants' looking behaviors by Carolyn Rovee-Collier (2001) suggests that Piaget was wise to distinguish between infants' looking and reaching. In some situations, looking may developmentally precede reaching for an object, as Piaget suggested. In other situations, however, infants' looking behavior does not predict their subsequent action on an object. Regardless of the specific measure used by researchers, infants gradually become more skilled at acting on their knowledge by searching in the right spot.

By 12–18 months of age (substage 5), the infant has overcome the A-not-B error but may continue to have trouble with invisible displacements—as when you hide a toy in your hand, move your hand under a pillow, and then remove your hand, leaving the toy under the pillow. The infant will search where the object was last seen, seeming confused when it is not in your hand and failing to look under the pillow, where it was deposited. Finally, by the end of the second year (18–24 months), the infant is capable of

Until an infant masters the concept of object permanence, objects that are outside of his visual sight are “out of mind.”

mentally representing such invisible moves and conceiving of the object in its final location. According to Piaget, the concept of object permanence is fully mastered at this point.

The Emergence of Symbols

Perhaps the most important cognitive achievement of infancy is the emergence of the **symbolic capacity**—the ability to use images, words, or gestures to represent or stand for objects and experiences. This allows infants and young children to manipulate ideas mentally, not just motorically, opening the door to more sophisticated thinking based on manipulating ideas in their heads. Consider how the emergence of symbolic capacity changes the quality of infants' play activities. During the first month, young infants react reflexively to internal and external stimulation. In the primary circular reactions substage (1–4 months), they are more interested in their own bodies than in manipulating toys. Moving their tongues or fingers around is entertainment enough at this age. Piaget named this substage **primary circular reactions** because he observed infants repeating (hence, the term *circular*) actions relating to their own bodies (that is, primarily to themselves) that had initially happened by chance. Piaget reports the example of his son, Laurent, at just over 1 month accidentally getting his thumb in his mouth. It falls out. This happens again on another day. Indeed, since the first accidental occurrence, Piaget observes it happening over and over again. Increasingly, a finger or thumb successfully makes it into the mouth, which pleases Laurent. He seeks opportunities to repeat this pleasant action involving his body (alas, Laurent was not to be a thumb-sucker for very long—by 2 or 3 months of age, Piaget had bandaged his son's hands to bring this pleasing activity to an end).

By the third substage of secondary circular reactions (4–8 months), infants derive pleasure from repeatedly performing an action on an object, such as sucking or banging a toy. Now the repetitive actions are called **secondary circular reactions** because they involve something in the infant's external environment (that is, secondary to the self). In the fourth substage (8–12 months), called **coordination of secondary schemes**, infants combine (that is,

coordinate) secondary actions to achieve simple goals such as when they *push* an obstacle out of the way in order to *grasp* a desired object.

Later, when they reach the substage of **tertiary circular reactions** (12–18 months), infants experiment in varied ways with toys, exploring them thoroughly and learning all about their properties. In this stage, a true sense of curiosity and interest in novel actions appears. Now it is interesting to the infant to repeat an action with variations, such as the infant who experiments with all the many ways that oatmeal can land on the floor and walls when launched from a highchair in different directions and at different velocities.

With the final substage, the beginning of thought (about 18 months), Piaget believed symbolic capacity became firmly established, allowing one object to be used to represent another. For example, a cooking pot becomes a hat or a shoe becomes a telephone—simple forms of pretend play. It is also in this stage, according to Piaget, that infants can imitate models no longer present, because they can now create and later recall mental representations of what they have seen. Perhaps most importantly, with symbolic capacity, infants and toddlers understand that a word can be used to represent something else, such as an object, which leads to the language explosion associated with toddlerhood, which we will have more to say about in Chapter 10.

As noted earlier, one weakness of Piaget's theory is the underestimation of young children's abilities. Pedro Palacios and Cintia Rodríguez (2015) tracked the emergence of symbol use from 9 to 15 months of age. They found fairly robust use of symbols by 15 months of age, earlier than suggested by Piaget. Yet consistent with Piaget's description of how symbolic capacity unfolds across the substages of the sensorimotor period, Palacios and Rodríguez (2015) did find gradual emergence of symbol use. At 9 months of age, infants could follow an adult's symbolic use of objects. By 12 months of age, infants could make some simple symbolic substitutions, as long as the symbol and object it represented were similar (e.g., talking into a plastic toy phone, representing an actual phone). By 15 months of age, infants could produce larger symbolic substitutions, such as holding a banana to their face and "talking" to it as though holding a phone.

● Checking Mastery

1. Why does the name “sensorimotor” stage seem to capture the essence of Piaget’s first stage of development?
2. What must infants master or acquire in order to understand object permanence?

● Making Connections

1. Suppose an infant fails to develop an understanding of object permanence. How would this deficit influence his behavior and knowledge of the world?
2. Trace the emergence of a behavior, such as opening a cabinet door to get to a box of animal crackers, from the beginning to the end of Piaget’s sensorimotor period.

7.5

The Child

LEARNING OBJECTIVES

- Describe the typical preschool-age child’s pattern of thinking.
- Outline the characteristics of thought that enable (or inhibit) a child’s ability to solve conservation tasks.
- Compare the elementary school child’s thinking to that of a preschool child.

As with the period of infancy, our understanding of cognitive development during childhood has benefitted from Piaget’s detailed observations of how children solve problems and what aspects of problems challenge their thinking. Here, we discuss how the largely symbolic thinking of preschoolers progresses to the logical thinking of elementary school-aged children.

Preschoolers: Symbolic Thinking

The *symbolic capacity* that emerged at the end of the sensorimotor stage runs wild in the preschool years and is the greatest cognitive strength of the preschooler. Imagine the possibilities: The child can now use words to refer to things, people, and events that are not physically present. Instead of being trapped in the immediate present, the child can refer to past and future. Pretend or fantasy play flourishes at this age: Blocks can stand for houses, cardboard boxes for trains. Some children even invent **imaginary companions**, which can take many forms including humans and animals. Although parents may worry about such flights of fancy, they are normal; their inventors know their companions are not real. Having an imaginary companion may lead to advanced cognitive and social development, as well as higher

levels of creativity and imagery use (Gleason & Kalpidou, 2014). Young children with imaginary companions engage in more private speech than other children (Davis, Meins, & Fernyhough, 2013; 2014), perhaps because they have a “buddy” with them at all times. As noted earlier in this chapter, private speech may help children work through complex problems, which could be the link to the more advanced development sometimes seen among children with these companions.

From his studies of children, Piaget concluded that the young child’s mind is limited compared with that of an older child. Piaget called the preschool-age child’s thinking *preoperational*, that is, not yet having logical mental operations. Although less so than infants, preschoolers are highly influenced by their immediate perceptions. They often respond as if they have been captured by, or cannot go beyond, the most perceptually salient aspects of a situation. This focus on **perceptual salience**, or the most obvious features of an object or situation, means that preschoolers can be fooled by appearances. They have difficulty with tasks that require them to use logic to arrive at the right answer. Their “logic,” if we can indeed refer to it as logic at all, is based on their intuitions. We can best illustrate this reliance on perceptions and lack of logical thought by considering Piaget’s classic tests of conservation (also see **Exploration 7.1**)

At the start of the conservation-of-liquid task, children confirm that the two glasses contain equal amounts of liquid.

Marmaduke St. John/Alamy Stock Photo

As the child watches, liquid from one of the original containers is poured into a new container that is a different size.

Now for the test: Does the new glass contain more, less, or the same amount of liquid as the glass next to it?

● EXPLORATION 7.1

Can There Really Be a Santa Claus?

Many young children around the world believe in Santa Claus, St. Nicholas, the Tooth Fairy, or some other magical being. This occurs despite the fact that the existence of these fantasy figures violates numerous principles of logic. How can this be? We know that children whose parents endorse and promote Santa or another mythical being are more likely to believe than children whose parents do not (Shtulman & Yoo, 2015). After all, children normally trust their parents and accept their statements about Santa at face value. Children also tend to accept supporting evidence of Santa (for example, there are gifts under the tree) without questioning whether this evidence is conclusive proof of Santa's existence (Tullos & Woolley, 2009; Woolley & Cornelius, 2013).

At what point, and why, do their beliefs in these figures begin to waver? Research with 5- and 6-year-old children shows that they are already somewhat less confident about the existence of Santa and the Tooth Fairy than they are about two invisible but scientifically proven entities—germs and oxygen (Harris et al., 2006). According to Piaget's theory, children would begin to seriously question the existence of Santa Claus when they acquire concrete-operational thought. With their ability to reason logically, they may begin to ask questions such as, "How can Santa Claus get around to all those houses in one night?"

"How can one sleigh hold all those gifts?" "Why haven't I ever seen a reindeer fly?" and "How does Santa get into houses that don't have chimneys?"

What made sense to the preoperational child no longer adds up to the logical, concrete-operational thinker. With their focus on static endpoints, preschool-age children may not have a problem imagining presents for all the children in the world (or at least those on the "nice" list) sitting at the North Pole waiting to be delivered and then sitting under decorated trees Christmas morning. But once children understand transformations, they are confronted with the problem of how all those presents get from the North Pole to the individual houses in record time. The logical thinker notes that the gifts under the tree are wrapped in the same paper that Mom has in her closet. Indeed, researchers delving into the mystery of Santa Claus have found that disbelief in Santa

Juice Images/Alamy Stock Photo

increases with children's burgeoning logical reasoning abilities (Shtulman & Yoo, 2015).

As adults, we can resolve some of these inconsistencies for children to help perpetuate children's beliefs in Santa Claus. We can, for example, point out that Santa has many helpers and that reindeer native to the North Pole are unlike those ever seen in the wild or in a zoo. Some parents who want to continue the Santa myth get tough and simply tell their children that non-believers will not get any presents. So level of cognitive development as well as the surrounding culture play roles in whether or not children believe in Santa Claus and for how long.

Lack of Conservation

As we noted in Chapter 2, one of the many lessons about the physical world that children must master is the concept of **conservation**—the idea that certain properties of an object or substance do not change when its appearance is altered in some superficial way. Find a 4- or 5-year-old and try Piaget's conservation-of-liquid-quantity task. Pour equal amounts of water into two identical glasses, and get the child to agree that the two glasses have the same amount of water. Then, as the child watches, pour the water from one glass into a shorter, wider glass. Now ask whether the two containers—the tall, narrow glass and the shorter, broader one—have the same amount of water to drink or whether one has more (or less) water than the other one. Children younger than 6 or 7 will usually say that the taller glass has more water than the shorter one. They lack the understanding that the volume of liquid is conserved despite the change in the shape it takes in different containers.

How can young children be so easily fooled by their perceptions? According to Piaget, the preschooler is limited because they lack certain mental operations, outlined in ● Table 7.3. For starters, they are unable to engage in **decentration**—the ability to focus on two or more dimensions of a problem at once. Consider the conservation-of-liquid task: The child must focus on height and width simultaneously and recognize that the increased width of the short, broad container compensates for its lesser height. Preoperational thinkers engage in **centration**—the tendency to center attention on a single aspect of the problem. They focus on height alone and conclude that the taller glass has more liquid; or, alternatively, they focus on width and conclude that the short, wide glass has more. In this and other ways, preschoolers seem to have one-track minds.

A second contributor to success on conservation tasks is **reversibility**—the process of mentally undoing or reversing an action. Older children often display mastery of reversibility by suggesting that the water be poured back into its original container to prove that it is

● **Table 7.3** Comparison of Preoperational and Concrete-Operational Thinking

Preoperational Thinkers	Concrete-Operational Thinkers
Fail conservation tasks because they have: <ul style="list-style-type: none"> • <i>Irreversible thought</i>—cannot mentally undo an action • <i>Centration</i>—center on a single aspect of a problem rather than two or more dimensions at once • <i>Static thought</i>—fail to understand transformations or processes of change from one state to another 	Solve conservation tasks because they have: <ul style="list-style-type: none"> • <i>Reversibility of thought</i>—can mentally reverse or undo an action • <i>Decentration</i>—can focus on two or more dimensions of a problem at once • <i>Transformational thought</i>—can understand the process of change from one state to another
<i>Perceptual salience.</i> Understanding is driven by how things look rather than derived from logical reasoning.	<i>Logical reasoning.</i> Children acquire a set of internal operations that can be applied to a variety of problems.
<i>Transductive reasoning.</i> Children combine unrelated facts, often leading them to draw faulty cause–effect conclusions simply because two events occur close together in time or space.	<i>Inductive reasoning.</i> Children draw cause–effect conclusions logically, based on factual information presented to them.
<i>Egocentrism.</i> Children have difficulty seeing things from other perspectives and assume that what is in their mind is also what others are thinking.	<i>Less egocentrism.</i> Children understand that other people may have thoughts different from their own.
<i>Single classification.</i> Children classify objects by a single dimension at one time.	<i>Multiple classification.</i> Children can classify objects by multiple dimensions and can grasp class inclusion.

still the same amount. The young child shows irreversibility of thinking and may insist that the water would overflow the glass if it were poured back. Indeed, one young child tested by a college student shrieked, “Do it again!” as though pouring the water back without causing the glass to overflow were some unparalleled feat of magic.

Finally, preoperational thinkers fail to demonstrate conservation because of limitations in **transformational thought**—the ability to conceptualize transformations, or processes of change from one state to another, as when water is poured from one glass to another. Preoperational thinkers engage in **static thought**, or thought that is fixed on end states rather than the changes that transform one state into another, as when the water is sitting in the two glasses, not being poured or manipulated.

In Piagetian theory, then, preoperational children do not understand the concept of conservation because they engage in centration, irreversible thought, and static thought. The older child, in the stage of concrete operations, has mastered decentration, reversibility, and transformational thought. The correct answer to the conservation task is a matter of logic to the older child; there is no longer a need to rely on perception as a guide. Another interpretation, though, has been offered by the neuroconstructivists, who report that success on logic tasks such as conservation is supported by increased activity in parts of the frontal cortex associated with greater cognitive control that inhibits responding on the basis of perceptual salience (Houdé & Borst, 2014; Simon et al., 2015). Consistent with this interpretation, research shows that being able to think logically requires being able to both activate a correct strategy *and* resist (or inhibit) an incorrect one (Borst et al., 2012; 2013). Preschoolers can be helped to overlook a salient, yet

irrelevant, task feature if its irrelevance is pointed out to them before they are asked to solve the problem (Yu & Kushmir, 2016).

Egocentrism

Another characteristic of preschool-age children in Piaget’s theory is their tendency to view the world solely from their own perspective and to have difficulty recognizing other points of view, what Piaget termed **egocentrism**. ■ **Figure 7.4** illustrates the task Piaget used to assess children’s understanding of perspective. Piaget asked children to choose a drawing that shows what the display of three mountains

■ **Figure 7.4** Piaget’s “Three Mountains” task to evaluate egocentrism. When the child is seated on the left and a doll is “seated” on the right, can the child correctly identify how the scene looks from the doll’s perspective?

would look like from a particular vantage point. Young children often chose the view that corresponded to their own position (Piaget & Inhelder, 1956). But this is one of those areas where Piaget may have underestimated young children's minds.

By reducing tasks to the bare essentials, several researchers have demonstrated that preschool children are not as egocentric as Piaget claimed. In one study, 3-year-olds were shown a card with a dog on one side and a cat on the other (Flavell et al., 1981).

The card was held vertically between the child (who could see the dog) and the experimenter (who could see the cat). When children were asked what the experimenter could see, these 3-year-olds performed flawlessly.

Difficulty with Classification

The limitations of relying on perceptions and intuitions are also apparent when young children are asked to classify objects and think about classification systems. When 2- or 3-year-old children are asked to sort objects on the basis of similarities, they make interesting designs or change their sorting criteria from moment to moment. Older preoperational children can group objects systematically on the basis of shape, color, function, or some other dimension of similarity (Inhelder & Piaget, 1964). However, even children ages 4–7 have trouble thinking about relations between classes and subclasses or between wholes and parts (Siegler & Svetina, 2006). For instance, given a set of furry animals, most of which are dogs but some of which are cats, preoperational children do fine when they are asked whether all the animals are furry and whether there are more dogs than cats. That is, they can conceive of the whole class (furry animals) or of the two subclasses (dogs and cats). However, when the question is, “Which group would have more—the dogs or the animals?” many 5-year-olds say, “Dogs.” They cannot simultaneously relate the whole class to its parts; they lack the concept of **class inclusion**—the logical understanding that the parts are included within the whole. Notice that the child centers on the most striking perceptual feature of the problem—dogs are more numerous than cats—and is again fooled by appearances.

Once again, though, other researchers have found that preschool children seem to know more about classification systems than Piaget believed. Sandra Waxman and Thomas Hatch (1992) asked 3- and 4-year-olds to teach a puppet all the different names they could think of for certain animals, plants, articles of clothing, and pieces of furniture. The goal was to see whether children knew terms associated with familiar classification hierarchies—for example, if they knew that a rose is a type of flower and is a member of the larger category of plants. Children performed well, largely because a clever method of prompting responses was used. Depending on which term or terms the children forgot to mention (rose, flower, or plant), they were asked about the rose: “Is this a dandelion?” “Is this a tree?” “Is this an animal?” Often, children

Are there more dogs or more animals in this picture? Children who understand class inclusion would correctly answer that there are more animals than dogs.

Ermolaev Alexander/Shutterstock.com

came up with the correct terms in response (for example, “No, silly, [it’s not an animal] it’s a plant!”). Even though young children typically fail the tests of class inclusion that Piaget devised, then, they appear to have a fairly good grasp of familiar classification hierarchies.

Research such as this also raises an important question about individual differences in cognitive development. Aubrey Alvarez and Amy Booth (2016) have found variability in causal understanding among 3- to

4-year olds, and the observed variability among preschoolers is relatively consistent over time. That is, those youngsters with higher levels of causal understanding at age 3 tend to continue to demonstrate high levels of causal thinking. Interestingly, preschoolers’ understanding of causal information is related to how much their mothers talk to them about causal relations. This suggests that interactions with a knowledgeable adult can strengthen young children’s thinking, which you should now recognize as being consistent with Vygotsky’s theory.

Elementary-Aged Children: Logical Thinking

About the time children start elementary school, their minds undergo another transformation. According to Piaget, this transformation corresponds to the concrete-operational stage of development, extending from roughly 7 to 11 years of age. The concrete operations stage involves mastering the logical operations missing in the preoperational stage—becoming able to perform systematic mental actions on objects, such as adding and subtracting Halloween candies, classifying dinosaurs, or arranging objects from largest to smallest. This allows school-age children to think effectively about the objects and events they experience in everyday life. For every limitation of the preoperational child, there is a corresponding strength of the concrete-operational child. These contrasts are summarized in Table 7.3.

Conservation

Given the conservation-of-liquid task, the preoperational child centers on either the height or the width of the glasses, ignoring the other dimension. The concrete-operational child can decenter and juggle two dimensions at once. Reversibility allows the child to mentally reverse the pouring process and imagine the water in its original container. Transformational thought allows the child to better understand the process of change involved in pouring the water. Overall, armed with logical operations, the child now knows that there must be the same amount of water after it is poured into a different container; the child has logic, not just appearance, as a guide.

First-grade children who demonstrate success on Piaget’s conservation-of-liquid task are also more likely to demonstrate

success on math problems relative to their peers who do not correctly solve the conservation task (Wubbena, 2013). The logical operations that allow children to understand conservation also allow them to solve addition and subtraction problems, skills that are important to success in school.

Seriation and Transitivity

To appreciate the nature and power of logical operations, consider the child's ability to think about relative size. A preoperational child given a set of sticks of different lengths and asked to arrange them from biggest to smallest is likely to struggle, awkwardly comparing one pair of sticks at a time. Concrete-operational children are capable of the logical operation of **seriation**, which enables them to arrange items mentally along a quantifiable dimension such as length or weight. Thus, they perform this seriating task quickly and correctly.

Concrete-operational thinkers also master the related concept of **transitivity**, which describes the necessary relations among elements in a series. If, for example, John is taller than Mark, and Mark is taller than Sam, who is taller—John or Sam? It follows logically that John must be taller than Sam, and the concrete operator grasps the transitivity of these size relationships. Lacking the concept of transitivity, the preoperational child will need to rely on perceptions to answer the question; she may insist that John and Sam stand next to each other to determine who is taller. Preoperational children probably have a better understanding of such transitive relations than Piaget gave them credit for (Gelman, 1978; Trabasso, 1975), but they still have difficulty grasping the logical necessity of transitivity (Chapman & Lindenberger, 1988).

Other Advances

The school-age child overcomes much of the egocentrism of the preschool-age child, becoming increasingly better at recognizing other people's perspectives. Classification abilities improve as

the child comes to grasp the concept of class inclusion and can bear in mind that subclasses (brown beads and white beads) are included in a whole class (wooden beads). Mastery of mathematical operations improves the child's ability to solve arithmetic problems and results in an interest in measuring and counting things precisely (and sometimes in fury if companions do not keep accurate score in games). Overall, school-age children appear more logical than preschoolers because they possess a powerful arsenal of "actions in the head." In addition, the school-aged child can inhibit the earlier incorrect or inefficient strategies of the preoperational stage (Lubin et al., 2015).

But surely, if Piaget proposed a fourth stage of cognitive development, there must be some limitations to concrete operations. Indeed, there are. This mode of thought is applied to objects, situations, and events that are real or readily imaginable (thus the term *concrete operations*). As you will see in the next section, concrete operators have difficulty thinking about abstract ideas and unrealistic hypothetical propositions.

● Checking Mastery

1. Name three ways that preoperational thought is limited relative to concrete-operational thought.
2. What is the defining feature of concrete-operational thought?

● Making Connections

1. As a substitute teacher, you sometimes find yourself teaching young children who are mostly preoperational thinkers, while at other times you are teaching children who are concrete-operational thinkers. How would you adjust your lesson plan for a science class to best address these different levels of thought?

7.6

The Adolescent

LEARNING OBJECTIVES

- Explain how adolescent thinking differs from the child's typical pattern of thinking.
- Describe the sorts of tasks that adolescents might be able to solve with their newly emerged reasoning skills.
- Assess Piaget's description of the adolescent as a formal-operational thinker who systematically considers hypothetical and abstract concepts.

Although tremendous advances in cognition occur from infancy to the end of childhood, other transformations of the mind are in store for the adolescent. If teenagers become introspective, question their parents' authority, dream of perfect worlds, and contemplate their futures, cognitive development may help explain why.

Emergence of Abstract Thought

Piaget set the beginning of the formal operations stage of cognitive development around age 11 or 12 and possibly later. If concrete operations are mental actions on objects (tangible things and

events), formal operations are mental actions on ideas. Thus, the adolescent who acquires formal operations can mentally juggle and think logically about ideas, which cannot be seen, heard, tasted, smelled, or touched. In other words, formal-operational thought is more hypothetical and abstract than concrete-operational thought; it also involves adopting a more systematic and scientific approach to problem solving (Inhelder & Piaget, 1964).

Hypothetical and Abstract Thinking

If you could have a third eye and put it anywhere on your body, where would you put it, and why? That question was posed to

Tanya's response

John's response

■ **Figure 7.5** Where would you put a third eye? Tanya (age 9) did not show much inventiveness in drawing her “third eye.” But John (age 11) wanted a third eye in the palm of his hand: “I could see around corners and see what kind of cookie I'd get out of the cookie jar.” John shows early signs of formal-operational thought.

9-year-olds—likely to be in the concrete-operational stage—and to 11- to 12-year-olds—the age when the first signs of formal operations often appear (Piaget, 1970). In their drawings, all the 9-year-olds placed the third eye on their foreheads between their existing eyes; many thought the exercise was stupid (as reported in Shaffer & Kipp, 2014). The 11- and 12-year-olds were not as bound by the realities of eye location. They could invent ideas contrary to fact (for example, the idea of an eye in the palm of a hand) and think logically about the implications of such ideas (■ **Figure 7.5**). Thus, concrete operators deal with realities, whereas formal operators can deal with possibilities, including those that contradict known reality.

Formal-operational thought is also more abstract than concrete-operational thought. The school-age child may define the justice system in terms of police and judges; the adolescent may define it more abstractly as a branch of government

concerned with balancing the rights of different interests in society. Also, the school-age child may be able to think logically about concrete and factually true statements, as in this syllogism: If you drink poison, you will die. Fred drank poison. Therefore, Fred will die. The adolescent can do this but also engage in such if-then thinking about contrary-to-fact statements (“If you drink milk, you will die”) or symbols (If P, then Q. P, therefore Q).

Scientific Reasoning

Formal operations also permit systematic and scientific thinking about problems. One of Piaget’s famous tests for formal-operational thinking is the pendulum task (■ **Figure 7.6**). The child is given several weights that can be tied to a string to make a pendulum and is told that he may vary the length of the string, the amount of weight attached to it, and the height

■ **Figure 7.6** The pendulum problem.

from which the weight is released to find out which of these factors, alone or in combination, determines how quickly the pendulum makes its arc. How would you go about solving this problem?

The concrete operator is likely to jump right in without much advanced planning, using a trial-and-error approach. That is, the child may try a variety of things but fail to test different hypotheses systematically—for example, the hypothesis that the shorter the string is, the faster the pendulum swings, all other factors remaining constant. Concrete operators are therefore unlikely to solve the problem. They can draw proper conclusions from their observations—for example, from watching as someone else demonstrates what happens if a pendulum with a short string is released, compared with a pendulum with a long string.

What will the formal-operational individual do? In all likelihood, the teenager will first sit and think, planning an overall strategy for solving the problem. All the possible hypotheses should be generated; after all, the one overlooked may be the right one. Then it must be determined how each hypothesis can be tested. This is a matter of **hypothetical-deductive reasoning**, or reasoning from general ideas or rules to their specific implications. In the pendulum problem, it means starting with a hypothesis and tracing the specific implications of this idea in an if-then fashion: “If the length of the string matters, then I should see a difference when I compare a long string with a short string while holding other factors constant.” The trick in hypothesis testing is to vary each factor (for example, the length of the string) while holding all others constant (the weight, the height from which the weight is dropped, and so on). (It is, by the way, the length of the string that matters; the shorter the string, the faster the swing.)

In sum, formal-operational thought involves being able to think systematically about hypothetical ideas and abstract concepts. It also involves mastering the hypothetical-deductive approach that scientists use—forming many hypotheses and systematically testing them through an experimental method. Before continuing, take a few minutes to assess your understanding of Piaget’s stages of cognitive development with the questions in **Engagement 7.1**.

Progress Toward Mastery of Formal Operations

Are 11- and 12-year-olds really capable of all these sophisticated mental activities? Anyone who has had dealings with this age group will know that the answer to this question is usually not. Piaget (1970) described the transition from concrete operations to formal operations as taking place gradually over years. Many researchers have found it useful to distinguish between early and late formal operations. For example, 11- to 13-year-olds just entering the formal operations stage are able to consider simple hypothetical propositions such as the three-eye problem. But most are not yet able to devise an overall game plan for solving a problem or to systematically generate

Adolescents are more likely than children to benefit from some types of science instruction because formal-operational thought opens the door for reasoning about abstract and hypothetical material.

Jon Feingersh/Getty Images

and test hypotheses. On a battery of Piagetian tasks designed to evaluate scientific reasoning, 11- to 14-year-old girls correctly solved only 20–30% of the problems (Martorano, 1977). By ages 16–17 this had improved, but only to 50–60% correct. Even with training, 11- to 12-year-olds continue to struggle to systematically coordinate multiple variables, although they may do fine on single-variable tasks (Kuhn, Pease, & Wirkala, 2009). Throughout adolescence, responses to scientific reasoning tasks reflect biases indicating that students more readily accept evidence consistent with their preexisting beliefs than evidence inconsistent with these beliefs (Klaczynski & Gordon, 1996a, 1996b; Kuhn, 1993).

Consider the findings from the Munich Longitudinal Study on the Ontogenesis of Individual Competencies (LOGIC) study (see Schneider, 2014; Schneider & Bullock,

● ENGAGEMENT 7.1

How Well Do You Understand Piaget's Stages of Cognitive Development?

Choose the appropriate answer for each of the following questions. Answers are printed upside down at the bottom of this box.

1. Baby Joel seems to be fascinated with the dog's tail: He repeatedly kicks at it with his foot, which makes the dog wag his big tail. Joel finds this highly amusing. This suggests that Joel is in which sub-stage of the sensorimotor period?
 - a. Primary circular reactions
 - b. Secondary circular reactions
 - c. Coordination of secondary schemes
 - d. Tertiary circular reactions
2. Brian is playing with his infant daughter, Carrie, showing her a stuffed bear and then dropping it behind the sofa. Carrie seems interested in the toy when it is in front of her, but as soon as Brian drops it behind the sofa, she stops "playing" the game and looks at other things. This illustrates that Carrie:
 - a. Has not yet developed object permanence
 - b. Is not really interested in the toy
 - c. Is mentally trying to figure out where the toy has gone after it is dropped
 - d. Is still operating with secondary circular reactions but has not yet learned to combine them to solve the problem
3. Which of the following statements is TRUE regarding Piaget's first stage of cognitive development?
 - a. Piaget may have overestimated infants' abilities by allowing them multiple attempts to solve problems.
 - b. Infants progress through the substages in an individualized order that does not permit researchers to make any generalizations about developments of this stage.
 - c. Piaget underestimated infants' abilities because he placed many task demands on them in assessing their knowledge.
 - d. Piaget was right on the mark with his description of the ages when infants typically acquire symbolic logic.
4. Jeremy used to just bang his shoe on the coffee table, but now he has started to run it along the floor as if it were a car. Jeremy has acquired:
 - a. Decentration
 - b. Transformational thought
 - c. Symbolic capacity
 - d. Object permanence
5. Mira emphatically tells her older brother that "there *is* a Santa Claus because I see lots of gifts under the tree!" Mira's thinking reflects:
 - a. The "A-not-B error"
 - b. Conservation
 - c. Transformational thought
 - d. The influence of perceptual salience
6. When Mom presents the kids with some cookies, big brother Derek immediately grabs for the unbroken cookie, saying he doesn't want the broken one. Little sister Sal happily takes the cookie broken in half, saying, "Ha-ha! I got more than you!" Sal seems to lack an understanding of:
 - a. Egocentrism
 - b. Conservation
 - c. Class inclusion
 - d. Object permanence
7. Ramon understands that if A is bigger than B, and B is bigger than C, then A must also be bigger than C. This shows that he has mastered:
 - a. Transitivity
 - b. Conservation
 - c. Seriation
 - d. Reversibility of thought
8. Kira is furious that her father won't let her go out with a friend on a school night. She screams, "You have no idea what I'm feeling! You just want me to be miserable." Kira's response indicates that she:
 - a. Has not yet acquired conservation of thought
 - b. Is spoiled or has unreasonable parents
 - c. Shows centration of thought
 - d. Shows adolescent egocentrism
9. An important distinction between concrete-operational thought and preoperational thought is:
 - a. The acquisition of logical reasoning skills in the concrete stage
 - b. The acquisition of symbolic logic in the concrete stage
 - c. The acquisition of hypothetical thinking in the concrete stage
 - d. The use of deductive reasoning in the concrete stage
10. The defining difference between concrete-operational thought and formal-operational thought is:
 - a. The use of logical reasoning
 - b. The ability to reason about abstract and hypothetical problems
 - c. The ability to imagine performing before an audience
 - d. The ability to use relativistic thinking

Answers: 1.b 2.a 3.c 4.c 5.d 6.b 7.a 8.d 9.a 10.b

2009). LOGIC began in the 1980s with 200 school-aged children who were observed and tested on multiple dimensions over a 20-year period. One of the areas of study was scientific reasoning, and in particular, whether participants understood a

crucial component of scientific reasoning—control of variables. Did they understand that scientific testing requires identifying and holding constant all relevant variables while systematically testing the effects of varying the variable of interest?

Figure 7.7 Performance on control of variables strategy (CVS) use for recognition and production tasks (percent correct)

Source: From Bullock, M., Sodian, B., & Koerber, S. (2009). Doing experiments and understanding science: Development of scientific reasoning from childhood to adulthood. In Schneider, W. & Bullock, M. (Eds.) (2009). *Human development from early childhood to early adulthood: Findings from a 20-year longitudinal study*, pp. 173–197. Reprinted by permission of Taylor & Francis Group.

The LOGIC participants were given a group of experiments to evaluate; each experiment contained a design error, such as not keeping all variables but one constant or not having a comparison group for an intervention study. In addition to evaluating experimental designs, participants were also tested to determine if they could produce their own experiments.

As **Figure 7.7** shows, most participants, even those as young as 10, showed an understanding of this important principle of scientific thinking. However, there was a marked difference between their ability to recognize good scientific reasoning and their ability to produce it. For example, among 12-year-olds, more than 80% could recognize good and bad examples of experiments, but only 35% could create a good experiment themselves. By age 18, though, the ability to create a good experiment was catching up to the ability to recognize a good experiment (91% versus 85%). Thus, adolescents show an awareness of scientific reasoning (“I know it when I see it”), but they may not be able to produce logical scientific reasoning until they are older (and see Kail, 2013).

Piaget claimed that the perceptual reasoning of young children is *replaced* by scientific reasoning as children age, but it turns out that the two forms of reasoning—intuitive and scientific—*coexist* in older thinkers (Klaczynski, 2013). Being able to shift between intuitive and scientific reasoning provides flexibility in problem-solving situations as long as the thinker can effectively select the appropriate strategy. However, like children (and adults), adolescents often seem to adopt an intuitive strategy, perhaps because it is generally easier than applying scientific reasoning. In cases where the conclusion from the intuitive approach is clearly incorrect, adolescents more readily shift to using scientific judgment (Klaczynski, 2013). In addition, adolescents are increasingly able to **decontextualize**, or separate prior knowledge and beliefs from the demands of the task at hand (Kuhn &

Franklin, 2006; Stanovich, 2011). For example, someone who believes that males are better at math than females may find it difficult to accept new evidence that girls attain higher classroom math grades than boys if intuitions based on their prior experiences do not allow them to scientifically process the new information. Decontextualizing increases the likelihood of using reasoning to analyze a problem logically rather than relying on intuition or faulty existing knowledge.

There is some evidence that recent cohorts of teens (ages 13–15) are better able than earlier cohorts to solve formal-operational tasks. For example, 66% of teens tested in 1996 showed formal-operational thought on a probability test, whereas only 49% of teens tested in 1967 showed such skills (Flieller, 1999). Why might formal-operational skills improve over time? Changes in school curricula are the likely explanation. Notably, science curricula were revised in the 1960s and have increasingly incorporated more hands-on discovery learning activities, perhaps reflecting adoption of

Piaget’s concept of active learning. The achievement of formal-operational thinking depends on opportunities to learn scientific reasoning, as through exposure to math and science education (Babai & Levit-Dori, 2009; Karpov, 2005). The more hands-on the learning, the greater the benefit to performance on hands-on, formal-operational tasks.

Progress toward the mastery of formal operations is slow, at least as measured by Piaget’s scientific tasks. These findings have major implications for secondary-school teachers, who are often trying to teach abstract material to students who have a range of thinking patterns. Teachers may need to give concrete thinkers extra assistance by using specific examples and demonstrations to help clarify general principles.

Implications of Formal Thought

Formal-operational thought contributes to other changes in adolescence—some good, some not so good. First, the good news: As you will see in upcoming chapters, formal-operational thought may prepare the individual to gain a sense of identity, think in more complex ways about moral issues, and understand other people better. Advances in cognitive development help lay the groundwork for advances in many other areas of development, including the appreciation of humor.

Now, the bad news: Hypothetical thinking may also be related to some of the more painful aspects of the adolescent experience. Children tend to accept the world as it is and to heed the words of authority figures. The adolescent armed with hypothetical and scientific reasoning abilities can think more independently, imagine alternatives to present realities, and raise questions about everything from why parents set certain rules to why there is injustice in the world. Questioning can lead to confusion and sometimes to rebellion against ideas

A teenage girl may feel that everyone is as preoccupied with her appearance as she is, a form of adolescent egocentrism known as the imaginary audience phenomenon.

Image Source/Getty Images

that do not seem logical enough. Some adolescents become idealists, inventing perfect worlds and envisioning logical solutions to problems they detect in the imperfect world around them, sometimes losing sight of practical considerations and real barriers to social change. Just as infants flaunt the new schemes they develop, adolescents may go overboard with their new cognitive skills, irritate their parents, and become frustrated when the world does not respond to their flawless logic.

Many years ago, David Elkind (1967) proposed that formal-operational thought also leads to **adolescent egocentrism**—difficulty differentiating one’s own thoughts and feelings from those of other people. The young child’s egocentrism is rooted in ignorance that different people have different perspectives, but the adolescent’s reflects an enhanced ability to reflect about one’s

own and others’ thoughts. Elkind identified two types of adolescent egocentrism: the imaginary audience and the personal fable.

The **imaginary audience** phenomenon involves confusing your own thoughts with those of a hypothesized audience for your behavior. Thus, the teenage girl who ends up with pizza sauce on the front of her shirt at a party may feel extremely self-conscious: “They’re all thinking what a slob I am! I wish I could crawl into a hole.” She assumes that everyone in the room is as preoccupied with the blunder as she is. Or a teenage boy may spend hours in front of the mirror getting ready for a date, then may be so concerned with how he imagines his date is reacting to him that he hardly notices her: “Why did I say that? She looks bored. Did she notice my pimple?” (She, of course, is equally preoccupied with how she is playing to her audience. No wonder teenagers are often awkward and painfully aware of their every slip on first dates.)

The second form of adolescent egocentrism is the **personal fable**—a tendency to think that you and your thoughts and feelings are unique (Elkind, 1967). If the imaginary audience is a product of the inability to differentiate between self and other, the personal fable is a product of differentiating too much. Thus, the adolescent in love for the first time imagines that no one in the history of the human race has ever felt such heights of emotion. When the relationship breaks up, no one—least of all a parent—could possibly understand the crushing agony. The personal fable may also lead adolescents to feel that rules that apply to others do not apply to them. Thus, they will not be hurt if they speed down the highway without wearing a seat belt or drive under the influence of alcohol. And they will not become pregnant if they engage in sex without contraception, so they do not need to bother with contraception. As it turns out, high scores on measures of adolescent egocentrism are associated with behaving in risky ways (Greene et al., 1996; Holmbeck et al., 1994).

Although the idea of adolescent egocentrism has some intuitive appeal, as many parents can attest to having to put up with bouts of “it’s all about me” from their teens, there has not been a great deal of research support for Elkind’s idea of adolescent egocentrism. In particular, researchers have been unable to link the onset of the formal operations stage to the rise of adolescent egocentrism (Galanaki, 2012). Indeed, Evangelia Galanaki (2012) tested various aspects of adolescent egocentrism and found only that preoccupation with one’s self increased during the transition from adolescence to young adulthood. In other research, Joanna Bell and Rachel Bromnick (2003) suggest that adolescents are preoccupied with how they present themselves in public not because of an imaginary audience but because of a *real audience*. That is, the research indicates that adolescents are aware that there are real consequences to how they present themselves. Their popularity and peer approval, as well as their self-confidence and self-esteem, are often influenced by how others (the real audience) perceive them. Adults, too, are aware that their actions and appearance are often judged by others, but although these adult concerns are usually assumed to be realistic, similar concerns by adolescents are sometimes viewed, perhaps unfairly, as trivial (Bell & Bromnick, 2003).

● Checking Mastery

1. What change in thinking marks the shift from concrete to formal-operational thinking?
2. What is the hypothetical-deductive approach to problem solving?

● Making Connections

1. Consider one or more assignments or tests that you recently completed for one (or more) of your courses. Conduct an analysis to determine whether your responses reflect primarily a concrete or a formal level of thinking. If they were primarily concrete, was this appropriate to the task demands? What distinguished the assignments that elicited concrete-operational answers from those that elicited formal-operational answers?
2. Design an educational plan or program that you think would help foster formal-operational thought in students who have not yet mastered it.

7.7

The Adult

LEARNING OBJECTIVES

- Outline the characteristic features of adult cognition.
- Discuss ways that adult thought is the most advanced level of thinking and ways that adult thought is limited.
- Evaluate whether a stage beyond Piaget's formal operations is warranted and outline what this stage might look like.
- Describe changes to cognitive skills in later adulthood.

Do adults think differently than adolescents do? Does cognition change over the adult years? Until fairly recently, developmentalists have not asked such questions. Piaget indicated that the highest stage of cognitive development, formal operations, was fully mastered by most people between age 15 and age 18. Why bother studying cognitive development in adulthood? As it turns out, it has been worth the effort. Research has revealed limitations in adult performance that must be explained, and it suggests that at least some adults progress beyond formal operations to more advanced forms of thought (Jacobs & Klaczynski, 2002).

Limitations in Adult Cognitive Performance

If many high school students are shaky in their command of formal operations, do most of them gain fuller mastery after the high school years? Gains are indeed made between adolescence and adulthood (Blackburn & Papalia, 1992). However, only about half of all college students show firm and consistent mastery of formal operations on Piaget's scientific reasoning tasks (Neimark, 1975). Those college students who have attained formal-operational thought perform better, as evidenced by higher GPAs, than those who are still functioning at the concrete-operational level (Fowler & Watford, 2000). Similarly, sizable percentages of American adults do not solve scientific problems at the formal level, and there are some societies in which no adults solve formal-operational problems (Neimark, 1975).

Why do more adults not do well on Piagetian tasks? An average level of performance on standardized intelligence tests seems to be necessary for a person to achieve formal-operational thought (Inhelder, 1966). What seems more important than basic intelligence, however, is formal education (Neimark, 1979). In cultures in which virtually no one solves Piaget's problems, people do not receive advanced schooling. If achieving formal-operational thought requires education or specific experiences, Piaget's theory may be culturally biased, and his stages may not be as universal as he believed.

But neither lack of intelligence nor lack of formal education is a problem for most college students. Instead, they have difficulty with tests of formal operations when they lack expertise in a domain of knowledge. Piaget (1972) suggested that adults are likely to use formal operations in a field of expertise but to use concrete operations in less familiar areas. This is precisely what seems to happen. For example, Richard De Lisi and Joanne Staudt (1980) gave three kinds of formal-operational tasks—the pendulum problem, a political problem, and a literary criticism problem—to college students majoring in physics, political science, and English. As **Figure 7.8** illustrates, each group of students did well on the problem relevant to that group's field of expertise. On problems outside their fields, however, about half the students failed. Consistent with these results, other research shows that task relevancy affects performance on reasoning tasks (Sebby & Papini, 1994). Possibly, then, many adolescents and adults fail to use formal reasoning on Piaget's scientific problems simply because these problems are unfamiliar to them and they lack relevant expertise.

Figure 7.8 Expertise and formal operations. College students show the greatest command of formal-operational thought in the subject area most related to their major.

Source: De Lisi, R., & Staudt, J. (1980). Individual differences in college students' performance on formal operations tasks. *Journal of Applied Psychology*, 1, 163–174.

As noted earlier, Fischer maintains that each person has an optimal level of cognitive performance that will show itself in familiar and well-trained content domains (Fischer, 1980; Fischer, Kenny, & Pipp, 1990). However, performance is likely to be highly inconsistent across content areas unless the person has had a chance to build knowledge and skills in all these domains. More often, adults may use and strengthen formal modes of thinking only in their areas of expertise. By adopting a contextual perspective on cognitive development, you can appreciate that the individual's experience and the nature of the tasks she is asked to perform influence cognitive performance across the life span (Salthouse, 1990).

Growth Beyond Formal Operations?

While some researchers have been asking why adults sometimes perform so poorly on cognitive tasks, others have been asking why they sometimes perform so well. Take Piaget. Was his ability to generate a complex theory of development no more than the application of formal-operational thought? This seems unlikely and, indeed, Fernando Vidal (1994) uses Piaget's own writings as a teen and young man to show how his thinking shifted over time from largely formal operational to something beyond formal operations. Others have argued that formal operations involves applying logic to a *closed* set of ideas and not to the *open* sets of ideas that characterize most adult issues (Broughton, 1984; Ricco, 1990). To illustrate this concept, consider again the pendulum problem. A defined or closed set of variables is associated with this problem; solving the problem is possible by systematically applying logic to this closed set of variables. You do not need to go beyond the problem set. But how do adults make decisions about complex dilemmas and problems that have no well-defined set of

variables or that have variables that are constantly changing rather than static?

Several intriguing ideas have been proposed about stages of cognitive development that may lie beyond formal operations—that is, about **postformal thought**, or ways of thinking that are more complex than those of the formal-operational stage (see Commons & Richards, 2003; Commons & Ross, 2008; Gurba, 2005). How might thought be qualitatively different in adulthood than it is in adolescence? Several theorists have taken a shot at exploring postformal thinking, and here we consider two of the possibilities: relativistic thinking and dialectical thinking.

As noted earlier, adolescents who have attained formal operations sometimes get carried away with their new powers of logical thinking. They insist that there is a logically correct answer for every question—that if you simply apply logic, you will arrive at the right answer, at some absolute truth. In contrast, adults often think flexibly and recognize that there is not a single right or wrong answer; there are shades of gray to many problems and flexible or creative thinking may be required to successfully navigate many of the complex issues of the adult world. Thus, adults are more likely to engage in **relativistic thinking**, or understanding that knowledge depends on its context and the subjective perspective of the knower (Marchand, 2002; Sinnott, 1984, 1996). Whereas an absolutist assumes that truth lies in the nature of reality and that there is only one truth, a relativist assumes that his starting assumptions influence the “truth” discovered and that a problem can be viewed in multiple ways.

Consider this logic problem: “Subject A grows 1 cm per month. Subject B grows 2 cm per month. Who is taller?” (Yan & Arlin, 1995, p. 230). The absolutist might say, “Subject B,” based on the information given, but the relativist would be more likely to say, “It depends.” It depends on how tall A and B were to begin with and on how much time passes before their heights are measured. The relativistic thinker will recognize that the problem is ill defined and that further information is needed, and he will be able to think flexibly about what the answer would be if he made certain assumptions rather than others.

Or consider this problem, given to preadolescents, adolescents, and adults by Gisela Labouvie-Vief and her colleagues (1983, p. 5):

John is known to be a heavy drinker, especially when he goes to parties. Mary, John's wife, warns him that if he gets drunk one more time she will leave him and take the children. Tonight John is out late at an office party. John comes home drunk.

Does Mary leave John? Most preadolescents and many adolescents quickly and confidently said, “Yes.” They did not question the assumption that Mary would stand by her word; they simply applied logic to the information they were given. Adults were more likely to realize that different starting assumptions were possible and that the answer depended on which assumptions were chosen. One woman, for example, noted that if Mary had stayed with

John for years, she would be unlikely to leave him now. This same woman said, “There was no right or wrong answer. You could get logically to both answers” (p. 12). Postformal thinkers seem able to devise more than one logical solution to a problem (Sinnott, 1996).

In a fascinating study of cognitive growth over the college years, William Perry (1970) found that beginning college students often assumed that there were absolute, objective truths to be found by consulting their textbooks or their professors. They looked to what they believed were authoritative sources for *the* answer to a question, as if all problems have a single, correct answer. As their college careers progressed, they often became frustrated in their search for absolute truths. They saw that many questions seemed to have several answers, depending on the perspective of the respondent. Taking the extremely relativistic view that any opinion was as good as any other, several of these students said they were not sure how they could ever decide what to believe. Eventually, many understood that some opinions can be better supported than others; they were then able to commit themselves to specific positions, fully aware that they were choosing among relative perspectives.

Between adolescence and adulthood, then, many people start as absolutists, become relativists, and finally make commitments to positions despite their more sophisticated awareness of the nature and limits of knowledge (Sinnott, 1996). Not surprisingly, students at the absolute level of thinking use fewer thinking styles; they stick mainly with traditional or conventional modes of thinking (Zhang, 2002). Students who are relativistic thinkers use a greater variety of thinking styles, including ones that promote creativity and greater cognitive complexity (see Wu & Chiou, 2008). Some refer to this as “thinking outside the box,” or thinking unconventionally. Try the 9-dot problem in **Figure 7.9** to see if you can think outside the box. (You can find the answer online.)

Another possibility for advanced thought beyond formal operations is **dialectical thinking**, or detecting paradoxes and inconsistencies among ideas and trying to reconcile them (Basseches, 1984, 2005; Kramer, 1989; Riegel, 1973). For example, you engage in dialectical thinking when you recognize that the problem facing you is multifaceted and will be difficult to

solve; you “wrestle” with it mentally, considering the various possibilities and trying to reconcile the pieces that do not immediately make sense to you. You may solicit input from several trusted friends and then consider the pros and cons of each possible solution. Finally, you make a decision on the best way to address the problem, knowing that it is not necessarily a perfect solution, but it is the best option under the current conditions. By engaging in dialectical thinking, advanced thinkers repeatedly challenge and change their understanding of what constitutes “truth.” For example, they may arrive at one conclusion, then think of an idea that contradicts their conclusion, and then synthesize the two ideas into a more complete understanding. They realize that the search for truth is an ongoing process and can take them down many different paths.

In an attempt to integrate various postformal ideas, Helena Marchand (2002) suggests these common features:

1. Understanding that knowledge is relative, not absolute; there are far more shades of gray than there are clear dichotomies of knowledge.
2. Accepting that the world (physical and mental) is filled with contradictions: inconsistent information can exist side by side.
3. Attempting to integrate the contradictions into some larger understanding.

Environments that expose us to a wider range of ideas, roles, and experiences seem to foster this higher level of thinking. College students who have greater diversity among their friends tend to exhibit more of these postformal characteristics than those whose friends are very similar (Galupo, Cartwright, & Savage, 2009). Among high school and college students, females report greater gender role conflict than males and also a more relativistic perspective on relationships (Kramer & Melchior, 1990).

It is not yet clear whether relativistic, dialectical, or other forms of advanced thinking might qualify as a new, postformal stage of cognitive development. Marchand (2002) concludes that a fifth stage of postformal thought may not be warranted. Adult thought may indeed be different or more advanced than the formal-operational thought of adolescence, though. Much research confirms that cognitive growth does not end in adolescence. Yet growth during adulthood may not reflect a new Piagetian stage—a qualitatively different, structural change in thinking that is universal and irreversible (Lerner, 2006).

Aging and Cognitive Skills

What becomes of cognitive capacities in later adulthood? Some mental abilities decline as the average person ages, and it appears that older adults often have trouble solving Piagetian tests of formal-operational thinking (Blackburn & Papalia, 1992). Indeed, elderly adults sometimes perform poorly relative to young and middle-aged adults even on concrete-operational tasks assessing conservation and classification skills.

This does not mean that elderly adults regress to immature modes of thought. For one thing, these studies have involved cross-sectional comparisons of different age groups. The poorer

Figure 7.9 Your task is to connect all nine dots using four straight lines or less, without lifting your pen or pencil from the paper. Hint: To be successful, you need to think outside the box! For the solution, try typing “Solution for Nine Dot Problem” into an Internet search engine.

performance of older groups does not necessarily mean that cognitive abilities are lost as people age. It could be caused by a cohort effect, because the average older adult today has had less formal schooling than the average younger adult has had. Older adults attending college tend to perform as well as younger college students on tests of formal operations (Blackburn, 1984; Hooper, Hooper, & Colbert, 1985). Moreover, brief training can quickly improve the performance of older adults long out of school, which suggests that the necessary cognitive abilities are there but merely need to be reactivated (Blackburn & Papalia, 1992).

Questions have also been raised about the relevance of the skills assessed in Piagetian tasks to the lives of older adults (Labouvie-Vief, 1985). Not only are these problems unfamiliar to many older adults, but they also resemble the intellectual challenges that children confront in school, not those that most adults encounter in everyday contexts. Thus, older people may not be motivated to solve them. Also, older adults may rely on modes of cognition that have proved useful to them in daily life but that make them look cognitively deficient in the laboratory (Salthouse, 1990).

Consider this example: Kathy Pearce and Nancy Denney (1984) found that elderly adults, like young children but unlike other age groups, often group two objects on the basis of some functional relationship between them (for example, putting a pipe and matches together because matches are used to light pipes) rather than on the basis of similarity (for example, putting a pipe and a cigar together because they are both ways of smoking tobacco). In school and in some job situations, Pearce and Denney suggest, people are asked to group objects on the basis of similarity, but in everyday life it may make more sense to associate objects commonly used together.

Such findings suggest that what appear to be deficits in older people may merely be differences in style. Similar stylistic differences in classification skills have been observed cross-culturally and can, if researchers are not careful, lead to the incorrect conclusion that uneducated adults from non-Western cultures lack basic cognitive skills. A case in point: Kpelle adults in Africa, when asked to sort foods, clothing, tools, and cooking utensils into groups, sorted them into pairs based on functional relationships. “When an exasperated

experimenter finally asked, ‘How would a fool do it?’ he was given sorts of the type that were initially expected—four neat piles with foods in one, tools in another, and so on” (Glick, 1975, p. 636).

So today’s older adults appear not to perform concrete-operational and formal-operational tasks as well as their younger contemporaries do. Planners of adult education for senior citizens might bear in mind that some (although by no means all) of their students may benefit from more concrete forms of instruction. However, these differences may be related to factors other than age, such as education and motivation; an age-related decline in operational abilities has not been firmly established. Most importantly, older adults who perform poorly on unfamiliar problems in laboratory situations often perform far more capably on the sorts of problems that they encounter in everyday contexts (Cornelius & Caspi, 1987; Salthouse, 1990). This is precisely the message from Fischer’s skill theory: Abilities vary with context. By providing older adults with a supportive context, we can optimize their level of performance.

● Checking Mastery

1. When, or under what conditions, is an adult most likely to use formal-operational thinking?
2. What is relativistic thinking?

● Making Connections

1. How important is it to achieve formal-operational thought? What limitations would you experience at work and school if you operated at a concrete-operational level all the time and never progressed to formal-operational thought?
2. What sorts of questions or answers do you contribute to class discussions? Do they reflect primarily concrete operational, formal operational, or something beyond formal-operational thinking such as relativistic or dialectical thinking?

Chapter Summary

7.1 Piaget’s Constructivist Approach

- Jean Piaget developed a theory of how children come to know their world by constructing their own schemes or cognitive structures through active exploration.
- Studying children using the clinical method, a flexible question-and-answer technique, Piaget formulated four stages of cognitive development in which children construct increasingly

complex schemes through an interaction of maturation and experience.

- Intelligence is a basic life function that allows organisms (including humans) to adapt to the demands of their environment.
- Children adapt to the world through the processes of organization and adaptation (assimilating new experiences to existing understandings and accommodating existing understandings to new experiences).

- Piaget’s theory has stimulated much research over the years, which has added considerably to our understanding of cognitive development. Piaget showed us that infants are active, not passive, in their own development. He argued that children think differently during different phases of their development, as reflected in his four qualitatively different stages.
- Piaget has been criticized for underestimating the capacities of infants and young children, not considering factors besides competence that influence performance, failing to demonstrate that his stages have coherence, offering vague explanations of development, and underestimating the role of language and social interaction in cognitive development.
- Modern constructivist theories such as neuroconstructivism propose that observed differences in cognitive skills result from experience-induced changes in the underlying neural structures supporting these skills.

7.2 Vygotsky’s Sociocultural Perspective

- Lev Vygotsky’s sociocultural perspective emphasizes cultural and social influences on cognitive development more than Piaget’s theory does.
- Through guided participation in culturally important activities, children learn problem-solving techniques from knowledgeable partners sensitive to their zone of proximal development.
- Language is the most important tool that adults use to pass culturally valued thinking and problem solving to their children. Language shapes their thought and moves from social speech to private speech and later to inner speech.

7.3 Fischer’s Dynamic Skill Framework

- Development results from changes in skill levels. Skills reflect what a person can do on a particular task in a specific context.
- People operate within a developmental range, with higher levels of performance demonstrated within a supportive context and after more experience with a task.

7.4 The Infant

- Infants progress through six substages of the sensorimotor period by perceiving and acting on the world; they progress from using their reflexes to adapt to their environment to using symbolic or representational thought to solve problems in their heads.
- Major accomplishments of the sensorimotor stage include the development of object permanence, or the realization

that objects continue to exist even when they are not directly experienced, and the symbolic capacity, or the ability to allow one thing to represent something else. The emergence of the symbolic capacity paves the way for language and pretend play.

7.5 The Child

- Preschool-age children are in Piaget’s preoperational stage and do not yet reason logically; instead they rely on perceptually salient features of a task or object. Their prelogical set of cognitive structures leads them to have trouble with conservation and classification tasks. In particular, preoperational children lack the abilities to decenter, reverse thought, and understand transformations. In addition, they tend to be egocentric—viewing the world from their own perspective and not recognizing others’ points of view.
- School-age children are in Piaget’s concrete-operational stage and can reason logically about concrete information, which allows them to solve conservation and classification tasks. Concrete-operational children have acquired the abilities of decentration, reversibility of thought, and transformational thought. They can think about relations, grasping seriation and transitivity, and they understand the concept of class inclusion.

7.6 The Adolescent

- Adolescents may advance to Piaget’s last stage of cognitive development—formal-operational thought, in which they can think about abstract concepts and apply their logical reasoning to hypothetical problems. Formal-operational thinkers can simultaneously consider multiple task components.
- Formal-operational thought may give rise to special forms of egocentrism, namely, the imaginary audience and personal fable.

7.7 The Adult

- Many adults seem to function at the concrete-operational level, rather than at Piaget’s highest level of formal-operational thought. Formal-operational thought appears to be highly dependent on formal education. It is also influenced by culture and area of expertise.
- Some adults may acquire advanced levels of thought not considered by Piaget, such as relativistic thinking, or understanding that knowledge is dependent on the knower’s subjective perspective, and dialectical thinking, or detecting and reconciling contradictory ideas.

Think about everything you have learned and experienced up to this point in your life. Like most people, you probably have a rich and varied set of memories relating to your family, friends, school, work, and life. You rely on these memories every day: They provide you with a solid grounding in who you are, where you have been, and where you hope to go. Now imagine that every one of these memories is gone. It's hard to imagine, but this is what happened to Su Meck at the age of 22. One minute, she was making macaroni and cheese in the kitchen and lifting her young son up in the air, and in the next minute, the ceiling fan had dislodged and struck Su in the head (De Vise, 2011). She awoke a week later with no memories of her past. None. She did not know herself, let alone her husband and two young children. She had to start over. According to her husband, "She was Su 2.0. She had rebooted. . . . It was literally like she had died. Her personality was gone" (McGrory, 2013).

Su Meck started over at the age of 22 when a freak accident wiped out every memory up to that point. Su 2.0, as her husband dubbed her, completed a college degree 23 years after her brain “rebooted.”

Matt McClain/The Washington Post/Getty Images

Over the next 30 years, Su would need to relearn everything and begin to form new memories. As her children were learning new things in school, Su would often be learning the same things alongside them. She eventually went to college (for the second time, as she had been in college prior to her freak accident) and earned a degree in music. To date, she has not recovered any memories from the first 22 years of her life.

This is an astonishing case of true **retrograde amnesia**, or loss of memory for information and events occurring prior to the incident that caused the amnesia. Such cases illustrate just how vital memory is to who we are and what we do; it allows us to learn from the past, function in the present, and plan for the future. It would be nearly impossible to overemphasize the importance of our memory system.

In this chapter, we consider how **memory**, our ability to store and later retrieve information about past events, develops and changes over the life span. We begin our journey down memory lane by examining the components of memory and the models that attempt to organize some of the findings that have emerged in the field of memory.

8.1

Conceptualizing Memory

LEARNING OBJECTIVES

- Explain the workings of the memory system, from first exposure to information or an event, to eventual retrieval of this information from memory.
- List and define the different forms of memory.
- Describe the neural underpinnings of memory.
- Discuss how stored information is processed to solve problems.

Modern models of memory originated about 60 years ago when Donald Broadbent (1958) speculated on how humans process information. At about this same time, the modern computer, with its capacity to systematically convert input to output, was emerging and garnering much interest. The computer seemed to provide a good analogy to the human mind, and indeed, efforts to program computers to play chess and solve other problems as efficiently as human experts helped scientists understand a great deal about the strengths and limitations of human cognition (Newell & Simon, 1961; Simon, 1995). The computer, then, was the model for the **information-processing approach** to human cognition, which emphasizes the basic mental processes involved in attention, perception, memory, and decision making. And just as today’s more highly developed computers have far greater capacity than those of the past, maturation of the nervous system plus experience presumably enable adults to remember more than young children can and to perform more complex cognitive feats with greater accuracy.

Richard Atkinson and Richard Shiffrin (1968) proposed a simple information-processing framework with three memory components, organized primarily by their duration:

- **Sensory register**, which ever-so-briefly (less than a second) holds the abundant sensory information—sights, sounds, smells, and more—that swirls around us
- **Short-term memory**, which holds a limited amount of information, perhaps only four chunks, for a short period of time

- **Long-term memory**, believed to be a relatively permanent and seemingly unlimited store of information

To illustrate the memory stores, imagine you are listening to a history lecture and among the many facts presented, your professor notes that the U.S. Constitution was ratified in 1789. This statement is an environmental stimulus “hitting” your sensory register. Assuming that you are not lost in a daydream, your sensory register will log it, holding it for a fraction of a second as a kind of afterimage (or, in this example, a kind of echo). Much that strikes the sensory register quickly disappears without further processing. Attentional processes (see Chapter 6) play a large role in what information enters the sensory register and may be processed further. If you think you may need to remember 1789, it will be moved into short-term memory, but to be remembered for any length of time, it will need to be moved into long-term memory, which represents what most people mean by memory. More than likely, you will hold the professor’s statement in short-term memory just long enough to record it in your notes. Later, as you study your notes, you will rehearse the information to move it into long-term memory so that you can retrieve it the next day or week when you are taking the test.

This simplified model shows what you must do to learn and remember something. The first step is to **encode** the information: get it into the system. If it never gets in, it cannot be remembered. Second, information undergoes **consolidation**, processes that stabilize and organize the information to facilitate long-term storage.

These processes include *synaptic consolidation*, which occurs in the minutes or hours after initial learning, and *system consolidation*, which takes place over a longer period of time (Dudai, 2004).

The processes of consolidation are facilitated by sleep (Barham et al., 2016; Marshall & Born, 2007; Rasch & Born, 2013) and disrupted by stress (McGaugh & Roozendaal, 2002). Consolidation is also assisted when we can relate new material with prior knowledge, a process reflected in patterns of brain activity measured during sleep (Hennies et al., 2016). In particular, when sleep spindles—those spikes of neural activity observed during REM sleep—are denser, there seems to be greater retention of new learning that is associated with prior knowledge (Hennies et al., 2016).

In the absence of consolidation, the information would not make the leap from the first step of encoding to the third step of storage. **Storage**, of course, refers to holding information in a long-term memory store. Memories fade over time unless they are appropriately stored in long-term memory. Research has also made it clear that storing memories is a constructive process and not a static recording of what was encoded. As Mary Courage and Nelson Cowan (2009) describe it, “human memory does not record experience as a video camera would, but rather as an historian would: as a dynamic and inferential process with reconstructions that depend on a variety of sources of information” (p. 2).

Finally, for the memory process to be complete, there must be **retrieval**—the process of getting information out when it is

needed. People say they have successfully remembered something when they can retrieve it from long-term memory. Retrieval can be accomplished in several ways. If you are asked a multiple-choice question about when the Constitution was ratified, you need not actively retrieve the correct date; you merely need to recognize it among the options. This is an example of **recognition memory**. If, instead, you are asked, “When was the Constitution ratified?” this is a test of **recall memory**; it requires active retrieval without the aid of cues. Between recognition and recall memory is **cued recall memory**, in which you would be given a hint or cue to facilitate retrieval (for example, “When was the Constitution ratified? It is the year the French Revolution began and rhymes with *wine*.”). Most people find questions requiring recognition memory easier to answer than those requiring cued recall, and those requiring cued recall easier than those requiring pure recall. This holds true across the life span, which suggests that many things people have apparently encoded or learned are “in there someplace” even though they may be difficult to retrieve without cues. Breakdowns in remembering may involve difficulties in initial encoding, storage, or retrieval.

Useful as this model has been, modifications and alternative models have been proposed as research has uncovered more and more about memory processes. A more comprehensive model is illustrated in **Figure 8.1**. It shows, for example, that short-term memory is more complex than originally conceived. For one,

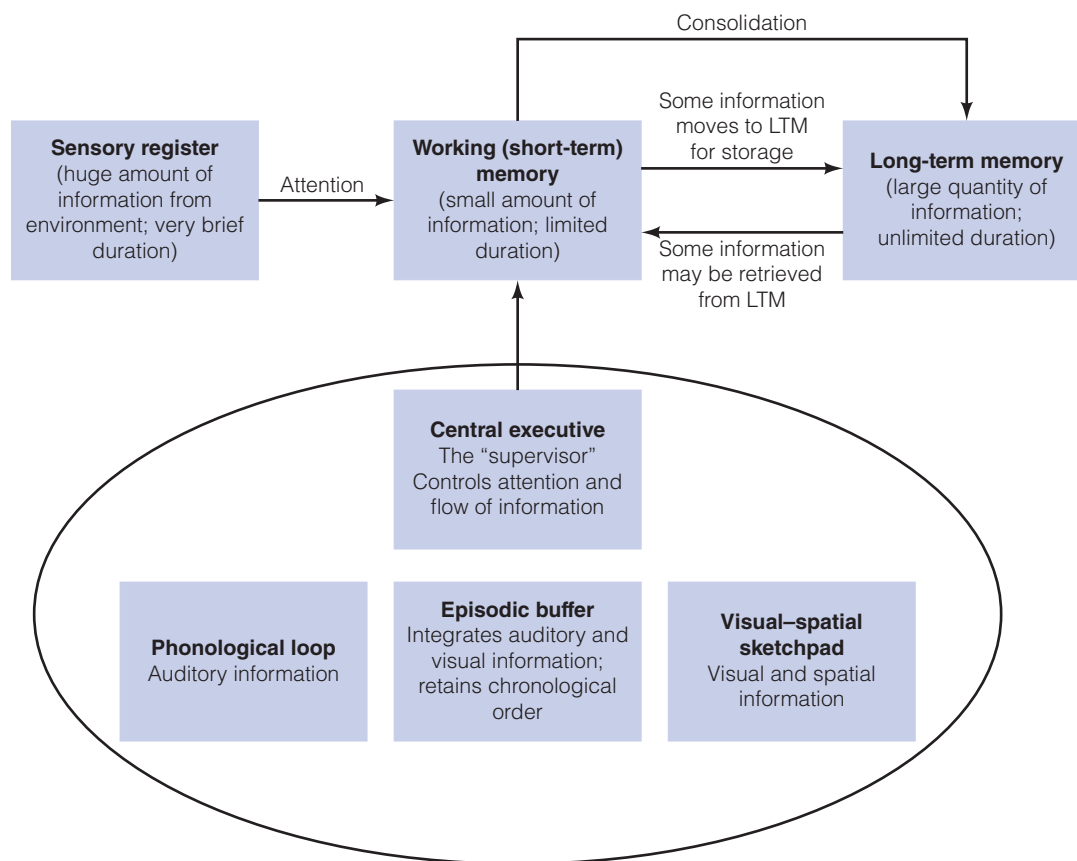

Figure 8.1 A comprehensive model of memory. The central executive manages the important business of the short-term memory store. The bottom three boxes show the three types of short-term memory: phonological, visual-spatial, and the episodic buffer, which integrates the other two types of short-term memory.

most cognitive researchers distinguish between passive and active forms of short-term memory and use the term **working memory** to refer to short-term memory being used to achieve a goal. Working memory is akin to a mental “scratch pad” that temporarily stores information while actively operating on it (Baddeley, 2012). It is what is being manipulated in one’s mind at any moment. As you know, people can juggle only so much information at once without some of it slipping away or “falling out” of working memory. To illustrate working memory, look at the following seven numbers. Then look away and add the numbers in your head while trying to remember them:

7256147

Most likely, having to actively manipulate the numbers in working memory to add them disrupted your ability to rehearse them to remember them. People who are fast at adding numbers would have better luck than most people, because they would have more working-memory space left for remembering the items (Byrnes, 1996).

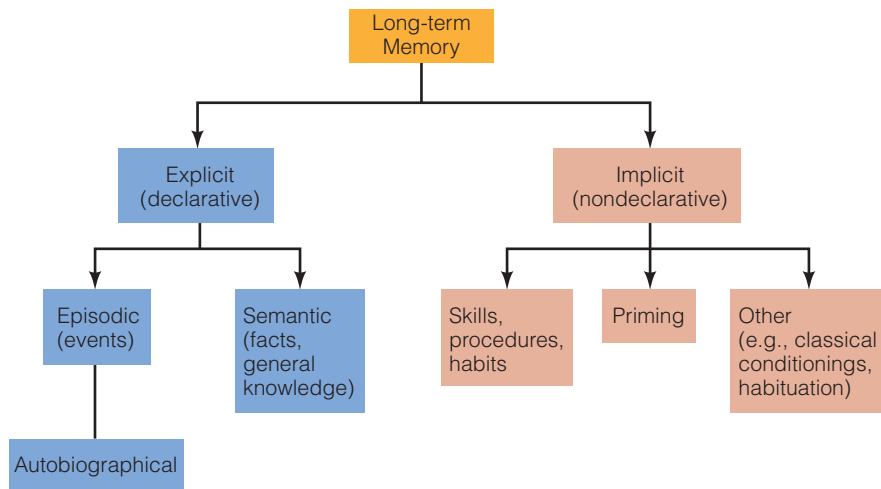

Alan Baddeley (1986, 2001, 2012) has proposed a four-component model of working memory to try to address the limitations in this area in the Atkinson and Shiffrin model. In particular, research showed that a single short-term memory store just was not sufficient, because verbal and visual memories seem to be stored separately (Baddeley & Hitch, 1974). As illustrated in Figure 8.1, this expanded view of short-term memory consists of a **central executive**, which directs attention and controls the flow of information; it is the supervisor of the working-memory system. In addition, there are three types of short-term memory storage:

- Phonological loop, which briefly holds auditory information such as words or music
- Visual-spatial sketchpad, which holds visual information such as colors and shapes
- Episodic buffer, which links auditory and visual information

The episodic buffer was added to this model when research showed that some memories are not visual or verbal per se, but instead serve to connect visual and verbal information and facilitate long-term storage of episodic memories (memories of events). In the next section, we’ll explore these episodic memories in greater detail.

Implicit and Explicit Memory

Memory researchers have concluded that the long-term memory store responds differently depending on the nature of the task (Schneider, 2015). They distinguish between **implicit memory** (also called nondeclarative memory), which occurs unintentionally, automatically, and without awareness, and **explicit memory** (also called declarative memory), which involves deliberate, effortful recollection of events (see ■ Figure 8.2). Explicit memory is tested through traditional recognition and recall tests (such as a course’s final exam with multiple-choice and essay questions) and

■ **Figure 8.2** Types of long-term memory.

can be further divided into **semantic memory** for general facts and **episodic memory** for specific experiences. Most memory experts agree that explicit memories, whether they are semantic general knowledge or the specific personal memories that make up episodic memories, are deeply entwined with language. To further clarify the two types of explicit memory, an example of episodic memory might be remembering that you were home sick when you heard on the news that a major earthquake had struck Nepal on April 25, 2015, killing more than 8,000 people. Semantic memory might be knowing that Nepal is situated between India and China or that its capital is Kathmandu. The first example illustrates memory for a specific event, whereas the second example reflects general knowledge about the world.

Implicit memory is a different beast. Learners are typically unaware that their memory is being assessed with implicit “tests.” Consider one of the most famous case studies of memory, that of Henry Molaison, who was known in the scientific literature only by his initials H.M. until his death at age 82 in 2008. At the age of 27, Henry had much of the hippocampus removed from both sides of his brain as part of an effort to control his severe seizures (see Shah, Pattanayak, & Sagar, 2014; Squire, 2009). What his neurosurgeon did not realize at the time was that Henry would suffer from catastrophic memory loss for the remaining 55 years of his life. In particular, Henry experienced **anterograde amnesia**: He was no longer able to form new memories; indeed, a book written about this case is titled *Permanent Present Tense* (Corkin, 2013). Henry could not remember what he had eaten for dinner or watched on television just minutes earlier, nor could he learn new words or remember new people. Despite this devastating loss of ability to form new episodic memories, Henry showed evidence of implicit memory (Lloyd & Miller, 2014). To test this, Henry was presented with a mirror tracing task in which he was asked to trace a diagram by looking only at his hand reflected in the mirror, which makes this rather challenging and requires practice to perfect the drawing. Henry did not recall repeatedly practicing this task, yet his performance improved over the course of three days, indicating some retention of this procedural task (see ■ Figure 8.3). He had acquired memory for the procedure without any awareness of doing so. Many forms of amnesia, like the one

(b) Performance of H.M. on mirror-tracing task

■ **Figure 8.3** H.M.'s performance on the mirror tracing task.

experienced by Henry, destroy explicit memory but leave implicit memory undamaged (Schacter, 1996). As Patricia Bauer (2007) describes it, explicit memory is fallible—subject to forgetting—whereas implicit memory is largely infallible—it remains intact.

Neural Bases of Memory

Until fairly recently, the neural underpinnings of memory were largely a mystery, with only small glimpses into the inner workings of the brain afforded by occasional case studies of patients who had sustained brain damage and with this, specific memory problems. Su Meck, described in this chapter's opening, and Henry Molaison, are fascinating examples of what we can learn from case studies.

Henry's unfortunate case provided the first solid evidence that memory has a neural basis. Up to that point, it was assumed that memories were somehow spread throughout the brain. Henry's surgeon reported that he had removed a specific region of the medial temporal lobe—the **hippocampus**—in order to treat Henry's seizures. Given the devastating loss of memory resulting from this removal, scientists concluded that the hippocampus was instrumental in creating new episodic memories, such as recalling that you went to the dentist on Monday morning.

Some 40 years after his surgery, technological advances in imaging allowed researchers to use functional magnetic resonance

imaging (fMRI) to get a closer look at Henry's brain. To their surprise, they found that the surgery had not removed all of the hippocampus, as his surgeon had believed. Yet, even with the remaining portion of the hippocampus, Henry had no memory for new information, indicating that there must be more to memory than this one structure. Not until after Henry's death would researchers be able to create a 3-dimensional model of his brain and find that a part of the temporal lobe, called the *entorhinal cortex*, had been removed (Annese et al., 2014). This structure plays a critical role in connecting the hippocampus to other parts of the brain. Annese and colleagues concluded that Henry's memory problems were likely a result of the loss of the entorhinal cortex, which effectively cut off the hippocampus from the rest of the brain.

Positron emission tomography (PET) scans of the brain have allowed researchers to make inferences about memory processes by observing brain activity taking place as subjects perform various types of memory tasks. From such studies, we have learned that different parts of the brain are involved in different forms of memory (see ■ **Figure 8.4**). Procedural memory (such as memory of how to ride a bike), which is a type of implicit memory, is mediated by an area of the forebrain

called the striatum. Explicit memory is largely localized in the medial temporal lobe of the brain (*medial* refers to the middle of the brain and the temporal lobe is located at the base of the brain). In particular, the medial temporal structures are thought to be crucial to consolidating information into a memory trace for long-term storage. As noted earlier, sleep facilitates the consolidation of memories. This process seems especially swift during childhood. Charline Urbain and her colleagues (2016) demonstrated that a 90-minute nap after a learning task helps integrate the new learning with existing knowledge and assists with retention of the new material among children.

The actual storage and retrieval of new information take place in whichever area of the cortex originally encoded or was activated by the information. For example, vocabulary seems to be stored in the limbic-temporal cortex, as evidenced by the vocabulary impairment experienced by individuals with damage to this part of the brain (Bauer, 2009). Thus, sensory information initially activates one of the cortical association areas distributed throughout the brain. This information then passes to the medial temporal lobe for consolidation. If and when this consolidation occurs, the resulting memory trace is stored in the cortical association area of the brain that first registered the information, and it is from this area that the information must be retrieved.

Figure 8.4 The hippocampus is part of the limbic system, located in the medial ("middle") temporal lobe of the brain. Scientists believe that the hippocampus is responsible for consolidation and formation of explicit memories. Just next to the hippocampus is the amygdala, which is involved in forming emotionally charged memories. Other parts of the brain, namely the basal ganglia and cerebellum, are important in the formation of procedural memories.

Research suggests that implicit memory develops earlier in infancy than explicit memory (Lloyd & Miller, 2014; Schneider, 2015). Explicit memory improves as the hippocampus becomes more mature during the second half of the first year (Nelson, Thomas, & de Haan, 2006). Further, the two types of memory follow different developmental paths. Explicit memory capacity increases from infancy to adulthood, then declines in later adulthood. By contrast, implicit memory capacity changes little; young children often do no worse than older children and elderly adults often do no worse than younger adults on tests of implicit memory (Schneider, 2015; Schneider & Bjorklund, 1998). Research on implicit memory shows that young and old alike learn and retain a tremendous amount of information from their everyday experiences without any effort.

Problem Solving

Think back to our example of the history professor who seems to want you to remember when the U.S. Constitution was ratified (1789, in case this did not get into your long-term memory store). Now imagine that you are asked how many years passed between this event and the signing of the Declaration of Independence (1776, remember?). This is a simple example of **problem solving**, or use of the information-processing system to achieve a goal or arrive at a decision (in this case, to answer the question). Here, too, the information-processing model describes what happens between stimulus and response. The question will move through the memory system. You will need to draw on your long-term memory to understand the question, then you will have to search long-term memory for the two relevant dates. Moreover, you will need to locate your stored

Advances in brain imaging have allowed researchers to "see" memory and problem solving by looking at patterns of blood flow in different regions of the brain. The yellow portions in this image show increased areas of blood flow as the person was remembering the image of a face.

NIMH Laboratory of Brain and Cognition

knowledge of the mathematical operation of subtraction. You will then transfer this stored information to working memory so that you can use your subtraction "program" (1789 minus 1776) to derive the correct answer.

Notice that processing information successfully requires both knowing what you are doing and making decisions. This is why researchers have added **executive control processes** to the memory model. These control processes run the show, guiding the selection, organization, manipulation, and interpretation of information throughout. Stored knowledge about the world and about information processing guides what is done with new information.

Cognitive psychologists now recognize that information processing is more complex than this model or similar models suggest (Bjorklund, 1997). For example, they appreciate that people, like computers, engage in **parallel processing**, carrying out multiple cognitive activities simultaneously (for example, listening to a lecture and taking notes at the same time) rather than performing operations in a sequence (such as solving a math problem by carrying out a series of ordered steps). They also appreciate that different processing approaches are used in different domains of knowledge. Still, the information-processing approach to cognition has the advantage of focusing attention on *how* people remember things or solve problems, not just on what they recall or what answer they give. A young child's performance on a problem could break down in any number of ways: The child might not be paying attention to the

relevant aspects of the problem, might be unable to hold all the relevant pieces of information in working memory long enough to do anything with them, might lack the strategies for transferring new information into long-term memory or retrieving information from long-term memory as needed, might simply not have enough stored knowledge to understand the problem, or might not have the executive control processes needed to manage the steps in solving a problem. If researchers can identify how information processes in the younger individual differ from those in the older person, they will gain much insight into cognitive development.

Many processes involved in memory and problem solving improve between infancy and adulthood and then decline somewhat in old age, although this pattern is not uniform for all processes or all people. Our task in this chapter is to describe these age trends and, of greater interest, to try to determine why they occur.

8.2

The Infant

LEARNING OBJECTIVES

- Explain how researchers are able to assess the memory capabilities of infants.
- Outline the characteristics of infant memory.
- Describe the types of information that infants are likely to remember.

You have already seen that infants explore the world thoroughly through their senses. But are they remembering anything of their experiences?

Uncovering Evidence of Memory

Assessing infant memory requires some ingenuity because infants cannot tell researchers what they remember. Several methods have been used to uncover infants' memory capabilities. Here we consider habituation, operant conditioning, object search, and imitation techniques before examining infants' abilities to recall previously presented information.

Habituation

One method to assess memory uses habituation, a simple and often overlooked form of learning introduced in Chapter 6. Habituation—learning *not* to respond to a repeated stimulus—might be thought of as learning to be bored by the familiar (for example, eventually not hearing the continual ticking of a clock or the drip of a leaky faucet) and is evidence that a stimulus is recognized as familiar. From birth, humans habituate to repeatedly presented lights, sounds, and smells; such stimuli are recognized as “old hat” (Rovee-Collier & Barr, 2010). Indeed, as we noted in Chapter 5, fetuses demonstrate through habituation that they can learn and remember prior to birth (see Leader, 2016). It is clear that newborns are capable of recognition memory and prefer a new sight to something they have seen many times. As they age, infants need less “study time” before a stimulus becomes old hat,

Checking Mastery

1. What steps are required in order to learn, remember, and recall material?
2. What is the difference between implicit and explicit memory?
3. Why are recognition tasks generally easier than recall tasks?

Making Connections

1. Consider your own memory profile. On what types of memory tasks and under what conditions is your memory good, and conversely, which types of tasks and conditions challenge your memory?
2. In creating a memory assessment, how would you tap into someone's implicit memories as opposed to their explicit memories?

and they can retain what they have learned for days or even weeks (Rovee-Collier & Cuevas, 2009b).

Operant Conditioning

To test long-term memory of young infants, Carolyn Rovee-Collier and her colleagues devised a clever task that relies on the operant conditioning techniques introduced in Chapter 2 (see Rovee-Collier & Cuevas, 2009b). When a ribbon is tied to a baby's ankle and connected to an attractive mobile, the infant will shake a leg now and then and learn very quickly (in minutes) that leg kicking brings about a positively reinforcing consequence: the jiggling of the mobile.

To test infant memory, the mobile is presented at a later time to see whether the infant will kick again. To succeed at this task, the infant must not only recognize the mobile but also recall that the thing to do is to kick. Before we review the research findings, what type of memory do you believe this task assesses? Consider whether infants are deliberately and effortfully remembering something or are unintentionally and automatically learning and remembering a connection between their kicking and the movement of the mobile. This task is tapping into implicit or procedural memory. When given two 9-minute training sessions, 2-month-olds remember how to make the mobile move for up to 2 days, 3-month-olds for about 1 week, and 6-month-olds for about 2 weeks (Rovee-Collier & Cuevas, 2009b). Using a modification of this task for older infants, Rovee-Collier and her colleagues (see Hartshorn et al., 1998) have shown that by 18 months, infants can remember for at least 3 months—rather impressive! Further, the researchers

could enhance young infants' memory by giving them three 6-minute learning sessions rather than two 9-minute sessions. Although the total training time was the same in the two conditions, the distributed, or spread out, training was more effective. As it turns out, distributed practice is beneficial across the life span—a good thing to keep in mind when you are studying for tests (Litman & Davachi, 2008).

What if stronger cues to aid recall are provided? Three-month-old infants who were reminded of their previous learning, by seeing the mobile move 2–4 weeks after their original learning experience, kicked up a storm as soon as the ribbon was attached to their ankles, whereas infants who were not reminded showed no sign of remembering to kick (Rovee-Collier & Barr, 2004). It seems, then, that cued recall (in this case, memory cued by the presence of the mobile or, better yet, its rotation by the experimenter) emerges during the first couple of months of life

and that infants remember best when they are reminded of what they have learned. Other research shows that verbal reminders are also effective with 15-month-olds and can help them remember an event after a month as well as they did after a week (Hayne & Simcock, 2009).

However, this research also suggests that young infants have difficulty recalling what they have learned if cues are insufficient or different. They have trouble remembering when the mobile (for example, the specific animals hanging from it) or the context in which they encountered it (for example, the design on the playpen liner) is even slightly different from the context in which they learned. In short, early memories are *cue-dependent and context-specific*.

Object Search

In Chapter 7, we noted that Piaget used an object search task, the A-not-B task, to help understand cognitive changes during infancy. Performance on this task can also contribute to our understanding of memory capabilities. For this task, an infant or toddler is seated at a table that contains two identical cloths, under which a small toy can be hidden (see ■ Figure 8.5). As the youngster watches, the toy is placed under one of the cloths (A). The infant who reaches for the correct location of A is demonstrating memory. After several successful trials of watching and retrieving the toy from location A, the researcher switches things up and hides the toy under the other cloth (location B). This stumps many infants, as demonstrated by their continued searching in the original location (hence the name of the task, A-not-B). By 8 months of age, though, more than half of infants correctly reach for the toy in location B (Bell & Morasch, 2007). But when researchers examine the *looking* behavior of infants, presumably less demanding than reaching, then infants as young as 5–6 months show memory for the correct location based on their looking behavior.

Imitation

Researchers can learn something about memory by noting whether or not infants can imitate an action performed by a model. Some studies suggest that young infants, even newborns, can imitate certain actions, such as sticking out the tongue or opening the mouth (see Meltzoff, 2004). These findings are exciting because they challenge Piaget's claim that infants cannot imitate actions until about 1 year, when they have some ability to represent mentally what they have seen.

Such findings have been viewed with skepticism by some, who believe that early tongue protrusions do not demonstrate true imitation but instead reflect reflexive responses to specific stimuli or attempts to “explore” interesting sights (see, for example, Bjorklund, 1995; Jones, 1996). However, observations of infants sticking out their tongues and moving their mouths in ways consistent with a model have now been replicated with different populations (Marshall & Meltzoff, 2014; Meltzoff & Moore, 1997). More importantly, though, infants as young as 6 months display **deferred imitation**, the ability to imitate a novel act after a delay, which clearly requires memory ability and represents an early form of explicit or declarative memory (Jones & Herbert, 2006; Sundqvist et al., 2016). Infants' deferred imitation

When ribbons are tied to their ankles, young infants soon learn to make a mobile move by kicking their legs. Carolyn Rovee-Collier has made use of this operant conditioning paradigm to find out how long infants will remember the trick for making the mobile move.

A-Not-B Error Phenomenon

■ **Figure 8.5** An illustration of Piaget's 'A-not-B' task.

of actions at age 9 months predicts their productive language skills at 16 months, showing a connection between performance on an early memory task and performance on a more complex memory task, in this case, words produced or remembered at 16 months (Sundqvist et al., 2016).

As infants age, they demonstrate recall or deferred imitation over longer periods. By 6 months, infants can defer their imitation of an action over a longer delay and can recall the order of a simple sequence of events (Bauer, 2007). By age 2, events can be recalled for months, and recall is more flexible—less bound by the specific cues present at the time of learning (see Lukowski & Bauer, 2014).

Patricia Bauer (1996; Bauer et al., 2000) and her colleagues have shown sequences of actions to infants of different ages and then asked them to imitate what they saw—for example, putting a teddy bear in bed, covering him with a blanket, and reading him a story. Infants as young as 13 months can reconstruct a sequence of actions for as long as 3 months afterward. Older infants (16 and 20 months) can store and retrieve events for 12 months after exposure (Bauer et al., 2000, 2011). Much like children and adults, infants remember best when they have repeated exposures to what they are to remember, when they are given plenty of cues to help them remember, and when the events they must remember occur in a meaningful or logical order.

By age 2, infants have become verbal and can use words to reconstruct events that happened months earlier. In one study, for example, researchers interviewed young children about emergency room visits for accidents the children had between about 1 and 3 years of age (Peterson & Rideout, 1998). Interviews were conducted soon after the ER visits and 6, 12, 18, or 24 months

later. Children who were 18 months or younger at the time of their ER visit were unable to verbally recall aspects of their visits after a 6-month delay, but children 20 months or older were able to do so. Children who were at least 26 months old at the time of their ER visit could retain information and answer verbal questions about their experiences for at least 2 years following the event. In addition, children as young as 2 years can benefit from simple verbal reminders about previously experienced events (Imuta, Scarf, & Hayne, 2013). It's clear that language helps memory performance.

Problem Solving

Infants, like children and adults, face problem-solving tasks every day. For example, they may want to obtain an object beyond their reach or to make a toy repeat the interesting sound it produced earlier. Can infants overcome obstacles to achieve desired goals? It appears they can. In one study, infants were presented with an object out of their reach; however, by pulling on a cloth with one hand, they could drag the object to within reach (Willats, 1990). Although 6-month-olds did not retrieve the object, 9-month-olds solved this problem. Even the younger infants were successful when given hints about how they might retrieve the object (Kolstad & Aguiar, 1995). In situations where solving the problem requires coordination of both hands, success does not occur until later in childhood (Birtles et al., 2011). By 14 months of age, infants have figured out that adults are often useful sources of information in problem-solving situations (Csibra & Gergely, 2009; Kovács et al., 2014). As they get older, infants increasingly pay attention to the cues provided by adults and they increasingly

solicit help by pointing, reaching, or otherwise letting the adult know that assistance is needed. Simple problem-solving behaviors improve considerably over the first 2 years of life and then, as you will see shortly, flourish during childhood.

● Checking Mastery

1. How can researchers assess memory abilities of preverbal infants?
2. At what age do infants begin to show reliable recall for events?

● Making Connections

1. Uncle Jed says there is no way a baby can learn or remember anything. His position is that babies just eat, sleep, cry, and poop. What three key pieces of evidence might you use to convince Uncle Jed that there is something going on inside the infant's head in terms of learning and memory?
2. Would you characterize infants' memory as robust or fragile? What factors influence the robustness of infants' memory?

8.3

The Child

LEARNING OBJECTIVES

- Discuss and evaluate the four major reasons why memory improves over childhood.
- Describe autobiographical memory, provide an example, and list contributing factors.
- Use evidence to evaluate the accuracy of children's eyewitness memory.
- Explain changes in problem-solving ability throughout childhood.

The 2-year-old is already a highly capable information processor, as evidenced by the rapid language learning that takes place at this age. But dramatic improvements in learning, memory, and problem solving occur throughout the childhood years as children learn everything from how to flush toilets to how to work advanced math problems.

Memory Development

In countless situations, older children learn faster and remember more than younger children do. For example, 2-year-olds can repeat back about two digits immediately after hearing them, 5-year-olds about four digits, and 10-year-olds about six digits. And second-graders not only are faster learners than kindergartners but also retain information longer. Why is this? Here are four major hypotheses about why learning and memory improve (see Schneider, 2011):

1. **Changes in basic capacities.** Older children have higher-powered “hardware” than younger children do; neural advances in their brains have contributed to more working-memory space for manipulating information and an ability to process information faster.
2. **Changes in memory strategies.** Older children have better “software”; they have learned and consistently use effective methods for putting information into long-term memory and retrieving it when they need it.
3. **Increased knowledge of memory.** Older children know more about memory (for example, how long they must study to learn things thoroughly, which kinds of memory tasks take more effort, and which strategies best fit each task).
4. **Increased knowledge of the world.** Older children know more than younger children about the world in general. This knowledge, or expertise, makes material to be learned more familiar, and familiar material is easier to learn and remember than unfamiliar material.

Changes in Basic Capacities?

Because the nervous system continues to develop in the years after birth, it seems plausible that older children remember more than younger children do because they have a better “computer”—a larger or more efficient information-processing system. We can rule out the idea that the storage capacity of long-term memory impairs memory performance in infants and young children. There is no consistent evidence that capacity changes much across the life span and, indeed, young and old alike probably have more room for storage than they could ever use (Cunningham, Yassa, & Egeth, 2015). If long-term storage capacity does not contribute to developmental differences in memory, then what about the encoding and consolidation processes needed to move information into long-term storage?

Encoding begins with the sensory registration of stimuli from the environment. As we learned in Chapter 6, the sensory systems are working fairly well from a very early age and undergo only slight improvements during the first year. But although the senses themselves are functioning well, there is evidence that the *encoding* of this information improves over the first several years of life as the prefrontal cortex and medial temporal lobes mature (see Ghetti & Lee, 2014). It is also clear that the memory consolidation process undergoes developmental change. Of course, information that is not encoded in the first place is not going to be consolidated and stored. But separate from the changes in encoding, consolidation and storage of memories show improvement over infancy and childhood that seem to correspond to maturation of the hippocampus within the medial temporal lobes as well as other parts of the brain believed to be centrally involved in consolidation of memories. We also know that the *speed* of mental processes improves with age, as neurons become myelinated, and this allows older children and adults to simultaneously perform more mental operations in working memory than young children can (Cowan, 2016; Ghetti & Lee, 2014). As basic mental

processes become automatic, they can also be performed with little mental effort. This, in turn, frees space in working memory for other purposes, such as storing the information needed to solve a problem.

The degree of improvement in short-term memory capacity that is evident as children age may depend on what is tested or how it is tested. That is, short-term memory capacity is domain-specific—it varies with background knowledge and type of task (see Schneider, 2015). Greater knowledge in a domain or area of study increases the speed with which new, related information can be processed. In other words, the more you know about a subject, the faster you can process information related to this subject.

In sum, the basic capacities of the sensory register and long-term memory do not change much with age. There are, however, improvements with age in operating speed and efficiency of working memory, which includes improvements in the encoding and consolidation processes through which memories are processed for long-term storage. These changes correspond to maturational changes in the brain. During infancy, brain activity during working-memory tasks is scattered and general (Bell & Wolfe, 2007). By age 4 or 5, working memory has found its “home” in the frontal lobes of the brain. Maturation of the frontal lobes continues throughout childhood and adolescence, bringing further improvements in working memory and consolidation of memories.

Changes in Memory Strategies?

If shown the 12 items in ■ Figure 8.6, 4-year-olds might recall only 2–4 of them, 8-year-olds would recall 7–9 items, and adults might recall 10–11 of the items after a delay of several minutes. Are there specific memory strategies that evolve during childhood to permit this dramatic improvement in performance?

Strategies to aid memory can be applied at the time information is presented for learning (encoding strategies) or they can be applied at the time when retrieval of the information is sought (retrieval strategies). Strategies can employ mental activities such as silent rehearsal of the names of items to be remembered, or can employ behavioral activities such as placing your book bag by the door as a cue to remember to take it to school. The

■ **Figure 8.6** A memory task. Imagine that you have 120 seconds to learn the 12 objects pictured here. What tricks or strategies might you devise to make your task easier?

likelihood of using a strategy to aid memory seems to be greater when the goal is personally relevant. For instance, children as young as 2 years can deliberately remember to do such “important” things as reminding Mom to buy candy at the grocery store. They are more likely to use external or behavioral memory aids (for example, pointing at or holding a toy pig when asked to remember where it was hidden) if they are instructed to remember than if they are not (Fletcher & Bray, 1996; 1997). However, children younger than 4 show little flexibility in switching from an ineffective strategy to an effective one, and they typically do not generate new strategies even as they gain experience with a task (Chen, 2007). In contrast, many 4- and 5-year-olds will flexibly switch strategies and generate new strategies, making them do better on memory tasks than younger children. Four-year-olds can also selectively focus on relevant information and ignore irrelevant information, although this ability is evident only on very simple tasks and will become more robust with age and experience (Schneider, 2015). Younger children have a tendency to make **perseveration errors**: they continue to use the same strategy that was successful in the *past* despite the strategy’s *current* lack of success. Thus, if they previously found their favorite toy under the sofa, they search this location on future occasions when the toy is lost (Chen, 2007). They seem to be unable to get the old strategy—ineffective in the new situation—out of their mind and move on to a different strategy that could be successful, similar to the infant and the “A-not-B error.” By age 4, we see a decline in these perseveration errors.

Yet even 4-year-olds have not mastered many of the effective strategies for moving information into long-term memory. For example, when instructed to remember toys they have been shown, 3- and 4-year-olds will look carefully at the objects and will often label them once, but they only rarely use the memory strategy called **rehearsal**—the repeating of items they are trying to learn and remember (Baker-Ward, Ornstein, & Holden, 1984). To rehearse the objects in Figure 8.6, you might simply say, “apple, truck, grapes . . .” repeatedly. John Flavell and his associates found that only 10% of 5-year-olds repeated the names of pictures they were asked to recall, but more than half of 7-year-olds and 85% of 10-year-olds used this strategy (Flavell, Beach, & Chinsky, 1966). This repetition is believed to help form memories by activating the hippocampus with each repetition.

Another important memory strategy is **organization**, or classifying items into meaningful groups. You might cluster the apple, the grapes, and the hamburger in Figure 8.6 into a category of foods and form other categories for animals, vehicles, and baseball equipment. You would then rehearse each category and recall it as a cluster. Another organizational strategy, **chunking**, could be used to break a long number (6065551843) into manageable subunits (606-555-1843, a phone number) or a series of letters (e.g., F R H O X T O X O L G S M) into meaningful chunks (FOX SOX HTML ORG). Organization is mastered later in childhood than rehearsal. Although 10-year-olds who use chunking recall more than 6-year-olds, the younger children still demonstrate effective use of chunking (Mathy et al., 2016). Under conditions where chunking could be used, 6-year-olds showed as much improvement in recall as 10-year-olds: Both groups recalled more than without chunking.

Finally, the strategy of **elaboration** involves actively creating meaningful links between items to be remembered. Elaboration is achieved by adding something to the items, in the form of either words or images. Creating and using a sentence such as “the apple fell on the horse’s nose” could help you remember two of the items in Figure 8.6. Elaboration is especially helpful in learning foreign languages. For example, you might link the Spanish word *pato* (pronounced pot-o) to the English equivalent *duck* by imagining a duck with a pot on its head. Children who can elaborate on the relationship between two items (for example, generating similar and different features of the items) have improved retention of these items (Howe, 2006).

Memory or encoding strategies develop in a fairly predictable order, with rehearsal emerging first, followed by organization, and then by elaboration. Children do not suddenly start using strategies, however, and even once they have demonstrated knowledge of a strategy, they do not consistently apply it in all situations. Initially, children have a **mediation deficiency**, which means they cannot spontaneously use or benefit from strategies, even if they are taught how to use them. Children with mediation deficiencies seem unable to grasp the concept of the strategy. This type of strategy deficiency is not common (Schneider, 2015). More typical is a **production deficiency**, in which children can use strategies they are taught but do not produce them on their own. A third problem is a **utilization deficiency**, in which children spontaneously produce a strategy but their task performance does not yet benefit from using the strategy. Why would children who use a strategy fail to benefit from it? One possibility is that using a new strategy is mentally taxing and leaves no free cognitive resources for other aspects of the task (Pressley & Hilden, 2006). Once using the strategy becomes routine, then other components of the task can be addressed simultaneously. Whatever the reason for utilization deficiencies, they reflect a child–task interaction; that is, it is not task difficulty per se, but how difficult a task is for a particular child that matters (Bjorklund et al., 2009).

Using effective encoding strategies such as rehearsal, organization, and elaboration to learn material is only half the battle;

retrieval strategies can also influence how much is recalled. Indeed, retrieving something from memory can often be a complex adventure when solving problems, such as when you try to remember when you went on a trip by searching for cues that might trigger your memory (“Well, I still had long hair then, but it was after Muffy’s wedding, and . . .”). In general, young children rely more on external cues or behavioral actions for both encoding and retrieving information than do older children (Schneider & Pressley, 1997). Thus, young children may need to put their toothbrushes next to their pajamas so that they have a physical reminder to brush their teeth before they go to bed. With repetition, older children can remember to brush their teeth as part of their evening routine, in the absence of having a physical reminder. In many ways, command of memory strategies increases over the childhood years, but the path to effective strategy use is characterized more by noticeable jumps than by steady increases (Schneider, 2015).

Increased Knowledge of Memory?

The term **metamemory** refers to knowledge of memory and to monitoring and regulating memory processes. It is knowing, for example, what your memory limits are, which memory strategies are more or less effective for you, and which memory tasks are more or less difficult for you. It is also noting that your efforts to remember something are not working and that you need to try something different. Sounds like this could be useful knowledge for a student to possess! More broadly, metamemory is one aspect of **metacognition**, or knowledge of the human mind and of the range of cognitive processes. Your store of metacognitive knowledge might include an understanding that you are better at learning a new language than at learning algebra, that it is harder to pay attention to a task when there is distracting noise in the background than when it is quiet, and that it is wise to check a proposed solution to a problem before concluding that it is correct.

When do children first show evidence of metacognition? If instructed to remember where the *Sesame Street* character Big Bird has been hidden so that they can later wake him up, even 2- and 3-year-olds will go stand near the hiding spot, or at least look or point at that spot; they do not do these things as often if Big Bird is visible and they do not need to remember where he is (DeLoache, Cassidy, & Brown, 1985). By age 2, then, children understand that to remember something, you have to work at it. Researchers have found that 3-year-olds understand the difference between thinking about an object in their heads and experiencing it in reality and that 4-year-olds realize behavior is guided by beliefs (Flavell, 1999). These findings indicate that metacognitive awareness is present at least in a rudimentary form at a young age but there continue to be significant improvements throughout childhood.

Are increases in metamemory a major contributor to improved memory performance over the childhood years? Children with greater metamemory awareness demonstrate better memory ability, but several factors influence the strength of this relationship (Geurten, Catale, & Meulemans, 2015; Schneider, 2015). Researchers are most likely to see a connection between metamemory and memory performance among older children and among children who have been specifically

This young girl is searching for a toy that she put away months ago when asked to clean up her room. What strategies might she use to help her recall the toy’s location?

Sappington Todd/Getty Images

asked to remember something (DeMarie & Ferron, 2003; Schneider & Bjorklund, 1998). Not only is task experience important, but the nature of the task is also relevant. Awareness of memory processes benefits even young children on tasks that are simple and familiar and where connections between metamemory knowledge and memory performance are fairly obvious (Schneider & Sodian, 1988). Yet children who know what to do may not always do it, so good metamemory is no guarantee of good recall (Geurten et al., 2015). It seems that children not only must know that a strategy is useful but also must know why it is useful in order to be motivated to use it and to benefit from its use. Metamemory is also influenced by children’s language skills and by their general knowledge about mental states and their roles in behavior—what is known as theory of mind (Lockl & Schneider, 2007; and see Chapter 13 for definition and discussion). The links between metamemory and memory performance, although not perfect, are strong enough to suggest the merits of teaching children more about how memory works and how they can make it work more effectively for them.

Increased Knowledge of the World?

As we have seen, 10-year-olds remember more than 2-year-olds do, but then 10-year-olds *know* more than 2-year-olds do. An individual’s knowledge of a content area to be learned, or **knowledge base**, as it is called, clearly affects learning and memory performance. Think about the difference between reading about a topic that you already know well and reading about a new topic. In the first case, you can read quickly because you are able to link the information to the knowledge you have already stored. All you really need to do is check for any new information or information that contradicts what you already know. Learning about a highly unfamiliar topic is more difficult (“It’s Greek to me”).

Perhaps the most dramatic illustration of the powerful influence of knowledge base on memory was provided by Michelene Chi (1978). She demonstrated that even though adults typically outperform children on tests of memory, this age difference could be reversed if children have more expertise than adults. Chi recruited children who were expert chess players and compared their memory skills with those of adults who were familiar with the game but lacked expertise. On a test of memory for sequences of digits, the children recalled fewer than the adults did, demonstrating their usual deficiencies. But on a test of memory for the locations of chess pieces, the children clearly beat the adults (■ **Figure 8.7**). Because they were experts, these children were able to form more and larger mental chunks, or meaningful groups, of chess pieces, which allowed them to remember more. When child experts were compared with adult experts, there were no differences in performance (Schneider et al., 1993). Knowledge in a content area probably allows you to make better use of the limited capacity of working memory.

■ **Figure 8.7** Effects of expertise on memory. Michelene Chi found that child chess experts outperformed adult chess novices on a test of recall for the location of chess pieces (although, in keeping with the usual developmental trend, these children could not recall strings of numbers as well as adults could).

Consider, though, some research by Nelson Cowan and his colleagues (2015). They tested college students as well as 7-, 9-, and 12-year-olds with two sets of materials, one consisting of familiar English language letters and another consisting of symbols from a language unfamiliar to the participants. Older children and the young adults performed better than younger children with both the familiar letters and the unfamiliar symbols, suggesting that memory improvements over this age span are not solely attributable to greater knowledge base. Thus, the older children performed better even when they were tested under conditions that eliminated any advantage they might have from increased knowledge of the world. What should we conclude, then, about changes in memory across childhood?

Revisiting the Explanations

We can draw four conclusions about the development of learning and memory:

1. Older children are faster information processors and can juggle more information in working memory. Maturation of the nervous system leads to improvements in consolidation of memories. Older and younger children, however, do not differ in terms of sensory register or long-term memory capacity.
2. Older children use more effective memory strategies in encoding and retrieving information. Acquisition of memory strategies reflects qualitative rather than quantitative changes.
3. Older children know more about memory, and good metamemory may help children choose more appropriate strategies and control and monitor their learning more effectively.
4. Older children generally know more, and their larger knowledge base may provide some boost to their ability to learn and remember. A richer knowledge base allows faster and more efficient processing of information related to the domain of knowledge.

Is one of these explanations of memory development better than the others? Darlene DeMarie and John Ferron (2003) tested whether a model that includes three of these factors—basic capacities, strategies, and metamemory—could explain recall memory

better than a single factor. For both younger (5–8 years) and older (8–11 years) children, the three-factor model predicted memory performance better than a single-factor model. Use of memory strategies was an especially strong predictor of recall. Importantly, there were also correlations among factors. Having good basic capacities, for example, was related to advanced metamemory and to command of strategies and had its own influence on recall as well. So all these phenomena may contribute something to the dramatic improvements in learning and memory that occur over the childhood years. We return to these four hypotheses when we consider changes in learning and memory in adulthood.

Autobiographical Memory

Children effortlessly remember all sorts of things: a birthday party last week, where they left their favorite toy, what to do when they go to a fast-food restaurant, and much more. Much of what children remember and talk about consists of personal experiences or events that have happened to them at a particular time and place. These **autobiographical memories**, episodic memories of personal events, are essential ingredients of present and future experiences as well as our understanding of who we are (see Berntsen & Rubin, 2012). Su Meck, introduced at the beginning of this chapter, lost all autobiographical memories from before her accident and with them, she lost herself, or at least the self she had been. Here we look at how autobiographical memories are stored and organized and at factors that influence their accuracy.

When Do Autobiographical Memories Begin?

You learned earlier in this chapter that infants and toddlers are able to store memories. You also know that children and adults have many specific autobiographical events stored in long-term memory. Yet research shows that older children and adults exhibit **childhood** (or infantile) **amnesia**; that is, they have few autobiographical memories of events that occurred during the first few years of life. As Patricia Bauer (2014) describes it, it's as though our lives don't really begin until we are at least 3 to 4 years of age (p. 519).

To determine how old we have to be when we experience significant life events to remember them, researchers typically ask adults to answer questions about early life experiences such as the birth of a younger sibling, a hospitalization, the death of a family member, or a family move early in life. In one study using this method, college students were able to recall some information from events that happened as early as age 2 (Usher & Neisser, 1993). But age 2 seems to be the lowest age limit for recall of early life events as an adult. Other research shows that most adults do not remember much until they were 4 or 5 years old (Davis, Gross, & Hayne, 2008; Jack & Hayne, 2007). For example, Nicola Davis and her colleagues (2008) asked college students who had experienced the birth of a younger sibling by the age of 5 to recall as much as they could about this early event. As **Figure 8.8** shows, college students who had been 1, 2, or 3 years old at the time recalled very little of the event, but those who were 4 or 5 when their sibling was born recalled significantly more. Why do we remember little about our early years? As you have seen, infants

and toddlers are certainly capable of encoding their experiences and young preschool children seem able to remember a good deal about events that occurred when they were infants. In one study, children between 4 and 13 years of age were interviewed twice, with a gap of about 2 years between the two interviews. On both occasions, children were asked to recall their earliest memories (Peterson, Warren, & Short, 2011). All of the children were able to describe events they had experienced at a young age, demonstrating solid autobiographical memory. But among children who were 4–7 years of age when first interviewed, most did not recall the same events two years later, suggesting these early autobiographical memories are prone to being forgotten.

Let's consider several reasons for this loss of early memories.

1. **Space in working memory.** One explanation of childhood amnesia is that infants and toddlers may not have enough space in working memory to hold the multiple pieces of information about actor, action, and setting needed to encode and consolidate a coherent memory of an event. As you learned earlier in this chapter, functional working-memory capacity increases with age as the brain, particularly the frontal lobe, matures. But this explanation is unsatisfactory because, as we have just noted, toddlers can remember these events, indicating that they were encoded to some degree.
2. **Lack of language.** Perhaps infants' lack of language is the answer. Because autobiographical memory seems to rely heavily on language skills, we would expect such memories to increase with increased language skills. Gabrielle Simcock and Harlene Hayne (Hayne & Simcock, 2009; Simcock & Hayne, 2002, 2003) assessed the verbal skills of young children (27, 33, and 39 months old) who participated in a unique event involving a “magic shrinking machine” that seemingly made items smaller in a matter of seconds. After a 6- or 12-month delay, children were tested for both verbal

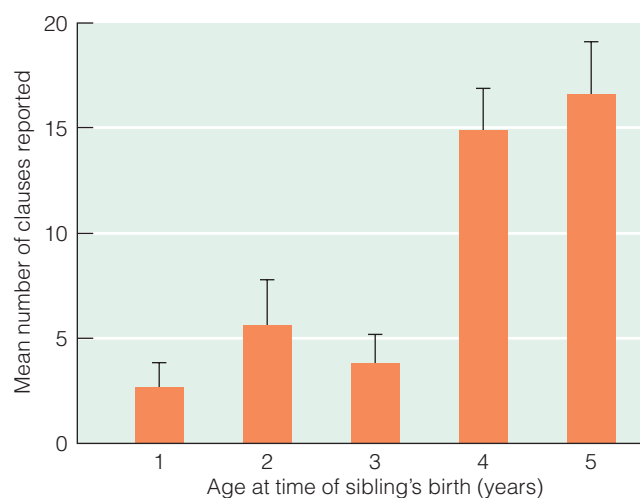

Figure 8.8 College students' recall of the birth of a younger sibling increases as a function of how old they were at the time of the event. Those who were at least 4 years of age when their sibling was born recall much more than those who were younger than 4.

recall (answers to open-ended questions) and nonverbal recall (identification of photos of the items used in the activity) of the unique event. Their nonverbal recall improved across the age groups but was good at all ages. Verbal recall was poor and largely dependent on the simpler verbal skills present at the time of encoding rather than the more developed verbal skills present at the time of recall. Although a relative lack of verbal skills during the first few years of life may limit what we are able to recall from this period, other research suggests that it does not completely block us from later attaching verbal labels to our preverbal memories (Bauer et al., 1998).

3. **Level of sociocultural support.** Although toddlers may have limited verbal skills, their parents presumably do not. There are large individual differences in toddler–parent “conversations” about past events (see Fivush, 2014). An examination of mother–toddler conversations about past events shows that some mothers provide rich elaborations of these events, whereas others do not, in the course of conversing with their toddlers (Fivush, 2014). Years later, adolescents whose mothers had been more elaborative during their early mother–toddler conversations have stronger autobiographical memories than adolescents whose mothers were less elaborative (Jack et al., 2009). It may be that regular rehearsal, in this case in the form of a parent repeating the story, is the sociocultural context needed to ensure long-term recall of an early event. Consider again the children who participated in the “magic shrinking machine” study. They were asked about the event 6 years later (Jack, Simcock, & Hayne, 2012). Only those whose parents had talked with them about the experience sustained any long-term recall of the event.
4. **Sense of self.** We need to consider that infants and toddlers lack a strong sense of self and as a result may not have the necessary ‘pages’ on which they can write memories of personally experienced events (Howe, 2014; Reese, 2014). Without a sense of self, it is difficult to organize events as “things that happened to *me*.” Indeed, young children’s ability to recognize themselves in a mirror is a good predictor of children’s ability to talk about their past (see Howe, 2014).
5. **Verbatim versus gist storage.** Some researchers have tried to explain childhood amnesia in terms of **fuzzy-trace theory** (Brainerd & Reyna, 2014; 2015). According to this explanation, children store verbatim and general accounts of an event separately. Verbatim information (such as word-for-word recall of a biology class lecture) is unstable and likely to be lost over long periods (Leichtman & Ceci, 1993); it is easier to remember the gist of an event (for example, recall of the general points covered in a biology lecture) than the details (Brainerd & Reyna, 2014; 2015). With age, we are increasingly likely to rely on gist or fuzzy memory traces, which are less likely to be forgotten and are more efficient than verbatim memory traces in the sense that they take less space in memory (Brainerd & Gordon, 1994; Klaczynski, 2001). Children pass through a transition period from storing largely verbatim memories to storing more gist memories, and the earlier verbatim memories are unlikely to be retained over time (Howe, 2000).
6. **Neurogenesis.** Finally, some intriguing research with mice suggests that neurogenesis, the birth of new cells, in the

hippocampus early in life ‘refreshes’ our memory store (Akers et al., 2014; Frankland & Josselyn, 2016). That is, new cells and new memories displace older cells and older memories. After birth, the period with the highest rate of neurogenesis is infancy, so perhaps this is why memories from infancy are largely nonexistent. More research is needed before we conclude that this is a legitimate cause of childhood amnesia.

Whether it is neurogenesis, insufficient working memory to encode events, language skills, a sense of self, or encoding only the verbatim details of what happened rather than a “fuzzy trace,” the events of our early childhood do not seem to undergo the *consolidation* needed to store robust memories of this time (Bauer et al., 2007).

Scripts

As children engage in routine daily activities such as getting ready for bed or eating at a fast-food restaurant, they construct **scripts** or **general event representations (GERs)** of these activities (Nelson, 1986; 2014). Scripts or GERs represent the typical sequence of actions related to an event and guide future behaviors in similar settings. For instance, children who have been to a fast-food restaurant might have a script like this: You wait in line, tell the person behind the counter what you want, pay for the food, carry the tray of food to a table, open the packages and eat the food, gather the trash, and throw it away before leaving. With this script in mind, children can act effectively in similar settings. Children as young as 3 years use scripts when reporting familiar events (Hudson & Mayhew, 2009; Nelson, 1997). When asked about their visit to a fast-food restaurant the day before, children usually report what happens *in general* when they go to the restaurant rather than what specifically happened during yesterday’s visit (Kuebli & Fivush, 1994). As children age, their scripts become more detailed. Perhaps more important than age, however, is experience: Children with greater experience of an event develop richer scripts than children with less experience (DeMarie, Norman, & Abshier, 2000).

Children develop scripts in memory for routine activities, such as visiting a fast-food restaurant, that guide their behavior in these situations.

Directphoto.org/Alamy Stock Photo

Children's scripts affect how they form memories of new experiences as well as how they recall past events. For example, when presented with information inconsistent with their scripts, preschoolers may misremember the information so that it better fits their script (Nelson & Hudson, 1988). Four-year-old Damian may have a script for birthdays that includes blowing out candles, eating cake, and opening presents. Although his brother is sick on his birthday and eats applesauce instead of cake, Damian later recalls that they all ate cake before opening presents. This demonstrates that memory is a reconstruction, not an exact replication (Hudson & Mayhew, 2009). This, in turn, has significant implications for **eyewitness memory** (or testimony), or the reporting of events witnessed or experienced—for example, a child's reporting that she saw her little brother snatch some candy before dinner. Children are increasingly asked to report events that have happened in the context of abuse cases or custody hearings. **Application 8.1** explores the accuracy of children's memory in these sorts of situations.

Problem Solving

Memories are vital to problem-solving skills. To solve any problem, a person must process information about the task, as well as use stored information, to achieve a goal. Thus, working memory is a critical component of problem solving. How do problem-solving capacities change during childhood? Piaget provided one answer

■ **Figure 8.9** The balance beam apparatus used by Robert Siegler to study children's problem-solving abilities. Which way will the balance beam tip?

Source: Siegler, R. S. (1981). Developmental sequences within and between concepts, *Monographs of the Society for Research in Child Development*, 46, (2, Serial No. 189). Copyright © 1981. Reprinted with permission of John Wiley & Sons, Inc.

to this question by proposing that children progress through broad stages of cognitive growth, but information-processing theorists were not satisfied with this explanation. They sought to pinpoint more specific reasons why problem-solving prowess improves so dramatically as children age.

Consider the problem of predicting what will happen to the balance beam in ■ **Figure 8.9** when weights are put on each side of the fulcrum, or balancing point. The goal is to decide which way the balance beam will tip when it is released. To judge correctly, you must take into account both the number of weights and their distances from the fulcrum. Piaget believed that concrete-operational thinkers can appreciate the significance of either the amount of weight or its distance from the center but will not grasp the inverse relationship between the two factors. Only when they reach the stage of formal

● APPLICATION 8.1

Children's Memory as Eyewitnesses

Children may be asked to provide information in situations with high stakes outcomes, such as custody hearings, sexual abuse cases, and a variety of criminal investigations (see Howe & Knott, 2015). To what extent can we "trust" a child's memory for events related to these situations? When asked generally about events ("Tell me what happened at Uncle Joe's house"), preschoolers recall less information than older children, but the recall of both groups is accurate (Goodman et al., 2014). Those children with stronger vocabulary skills are able to provide more information about an event than their peers with weaker vocabulary skills (Chae et al., 2014; 2016). The use of general prompts (such as "What happened next?" or "Tell me more about that . . .") can elicit additional recall of information. Specific questions ("Was Uncle Joe wearing a red shirt?") can also elicit more information, but accuracy of recall begins to slip, especially as the questions become more directed or leading ("Uncle Joe touched you here, didn't he?").

Preschool-age children, more so than older children and adults, are suggestible; they can be influenced by information implied in direct questioning and by relevant information introduced after the event (Schaaf, Alexander, & Goodman, 2008).

Perhaps it is unfortunate, then, that preschoolers, because they initially offer less information in response to open-ended questions, may be asked a larger number of directed questions than older children. They are also frequently subjected to repeated questioning, which increases errors in reporting among children (Bjorklund, Brown, & Bjorklund, 2002). Although repeated questioning with general, open-ended questions can increase accuracy, repeated questioning with directed or closed questions can decrease accuracy. For example, in a study with 5- and 6-year-olds, researchers "cross-examined" children about events that occurred on a field trip to a police station during which the children saw a jail cell and police car and were fingerprinted and photographed

(Zajac & Hayne, 2003). After a delay of 8 months, children's memories were probed using irrelevant, leading, and ambiguous questions like those you might hear in a courtroom. Many children "cracked" under the pressure as evidenced by backing down and changing their answers in response to the questioning. Fully one out of three children changed *all* their answers, and most changed at least one answer. So although children can demonstrate accurate recall when asked clear and unbiased questions, this study shows that young children's memory for past events can quickly become muddled when the questioning becomes tough.

Fortunately, protocols for interviewing young children have evolved to incorporate greater understanding of how memory develops and how it functions (see Goodman et al., 2014). These retrieval protocols may improve the collection of eyewitness testimony, but memory remains highly dependent on characteristics of the individual as well as the context of the event.

operations will new cognitive structures allow them to understand that balance can be maintained by decreasing a weight *and* moving it farther from the fulcrum or by increasing a weight *and* moving it closer to the fulcrum (Piaget & Inhelder, 1969).

Robert Siegler (1981, 2000) proposed that the information-processing perspective could provide a fuller analysis. His **rule assessment approach** determines what information about a problem children take in and what rules they then formulate to account for this information. This approach assumes that children’s problem-solving attempts are not hit or miss but are governed by rules; it also assumes that children fail to solve problems because they fail to encode all the critical aspects of the problem and are guided by faulty rules.

Siegler (1981) administered balance beam problems to individuals ages 3–20. He detected clear age differences in the extent to which both weight and distance from the fulcrum were taken into account in the rules that guided decisions about which end of the balance beam would drop. Few 3-year-olds used a rule; they guessed. By contrast, 4- and 5-year-olds were governed by rules. More than 80% of these children used a simple rule that said the side of the balance beam with greater weight would drop; they ignored distance from the fulcrum. By age 8, most children had begun to consider distance from the fulcrum and weight under some conditions: When the weight on the two sides was equal, they appreciated that the side of the balance beam with the weights farthest from the fulcrum would drop. By age 12, most children considered both weight and distance on a range of problems, although they still became confused on complex problems in which one side had more weights but the other had its weights farther from the fulcrum. Finally, 30% of 20-year-olds discovered the correct rule—that the pull on each arm is a function of weight times distance. For example, if there are three weights on the second peg to the left and two weights on the fourth peg to the right, the left torque is $3 \times 2 = 6$ and the right torque is $2 \times 4 = 8$, so the right arm will drop.

The increased accuracy of young adults comes with a price—increased time to solve the problem (van der Maas & Jansen, 2003). Although, in general, information-processing time gets faster with age, the complex rules needed to successfully solve all the variations of the balance beam problem demand more time. So on some problems, adults are slower than children because they are using a more sophisticated strategy.

In most important areas of problem solving, Siegler (1996) concluded, children do not simply progress from one way of thinking to another as they age, as his balance beam research suggested (see also Hofman et al., 2015). Instead, in working problems in arithmetic, spelling, science, and other school subjects, most children in any age group use multiple rules or problem-solving strategies rather than just one. In working a subtraction problem such as $12 - 3 = 9$, for example, children sometimes count down from 12 until they have counted off 3 and arrive at 9 but other times count from 3 until they reach 12. In one study of second- and fourth-graders, more than 90% of the children used three or more strategies in working subtraction problems (Siegler, 1989). Similarly, Michael Cohen (1996) found that most preschoolers used all possible strategies when attempting to solve a practical mathematical problem in the context of playing store. He also found that children’s selection and use of strategies became more

efficient over multiple task trials; that is, they increasingly selected strategies that would allow them to solve the task in fewer steps.

Success on memory and problem-solving tasks improves over time as we increasingly test out strategies, keeping those that lead to greater success and dropping the ones that are duds. Rather than picturing development as a series of stages resembling stair steps, Siegler argues, we should picture it as overlapping waves, as shown in **Figure 8.10**. According to Siegler’s (2006) **overlapping waves theory**, the development of problem-solving skills is a matter of knowing a variety of strategies, becoming increasingly selective with experience about which strategy to use, changing strategies as needed, and getting better at using known strategies (Fazio, DeWolf, & Siegler, 2016). At each age, children have multiple problem-solving strategies available to them. As children gain more experience, which typically occurs as they age, they decrease their use of less-adaptive strategies and increase their use of more-adaptive strategies; occasionally, new strategies may appear. Strategies evolve from their initial acquisition in a particular context to their generalization to other contexts, which helps strengthen the fledgling strategies.

Gradually, children not only learn to choose the most useful strategy for a problem but also become increasingly effective at executing new strategies. Familiarity with a task and with strategies frees processing space, allowing children to engage in more meta-cognitive analysis of the strategies at their disposal. Throughout, there is significant variability—both between children and within the same child across time and tasks. Research with students of varying mathematical abilities suggests that one of the problems for the low-performing students is their regular choice of a ‘questionable’ strategy (Fazio et al., 2016). Training on selecting an effective strategy from among the options is a start, but it must be paired with training on effective *use or application* of the strategy.

Imagine how effective teachers might be if they, like Siegler, could accurately diagnose the information-processing strategies of their learners to know what each child is noticing (or failing to notice) about a problem and what rules or strategies each child is

Figure 8.10 Cognitive development may resemble overlapping waves more than a staircase leading from one stage to another. Children of a particular age typically use multiple thinking strategies rather than just one.

Source: Siegler, R. S. (1996). *Emerging minds: The process of change in children’s thinking*. Copyright © 1996 by Oxford University Press, Inc. Used by permission of Oxford University Press, Inc.

using, and when. Like a good car mechanic, the teacher would be able to pinpoint the problem and encourage less use of faulty strategies and rules and more use of adaptive ones. Much remains to be learned about how problem-solving strategies evolve as children age, and why. However, the rule-assessment approach and overlapping waves theory give a fairly specific idea of what children are doing (or doing wrong) as they attack problems and illustrate how the information-processing approach to cognitive development provides a different view of development than Piaget's account does.

● Checking Mastery

1. What are two reasons why older children have improved memories relative to younger children?
2. How do scripts or GERS relate to memory?
3. What is the "take-home" message of the overlapping waves theory of problem solving?

● Making Connections

1. You are a first-grade teacher, and one of the first things you notice is that some of your students remember a good deal more than others about the stories you read to them. Based on what you have read in this chapter, what are your main hypotheses about why some children have better memories than other children the same age?
2. You have been called in to interview a young child who may have witnessed a shooting. Given the research on children's memory, how will you gather information from your young witness?
3. If you are typical, then you probably have few, if any, memories from the period of your infancy and even toddlerhood. Why can't we remember the early events of our lives?

8.4

The Adolescent

LEARNING OBJECTIVES

- Compare the typical adolescent's memory capabilities to those of the typical child.
- Explain why adolescents demonstrate stronger memory abilities than children.

Although parents in the midst of reminding their adolescent sons and daughters to do household chores or homework may wonder whether teenagers process any information at all, learning, memory, and problem solving continue to improve considerably during the adolescent years. Research on episodic memory shows that the performance of young teens (11–12 years) is quite similar to that of children, and both groups do markedly worse than young adults (Brehmer et al., 2007). Clearly, then, there is room for improvement during adolescence. How does this improvement occur?

Strategies

First, new learning and memory strategies emerge. It is during adolescence that the memory strategy of elaboration is mastered (Schneider & Pressley, 1997). Adolescents also develop and refine advanced learning and memory strategies highly relevant to school learning—for example, note-taking and underlining skills. They make more deliberate use of strategies that younger children use unconsciously (Bjorklund, 1985). For example, they may deliberately organize a list of words instead of simply using the organization or grouping that happens to be there already. And they use existing strategies more selectively. For example, they are adept at using their strategies to memorize the material on which they know they will be tested and at letting go of irrelevant information. To illustrate, Patricia Miller and Michael Weiss (1981) asked children and adolescents to remember the locations of animals that had been hidden behind small doors and to ignore the

household objects hidden behind other doors. As **Figure 8.11** shows, 13-year-olds recalled more than 7- and 10-year-olds about where the animals had been hidden, but they remembered less about task-irrelevant information (the locations of the household

Adolescents are more aware than children that they need to use strategies such as note-taking to help with encoding and retrieval of information to be remembered.

Joanne Harris/Dreamstime.com

Figure 8.11 Adolescents are better able than children to concentrate on learning relevant material and to ignore irrelevant material.

Source: Miller, P. H. & Weiss, M. G. (1981). Children's attention allocation, understanding of attention and performance on the incidental learning task, *Child Development*, 52, 1183–1190. Reprinted with permission of John Wiley & Sons, Inc.

objects). Apparently, they are better able to push irrelevant information out of working memory so that it does not interfere with task performance (Lorsbach & Reimer, 1997). So, during elementary school, children get better at distinguishing between what is relevant and what is irrelevant, but during adolescence they advance further by selectively using their memory strategies only on the relevant material. If it is not going to be on the test, forget it!

Basic Capacities

In addition to these changes in memory strategies, basic capacities continue to increase during adolescence. As discussed earlier in this chapter, adolescents have greater functional use of their working memory because maturational changes in the brain allow them to process information more quickly and to simultaneously process more chunks of information. Younger teens (13 years) with greater working memory perform better on a variety of academic subjects (Alloway, Banner, & Smith, 2010), perhaps because greater working memory is associated with better reading skills (Alexander & Fox, 2011; Titz & Karbach, 2014). Interestingly, weaker working memory is associated with impulsivity and adolescent alcohol use (Khurana et al., 2013). Improving working memory may help strengthen academic skills as well as nonacademic decision-making. Fortunately, there is evidence that training programs can improve working memory among teenagers, including those born with extremely low birth weight (Lohaugen et al., 2011).

Metamemory and Knowledge Base

There is little to say about knowledge base other than that it continues to expand during adolescence. Therefore, adolescents may do better than children on some tasks simply because they know more about the topic.

Metamemory and metacognition also improve. In general, adolescents are more skilled than children at adjusting their learning strategies to different purposes (e.g. studying versus skimming) and better able to judge when a task is likely to be 'easy' versus 'hard' (Paulus et al., 2014; Weil et al., 2013). About 80% of twelfth-graders report that they monitor their memory and learning strategies. But only 50–60% report that they think in advance to develop an effective plan for a difficult task or think back after completing a task to evaluate what worked or did not work (Leutwyler, 2009). Teenagers who have received explicit training on metacognitive skills from their teachers show improvements in learning outcomes (Williams et al., 2002). This suggests that it may be important to teach not only content but also how to monitor one's understanding of content acquisition (Farrington et al., 2012).

Successful metacognition can be seen in adolescents who choose the strategy of elaboration over rote repetition when they realize that the former is more effective (Pressley, Levin, & Ghatala, 1984). Adolescents are also fairly accurate at monitoring whether or not they have allocated adequate study time to learn new material, and they allocate more study time to information judged to be difficult. This regulation of study time shows awareness of the task demands as well as their own strengths in light of the task's difficulty (Lai, 2011).

Interestingly, when pressed for time, college students devote more study time to easy items (Dunlosky & Ariel, 2011; Metcalfe, 2009). Apparently, they decide it is futile to work on the difficult material when they do not have adequate time, so they spend their time on what seems most likely to pay off. Hopefully, you can see the implication of this for your own studying: Set aside enough time to study all the material; otherwise, you may end up in a time crunch reviewing only the easy material. When time is available, students proceed from the material they judge to be easy to the more difficult material. For more tips on how to improve your memory, which may help you perform better on your next test, visit **Engagement 8.1**.

Before leaving this section, it is interesting to note that use of metacognition during cognitive tasks varies by gender and socioeconomic background (Leutwyler, 2009). Adolescent girls consistently report using more metacognitive strategies than adolescent boys. This may help explain why girls earn higher grades in school than boys, a finding that we will explore in greater detail in Chapter 10. And students from higher socioeconomic backgrounds report more use of metacognitive strategies than their lower socioeconomic peers. Families with higher socioeconomic status may have more resources, such as books in the home, and may talk more explicitly about effective learning strategies.

Growth in strategies, basic capacities, knowledge base, and metacognition probably also helps explain the growth in everyday problem-solving ability that occurs during the adolescent years. Teenagers perfect several information-processing skills and become able to apply them deliberately and spontaneously across a variety of tasks.

● ENGAGEMENT 8.1

Improve Your Memory!

What are some practical steps you can use to improve your memory? First, keep in mind that your brain, which is absolutely essential for memory, does not operate in isolation from the rest of you. Your brain, and therefore your memory, is affected by such factors as the amount of sleep you get, your nutrition, and your physical activity.

Consider sleep. The process of consolidation of memories is critical to moving them into long-term storage and is improved with sleep. Try reviewing to-be-remembered information right before you go to sleep at night and then get the recommended hours of sleep for your age (see Chapter 5). Studying in the afternoon and then taking a nap has also been shown to help consolidate memories. And before you start to study, plan to do some aerobic exercise. This increases oxygen to your brain and also helps you stay alert and focused once you settle down to study. As for nutrition, a growing body of research suggests that omega-3 fatty acids contribute to brain function, as do B vitamins and antioxidants. A good meal for your brain might be salmon, spinach salad, and a strawberry-blueberry smoothie.

So you have adopted healthy eating, exercise, and sleep habits. What can you do to improve your memory when actually studying course material for that upcoming test? We'll focus on a few things that will assist with encoding and consolidation of memories, as well as some helpful hints for retrieval.

1. **PAY ATTENTION!** If you are daydreaming in class or thinking of something else or multitasking while reading, you will not encode the information to be learned. If you don't encode it, you will be out of luck when it comes time to retrieve the memory—it simply won't be there. To increase your attention, reduce the distractions that may be present in your environment.
2. **ORGANIZE AND MAKE CONNECTIONS** to existing knowledge. Organizing to-be-learned material into logical groups can aid in consolidation and storage of the information. What is logical depends on each individual and each task. The organizational scheme must make sense to the learner in the context that it needs to be learned. Consolidation is also more likely to occur when the new material can be related to existing knowledge. Think of how you might use familiar ideas to help you remember new ideas.
3. **USE STRATEGIES THAT ENRICH AND ELABORATE** the new material. Repeating items over and over is a simplistic strategy that helps store fairly simple facts. You need to dig deeper into your toolbox of strategies and choose those that will create richer connections to existing material or will allow you to elaborate the new material. Examples of these strategies might be to associate each new word to an existing concept; this could be taken a step further—elaborated—by thinking of the similarities and differences between the new and old material. Or think of an acronym using the first letter of each to-be-learned word. You could create a story that ties together a new set of concepts that you want to recall later; by retelling the story, you recall the concepts.
4. **CUSTOMIZE YOUR LEARNING STRATEGIES** to optimize your learning style. Some research suggests that students who use the strategy of verbal elaboration (that is, creating sentences about the material) have better recall than students who use mental imagery or another visual strategy (Kirchhoff & Buckner, 2006). But this same research also showed that individuals choose different strategies to learn the same material. Some learners tend to be more visual, whereas others excel with more verbal material and strategies.
5. **OVERLEARN** new material. If you study new material just enough to recognize or recall it for a short period, chances are good you will forget a considerable amount of this material. To prevent this from happening, you need to overlearn the material. Don't stop studying when you reach that point where you think you might be able to remember the material if you take the test very soon. Keep studying until retrieval of the information becomes quick and effortless. There is evidence that overlearning strengthens the neural connections involved in storing information and makes it more likely that you will be able to retrace these neural paths when it comes time to retrieve it.

● Checking Mastery

1. What are the differences in basic memory capacities of children and adolescents?
2. What memory improvements are we likely to notice when a child becomes an adolescent?

● Making Connections

1. Using the information-processing model presented earlier in the chapter (see Figure 8.1), explain why 17-year-old Nathaniel outperforms his 7-year-old sibling when asked to recall a TV program on the Civil War both watched last week.
2. Abigail has a big exam coming up—the results could determine whether or not she earns a scholarship for college. How should she prepare for the exam and what characteristics of the test itself or the testing conditions might affect her performance?

8.5

The Adult

LEARNING OBJECTIVES

- Distinguish characteristics of someone with expertise in a field relative to someone who is a novice.
- Describe the characteristics of adult autobiographical memory.
- Discuss age-related changes in memory across adulthood, noting factors that enhance and factors that impede memory.
- Explain how older adults may compensate for declines in memory and problem-solving ability.

For many years, researchers have used emerging adult college students as the standard of effective information processing, against which all other age groups are compared. This occurs because information processing is thought to be most efficient—at its peak—in emerging and young adults. Still, improvements in cognitive performance continue during the adult years before aging begins to take its toll on some memory and problem-solving capacities.

Developing Expertise

Comparing people new to their chosen fields of study with those more experienced tells researchers that experience pays off in more effective memory and problem-solving skills. In Chapter 7, you saw that people in Piaget’s highest stage of cognitive development, formal operations, often perform better in their areas of specialization than in unfamiliar areas. Similarly, information-processing research shows that adults often function best cognitively in domains in which they have achieved expertise (Ericsson, 1996; Glaser & Chi, 1988). It has been estimated that it takes about 10 years of training and experience to become a true expert in a field and to build a rich and well-organized knowledge base (Ericsson, 1996). But once this base is achieved, the expert not only knows and remembers more but also thinks more effectively than individuals who lack expertise.

Consider first the effects of semantic memory, or knowledge base, on performance. Adults who have considerable interest in and knowledge of cars—experts in the domain of cars—are more successful on recognition and recollection tasks about cars than the typical adult who is a car novice (Herzmann & Curran, 2011). Similar knowledge base effects are found for other areas of expertise, including American football (Van Overschelde et al., 2005), chess (Gong, Ericsson, & Moxley, 2015), maps (Ooms, De Maeyer, & Fack, 2015), and taxi drivers’ knowledge of street names (Kalakoski & Saariluoma, 2001). Expertise provides an advantage because, in part, it allows experts to hold and manipulate more information in short-term memory than nonexperts (see Tashman, 2013). Chess experts, for example, might look at a chess board with 20 pieces and “see” 3 or 4 clusters of chess pieces in play, whereas the novice chess player looks at the same board and sees 20 different chess pieces that seem to have little logic to their placement. Creating meaningful chunks out of the pieces on the chess board also shows that long-term memory plays a role in expertise. What

expert players have previously learned allows them to quickly identify meaningful patterns when shown a new chess board with pieces in play.

In addition, experts are able to use their elaborately organized and complete knowledge bases to solve problems effectively and efficiently (Bilalić et al., 2012; Sheridan & Reingold, 2014). They are able to size up a situation quickly, see what the problem really is, and recognize how a new problem is similar to and different from problems encountered in the past (Glaser & Chi, 1988). They can quickly, surely, and almost automatically call up the right information from their extensive knowledge base to devise effective solutions to problems and to carry them out efficiently.

Are the benefits of expertise content-specific, or does gaining expertise in one domain carry over into other domains and make a person a more generally effective learner or problem solver? This is an interesting and important question. One research team (Ericsson, Chase, & Faloon, 1980) put an average college student to work improving the number of digits he could recall. He practiced for about 1 hour a day, 3–5 days a week, for more than 1½ years—more than 200 hours in all. His improvement? He went from a memory span of 7 digits to one of 79 digits! His method involved forming meaningful associations between strings of digits and, of all things, running times because of his keen interest in running. For example, he would convert the numbers 3492 to “3 minutes and 49 point 2 seconds, near world-record mile time” (p. 1181). It also involved chunking numbers into groups of three or four, then organizing the chunks into large units.

Did all this work pay off in a better memory for information other than numbers? Not really. When he was given letters of the alphabet to recall, this young man’s memory span was unexceptional (about six letters). Clearly the memory ability he developed was based on strategies of use only in the subject matter he was trying to remember. Similarly, Bob Petrella, a man with an exceptional memory for anything and everything related to sports, turns out to have ordinary prospective memory, or remembering things that need to be done in the future (ABC News, 2010). Each expert apparently relies on domain-specific knowledge and domain-specific information-processing strategies to achieve cognitive feats (Ericsson & Kintsch, 1995; Schunn & Anderson, 1999).

Overall, experts know more than novices do, their knowledge base is more organized, and they are able to use their

Adults who have gained proficiency in their chosen fields can draw from their well-organized knowledge bases to find just the right information to fit the problem at hand. Solving problems is automatic and effortless for experts.

Robert Gerhardt/Dreamstime.com

knowledge and the specialized strategies they have devised to learn, remember, and solve problems efficiently in their areas of expertise—but not in other domains. In effect, experts do not need to think much; they are like experienced drivers who can put themselves on “autopilot” and carry out well-learned routines quickly and accurately (Callan & Naito, 2014). By gaining expertise over the years, adults can often compensate to some extent for age-related losses in information-processing capacities (Badham et al., 2016; Jastrzembski, Charness, & Vasyukova, 2006).

Autobiographical Memory

Earlier in this chapter, we examined the emergence of autobiographical memories and you learned that most adults do not remember much about their first few years of life. Yet we also noted that the long-term memory store seems limitless in terms of space and longevity. Is everything we have ever experienced “in there” somewhere? Likely not, as most adults report difficulties recalling past events. So what determines whether an event is likely to be recalled at a later point in time? We will consider four factors identified by Patricia Bauer (2007) that may influence autobiographical memories: personal significance, distinctiveness, emotional intensity, and life phase of the event.

1. Most people believe that the *personal significance* of an event affects our memory for the event—that events of great importance to the self will be remembered better than less important events. As it turns out, the personal significance of an event, as rated at the time the event occurs, has little effect on one’s ability to later recall the event. It may be that what was once considered important becomes less so with the passage of time and with the broader perspective gained over

the years. For example, imagine that at age 19, you break up with your boyfriend or girlfriend of 2 years. This is traumatic and of great importance to you as a 19-year-old. You expect you’ll never get over it and that the details of the event will be forever etched into your memory. But over the next 10, 20, 30 years, or more, so many other events occur that the importance of this youthful breakup fades as you date others, marry, work, raise children, and so on. Thus, personal significance of events may influence memory for these events as long as they remain important to us (Bauer, Hättenschwiler, & Larkina, 2016). But as some events become less important and others become more important over time, there is an associated shift in memory for these events.

2. The *distinctiveness* or *uniqueness* of an event has been consistently associated with better recall (Bauer, 2007). The more unique an event is, the more likely it is to be recalled later on, and to be recalled as a distinct event with relevant details. Common events and experiences are often recalled, if at all, as multiple events lumped together as one (Burt, Kemp, & Conway, 2003). Thus, if you attended the same camp every summer throughout your childhood, you may retain fond memories of your experiences at the camp. But the chances are good that you have integrated in your memory many of the common and similar camp experiences: You remember singing songs around the campfire, but because you did this every year of the camp, you don’t recall the experience of one year as separate from your experience of all the other years. On the other hand, consider the rather unique event of experiencing a tornado. Teenagers who had been young children at the time of the event, as well as adults, had good recall of this distinctive event 9 years after its occurrence (Bauer et al., 2016).
3. The *affective* or *emotional intensity* of an event also influences later recall (Bauer, 2007). Events associated with either highly negative or highly positive emotions are recalled better than events that were experienced in the context of more neutral emotions. This enhanced memory for emotion-arousing events occurs even though the emotion associated with the event tends to dissipate with time, especially if it is a negative emotion (Paz-Alonso et al., 2009). It is likely that strong emotions activate the body’s arousal system and the neural components associated with arousal enhance encoding and consolidation of events. This can be seen with fMRI scans of the brain as participants are cued to retrieve an autobiographical memory. The brain scans show activation of the amygdala, an area of the brain associated with emotions, when participants retrieve an emotionally charged memory but not when they retrieve a neutral memory (see Rubin, 2012; St. Jacques, 2012). And if you are an angry person, you tend to recall more negative, angry autobiographical memories (Hung & Bryant, 2016). Similar findings have emerged for other personal characteristics, which may provide valuable insight into the variability of memory across individuals.
4. Finally, research on autobiographical memory has revealed that people recall more information from the *life phase* of

their teens and 20s than from any other time except the near present (Fitzgerald, 1999; Rubin, 2002). ■ **Figure 8.12** shows the number of memories recalled by 70-year-old adults. Not surprisingly, they recalled a lot from their recent past (for example, age 65). But the number of memories recalled from about ages 15–25 was higher than the number recalled from other points of the life span, especially for positive life events (Zaragoza et al., 2015). This memory or **reminiscence bump** (Koppel & Berntsen, 2016; Koppel & Rubin, 2016) may occur because memories from adolescence and early adulthood are more easily accessible than memories from other periods of the life span. They are more accessible because of their distinctiveness and the effort applied by adolescents and young adults to understanding the meaning of the events. Notably, this time of life typically coincides with the major life events of leaving home, acquiring education or training for a job or career, forming romantic relationships, starting a family, and having other experiences signifying adulthood (Bohn & Berntsen, 2014). These events form one’s cultural **life script**, those stories of our lives that we tell over and over again (see Chapter 11 on narrative identities). These life scripts are biased toward positive, life-affirming events. A typical life script might go something like this: “After high school, I traveled half-way across the country to go to college, where I met my future spouse. Upon graduation from college, we both managed to get jobs in the same large city, close to his family but far from where I had grown up. We ended up staying there for

5 years, establishing our careers while helping out his ailing parents. Once they passed away, though, we saw an opportunity to move to a more ideal setting and settle down to have a family.” Such life scripts are repeated over time and contexts, becoming further consolidated with each retelling, ensuring that these major life events are solidly secured in our memory system. Research shows that there may be other “bumps” in memory across the life span that are influenced by what particular cultures prescribe as important life events (Berntsen & Rubin, 2004; Fitzgerald & Broadbridge, 2012).

Memory and Aging

No less an expert on learning than B. F. Skinner complained about memory problems: “One of the more disheartening experiences of old age is discovering that a point you have just made—so significant, so beautifully expressed—was made by you in something you published a long time ago” (Skinner, 1983, p. 242). Most elderly adults report that they have at least minor difficulties remembering things (Reid & MacLulich, 2006; Vestergren & Nilsson, 2011). They are especially likely to have trouble recalling names and items they will need later; they are also more upset than young adults by memory lapses, perhaps because they view them as signs of aging. **Exploration 8.1** describes when forgetfulness is normal and when it is indicative of a more serious problem.

Areas of Strength and Weakness

Much research indicates that, on average, older adults do not fare as well as younger adults under a variety of conditions that require memory. However, as we discuss areas of concern with memory of older adults, keep in mind the following qualifications:

- Most of the research is based on cross-sectional studies that compare age groups, which suggests that the age differences detected could be related to factors other than age. (If needed, you can refresh your memory of the strengths and weaknesses of cross-sectional designs by referring back to Chapter 1.)
- Declines, when observed, typically do not become noticeable until we hit our 70s.
- Difficulties in remembering affect elderly people more noticeably as they continue to age and are most severe among the oldest elderly people.
- Not all older people experience these difficulties.
- Not all kinds of memory tasks cause older people difficulty.

Studies of memory skills in adulthood suggest that the aspects of learning and memory in which older adults look most deficient in comparison with young and middle-aged adults are some of the same areas in which young children compare unfavorably with older children (see Bauer, 2007). Older adults often struggle to perform well on memory tasks that are timed, i.e., where completing the task quickly is more advantageous than completing the task at a slower pace. In contrast, on tasks where timing is not an issue and respondents have as much time as they want,

■ **Figure 8.12** Seventy-year-olds recall the times of their lives: What does this graph illustrate about the recall of autobiographical memories by older adults?

● EXPLORATION 8.1

Forgetting: What Is Normal and What Is Not?

As we age, or watch parents and grandparents age, how can we distinguish between normal forgetfulness and abnormal memory changes? Many older adults worry that forgetting an appointment or where they put their reading glasses is a precursor to the devastating memory loss associated with Alzheimer's disease (AD) (see Chapter 16). Fortunately, most of us will not develop AD and the atypical memory changes that accompany it. Most will, however, exhibit some changes in memory and information-processing skills. So how can we discriminate between normal memory changes and those associated with disease?

Cynthia Green (2001) suggests three criteria that can be used to alert us to atypical memory problems:

- Has memory gotten noticeably worse over the past 6 months?
- Do memory problems interfere with everyday activities at home or work?
- Are family and friends concerned about an individual's memory problems?

Answering “yes” to these questions may indicate unusual memory loss that should be evaluated by a professional.

In practical terms, it is normal to forget where you put something but abnormal to forget how to use it (Cherry & Smith, 1998). Thus, do not worry when Grandpa cannot find his car keys, but be alert if he cannot remember how to use them when they are in his hand. Similarly, it is normal to forget a new phone number you recently looked up in the phone book but abnormal to forget phone numbers you have known and used for years.

Researchers who study memory have identified a step between normal memory loss with age and severe, disease-related loss

(Brandt et al., 2009; Petersen et al., 1997, 2001). Individuals with **mild cognitive impairment** experience significant memory problems—forgetting important appointments, having trouble learning new names, and repeating themselves to the same person—but otherwise do not appear to be suffering from dementia. At least not yet. Some research suggests that a majority of those with mild cognitive impairment will eventually develop forms of dementia such as AD (Lopez, 2013). Research also suggests that patients with mild cognitive impairment display deficits on other cognitive tasks as well, which could mean their problem is more general than memory impairment (Ribeiro, de Mendonca, & Guerreiro, 2006). This is a serious concern because 22% of older adults may have mild cognitive impairment and will require increased assistance as they continue to age (Plassman et al., 2008).

The good news is that age-related memory loss may be preventable, and some losses may be reversible. Reducing stress, for example, is one way to improve memory performance (Bremner & Narayan, 1998). Chronic stress elevates levels of cortisol in the brain, which impedes memory. Studies by the Mayo Clinic and the MacArthur Foundation found that three things predicted good memory over time: physical fitness and activity, mental activity, and a sense of control over life events (Geda et al., 2012; Rowe & Kahn, 1998). Mental activity—working crossword puzzles, reading, using a computer—increases connections among neurons. Physical activity increases blood flow to the brain and seems to release chemicals that protect neurons involved in cognitive function. Older adults who engage in moderate to high levels of physical activity are less likely to develop cognitive impairment

Fuse/Corbis/Getty Images

than those who are not active (Etgen et al., 2010). Thus, remaining physically and mentally active can help protect against memory loss associated with aging. Having a sense of control over memory can boost both confidence and memory performance.

In sum, significant memory loss is not likely among healthy older adults. It is true that, relative to young adults, older adults exhibit poorer memory performance in some situations. But these changes are minor and can often be avoided or minimized by remaining physically and mentally active. Families and professionals should be on the lookout for older adults who show marked declines in their memory performance. They may be experiencing mild cognitive impairment and may eventually develop AD and impaired memory. The earlier they are identified and receive treatment, the better (see Chapter 16).

older adults may not show significant memory deficits, at least not until very old age. As well, older adults fare poorly compared with younger adults when the material to be learned is unfamiliar or unimportant to them. Lars Bäckman (1991) tested young and old adults for facial recognition of two groups of people:

those who had been famous in the 1930s and 1940s when the older adults were young and those who were famous 50–60 years later when the research was conducted. Findings supported the researcher's predictions that the older adults would perform better with the faces familiar to them from long ago, whereas the

young adults would perform better with the contemporary faces that were presumably familiar to them. Researchers often do not take into consideration that stimuli familiar to one group of participants may not be especially familiar to another group of participants. Yet as this study and others have shown, familiarity with the information-to-be-remembered contributes to success (Badham et al., 2016).

Like their younger counterparts, older adults are likely to be more deficient on tasks requiring recall memory than on tasks requiring only recognition of what was learned. In a classic study of memory for high school classmates (Bahrick, Bahrick, & Wittlinger, 1975), even adults who were almost 35 years past graduation showed remarkable recognition memory: They could recognize which of five names matched a picture in their yearbook about 90% of the time. However, the ability to actively *recall* names of classmates when given only their photos as cues dropped considerably as the age of the rememberer increased. A large gap between recognition and recall shows that older people have encoded and stored the information but cannot retrieve it without the help of cues. Sometimes older adults fail to retrieve information because they never thoroughly encoded or learned it, but at other times they simply cannot retrieve information that is “in there.”

Finally, older adults seem to have more trouble with explicit memory tasks that require mental effort than with implicit memory tasks that are largely automatic (Nyberg et al., 2012). Older adults, then, have little trouble with skills and procedures that have been routinized over the years—established as habits—although there might be some slight decline, often in the form of slower response times (Ward, Berry, & Shanks, 2013). And with explicit memory, where there tends to be a larger decline, the magnitude of the decline varies with the type of explicit memory. Older adults retain fairly good semantic memory (general factual knowledge accumulated over time) but show steady declines in episodic memory (recall of specific events that are tied to a specific time and place) (Nyberg et al., 2012).

Overall, these findings suggest that older adults, like young children, have difficulty with tasks that are cognitively demanding—that require speed, the learning of unfamiliar material, the use of unexercised abilities, recall rather than recognition, or explicit and effortful rather than implicit and automatic memory. Yet older adults and young children have difficulty for different reasons, as you will now see.

Explaining Declines in Old Age

In asking why some older adults struggle with some learning and memory tasks, we will first return to the hypotheses used to explain childhood improvements in performance: knowledge base, metamemory, strategy use, and basic processing capacities. Then we will consider some additional possibilities.

Knowledge Base. If you start with the hypothesis that differences in knowledge base explain memory differences between older and younger adults, you immediately encounter a problem: Young children may lack knowledge, but elderly adults do not. Indeed, older adults are generally at least as knowledgeable

as young adults: Semantic memory for vocabulary *increases* until about age 65 (Rönnlund et al., 2005; Salthouse, 2016). Verbal knowledge shows no decrease throughout mid- and older adulthood and may not decline until we are pushing 90 (Park et al., 2002)! Older adults also know more than younger adults about real-world categories of information such as U.S. presidents, countries, international cities, and bodies of water (Foos & Sarno, 1998; Rendell, Castel, & Craik, 2005). In an important study, Harry Bahrick (1984) tested adults of various ages on their retention of Spanish vocabulary from high school or college classes. Amazingly, as much as 50% of the vocabulary learned was retained nearly *50 years* later! And it may be worth your time and effort to learn as much as you can in your classes now: Bahrick also found that the more classes taken in a subject and the higher the grades in those courses, the better the retention of this material in the years to come. Adults who took several Spanish classes and earned “A” grades remembered more Spanish vocabulary 50 years later than adults who took one Spanish class and earned “C” grades remembered after a delay of just 1 year. Information that undergoes meaningful consolidation can clearly be retained in long-term memory for many years to come. So deficiencies in knowledge base are probably not the source of most memory problems that many older adults display. On the contrary, gains in knowledge probably help older adults compensate for losses in information-processing efficiency (Salthouse, 2015).

Metamemory. Could elderly adults, like young children, be deficient in the specific knowledge called metamemory? Is their knowledge of some of the strategies that prove useful in school learning—and in laboratory memory tasks—rusty? This theory sounds plausible, but research shows that older adults seem to know as much as younger adults about such things as which memory strategies are best and which memory tasks

Dorothy Emmrich, 100, uses a memory program to exercise her information-processing skills. Research suggests that both physical and mental workouts can aid memory across the life span.

Bloomberg/Getty Images

are hardest (Castel, McGillivray, & Friedman, 2012). They can also monitor their memory to assist their learning (Hines, Tournon, & Hertzog, 2009). Still, older adults are more likely than younger ones to misjudge the accuracy of some aspects of their memory, such as the source of the memories (Dodson, Bawa, & Krueger, 2007).

So whereas metamemory seems largely intact across the life span, there may be some isolated areas of weakness. Moreover, although older adults know a lot about memory, they express more negative beliefs about their memory skills than do younger adults (Cavanaugh, 1996). Memory loss may contribute to a drop in confidence in memory skills, but negative beliefs about one's memory skills also appear to hurt memory performance (Barber & Mather, 2014; Hess & Hinson, 2006). Therefore, it's not clear whether declines in actual memory performance lead to the development of negative beliefs about memory or whether negative beliefs—either one's own or those of the surrounding culture—undermine memory performance.

Becca Levy (1996) has shed light on this issue by showing that activating negative stereotypes in the minds of elderly adults (through rapid, subliminal presentation of words such as *Alzheimer's* and *senile* on a computer screen) causes them to perform worse on memory tests and to express less confidence in their memory skills than when positive stereotypes of old age are planted in their minds (through words such as *wise* and *sage*). In another study, Levy and her colleagues (2012) assessed beliefs about aging among adults aged 22 to 77 years. Over the next 38 years, the researchers found that these beliefs predicted memory performance. In particular, those who had more negative beliefs about old people experienced a 30% decline in memory compared to other adults the same age who had less negative beliefs. Findings such as these clearly call into question the idea of a universal decline in memory skills in later life and point to the influence of culture and its views of aging on performance (see also Castel et al., 2012; Nelson, 2016).

Memory Strategies. What about the hypothesis that failure to use effective memory strategies accounts for deficits in old age? Many older adults do not spontaneously use strategies, even those as simple as writing notes to help remember a phone message (Schryer & Ross, 2013). At least some older adults show improved memory performance when they are prompted to use a strategy (Frankenmolen et al., 2016). Whether or not memory improves seems to depend on a person's level of intelligence: Those with higher intelligence benefit from strategy use whereas those with lower intelligence do not benefit, possibly because they do not correctly implement the strategy (Frankenmolen et al., 2016).

Other research shows that older adults can be trained to use cognitive strategies. George Rebok, Sherry Willis, and their colleagues (see Rebok et al., 2014) in the Advanced Cognitive Training for Independent and Vital Elderly (ACTIVE) Group followed four groups of older adults (average age of 74 years at the start of the study) over a period of 10 years. The groups differed in the type of cognitive training they received at the beginning of the study:

- Memory training—participants were taught strategies of organization, visualization, and association to remember verbal material.
- Reasoning training—participants were taught strategies for detecting a pattern in a series of letters or words.
- Speed training—participants learned to complete visual search tasks in increasingly less time, and they were trained to divide their attention between two tasks.
- No training—these participants served as a control group.

How did the groups fare across the 10 years? Compared with the control group, the adults who received memory training did better on memory tasks for the first 5 years, but this advantage was washed out by 10 years. Those who received reasoning training performed better on reasoning tasks and those who received speed training were much faster, and both of these findings held true across the entire 10-year period of the study. Importantly, the benefits of training were evident not just on laboratory tasks but on activities important to daily living, such as driving or understanding the interactions and side-effects of prescription drugs.

This study and others (e.g., Karbach & Verhaeghen, 2014; Zinke et al., 2014) show that older adults can profit from mental exercise that increasingly challenges them. Just as physical exercise contributes to overall physical well-being, mental exercise contributes to overall mental well-being. And just as your physical workouts need to increasingly challenge you (if you start out walking a half-mile at a slow pace, you need to increase your distance and/or your pace to reap the most benefits), your mental workouts must become more rigorous. If you start out solving easy Sudoku puzzles, you need to push yourself to move on to more difficult ones.

Basic Processing Capacities. Changes in basic processing capacities that occur with age are perhaps the biggest issue with memory. For starters, declines in sensory abilities may tax available processing resources, leading to memory deficits (Baltes & Lindenberger, 1997). In addition, working-memory capacity diminishes with age. Research indicates that working-memory capacity increases during childhood and adolescence, peaks around age 45, then begins to decline (Swanson, 1999). Moreover, working-memory capacity predicts how well adults will perform on a range of cognitive tasks (Hoyer & Verhaeghen, 2006). Older adults do fine on short-term memory tasks that require them to juggle just a few pieces of information in working memory. However, when the amount of information that they are to “operate on” increases, they begin to show deficits. Older adults may have more trouble than younger ones ignoring irrelevant task information. For instance, trying to memorize a list of words while walking is more problematic for older adults than for middle-aged or younger adults (Li et al., 2001; Lindenberger, Marsiske, & Baltes, 2000). Brain research confirms that older adults show a pattern of neural activity consistent with increased monitoring of their environment when working under conditions with more distractions and task-irrelevant information (Stevens et al., 2008). Thus, their working-memory

space may become cluttered with unnecessary information, limiting the space available for the task at hand (Hoyer & Verhaeghen, 2006).

Limitations in working-memory capacity are most likely rooted in slower functioning of the nervous system both early and late in life (see Hartley, 2006; also see Chapter 5). Much research shows that speed of processing increases during childhood and adolescence, peaks in early adulthood, then declines slowly over the adult years (Baudouin et al., 2009). Age differences in performance on cognitive tasks often shrink when age differences in speed of information processing are taken into account and controlled. Experience in a domain of learning can certainly enhance performance, but if children and older adults generally have sluggish “computers,” they simply may not be able to keep up with the processing demands of complex learning and memory tasks (Hartley, 2006).

Using brain imaging techniques, researchers have also identified different patterns of activity during memory tasks in the prefrontal cortex of younger and older adults (see, for example, Galdo-Alvarez, Lindin, & Diaz, 2009; Rypma et al., 2001). Although some studies show underactivity in older adults’ brains, others show overactivity. Underactivity in the older brain is assumed to result from a deficiency of either the hardware of the brain or of the software it uses, such as the strategies that could be employed on a task (Reuter-Lorenz & Cappell, 2008). Overactivity, on the other hand, may indicate that the older brain is trying to compensate for age-related losses. By compensating, or working harder and drawing on more brain areas, the older brain may be able to perform as well as a younger brain, at least until this overactivity can no longer overcome steeper age-related declines (Meulenbroek et al., 2010).

Some promising research with mice points to the role of a protein (called B2M) that accumulates with age and inhibits the formation of new brain cells and results in an associated loss of memory (Villeda et al., 2014). Injecting this “old age” protein into young mice led to impaired memory but once the protein had dispersed from their bodies, their memories rebounded to normal levels. And consistent with our discussion in Chapter 5 about the importance of a good night’s sleep, sleep deprivation, at least in mice, interferes with the synthesis of hippocampal protein, leading to memory deficits (Tudor et al., 2016). Future research needs to determine whether the same connection between this protein and memory exists for humans and, if so, what—if anything—can be done to circumvent this potential problem.

Slow neural transmission as well as too much or too little of certain proteins, then, may be behind limitations in working memory in old age. Limitations in working memory, in turn, may contribute not only to limitations in long-term memory but also to difficulties performing a range of cognitive tasks, including problem-solving tasks and tests of intelligence, even those that have no time limits (Salthouse, 2015).

To this point, then, you might conclude that many older adults, although they have a vast knowledge base and a good deal of knowledge about learning and memory, experience declines

in basic processing capacity that make it difficult for them to carry out memory strategies that will drain their limited working-memory capacity. But the basic processing capacity hypothesis cannot explain everything about age differences in memory. We need to dig deeper and consider several contextual factors.

Contextual Contributors. Many researchers have adopted a contextual perspective on learning and memory, emphasizing both biological and genetic factors along with environmental and situational factors (Hess & Emery, 2012). They emphasize that performance on learning and memory tasks is the product of an interaction among (1) characteristics of the learner, such as goals, motivations, abilities, and health; (2) characteristics of the task or situation; and (3) characteristics of the broader environment, including the cultural context in which a task is performed. They are not convinced that there is a universal biological decline in basic learning and memory capacities, because older individuals often perform capably in certain contexts.

First, cohort differences in education and IQ can explain age differences in some learning and memory skills. Elderly people today are less educated, on average, than younger adults are, and they are further removed from their school days. When education level is controlled for, age differences shrink, although they do not disappear (Nilsson et al., 2002; Rönnlund et al., 2005). Thus, to some extent, education can compensate for aging. Older adults who are highly educated or who have high levels of intellectual ability often perform as well as younger adults (Cherry & LeCompte, 1999; Haught et al., 2000). Similarly, health and lifestyle differences between cohorts may contribute to age differences in learning and memory. Older adults are more likely than younger adults to have chronic or degenerative diseases, and even mild diseases can impair memory performance (Houx, Vreeling, & Jolles, 1991; Hulstsch, Hammer, & Small, 1993). Older adults also lead less active lifestyles and perform fewer cognitively demanding activities than younger adults do, on average. These age group differences in lifestyle also contribute to age differences in cognitive performance. Older adults who engage in fitness training show enhanced cognitive ability, possibly because physical activity increases blood flow to the brain (Colcombe et al., 2004; Etgen et al., 2010). Increased blood flow to the hippocampus is associated with improved memory performance (Heo et al., 2010). Similarly, older adults who remain *mentally* active or take on challenging mental activities outperform other older adults on working memory and other cognitive tasks (Stine-Morrow et al., 2008).

Notice that if we compare older adults with lower education levels to younger adults with higher education levels, or compare older adults with health challenges to younger, healthy adults, then in both cases, we are conducting cross-sectional research (see Chapter 1). Cross-sectional research on memory performance often paints a more negative picture of aging than longitudinal research (Nyberg et al., 2012). ■ **Figure 8.13** illustrates the typical pattern of a fairly steep drop in both semantic and episodic memory found with cross-sectional studies (top half of figure) compared to the pattern found with longitudinal studies

Figure 8.13 Episodic and semantic memory changes typically found with cross-sectional research (top half) and longitudinal research (bottom half). The rather sharp decline in memory suggested by cross-cultural studies may reflect cohort differences rather than effects of aging per se.

Source: Adapted from Figure 1, Lars Nyberg, Martin Lövdén, Katrine Riklund, Ulman Lindenberger, & Lars Bäckman, (2012). Memory aging and brain maintenance, *Trends in Cognitive Sciences*, Volume 16, Issue 5, 292–305.

where memory performance actually improves across much of the life span with only a small dip after the age of about 75 (bottom half of figure).

The implications of such research are clear: Declines in information-processing skills are not inevitable or universal. Nature may place some boundaries on the information-processing system, but nurture plays a significant role in sustaining memory and problem-solving skills. Older adults may be able to maintain their memory skills if they are relatively well educated, stay healthy, and exercise their bodies and minds. Still, factors such as education and health cannot account completely for age differences in cognitive performance.

Perhaps the truth lies somewhere between the basic processing capacity view, which emphasizes nature by pointing to a universal decline in cognitive resources, such as speed and working memory, that affect performance on many cognitive tasks, and the contextual view, which emphasizes nurture. Contextual theorists stress variability from person to person and situation to situation based on cohort differences, motivational factors, and task demands. Most adults, at least if they live to an advanced old age, may experience some loss of basic processing resources. However, they may also have developed specialized knowledge and strategies that allow them to compensate for these losses as they carry out the everyday cognitive activities most important to them.

Problem Solving and Aging

You know that problem-solving skills improve steadily from early childhood through adolescence, but what becomes of them in adulthood? On the one hand, you might expect to see a decline in problem-solving prowess paralleling declines in learning and memory performance. On the other hand, if adults increase their knowledge bases and develop expertise as they age, might not older adults outwit younger novices on many problem-solving tasks?

Familiar versus Unfamiliar Tasks

When given traditional problem-solving tasks to perform in the laboratory, young adults typically perform better than middle-aged adults, who in turn outperform older adults (Denney, 1989). However, consider research using the Twenty Questions task in which participants are shown an array of items and asked to find out, using as few questions as possible, which item the experimenter has in mind. The best problem-solving strategy is to ask **constraint-seeking questions**—ones that rule out more than one item (for example, “Is it an animal?”). Young children and older adults tend to pursue specific hypotheses instead (“Is it a pig?” “Is it a pencil?”). Consequently, they must ask more questions to identify the right object. However, if the task is altered to make it more familiar (for example, through the use of playing cards as stimuli), then older adults do far better. The familiarity of the material allows them to draw on their knowledge base to solve the problem. Thus, older adults are capable of using effective problem-solving strategies but do not use them in some contexts, especially when given unfamiliar tasks in a laboratory.

What if adults are asked to deal with real-life problems such as leaky water pipes, family squabbles, or refrigerators that break down in the middle of the night? Nancy Denney and Kathy Pearce (1989) asked elderly adults to help them devise everyday problems that would be meaningful and familiar to older individuals. One problem was to generate ideas about how a 65-year-old recently widowed woman could improve

her social life; another was to advise an elderly couple living on Social Security what to do when they were unable to pay their heating bill one winter. On these everyday problems, performance increased from early adulthood to middle age and declined in old age.

Other findings echo this one: When given everyday problems to which they can apply the expertise they have gained through experience, middle-aged adults often outperform young adults. Elderly adults sometimes equal and sometimes do worse than young and middle-aged adults; either way, they show smaller deficits on the everyday problems than they do on unfamiliar problems in the laboratory (Berg & Klaczynski, 1996; Marsiske & Willis, 1995). Ultimately, declines in basic capacities may limit the problem-solving skills of many elderly adults, not only in the laboratory but also in real life (Denney, 1989; Kasworm & Medina, 1990). You should bear in mind, however, the contextual view that cognitive competence among older adults varies widely because of differences in health, education, experience, and so on.

Selection, Optimization, and Compensation

Some cognitive researchers believe that older adults may approach problem solving differently than younger adults. It's true that younger adults generate more possible solutions to a problem than do older adults. But the solutions generated by older adults tend to be more goal-focused and selective, emphasizing quality over quantity (Marsiske & Margrett, 2006). When faced with a broken water pipe in the middle of the night, an older couple may generate one solution—call their grown son who lives down the street. Although this may not seem like an ideal solution to the son, the older adults may realize that this is the easiest and fastest solution.

In addition, researchers have proposed a framework called **selective optimization with compensation (SOC)**, to understand how older adults may cope with and compensate for their diminishing cognitive resources (Baltes & Baltes, 1990; Baltes & Rudolph, 2013; Riediger, Li, & Lindenberger, 2006; and see Chapter 11). Three processes are involved: *selection* (focus on a limited set of goals and the skills most needed to achieve them), *optimization* (practice those skills to keep them sharp), and *compensation* (develop ways around the need for other skills). If cognitive resources are limited or unstable, then you can't take on everything; you need to be selective. Choose those tasks that are most important or have to be done. For example, prepare dinner (after all, you have to eat), but don't worry about getting every surface of the house dusted. Focus on what you do well—optimize your strengths and minimize weaknesses. If you still have the skills to balance a checkbook and this is something your partner struggles with, then you should take over managing the checkbook. If your vision is so bad that you cannot tell that your "clean" dishes have chunks of food remaining on them, then offload this task to a dishwasher or partner.

Research suggests that both middle-aged and older adults take advantage of SOC, although older adults less so than middle-aged ones (Robinson, Rickenbauch, & Lachman, 2016). Both groups are more likely to use SOC on days when they experience greater stress. In addition, SOC has been used to try to help older adults overcome weaknesses in explicit memory by taking advantage of their relative strength of implicit memory. For instance, Cameron Camp and his colleagues (Camp et al., 1996; Camp & McKittrick, 1992) have worked with patients who have dementia caused by Alzheimer's disease (AD). They have taught patients with AD to remember the names of staff members by having the patients name photos of staff members repeatedly and at ever longer intervals between trials. People who could not retain names for more than a minute were able to recall the names weeks later after training. The technique appears to work because it uses implicit memory processes that are often retained even when explicit memory ability is lost; adults learn effortlessly when they repeatedly encounter the material to be learned. By selecting and optimizing, older adults can often compensate for their diminishing explicit memory, allowing them to maintain independence for a longer period of time (Riediger et al., 2006).

● Checking Mastery

1. On what types of tasks are older adults most likely to experience memory problems?
2. How can adults minimize the effects of aging on memory and problem-solving tasks?

● Making Connections

1. As a teacher in an Elderhostel program for older adults, you want to base your teaching methods on knowledge of the information-processing capacities of elderly adults. What practical recommendations would you derive from (a) the view that there is a universal decline with age in basic processing capacities and (b) the contextual perspective on cognitive aging?
2. Revisit Figure 8.12 showing the distribution of autobiographical memories over the life span. What factors might account for the rise and fall of autobiographical memories at different phases of the life span?
3. Every time your mother and grandmother forget something, they express concerns about "losing it" and "getting senile." Knowing that you have taken a course in life-span human development, they seek you out for reassurance. What can you tell them about memory and aging that might alleviate their concerns?

Chapter Summary

8.1 Conceptualizing Memory

- The information-processing approach uses a computer analogy to illustrate how the mind processes information. The human “computer” takes in information through the sensory registers, which hold the information for a very brief period. Information attended to may be further processed in short-term, or working, memory.
- Eventually, information may be stored in long-term memory, which seems to be unlimited in terms of size and permanency. In order for something to move into the long-term memory store, it must undergo a process of consolidation in which a memory trace of the event is created.
- Encoding and retrieval strategies influence memory performance. Types of retrieval include recognition, recall, and cued recall.
- Explicit memory is deliberate and effortful and changes over the life span, whereas implicit memory is automatic and relatively stable over the life span. Explicit and implicit memories are separate components of long-term memory and are localized in different parts of the brain.
- Memory has neurological underpinnings that influence memory effectiveness and contribute to developmental changes across the life span.
- Stored memories are instrumental to success at problem solving; stored information is used to achieve a goal. Executive control processes select, organize, manipulate, and interpret what is going on in the context of problem solving.

8.2 The Infant

- Using imitation, habituation, and operant conditioning techniques, researchers have gone from believing that infants have no memory beyond a few seconds to appreciating that even young 1-year-olds can recall experiences for weeks and even months under certain conditions.
- Infants clearly show recognition memory for familiar stimuli at birth and cued recall memory by about 2 months. More explicit memory, which requires actively retrieving an image of an object or event no longer present, appears to emerge toward the end of the first year. By age 2, it is even clearer that infants can recall events that happened long ago, for they, like adults, use language to represent and describe what happened.
- Simple problem solving improves throughout infancy, and infants realize that they can get adults to help them solve problems.

8.3 The Child

- Basic information-processing capacity increases as the brain matures and fundamental processes are automated to free working-memory space.

- Memory strategies such as rehearsal, organization, and elaboration improve. Metamemory improves and the general knowledge base grows. All these changes improve the processing of new information in areas of expertise.
- According to Robert Siegler, even young children use systematic rules to solve problems, but their problem-solving skills improve as they replace faulty rules with ones that incorporate all the relevant aspects of the problem. Multiple strategies are used at any age so that development proceeds through a natural selection process and resembles overlapping waves more than a set of stairsteps leading from one way of thinking to the next.
- Memory improves during childhood with increased efficiency of basic information-processing capacities, greater use of memory strategies, improvement in metamemory, and growth of general knowledge base.
- By age 3, children store routine daily events as scripts that they can draw on in similar situations. Our scripts influence what we remember about an event, which is also influenced by information related to but coming after the event.
- Much of what we remember is autobiographical. Even though infants and toddlers show evidence of memory, older children and adults often experience childhood amnesia, or lack of memory for events that happened during infancy and early childhood.

8.4 The Adolescent

- Adolescents master advanced learning strategies such as elaboration, note-taking, and underlining, and they use their strategies more deliberately and selectively.
- Adolescents have larger knowledge bases, and their metamemory skills also improve and contribute to increased memory performance and problem-solving ability.

8.5 The Adult

- As adults gain expertise in a domain, they develop large and organized knowledge bases and highly effective, specialized, and automated ways of retrieving and using their knowledge.
- Many older adults perform less well than young adults on memory tasks that require speed, the learning of unfamiliar or meaningless material, the use of unexercised abilities, recall rather than recognition memory, and explicit rather than implicit memory.
- Declines in basic processing capacity and difficulty using strategies, plus contextual factors such as cohort differences and the irrelevance of many laboratory tasks to everyday life, contribute to age differences in memory.
- On average, older adults also perform less well than younger adults on laboratory problem-solving tasks, but everyday problem-solving skills are likely to improve from early adulthood to middle adulthood and to be maintained in old age.

Integrating Cognitive Perspectives

Do you know someone who is very intelligent but still manages to do things that seem stupid or foolish? If you don't personally know someone like this, then perhaps you are familiar with the fictional character Sheldon Cooper on television's *The Big Bang Theory*. Sheldon is super smart, with an alleged IQ of 187. He graduated from college at age 14, obtained multiple advanced degrees, and works as a theoretical physicist. Despite his high level of intelligence, there are times when Sheldon shows evidence of irrational thought and lack of social understanding. This sort of incongruity raises many questions. Is intelligence a general ability that should somehow be available and applied in all situations? Are there different types of intelligence and, depending on our particular profiles of ability, might we be intelligent in one situation but not so intelligent in others? If we have gaps in intelligence, can these be filled in with training? And if people like Sheldon can have high scores on intelligence tests but show less than intelligent behavior in 'real-world' settings, can these tests really be measuring intelligence? Finally, how does intelligence relate to creativity? In many cultures and many workplaces, creativity is highly valued, both in terms of the products that result from it, such as artistic masterpieces, and in terms of the process behind it, such as when a creative approach to a problem leads to a brilliant solution that may not otherwise have been considered.

Is being intelligent the same as being smart?

Collection Christophel/Alamy Stock Photo

In this chapter, we tackle these sorts of fascinating questions. In doing so, we examine how performance on intelligence tests typically changes and stays the same over the life span, what IQ tests reveal about a person, and why people's IQ scores differ. We also look at both gifted and intellectually disabled individuals from a life-span perspective. We consider what might be missed by intelligence tests, including creativity and 'street smarts,' or what some scientists call rational thought (Stanovich, 2009). Before going further, take the quiz in **Engagement 9.1** to see if you have any misconceptions about intelligence and intelligence tests; this chapter will clarify why the correct answers are correct.

9.1

Defining Intelligence and Creativity

LEARNING OBJECTIVES

- State how intelligence and creativity are typically defined.
- Analyze the accuracy and usefulness of traditional IQ tests.
- Explain the most prominent theories of intelligence.
- Evaluate the strengths and weaknesses of the theories of intelligence.

Let's begin by trying to understand intelligence as defined by some of the most prominent scholars in this field. As noted in Chapter 7, Piaget defined intelligence as thinking or behavior that is adaptive to the demands of your situation or environment. Other experts have offered different definitions, many of them centering on the ability to think abstractly or to solve problems effectively (for example, Sternberg, 2010a, 2010b). Early definitions of intelligence tended to reflect the assumption that intelligence is an innate ability—that it is genetically determined and fixed at conception. But it has become clear that intelligence is not fixed; it is changeable and subject to environmental influence (see Nisbett et al., 2012). As a result, an individual's intelligence test scores sometimes vary considerably over a lifetime. Bear in mind that understanding of this complex human quality has changed since the first intelligence tests were created at the turn of the last century—and that there is still no single, universally accepted definition of intelligence.

The Psychometric Approach

The research tradition that spawned the development of standardized tests of intelligence is the **psychometric approach**. According to psychometric theorists, intelligence is a trait or a set of traits that characterizes some people to a greater extent than others. The goals, then, are to identify these traits precisely and to measure them so that differences among individuals can

be described. But from the start, experts could not agree on whether intelligence is one general cognitive ability or many specific abilities.

Early on, Charles Spearman (1927) proposed a two-factor theory of intelligence involving, first, a general mental ability (called *g*) that contributes to performance on many different kinds of tasks. This *g* factor is what accounts for Spearman's observation that people were often consistent across a range of tasks. For example, general intelligence has been found to correlate with performance on exams in 25 different academic subjects (Deary et al., 2007). However, Spearman also noticed that a student who excelled at most tasks might score low on a particular measure (for example, memory for words). So he proposed a second aspect of intelligence: *s*, or special abilities, each of which is specific to a particular kind of task. Some research suggests that *g* may play a greater role in IQ test performance during childhood than it does during adolescence (Kane & Brand, 2006). By adolescence, many effortful processes that underlie the expression of *g* have become automated, freeing up cognitive resources to sharpen certain specific abilities.

Raymond Cattell and John Horn have greatly influenced current thinking concerning intelligence by distinguishing between two broad dimensions of intellect: fluid intelligence and crystallized intelligence (Cattell, 1963; Horn & Cattell, 1967; Horn & Noll, 1997). **Fluid intelligence** is the ability to use your mind actively to solve novel problems such as recognizing relationships

● **ENGAGEMENT 9.1**

What Do You Know about Intelligence and Creativity?

Answer each question true or false:

1. On the leading tests of intelligence, a score of 100 is average.
2. Scholars now conclude that there is no such thing as general intelligence; there are only separate mental abilities.
3. Individuals who are intellectually gifted are typically gifted in all mental abilities.
4. Intellectually gifted children do well in school but are more likely than most children to have social and emotional problems.
5. IQ predicts both a person's occupational status and his success compared with others in the same occupation.
6. On average, performance on IQ tests declines for people in their 70s and 80s.
7. Qualities associated with wisdom are as common among young and middle-aged adults as among elderly adults.
8. It has been established that children's IQs are far more influenced by their environments than by their genes.
9. How well a child does on a test of creativity cannot be predicted well from her IQ score.
10. Creative achievers (great musicians, mathematicians, writers, and so on) typically do all their great works before about age 40 or 45 and produce only lesser works from then on.

Answers: 1-T, 2-F, 3-F, 4-F, 5-T, 6-T, 7-T, 8-F, 9-T, 10-F

among geometric figures (■ **Figure 9.1**). The skills involved—reasoning, seeing relationships among stimuli, and drawing inferences—are usually not taught and are believed to represent a person's “raw information processing power” (Gottfredson & Saklofske, 2009). **Crystallized intelligence**, in contrast, is the use

of knowledge acquired through schooling and other life experiences. Tests of general information (At what temperature does water boil?) and word comprehension (What is the meaning of *duplicate*?) are measures of crystallized intelligence. Thus, fluid intelligence involves using your mind in new and flexible ways, whereas crystallized intelligence involves using what you have already learned through experience.

Obviously, there is no single answer to the question *What is intelligence?* Nonetheless, some consensus has emerged from the vast amount of research conducted over the years on this construct. Intelligence is most often viewed as a hierarchy that includes (1) a general ability factor at the top that influences how well people do on a range of cognitive tasks; (2) a few broad dimensions of ability that are distinguishable in a **factor analysis**, a statistical technique in which test items are correlated to identify groups of items that correlate highly with each other but not with other groups of items (for example, fluid intelligence, crystallized intelligence, memory capacity, and processing speed); and (3) at the bottom, many specific abilities such as numerical reasoning, spatial discrimination, and word comprehension that also influence how well a person performs cognitive tasks that tap these specific abilities (Carroll, 1993; Horn & Noll, 1997).

One of the most significant contributions to the psychometric approach to intelligence occurred in 1904 when Alfred Binet and Theodore Simon were commissioned by the French government to devise a test that would identify “dull” children who might need special instruction. Binet and Simon devised a set of tasks measuring the skills believed to be necessary for classroom learning: attention, perception, memory, reasoning, verbal comprehension, and so on. Items that discriminated between typically developing children and those described by their teachers as slow were kept in the final test.

■ **Figure 9.1** An example of a problem used to assess fluid intelligence. Which of the 8 numbered pieces would you select to complete the design shown in the large box? If you chose #7, you are correct.

This forerunner of the modern IQ test was soon revised so that the items were age-graded. For example, a set of “6-year-old” items could be passed by most 6-year-olds but by few 5-year-olds; “12-year-old” items could be handled by most 12-year-olds but not by younger children. This approach permitted the testers to describe a child’s **mental age (MA)**—the level of age-graded problems that the child is able to solve. Thus, a child who passes all items at the 5-year-old level but does poorly on more advanced items—regardless of the child’s actual age—is said to have a MA of 5.

Binet’s test became known as the **Stanford–Binet Intelligence Scale** after Lewis Terman of Stanford University translated and published a revised version of the test for use with American children. Terman developed a procedure for comparing a child’s MA with his chronological age (CA) by calculating an **intelligence quotient (IQ)**, which consisted of MA divided by CA and then multiplied by 100 ($IQ = MA/CA \times 100$). An IQ score of 100 indicates average intelligence, regardless of a child’s age: The average child passes just the items that age-mates typically pass; MA increases each year, but so does CA, so that typically IQ remains about the same. The child of 8 with a MA of 10 has experienced rapid intellectual growth and has a high IQ (specifically, 125); if she suffered brain damage and still had a MA of 10 at age 15, she would have an IQ of only 67 and would clearly be below average compared with children of the same age.

The Stanford–Binet has been revised numerous times over the years and is still in use. Its **test norms**—standards of normal performance expressed as average scores and the range of scores around the average—are based on the performance of a large, representative sample of people (2-year-olds through adults) from many socioeconomic and racial backgrounds. The concept of MA is no longer used to calculate IQ; instead, individuals receive scores that reflect how well or how poorly they do compared with others of the same age. An IQ of 100 is still average, and the higher the IQ score an individual attains, the better the performance is in comparison with that of age-mates.

David Wechsler constructed a set of intelligence tests, collectively referred to as the **Wechsler Scales**, also in wide use. The Wechsler Preschool and Primary Scale of Intelligence (WPPSI-IV) is for children between ages 3 and 8 (Wechsler, 2012). The Wechsler Intelligence Scale for Children (WISC-V) is appropriate for schoolchildren ages 6–16 (Wechsler, 2014), and the Wechsler Adult Intelligence Scale (WAIS-IV) is used with adults (Wechsler, 2008). The Wechsler tests yield a verbal IQ score based on items measuring vocabulary, general knowledge, arithmetic reasoning, and the like, and a performance IQ score based on such nonverbal skills as the ability to assemble puzzles, solve mazes, reproduce geometric designs with colored blocks, and rearrange pictures to tell a meaningful story. As with the Stanford–Binet, a score of 100 is defined

Individually administered intelligence tests such as the Stanford–Binet and the Wechsler Scales assess a wide range of intellectual abilities that comprise intelligence.

LAURENT/AUBOURG/BSIP SA/Alamy Stock Photo

as average performance for the person’s age. A person’s full-scale IQ is a combination of the verbal and performance scores.

Scores on both the Stanford–Binet and Wechsler Scales form a **normal distribution**, or a symmetrical, bell-shaped spread around the average score of 100 (■ Figure 9.2). Scores around the average

■ **Figure 9.2** A normal distribution curve showing traditional intelligence test scores in the classic bell shape around the average score of 100.

are common; very high and very low scores are rare. We also know that the standard deviation is 16 points for the Stanford–Binet and 15 points for the Wechsler Scales. The **standard deviation** is a measure of how tightly the scores are clustered around the mean score. As Figure 9.2 shows, about two-thirds of people taking the Wechsler test have scores between 85 and 115 (one standard deviation unit above and below the mean) and nearly 95% have scores between 70 and 130 (two standard deviation units above and below the mean). Fewer than 3% have scores of 130 or above, a score often used as one criterion of giftedness. Similarly, fewer than 3% have IQs below 70, a cutoff commonly used to define intellectual disability.

In the end, the intelligence tests guided by psychometric theories have emphasized general intellectual ability by summarizing performance in a single IQ score, and they have assessed only some of the specialized abilities humans possess. Critics believe traditional psychometric tests have not fully described what it means to be an intelligent person, and some have offered alternative ways of thinking about intelligence that represent challenges to the traditional view. Reading about these approaches in the following sections will help you capture the nature of intelligence and appreciate the limitations of the tests used to measure it.

Gardner’s Theory of Multiple Intelligences

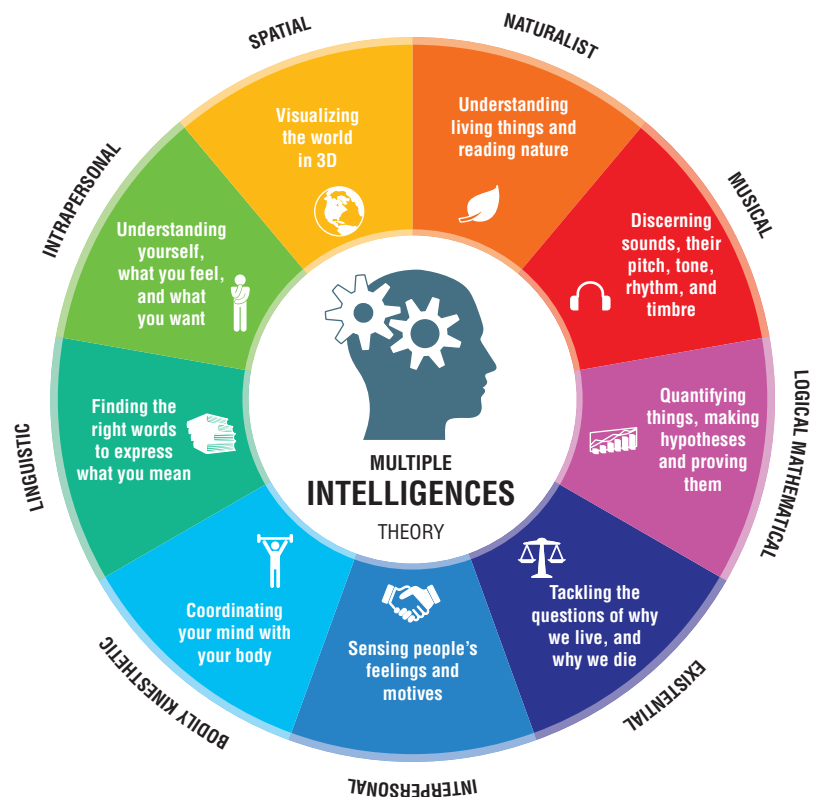

As noted, not everyone agrees that the psychometric approach that led to the development of IQ tests is the best way to understand intelligence. Howard Gardner (1999/2000) rejects the idea that a single IQ score is a meaningful measure of human intelligence. He argues that there are many intelligences, most of which have been ignored by the developers of standardized intelligence tests. Instead of asking, “How smart are you?” researchers should be asking, “How are you smart?” and identifying people’s strengths and weaknesses across the full range of human mental faculties (Chen & Gardner, 1997). Gardner (1999/2000) argues that there are eight or nine distinct intellectual abilities, which are shown in ■ Figure 9.3.

Traditional IQ tests emphasize two of Gardner’s multiple intelligences: linguistic and logical–mathematical intelligence, and to some extent they test a third intelligence, spatial intelligence, perhaps because those are the forms of intelligence Western societies value most highly and work the hardest to nurture in school. But IQ tests can be faulted for ignoring most of the other forms of intelligence. Although Gardner does not claim that his is the definitive list of intelligences, he presents evidence suggesting that each of the abilities is distinct. For example, it is clear that a person can be exceptional in one ability but poor in others—witness **savant syndrome**, the phenomenon in which extraordinary talent in a particular area is displayed by a person otherwise intellectually challenged (Treffert, 2010; 2014). Leslie Lemke, one such individual, is affected by cerebral palsy, blindness, and intellectual

disability, and could not talk until he was an adult (Treffert, 2010). Yet he can hear a musical piece once and play it flawlessly on the piano or imitate songs in perfect German or Italian even though his own speech is primitive. He clearly has a high level of musical intelligence despite a traditional IQ score of 58 (Treffert, 2014). Other savants, despite IQs below 70, can draw well enough to gain admittance to art school or can calculate on the spot what day of the week it was January 19, 1909 (Kennedy & Squire, 2007). Some scholars think that the skills shown by savants are so specific and depend so much on memory that they do not qualify as separate “intelligences.” Analyses of **prodigies**, those endowed with one or more extraordinary abilities, similarly suggest that their skills are related to their exceptional working memory abilities as well as their elevated attention to detail, and not to exceptional intelligence, either *g* or *s* (Ruthsatz, Ruthsatz-Stephens, & Ruthsatz, 2014; Ruthsatz & Urbach, 2012).

Gardner has amassed evidence to show that each type of intelligence has its own distinctive developmental course. Many great musical composers and athletes, for example, revealed their genius in childhood, whereas exceptional logical–mathematical intelligence typically shows up later, after the individual has gained the capacity for abstract thought and has mastered an area of science. Gardner also links his distinct intelligences to distinct structures in the brain, arguing that the multiple intelligences are neurologically distinct.

Gardner’s theory has been adopted by educators to help understand differences in how students learn and how instruction might be modified to better resonate with students who have different styles (Baum, Viens, & Slatin, 2005). In many cases, schools use a simplified version of Gardner’s multiple intelligences by

■ Figure 9.3 Gardner’s theory of multiple intelligences.

focusing on three of them: visual, auditory, and kinesthetic. These educators believe that some students learn by *seeing* (e.g., looking at PowerPoint slides, textbooks), others by *hearing* (e.g., listening to lectures, participating in discussions), and still others by *doing* (e.g., conducting experiments, acting out scenes from a novel).

Sternberg's Triarchic Theory and Successful Intelligence

Agreeing with Gardner that the traditional psychometric approach does not capture all that it means to be an intelligent person, Robert Sternberg (1985, 1988a, 2003, 2009b, 2011) has proposed a **triarchic theory of intelligence** that emphasizes three components that jointly contribute to intelligent behavior: practical, creative, and analytic intelligences (■ Figure 9.4).

The Practical Component

First, according to the **practical component**, what is defined as intelligent behavior varies from one sociocultural context to another. What might be intelligent in one context may be quite illogical in another. People who are high in this practical component of intelligence can adapt to the environment that they find themselves in, and they can shape the environment to optimize their strengths and minimize their weaknesses. These people have “street smarts,” or common sense.

Just as intelligent behavior varies from one context to another, it also changes over time. Numerical abilities may not play as

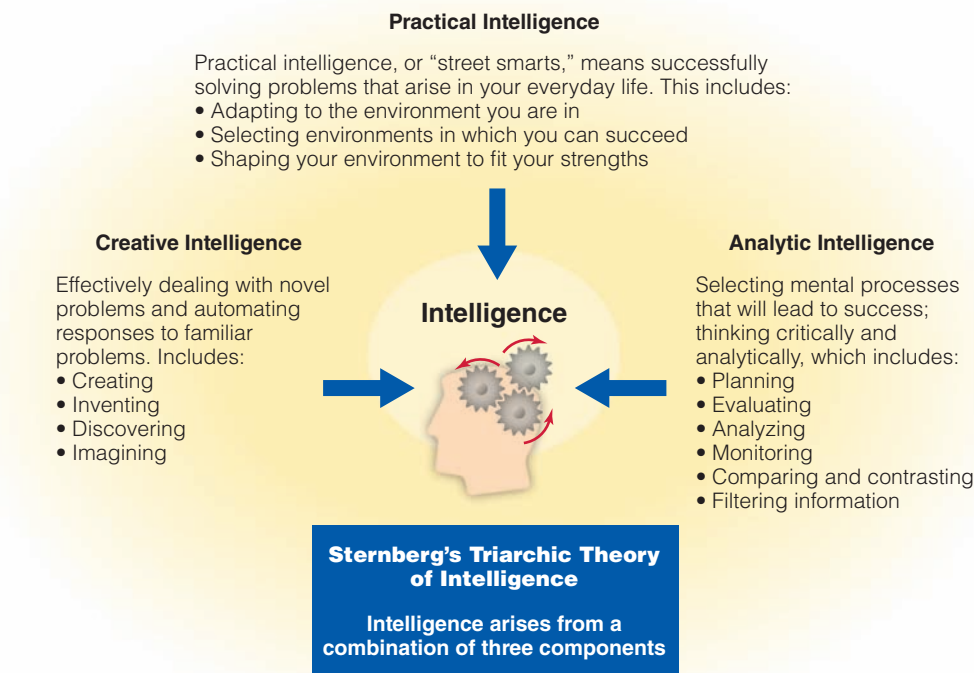

important a role in intelligent behavior now that calculators and computers are widely used, for example, whereas analytical skills may be more important than ever in a complex, urban world. And certainly the infant learning how to master new toys shows a different kind of intelligence than the adult mastering a college curriculum. Thus, the definition of intelligence in the context of infancy must differ from the definition of intelligence in the context of adulthood.

The practical component of Sternberg's triarchic theory, then, defines intelligent behavior differently depending on the context in which it is displayed. Intelligent people adapt to the environment they are in (for example, a job setting), shape that environment to make it suit them better, or find a better environment. They can walk into a new situation, quickly evaluate it, and adapt their behavior to be successful in this new context. Although recognized by many people as an important form of intelligence, this real-world adaptability is not assessed by traditional intelligence tests.

The Creative Component

According to the **creative component** of the triarchic theory, what is intelligent when a person first encounters a new task is not the same as what is intelligent after extensive experience with that task. The first kind of intelligence, *response to novelty*, requires active and conscious information processing. Sternberg believes that relatively novel tasks provide the best measures of intelligence because they tap the individual's ability to come up with creative ideas or fresh insights.

In daily life, however, people also perform more or less intelligently on familiar and repetitive tasks (driving a car, for example).

■ **Figure 9.4** Sternberg's triarchic theory of intelligence includes three components: practical, creative, and analytic intelligences.

This second kind of intelligence reflects **automatization**, or an increased efficiency of information processing with practice. It is intelligent to develop little “programs in the mind” for performing common, everyday activities efficiently and unthinkingly. Thus, according to Sternberg, it is crucial to know how familiar a task is to a person before assessing that person’s behavior. For example, giving people of two different cultural groups an intelligence test whose items are familiar to one group and novel to the other introduces **culture bias** into the testing process, making it difficult to obtain a fair assessment of the groups’ relative abilities.

The Analytic Component

The third aspect of the triarchic theory, the **analytic component**, focuses on the information-processing skills that produce answers to questions in traditional intelligence tests. These include thinking critically and analytically. Specifically, people who are high on this component can plan what to do, monitor progress, filter out irrelevant information and focus on the relevant, compare new information to existing knowledge, and evaluate outcomes.

As an information-processing theorist, Sternberg believes that the theories of intelligence underlying the development of traditional IQ tests ignore *how* people produce intelligent answers. He argues that a full picture of intelligence includes not only the number of answers people get right but also the processes they use to arrive at their answers and the efficiency with which they use those processes. So, to fully assess how intelligent people are, researchers must consider the *practical context* in which they perform (their age, culture, and historical period), their ability to respond *creatively* to new tasks, and their *analytic* strategies. Individuals who are intelligent, according to this triarchic model, are able to carry out logical thought processes efficiently and effectively to solve both novel and familiar problems and to adapt to their environment. Before moving on, review Sternberg’s three components of intelligence with the examples provided in ● Table 9.1.

Successful Intelligence

Sternberg (1999b, 2003, 2011) expanded his triarchic theory to include what he calls the theory of **successful intelligence**. According to the most recent version of this theory, successful intelligence consists of being able to:

Robert Sternberg has advanced our thinking about intelligence by proposing a triarchic theory. What are the three components of this theory?

AP Images/Michelle McLoughlin

- establish and achieve reasonable goals consistent with your skills and circumstances,
- optimize your strengths and minimize weaknesses,
- adapt to the environment through a combination of selecting a good environment and making modifications to yourself or the environment to increase the fit,
- use all three components of intelligence—analytic, creative, and practical.

The path to successful intelligence, then, is figuring out a reasonable goal given your skills and circumstances, and positioning yourself to allow your strengths to blossom and weaknesses to fade. It also means that when circumstances or skills change, you can adapt or alter the environment or move on to something that is a better fit. Consider Bob’s story. After struggling with academics throughout middle and high school, Bob decided that college was not his best option. Instead, he found himself “in the right place at the right time” as his grandfather was getting older and looking for some help with his landscaping business. Bob had always loved working outdoors and had an eye for how to arrange plantings to their best advantage, something for which his grandfather never

● **Table 9.1** Sternberg’s Triarchic Theory of Intelligence: Examples of Three Hypothetical Students, Each Excelling at One of the Three Components

Component	Description of Hypothetical Student
Practical	Practical Patty is not terribly creative, nor does she get the best grades in the classroom. However, if you want to get something done, enlist Patty’s help; she can figure out a way to get a job done or get from point A to point B efficiently.
Analytic	Many people rate Analytic Alice as a gifted student, and teachers love having her in their classrooms. Although not very imaginative, she is able to analyze a collection of ideas and provide a logical critique of them.
Creative	Creative Cathy does not get as “deep” into understanding the material as her classmate Alice. But she generates lots of new ideas and can be counted on to offer a different perspective in class discussions.

had much patience. After a few years, when his grandfather was ready to retire, Bob knew he had most of the skills needed to take over the business. He realized, though, that the business had not really been modernized and that he himself lacked the bookkeeping skills that would be needed to maintain and grow the business. He took a few courses at the local college and talked to some of the customers about their needs. From this, he developed a marketing and growth plan for the business. The business thrived, but after a few years, Bob recognized that his customers increasingly asked about water gardens, something he had not previously offered. After considering the pros and cons of branching out, Bob decided he could handle it. After all, he didn't want to lose customers to his competitors just because water gardens had not been "his thing" in the past. He figured he knew enough to incorporate this alternative type of garden into the business.

Bob does not necessarily exhibit the type of intelligence that many people may think of when they consider the meaning of intelligence, that is, intelligence for academic tasks. However, Bob illustrates successful intelligence: establishing a goal that made sense for him given his situation, being aware of his strengths and weaknesses, and adapting to changes over time. Take a few minutes to consider your own goals, your circumstances, and your pattern of strengths and weaknesses. What path might be an intelligent option for you?

Creativity

According to Sternberg, creativity is one of the three main components of intelligence. Most scholars define **creativity** as the ability to produce novel responses appropriate in context and valued by others—products both original and meaningful (e.g., Runco & Jaeger, 2012). Thus, someone who comes up with a novel and useful idea is considered creative, whereas someone who comes up with a novel idea that has no apparent value may not be considered creative. Some researchers who study creativity, however, have concerns about limiting the definition of creativity to include only those ideas that are deemed useful (Simonton, 2012). After all, who decides what is useful, and who is to say whether something will be valued by someone at some time? Consequently, some researchers examine all novel outputs and not just those that are deemed useful or valuable.

Research shows some correlation between creativity and intelligence, although not a particularly strong one (see Kaufman & Plucker, 2011). It turns out that IQ scores and creativity scores do not correlate very well because they measure two different types of thinking. IQ tests measure **convergent thinking**, which involves "converging" on the best answer to a problem. If we could typecast someone as a *convergent thinker*, it would be the person who wants to know *the* correct answer to a problem. In contrast, creativity involves **divergent thinking**, or coming up with a variety of ideas or solutions to a problem when there is no single correct answer. Responses on divergent thinking tasks can be analyzed along three dimensions: the originality or uniqueness of the generated ideas, the flexibility of thinking or how many different categories are expressed by the ideas, and the fluency of the ideas (Runco, 2014). This last one—**ideational fluency**, or the sheer number of different (including novel) ideas that a person

can generate—is most often used to assess creativity because it is easy to score. **Quick**—list all the uses you can think of for a pencil. An uncreative person might say you could write letters, notes, postcards, and so forth; by contrast, one creative person envisioned a pencil as "a backscratcher, a potting stake, kindling for a fire, a rolling pin for baking, a toy for a woodpecker, or a small boat for a cricket" (Richards, 1996, p. 73).

This use of divergent thinking tasks to assess creativity reflects a psychometric approach. That is, it assumes that creativity is a trait that is held to a greater or lesser degree by individuals and can be measured. While the psychometric approach can be useful, it may not consider the multitude of factors that constitute creativity. This is where Sternberg's **investment theory** of creativity is valuable (Sternberg, 2012). According to studies of creative achievement, creativity emerges from a *confluence*, or coming together, of these six factors:

- intellectual skills that include the trio of abilities comprising Sternberg's triarchic theory of intelligence discussed earlier,
- enough knowledge of a field to have an understanding of the current state and what might be missing or needed in the field,
- a thinking style that "enjoys" mentally toying with ideas,
- a personality style that is open to some risk and is comfortable stepping outside the norm,
- motivation to stay focused on the task and not give up when faced with obstacles,
- an environment that supports and rewards creative output.

Thus, according to the investment theory, creativity is a confluence of many factors, each added in appropriate concentrations at the proper time. We might think of creativity as analogous to making a good soufflé: It requires certain ingredients—including intelligence—in specific amounts, sometimes combined in a particular order, baked at the proper temperature, and for the right amount of time. All these things must come together or your soufflé will be a flop. And so it is with creativity.

As you can see, although the two constructs are related, intelligence, with its focus on convergent thinking, and creativity, with its focus on divergent thinking, are distinct, although there may be tasks best solved through application of both types of thinking. In subsequent sections, as we discuss the intellectual profiles of children, adolescents, and adults, we will also consider the development of their creative selves. Note, however, that the infant is not included in our discussion of creativity because, to date, researchers have not developed a method for uncovering signs of creativity at this young age.

● Checking Mastery

1. What is the difference between fluid and crystallized intelligence?
2. What is the main point of Gardner's theory of intelligence?
3. What three factors contribute to intelligence according to Sternberg?
4. How does creativity compare to intelligence and how is it typically measured?

● Making Connections

1. Imagine that you are chosen to head a presidential commission on intelligence testing whose task it is to devise an IQ test for use in the schools that is better than any that currently exists. Sketch out the features of your model IQ test. What would be included and excluded from your definition of intelligence? How would you measure intelligence? In what ways would your test improve upon the tests that are currently used?
2. Traditional IQ tests assess convergent thinking. Should they also assess divergent thinking? Why or why not?

9.2

The Infant

LEARNING OBJECTIVES

- Name and describe methods of assessing infant intelligence.
- Indicate the infant behaviors that are best connected to later intelligent behaviors and explain the reason for this connection.

As you saw in Chapters 7 and 8, the mind develops rapidly in infancy. But how can an infant's intellectual growth be measured? Is it possible to identify infants who are more or less intelligent than their age-mates? And how well does high (or low) intelligence in infancy predict high (or low) intelligence in childhood and adulthood?

Bayley Scales

None of the standard intelligence tests can be used with children much younger than 3, because the test items require verbal skills and attention spans that infants and toddlers do not have. Some developmentalists have tried to measure infant intelligence by assessing the rate at which infants achieve important developmental milestones. Perhaps the best known and most widely used infant test is the **Bayley Scales of Infant Development (BSID)** now in its third edition (Bayley, 2006). This test, designed for infants and toddlers ages 1 month to 42 months, collects information on social-emotional skills and adaptive behavior from parents and has three parts administered to the child:

- The *motor scale* measures the infant's ability to do such things as grasp a cube and throw a ball.
- The *cognitive scale* assesses how the young child thinks and reacts to various typical events such as reaching for a desirable object, searching for a hidden toy, and following directions.
- The *language scale* rates the child's preverbal communication and budding vocabulary skills.

On the basis of responses on the various scales, the infant is assigned scores for cognitive, language, motor, and social-emotional development, and all of these contribute to a **General Adaptive Composite (GAC)**. The Bayley GAC summarizes how well or how poorly the infant performs in comparison with a large norm group of infants and toddlers the same age.

Infant Intelligence as a Predictor of Later Intelligence

As they age, infants progress through many developmental milestones of the kind assessed by the Bayley scales, so such scales are useful in charting infants' developmental progress. They can provide valuable

The Bayley Scales of Infant Development allow practitioners to evaluate an infant's performance relative to their peers on important developmental milestones.

Cliff Moore/Science Source

information to assist with diagnosing neurological problems and intellectual disability—even when these conditions are mild and difficult to detect through standard pediatric or neurological examinations (Honzik, 1983; 1986). But developmentalists have also been interested in the larger issue of continuity versus discontinuity in intellectual development: Is it possible to predict which infants are likely to be gifted, average, or intellectually disabled during the school years?

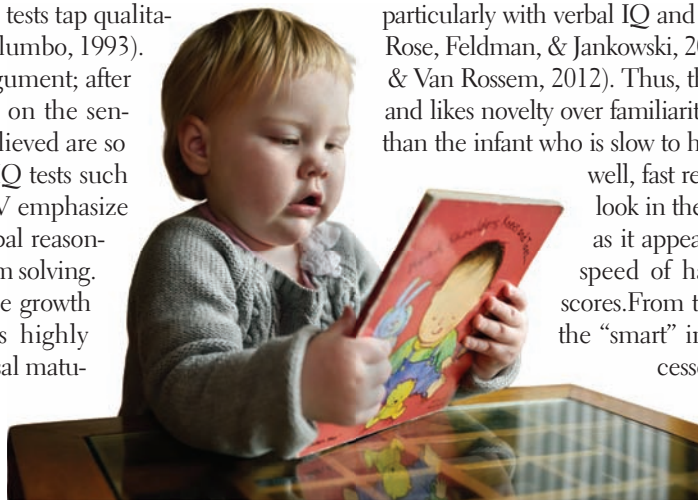

Not from their Bayley scores, at least not from the earlier versions of the Bayley (see, for example, Bode et al. 2014 for predictive validity of the most recent Bayley Scales). For the most part, correlations between infant Bayley scores and child IQ scores have been low, demonstrating that the infant who does well on the Bayley scales or other infant tests may or may not obtain a high IQ score later in life (Hack et al., 2005). True, the infant who scores markedly low on an infant test often turns out to be intellectually challenged, but otherwise there seems to be a great deal of discontinuity between early and later scores—at least until an infant is one year or older.

What might explain the poor connection between scores on infant development scales and children's later IQs? The main reason

seems to be that infant tests and IQ tests tap qualitatively different kinds of abilities (Columbo, 1993). Piaget would likely support this argument; after all, the infant scales focus heavily on the sensory and motor skills that Piaget believed are so important in infancy. In contrast, IQ tests such as the Stanford–Binet and WISC-V emphasize more abstract abilities, such as verbal reasoning, concept formation, and problem solving.

Another explanation is that the growth of intelligence during infancy is highly influenced by powerful and universal maturational processes (McCall, 1981; 1983). Maturation forces (such as genetically influenced changes in the brain) pull infants back on course if environmental influences (such as growing up in an impoverished home and neighborhood) cause them to stray. For this reason, higher or lower infant test scores may be nothing more than temporary deviations from a universal developmental path. As the child nears age 2, maturational forces become less strong, so individual differences become larger and more stable over time. Consistent differences, related to both individual genetic makeup and environment, begin to emerge.

Rather than sticking with the traditional infant development scales focused on motor milestones, some researchers looked to the information-processing approach discussed in Chapter 8 to give new life to the idea that there is continuity in intelligence from infancy to childhood. Joseph Fagan and other researchers have found that certain measures of infant attention predict later IQ better than do the rather misnamed infant intelligence tests (Fagan, 2011). For example, speed of habituation (how fast the infant loses interest in a repeatedly presented stimulus) and preference for novelty (the degree to which an infant prefers a novel stimulus to a familiar one), assessed in the first year of life, have an average correlation of about 0.45 with IQ in childhood,

Infants who are able to quickly process new information and move on to the next 'new' thing may grow up to be more intelligent than their peers who needed more time to process new information.

Paul Baldesare/Alamy Stock Photo

particularly with verbal IQ and memory skills (Cuevas & Bell, 2014; Rose, Feldman, & Jankowski, 2003; 2009; Rose, Feldman, Jankowski, & Van Rossem, 2012). Thus, the infant who quickly becomes bored and likes novelty over familiarity is likely to be brighter in childhood than the infant who is slow to habituate and does not like novelty. As well, fast reaction time in infancy (time taken to look in the direction of a visual stimulus as soon as it appears) predicts later IQ about as well as speed of habituation and novelty preferences scores. From this information, we can characterize the “smart” infant as the speedy information processor—the infant who quickly becomes bored by the same old thing, seeks novel experiences, and soaks up information rapidly. There seems to be some continuity between infant intelligence and childhood intelligence after all (Fagan, 2011; Rose et al., 2012). Such Bayley scale accomplishments as throwing a ball are unlikely to carry over into vocabulary-learning or problem-solving skills in childhood. However, the extent to which the young infant processes information quickly can predict the extent to which he will learn quickly and solve problems efficiently later in childhood.

● Checking Mastery

1. What do the Bayley Scales of Infant Development assess?
2. What characteristics or behaviors of infants are associated with later intelligence?

● Making Connections

1. Are there specific activities that parents should be doing with their infants to ensure that they develop to their intellectual potential? What might some of these activities be?

9.3

The Child

LEARNING OBJECTIVES

- Summarize the research on stability of IQ scores over the course of childhood and indicate reasons why IQ scores might change or remain the same.
- Discuss the effects of poverty on children’s intellectual abilities.
- Chart the path of creative abilities across childhood.

Over the childhood years, children generally become able to answer more questions, and more difficult questions, on IQ tests. That is, their mental ages increase. But what happens to the IQ scores of individual children, which reflect how they compare with peers?

The Stability of IQ Scores during Childhood

It was once assumed that a person’s IQ reflected her genetically determined intellectual capacity and therefore would remain stable over

time. In other words, a child with an IQ of 120 at age 5 was expected to obtain a similar IQ at age 10, 15, or 20. Is this idea supported by research? As you have seen, infant Bayley scores do not do a very good job of predicting later IQ scores. However, starting around age 4 there is a fairly strong relationship between early and later IQ, and the relationship grows even stronger by middle childhood. We know this from such studies as the Munich Longitudinal Study on the Ontogenesis of Individual Competencies (LOGIC), which tracked various cognitive measures over a period of 20 years (see Schneider & Bullock, 2009; Schneider, Niklas, & Schmiedeler, 2014). The

● **Table 9.2** Correlations of IQs Measured at Various Ages

Correlation of IQ Scores				
Age at First (Earlier) Testing	Retested at Age 9	Retested at Age 12	Retested at Age 17	Retested at Age 23
5	0.66	0.60	0.54	0.48
7	0.78	0.75	0.64	0.58
9	–	0.84	0.72	0.66
12	–	–	0.89	0.88
17	–	–	–	0.95

Source: Schneider, W., Niklas, F., & Schmiedeeler, S. (2014). Intellectual development from early childhood to early adulthood: The impact of early IQ differences on stability and change over time. *Learning and Individual Differences, 32*, 156–162.

correlations of intelligence scores at different points of time over the course of this study are summarized in ● **Table 9.2**. We can see that correlations are higher when the interval between two testings is shorter. Even when several years have passed, however, IQ seems to be a stable attribute. For instance, the scores children obtain at age 12 are clearly related to those they obtain 11 years later, at age 23.

These correlations do not reveal everything, however. They are based on a large group of children, and they do not necessarily mean that the IQs of individual children will remain stable over the years. As it turns out, many children show sizable ups and downs in their IQ scores over the course of childhood. Patterns of change differ considerably from child to child, as though each were on a private developmental trajectory (Gottfried et al., 1994). For instance, in one study, stability of scores was examined over a 2- to 3-year period (Watkins & Smith, 2013). For most of these children—three out of four—scores from one time to the next were relatively stable, with variations of just a few points. Indeed, the average difference in scores for the entire group of children was less than one-quarter of one point, indicating remarkable stability for the group as a whole. However, for the remaining one out of four children, the test–retest scores varied by 10 or more points. One child’s score changed by a whopping 28 points (Watkins & Smith, 2013).

How do researchers reconcile the conclusion that IQ is relatively stable with this clear evidence of instability, at least for some children? They can still conclude that, *within* a group, children’s rankings (high or low) in comparison with peers stay stable from one point to another during the childhood years (Stenberg, Grigorenko, & Bundy, 2001). But many individual children experience drops or gains in IQ scores over the years. Remember, however, that this relates to performance on IQ tests rather than underlying intellectual competence. IQ scores are influenced not only by people’s intelligence but also by their motivation, testing procedures and conditions, and many other factors that we will discuss in this chapter. As a result, IQ may be more changeable over the years than intellectual ability.

Causes of Gain and Loss

Some wandering of IQ scores upward or downward over time is just random fluctuation—a good day at one testing, a bad day at the next. Yet there are patterns. Children whose scores fluctuate

the most tend to live in unstable home environments; their life experiences fluctuate between periods of happiness and turmoil.

In addition, some children gain IQ points over childhood and others lose them. Who are the gainers, and who are the losers? Gainers seem to have parents who converse more with them, exposing them to a wide vocabulary, and offer more encouragement relative to the inevitable reprimands (Hart & Risley, 1995). Noticeable drops in IQ with age often occur among children who live in poverty. Poverty is often defined by low family income, but **child poverty** involves more than low parent income: It also involves low levels of meeting children’s basic needs (see Lipina & Colombo, 2009). Thus, children who live in poverty often have inadequate health and dental care and nutrition; they live in overcrowded and unsafe neighborhoods; their families experience chronic stress; their relationships with parents are often not as affectionate or supportive; and they lack opportunities for cognitive stimulation that are commonplace in other homes. Numerous studies with animals demonstrate that being raised in an impoverished environment has a direct impact on brain development (see, for example, Markham & Greenough, 2004; Rosenzweig & Bennett, 1996). For example, rats raised in a large cage with a few other rats for company, wheels for exercising, and blocks to play with develop more neurons, more connections between neurons, and more glial cells supporting neurons than rats raised in isolation (Greenough, Black, & Wallace, 1987; Mohammed et al., 2002). The message is clear: The brain is influenced by the environment. Later in this chapter, we will consider more directly what happens when children are raised in impoverished environments.

The Emergence of Creativity

We often hear young children’s play activities and artwork described as “creative.” When does creativity emerge, and what is the child who scores high on tests of creativity like? To answer the first question, researchers have measured divergent thinking at different ages throughout childhood. Early on, it became apparent that preschool-aged children display fairly high levels of divergent thought—generating many original ideas. As ■ **Figure 9.5** shows, creativity scores, as measured by *ideational fluency*, how many different ideas can be produced, increase until about third grade, level off during fourth and fifth grade, and then begin to decline rather significantly (Kim, 2011). Another measure of creativity, *originality*, the ability to produce original ideas, shows a sharp drop-off starting in sixth grade (see again Figure 9.5). Such declines may reflect pressures in middle school to conform to the group rather than be a “free spirit.” Traditional classrooms tend to emphasize and reinforce convergent thinking, with tests constructed to assess whether students know *the* answer to a problem.

To address the second question, what the creative child is like, one group of researchers compared children who had high creativity scores but normal-range IQ scores with children who scored high in IQ but not in creativity (Getzels & Jackson, 1962). Personality measures suggested that the creative children showed more freedom, originality, humor, aggression, and playfulness than the high-IQ children. Perhaps as a result, the high-IQ children were

Figure 9.5 Two measures of creativity. On the left, fluency scores increase from kindergarten to third grade, but then plateau and begin a marked decline from fifth grade on. On the right, originality scores peak in fifth grade, drop dramatically, and then increase from high school to adulthood. What factors might explain these patterns of creativity?

Adapted from Figure 1 (p. 288) of Kim, K. H. (2011). The creativity crisis: The decrease in creative thinking scores on the Torrance Tests of Creative Thinking. *Creativity Research Journal*, 23, 285–295.

more success oriented and received more approval from teachers. The unconventional responses of highly creative children are not always appreciated in the conventional classroom (Runco, 2014). Compared with their less creative peers, creative children also engage in more fantasy or pretend play, often inventing new uses for familiar objects and new roles for themselves (Kogan, 1983). They have active imaginations, and their parents are often tolerant of their sometimes unconventional ideas (Runco, 2014). Finally, creative children are more likely to be open to new experiences and ideas, as are their parents (Simonton, 1999).

As you will see later in this chapter, average IQ scores differ across racial and socioeconomic groups, but scores on creativity tests usually do not, nor do self-perceptions of one’s creativity (Kaufman, 2006; Kogan, 1983). Moreover, genetic influences (a source of individual differences in IQ) have little to do with performance on tests of creativity; twins are similar in the degree of creativity they display, but identical twins are typically no more similar than fraternal twins (Plomin, 1990; Reznikoff et al., 1973). This suggests that certain qualities of the home environment tend to make brothers and sisters alike in their degree of creativity. What qualities? Although there is little research to go on, parents of creative children and adolescents tend to value nonconformity and independence, accept their children as they are, encourage their curiosity and playfulness, and grant them a good deal of freedom to explore new possibilities on their own (Harrington, Block, & Block, 1987). In some cases, the parent–child relationship is even distant; a surprising number of eminent creators seem to have experienced rather lonely, insecure, and unhappy childhoods (Ochse, 1990; Simonton, 1999). Out of their adversity may have come an active imagination and a strong desire to develop their talents. Although this may

be true for some creative individuals, it is certainly not true for all of them. Overall, though, creative abilities are influenced by factors distinct from those that influence the cognitive abilities measured on IQ tests.

Creativity takes many different forms.

● Checking Mastery

1. Once children reach elementary school, how stable are their IQ scores as a group?
2. What is one reason for an individual's IQ score to increase and what is one reason for an individual's IQ score to decrease during childhood?

● Making Connections

1. Would you want to know your IQ or your child's IQ? How might this knowledge affect you? Would you think or act any differently if you learned that you (or your child) had an IQ of 105 versus an IQ of 135? You might also consider whether teachers should know their students' IQ scores. What are some potential pros and cons of teachers having access to this information?
2. Would you rather have a child who has average intelligence but is highly creative or one who has high intelligence but average creativity? What are the pros and cons of each?

9.4

The Adolescent

LEARNING OBJECTIVES

- Describe the Flynn effect and what factors might account for this finding.
- Explain how IQ scores relate to school achievement.
- Discuss how schools and parents can foster creativity during adolescence.

Intellectual growth continues its rapid pace in early adolescence, then slows and levels off in later adolescence (Thorndike, 1997). As noted in Chapter 5, a spurt in brain development occurs around age 11 or age 12, when children are believed to enter Piaget's formal operational stage. Brain development may give children the information-processing speed and working-memory capacity they need to perform at adultlike levels on IQ tests (Kail & Salthouse, 1994). Thus, basic changes in the brain in early adolescence may underlie a variety of cognitive advances—the achievement of formal operations, improved memory and information-processing skills, and better performance on tests of intelligence.

Although adolescence is a time of impressive mental growth, it is also a time of increased stability of individual differences in intellectual performance. During the teen years, IQ scores become even more stable than they were in childhood and strongly predict IQ in middle age (Deary et al., 2004). Even while adolescents as a group are experiencing cognitive growth, then, each individual is establishing a characteristic level of intellectual performance that will most likely be carried into adult life unless the individual's environment changes dramatically.

Flynn Effect

Some evidence suggests that today's teens are smarter than their parents and grandparents were as teenagers. Indeed, over the 20th century, average IQ scores have increased in all countries studied, a phenomenon called the **Flynn effect** after James Flynn (1987, 1998, 1999, 2007, 2011), who focused our attention on this phenomenon. In the United States, the increase has amounted to about 3 IQ points per decade. So a group of adults born in, say, 1980, scores on average 3 points higher than a similar group of adults born in 1970 and 6–8

points higher than those born in 1960 (Trahan et al., 2014). **Figure 9.6** illustrates the gains in intelligence over a period of more than 50 years. Full-scale IQ scores have increased 18 points over this time, with scores on some subscales increasing as much as 24 points (for example, similarities and Raven's progressive matrices), others increasing 10 points (such as comprehension), and some increasing a slight 2–3 points (for example, information, arithmetic, and vocabulary). Further, Flynn (2007) presents data that suggest these trends extend

Figure 9.6 Over a 50-year period, test scores on several measures of intelligence have risen substantially, illustrating the “Flynn effect.” Are people really getting smarter? What factors might explain such a rise in intelligence test scores?

Source: Flynn, J. R. (2007). *What is intelligence? Beyond the Flynn effect*, Figure 1, p. 8. Reprinted by permission of Cambridge University Press.

back more than 100 years, leading him to ask, “How can our recent ancestors have been so unintelligent compared to ourselves?” (p. 9). How indeed?

Many researchers argue that increases of this size cannot be caused by genetic evolution and therefore must have environmental causes. For one thing, children today are better educated than earlier generations; 85% today complete high school, compared with just 5% in 1895 (Greve, 2006). But Flynn and others have suggested that improved economic conditions have brought improved nutrition and living conditions over the course of the 20th century, and this has contributed to the rise in intellectual functioning (Pietschnig & Voracek, 2015).

Researchers have examined average IQ scores by country and found that they are associated with the country’s incidence and prevalence of infectious disease (Eppig, Fincher, & Thornhill, 2010). People in countries where rates of infectious diseases are high have, on average, lower IQ scores than those in countries where rates of infectious diseases are low. The researchers believe that infectious diseases, especially parasitic diseases that cause diarrhea in infants and children, divert energy from the brain and rob the brain of needed nutrients. As developing countries reduce airborne and water-borne diseases through vaccinations, clean water, and sewers, we can expect to see a rise in the average IQ scores of their citizens.

IQ and School Achievement

The original purpose of IQ tests was to estimate how well children would do in school, and they do this fairly well. Correlations between children’s and adolescents’ IQ scores and their grades range from 0.50 to 0.86, making general intellectual ability one of the best predictors of school achievement available (Deary et al., 2007; Neisser et al., 1996). Adolescents with high IQs are also less likely to drop out of high school and more likely to go on to college than their peers with lower IQs; the correlation between

IQ and years of education obtained averages 0.55 (Neisser et al., 1996). However, IQ scores do not predict college grades as well as they predict high school grades (Brody & Brody, 1976). Most college students probably have at least the average intellectual ability needed to succeed in college; success is therefore more influenced by personal qualities such as motivation. Overall, an IQ score is a good predictor of academic achievement, but it does not reveal everything about a student. Factors such as work habits, interests, and motivation to succeed also affect academic achievement.

Fostering Creativity

We noted earlier that there is a drop in creativity as children enter middle school. What happens during adolescence? In general, creativity, as measured by traditional divergent tasks or ideational fluency, remains rather depressed throughout adolescence, yet some evidence shows continuity between childhood scores on creativity tasks and later creative output during adulthood (Cramond et al., 2005). This suggests that adolescents may be putting their creativity temporarily “on hold,” perhaps to focus on other pressing issues of this important developmental period, but their creativity is not lost. There is at least one measure of creativity—the ability to elaborate on ideas—that continues to increase across adolescence and does not begin to drop until adulthood (Kim, 2011). Elaborating on ideas is one form of creative thinking that may continue to be emphasized and rewarded in the classroom. Overall, the developmental course of creativity may vary depending on when children are pressured to conform and whether unusual answers are rewarded in school.

Is it possible to foster creativity? Training studies indicate that people can learn techniques to improve their creativeness (Ma, 2006; Scott et al., 2004). But training may only be effective if the person’s environment supports and rewards creativity. Researchers have looked at individuals who demonstrate creativity in a particular field to try to identify the factors that contribute to their accomplishments. David Feldman (1982, 1986), for example, has studied children and adolescents who are prodigies in such areas as chess, music, and mathematics. These individuals were generally similar to their peers in areas outside their fields of expertise. What contributed to their special achievements? On the nature side, they had *talent* as well as a powerful *motivation* to develop their special talents—a real passion for what they were doing. Olympic gymnast Olga Korbut put it well: “If gymnastics did not exist, I would have invented it” (Feldman, 1982, p. 35). Other research confirms that internal motivation and a thirst for challenge are crucial elements of creative productivity (Sternberg, 2010a; 2010b; Yeh & Wu, 2006). Individuals with a positive outlook also seem more likely to display creativity, perhaps because they are more open to challenges and derive more pleasure from challenges (see Yeh & Wu, 2006). Creative thinkers have other personal qualities as well—they display a willingness to take risks and are able to put up with some ambiguity without becoming frustrated (Heilman, 2016; Sternberg, 2010a; 2010b).

On the nurture side, creative individuals seem to be blessed with *environments* that recognize, value, and nurture

Intelligence ‘flows’ into nearly all we do, but certainly the classroom offers unique opportunities to exercise our intelligence.

Cultura Creative (RF)/Alamy Stock Photo

their creative endeavors (Sternberg, 2010a; 2010b). Their environments allow them a certain degree of independence to explore different fields and acquire knowledge of their chosen field. According to Feldman (1982), the child with creative potential in a specific field must become intimately familiar with the state of the field if he is to advance or transform it, as the groundbreaking artist or musician does. Thus, building a

knowledge base is a necessary, although not sufficient, component of creativity (Sternberg, 2006b). So parents can help foster creativity by giving their children freedom to explore and opportunities to experiment with ideas and activities. Likewise, schools can assist by encouraging idea generation, multiple correct answers, or multiple pathways to arrive at an answer, and elaboration of ideas.

● Checking Mastery

1. Is creativity or intelligence more stable during adolescence?
2. What might explain the rise in IQ scores over the past century?
3. What is one environmental factor that could help enhance creativity?

● Making Connections

1. To what extent have your schools fostered creativity? Is this something that *can* be fostered in schools and *should* it be fostered in schools?
2. IQ scores stabilize in adolescence and are highly correlated with adult IQ scores. Given this stability, should greater use be made of IQ scores? If so, what would be one or two meaningful uses of IQ scores during adolescence?

9.5 The Adult

LEARNING OBJECTIVES

- Evaluate whether IQ scores are a useful predictor of occupational status and health status of adults.
- Explain how intelligence might be expected to change over adulthood.
- Analyze the connection between wisdom and intelligence and determine who might be most likely to develop wisdom.
- Summarize the research on creative endeavors during adulthood.

We turn our attention now to intelligence during adulthood. Do IQ scores predict achievement and success after people have left school? Does performance on IQ tests change during the adult years? And do IQ scores decline in old age, as performance on Piagetian cognitive tasks and some memory tasks does?

IQ and Occupational Success

What is the relationship between IQ and occupational status? Professional and technical workers (such as scientists and engineers) score higher on IQ tests than white-collar workers (such as bank managers), who in turn score higher than blue-collar, or manual, workers (such as construction workers) (Nyborg & Jensen, 2001; Schmidt & Hunter, 2004). The connections between intelligence and income and occupational prestige are striking when we look at findings from a longitudinal study of a large U.S. sample (Judge, Klinger, & Simon, 2010). ■ **Figure 9.7** shows that over the nearly 30-year period of the study, general intelligence was significantly related to both income and occupational prestige. Further, the gap between those with higher intelligence and those with lower intelligence widened considerably over time. Those with higher intelligence started with a slight advantage for income and occupational prestige but quickly began rising at a faster rate than those with lower intelligence. Also, income did not plateau and occupational prestige did not drop among those with higher intelligence as they did for those with lower intelligence.

The reason for the relationship between IQ and occupational success is clear: It undoubtedly takes more intellectual

ability to complete law school and become a lawyer, a high-status and higher-paying occupation, than it does to be a farmhand, a low-status and lower-paying occupation. However, the prestige or status of the occupation is not as important as the complexity of the work (Gottfredson, 1997; Kuncel, Hezlett, & Ones, 2004). Greater intelligence is required to handle more complex or cognitively challenging work. Those with higher intelligence obtain more education and training and they use this knowledge to tackle more demanding jobs, which leads to a faster and steeper rise to the top of the occupational ladder (Judge et al., 2010). Still, IQs vary considerably in every occupational group, so many people in low-status jobs have high IQs.

Now a second question: Are bright lawyers, electricians, or farmhands more successful or productive than their less intelligent colleagues? The answer seems to be yes, as correlations between scores on tests of intellectual ability and such measures of job performance as supervisor ratings average 0.30 to 0.50 (Drasgow, 2012; Neisser et al., 1996). Before we go further, though, we should note that not all scholars are convinced that there is a solid correlation between IQ and job performance (Richardson & Norgate, 2015). Instead, the correlation might reflect the role of other factors such as socioeconomic status, motivation, education, and opportunity. Those individuals raised in higher socioeconomic families typically live in better neighborhoods, go to better schools, and have better connections when it comes to landing internships and jobs. Whether it is intelligence per se, or other factors that correlate with intelligence, it does seem that more intellectually capable

Figure 9.7 The two graphs show income (*left*) and occupational prestige (*right*) of participants over nearly 30 years in relation to their intelligence test performance: Those with high intelligence start with a slight advantage over their less intelligent peers but quickly leave them behind. Why don't those with lower intelligence keep rising at the same rate over the years?

Source: Judge, T. A., Klinger, R. L., & Simon, L. S. (2010). Time is on my side: Time, general mental ability, human capital, and extrinsic career success. *Journal of Applied Psychology, 95*(1): 92–107. Figure 2. Copyright © 2010 American Psychological Association.

adults are better able to learn what they need to know about their occupations and to solve the problems that arise. This literally pays off (see again Figure 9.7): Individuals with greater cognitive ability earn more money than those with lower cognitive ability (Judge et al., 2010). However, as **Exploration 9.1** notes, intelligent people are by no means infallible.

jobs, giving them the resources to obtain better health care. But when living conditions are statistically controlled (that is, held constant), there is still a connection between intelligence and health (Gottfredson & Deary, 2004). Similarly, providing equal access to health care reduces but does not eliminate social-class differences in health (Steenland, Henley, & Thun, 2002).

IQ and Health

People who score higher on measures of intelligence tend to be healthier and live longer than those who score lower on these tests (see, for example, Gottfredson, 2004; and Leon et al., 2009). This connection between intelligence and health and longevity has now been confirmed by research in multiple countries. For instance, researchers in Scotland tracked nearly everyone born in that country in 1921 and 1936 who had taken an intelligence test during childhood (Deary, Whalley, & Starr, 2009). Following up on health and death records of these individuals decades later, researchers found that those who scored one standard deviation (15 points) below the average were less likely to be alive at age 76 and more likely to have experienced stomach or lung cancers and cardiovascular or coronary heart disease. Indeed, those children who scored in the top 25% on intelligence at age 11 were 2–3 times more likely to be alive 65 years later than those scoring in the bottom 25% (Deary et al., 2009). Similar results are emerging from a study in the United States that has tracked participants from adolescence to age 40 (Der, Batty, & Deary, 2009). Consistent with the Scotland research, higher intelligence in early adolescence is associated with fewer health problems at age 40.

A common explanation for this connection between IQ and health is socioeconomic status: Smart people may have better

Research shows a connection between intelligence and health, perhaps because more-intelligent folks are knowledgeable of the value of preventive measures, such as applying sunscreen.

● EXPLORATION 9.1

Intelligent AND Dumb?

If done properly, thinking can be hard work!

Wavebreak Media/Alamy Stock Photo

Are intelligent people always smart or are there conditions that might lead even the most intelligent among us to do dumb things or make poor decisions? Alas, yes. Keith Stanovich (2009; 2016) has even coined a term for this paradox: **dysrationalia**, which he defines as the inability to think and behave rationally despite having adequate intelligence” (Stanovich, 2009, p. 7). Stanovich argues that standard intelligence tests measure some aspects of what is considered to be intelligent, but miss a very important aspect, namely thinking rationally. Questions on intelligence tests have been carefully framed and worded to assess how test takers handle the information provided to them. But, as Stanovich notes in his book, *What Intelligence Tests Miss*, IQ tests do not assess whether a person can frame a logical question, collect relevant and unbiased data, and then critically assess this information and arrive at a decision based on rational thought. Outside of classrooms and intelligence tests, many of life’s problems are unscripted and messy. We must determine the root of the problem, identify possible solutions, and then select the best option. So if we are intelligent, why don’t we always solve problems

in the most logical or rational manner?

It turns out that, when it comes to thinking (and most other human behaviors), we are inclined to go with the easiest or most obvious solution first. And why wouldn’t we? If there is a quick and easy way to get an answer, it can certainly be efficient to go in this direction rather than embarking on a long and difficult process. The key may be knowing when it is OK to stick with the quick and easy versus knowing when the long and difficult is needed.

Scholars have referred to this as the dual process approach to cognition, with two systems or two types of thinking (Kahneman, 2011; Toplak, West, & Stanovich, 2014). The operation of System 1 is automatic: An event occurs or a situation is presented to us and we respond quickly and almost automatically, *without thinking*. An advantage of System 1 is that an answer or response is arrived at in a very short amount of time with very little effort, that is, it’s easy. Unfortunately, this leads to the disadvantage of System 1 thinking, which is that the answer is not always correct. In contrast, the operation of System 2 thinking is slow and deliberate, and many times leads to a correct answer, an advantage, yet it does so by expending a great deal of our time and energy. Susan Fiske and Shelley Taylor (1984) first used the term “cognitive miser” to label our inclination to default to System 1, but the origins of this idea go back to Nobel prize-winning work on heuristics, or mental shortcuts, by Amos Tversky and Daniel Kahneman (Tversky and Kahneman, 1971, 1973; Kahneman & Tversky, 1973). People use mental shortcuts all the time to make decisions quickly and efficiently.

There are many different heuristics, but let’s consider just one—the availability heuristic—as an example. To test this, Tversky and Kahneman (1973) gave participants this mental puzzle to ponder: “If a random word is taken from an English text, is it more likely that the word starts with a K, or that K is the third letter?” If you are like many folks, you immediately start thinking of words that begin with the letter K, and you also manage to think of some words that have K as the third letter. In the end, though, you probably came up with more words that begin with K than words with K as the third letter, making words that begin with K more available to you. Being able to think of more words that begin with K, the tendency is to conclude that it is more likely that a random word taken from an English text begins with K. If this was your answer, then you are incorrect. There are three times as many words with K as the third letter, but because these are harder to think of, this information is not readily available to us.

People along the full continuum of intelligence use heuristics or mental shortcuts to lighten their cognitive load. This helps explain how intelligent people can make some not-so-intelligent decisions. Ideally, what we should do is go ahead and ‘allow’ our minds to use a mental shortcut or apply System 1 thinking; after all, we will probably form an automatic response without even consciously deciding to do so. But, we should then stop and consider whether we need to apply more effortful cognitive processes, which will take more time and energy, but may help us avoid making an irrational and possibly costly decision. Finally, we need to keep reminding ourselves that we are just as fallible as the next person. We might be intelligent, but we can be just as likely to engage in some lazy cognitive processing as the next person.

So what else could be going on? Linda Gottfredson (2004) argues that good health takes more than access to material resources. It requires some of the abilities measured by intelligence tests, such as efficient learning and problem solving. In other words, successfully monitoring one’s health and properly applying treatment protocols require a certain amount of

intelligence. Consider the chronic illness diabetes. Successful management requires acquiring knowledge of the disease symptoms and course, identifying signs of inappropriate blood sugar levels, and making judgments about how to respond to blood sugar fluctuations. A patient’s IQ predicts how much knowledge of diabetes she acquires during the year following diagnosis (Taylor

et al., 2003). Other research shows that many people with diabetes who have limited literacy, which correlates with intelligence, do not know the signs of high or low blood sugar and do not know how to correct unhealthy levels (Williams et al., 1998).

A study of nearly 10,000 adults examined the relationship between their IQ scores at age 11 and markers of health collected from blood samples at age 45 (Calvin et al., 2011). Blood samples were examined for two inflammatory markers associated with cardiovascular disease. Higher IQ scores at age 11 were associated with lower levels of these cardiovascular disease markers in adulthood. The connection was partly explained by differences in parental socioeconomic status between higher and lower IQ adults. Research on relationships between IQ and health is still relatively new, but it suggests that IQ influences socioeconomic status, which in turn influences health, and that IQ also influences health directly to the extent that smarter people are able to apply their intellectual skills to understanding and managing their health.

Changes in IQ with Age

Perhaps no question about adult development has been studied as thoroughly as that of how intellectual abilities change with age. We know that an individual's IQ score remains relatively stable from pre-adolescence (age 11) until well into older adulthood (Deary, Pattie, & Starr, 2013; Tucker-Drob & Briley, 2014). Ian Deary and his colleagues (2013) have examined stability of intelligence over a lifetime by following up with individuals born in 1921 who had completed an intelligence test at age 11 and were tested again at age 90.

In general, the findings of this remarkable longitudinal study show a high level of stability over many decades of life. The strongest predictor of intelligence in old age was intelligence at age 11. Such factors as education and socioeconomic status contributed only slightly to changes in IQ scores. Thus, where a person's IQ score falls within the spread of scores in a group is a good predictor of where this person's score will fall if retested with the same group later in life: High scorers tend to remain high scorers and low scorers tend to remain low scorers. Other longitudinal research confirms this conclusion of very stable intelligence over adulthood (Rönnlund, Sundström, & Nilsson, 2015; Schalke et al., 2013).

As we learned earlier from the research on IQ scores in childhood, even when there is high group stability, there are still bound to be some changes in individuals' IQs. This is true for adults as well. What might account for changes in IQ scores in adulthood? A comprehensive sequential study directed by K. Warner Schaie (2012) provides some evidence regarding the pattern of changes in IQ. Schaie's study began in 1956 with a sample of members of a health maintenance organization ranging in age from 22 to 70. They were given a revised test of primary mental abilities that yielded scores for five separate mental abilities: verbal meaning, spatial ability, reasoning, numerical ability, and word

fluency. Seven years later, as many of them as could be found were retested. In addition, a new sample of adults ranging from their 20s to their 70s was tested. This design made it possible to determine how the performance of the same individuals changed over 7 years and to compare the performance of people who were 20 years old in 1956 with that of people who were 20 years old in 1963. This same strategy was repeated at regular intervals, giving the researchers a wealth of information about different cohorts, including longitudinal data on some people over a 45-year period.

Several findings have emerged from this important study. First, it seems that *when a person was born* has at least as much influence on intellectual functioning as age does. In other words, there are cohort or generational differences in performance. This evidence confirms the suspicion that cross-sectional comparisons of different age groups have usually yielded too grim a picture of declines in intellectual abilities during adulthood. Specifically, recently born cohorts (the youngest people in the study were born in 1973) tended to outperform earlier generations (the oldest were born in 1889) on most tests. Yet on the test of numerical ability, people born between 1903 and 1924 performed better than both earlier and later generations. Inductive reasoning scores have increased with every cohort tested since 1889. Scores on verbal meanings increased until 1952 but dropped off in the three most recently born cohorts (Schaie & Zanjani, 2006). So different generations may have a special edge in different areas of intellectual performance. Overall, though, judging from Schaie's findings, young and middle-aged adults today can look forward to better intellectual functioning in old age than their grandparents experienced—more evidence of the Flynn effect.

Another important message of Schaie's study, and of other research, is that patterns of aging differ for different abilities (■ Figure 9.8). Fluid intelligence (those abilities requiring active

■ **Figure 9.8** The lines on this chart show that scores on measures of crystallized intelligence remain high throughout life. In contrast, scores on various measures of fluid intelligence are on a downward trajectory through all of adulthood, apparently starting as soon as most people complete their education.

Source: Park & Bischof (2013). The aging mind: neuroplasticity in response to cognitive training. *Dialogues Clin Neurosci*, 15(1): 109–119.

thinking and reasoning applied to novel problems, as measured by tests such as the primary mental abilities tests of reasoning and space) usually declines earlier and more steeply than crystallized intelligence (those abilities involving the use of knowledge acquired through experience, such as in answering the verbal meaning test used by Schaie). Consistently, adults lose some of their ability to grapple with new problems starting in middle age, but their crystallized general knowledge and vocabulary stay steady throughout middle and older adulthood.

Why is this? Tests of performance and fluid IQ are often timed, and, as noted in Chapter 8, performance on timed tests declines more in old age than performance on untimed tests does. This may be linked to the slowing of central nervous system functioning that most people experience as they age. When researchers control for processing speed, declines are not as steep (Scheiber et al., 2016). We have seen that speed of information processing is related to intellectual functioning across the life span. Not only is rapid information processing in infancy associated with high IQ scores in childhood, but young adults with quick reaction times also outperform their more sluggish age-mates on IQ tests, and adults who lose information-processing speed in later life lose some of their ability to think through complex and novel problems (Jensen, 1993). It is not just that older adults cannot finish tests that have time limits; declines in performance intelligence occur in later life even on untimed tests (Kaufman & Kaufman, 1997). The problem is that the slower information processor cannot keep in mind (that is, in working memory) and process simultaneously all relevant aspects of a complex problem.

You now have an overall picture of intellectual functioning in adulthood. Age group differences in performance suggest that older adults today are at a disadvantage on many tests compared with younger adults, partly because of deficiencies in the amount and quality of education they received early in life. But actual declines in intellectual abilities associated with aging are generally minor until people reach their late 60s or 70s. Even in old age, declines in fluid intelligence, performance intelligence, and performance on timed tests are more apparent than declines in crystallized intelligence, verbal intelligence, and performance on untimed tests. As you will soon see, declines in fluid intelligence can be reduced when adults remain cognitively stimulated through work or other activities (Weinert & Hany, 2003).

One last message of this research is worth special emphasis: Declines in intellectual abilities are not universal. Even among the 81-year-olds in Schaie's study, only about 30%–40% had experienced a significant decline in intellectual ability in the previous 7 years (Schaie, 2012). Moreover, although few 81-year-olds maintained all five mental abilities, almost all retained at least one ability from testing to testing and about half retained four out of five (Schaie & Zanjani, 2006). The range of differences in intellectual functioning in a group of older adults is extremely large, which means that anyone who stereotypes all elderly adults as intellectually limited is likely to be wrong most of the time.

Predictors of Decline

What is most likely to affect whether or not a person experiences declines in intellectual performance in old age? *Poor health*, not surprisingly, is one risk factor. People who have cardiovascular

diseases or other chronic illnesses show steeper declines in mental abilities than their healthier peers (Schaie, 2012). Diseases (and most likely the drugs used to treat them) also contribute to a rapid decline in intellectual abilities within a few years of death (Johansson, Zarit, & Berg, 1992; Singer et al., 2003). This phenomenon has been given the depressing label **terminal drop**. Perhaps there is something, then, to the saying “Sound body, sound mind.”

A second factor in decline of intellectual performance is an *unstimulating lifestyle*. K. Warner Schaie and his colleagues found that the biggest intellectual declines were shown by elderly widows who had low social status, engaged in few activities, and were dissatisfied with their lives (Schaie, 2012). These women lived alone and seemed disengaged from life. Individuals who maintain their performance or even show gains tend to have above-average socioeconomic status, advanced education, intact marriages, intellectually capable spouses, and physically and mentally active lifestyles. Interestingly, married adults are affected by the intellectual environment they provide for each other. Their IQ test scores become more similar over the years, largely because the lower-functioning partner's scores rise closer to those of the higher-functioning partner (Gruber-Baldini, Schaie, & Willis, 1995; Weinert & Hany, 2003).

The moral is “Use it or lose it.” This rule, applicable to muscular strength and sexual functioning, also pertains to intellectual functioning in later life. The plasticity of the nervous system throughout the life span enables elderly individuals to benefit from intellectual stimulation and training, to maintain the intellectual skills most relevant to their activities, and to compensate for the loss of less-exercised abilities (Dixon, 2003; Weinert & Hany, 2003; see also **Application 9.1**). There is still much to learn about how health, lifestyle, and other factors shape the individual's intellectual growth and decline. What is certain is that most people can look forward to

People tend to believe that age brings wisdom, which may help explain why U.S. Supreme Court justices such as Ruth Bader Ginsberg, pictured here, are often not appointed until middle adulthood and serve well into 'old age.'

Intelligence Training for Aging Adults

Can you teach old dogs new tricks? And can you reteach old dogs who have suffered declines in mental abilities the old tricks they have lost? K. Warner Schaie, Sherry Willis, and their colleagues (1986; 2010; 2013; Willis & Schaie, 1986) have sought an answer to these questions by training elderly adults in spatial ability and reasoning, two of the fluid mental abilities most likely to decline in old age. Within a group of older people ranging in age from 64 to 95 who participated in Schaie's longitudinal study of intelligence, they first identified individuals whose scores on one of the two abilities had declined over a 21-year period and individuals who had remained stable over the same period. The goal with the decliners would be to restore lost ability; the goal with those who had maintained their ability would be to improve it. Participants took pretests measuring both abilities, received 5 hours of training in either spatial ability or reasoning, and then were given posttests on both abilities. The spatial training involved learning how to rotate objects in space, at first physically and then mentally. Training in reasoning involved learning how to detect a recurring pattern in a series of stimuli (for example, musical notes) and to identify what the next stimulus in the sequence should be.

The training worked. Both those who had suffered ability declines and those who had maintained their abilities before the study improved, although decliners showed significantly more improvement in spatial ability than non-decliners did. Schaie and Willis found that about 40% of the decliners gained enough through training to bring them back to the level of performance they had achieved when originally tested, before decline set in. What is more, effects of the training among those who had experienced declines in performance were still evident from one testing

to the next. And, as noted in Chapter 8, the benefits of cognitive training with older adults extends beyond improving their performance on laboratory-type tests; their daily functioning improved as well (Willis et al., 2006).

Other research shows similar evidence of *neuroplasticity*, or restructuring of the brain in response to training or experience, among older adults. Michelle Carlson and her colleagues (2009) conducted a pilot study with older women who were either trained for and then served as volunteers in the Experience Corps program or were on a waitlist for future participation and served as the control group. Experience Corps volunteers spend 15 hours per week for 6 months in classrooms assisting kindergarten through third-graders with their learning. Their activities draw upon memory, literacy, and problem-solving skills. The researchers took a look inside their brains using functional magnetic resonance imaging (fMRI). The results, seen in the figure in this box, are striking: Women

who volunteered in the classroom as part of the Experience Corps program showed significant gains in brain activity relative to the women who had not yet volunteered. Their activity changed the workings of their brains. Similar findings are emerging from other programs, such as the “Synapse” project (see Park & Bischof, 2013).

The larger messages? You can teach old dogs new tricks—and reteach them old tricks—in a short amount of time. This research does not mean that cognitive abilities can be restored in elderly people who have Alzheimer's disease or other brain disorders and have experienced significant neural loss. Instead, it suggests that many intellectual skills decline in later life because they are not used—and that these skills can be revived with a little coaching and practice. This research, combined with research on children, provides convincing evidence of the neuroplasticity of cognitive abilities over the entire life span (see Hertzog et al., 2009).

Activity in the prefrontal cortex was greater for older adults who engaged in ‘mental calisthenics.’

Carlson, M. C., et al. (2009). Evidence for neurocognitive plasticity in at-risk older adults: The Experience Corps Program. *Journal of Gerontology A: Biological Sciences and Medical Sciences*, 64(12): 1275–1282. Figure 3. Reprinted by permission of Oxford University Press.

many years of optimal intellectual functioning before some of them experience losses of some mental abilities in later life.

Potential for Wisdom

Many people believe—incorrectly, as you have seen—that intellectual decline is an inevitable part of aging. Yet many people also believe that old people are wise. Indeed, this belief has been expressed in many cultures throughout history. It is also featured in Erik Erikson's influential theory of life-span development. Erikson says that older adults often gain wisdom as they face

the prospect of death and attempt to find meaning in their lives (see Chapter 11). Notice, too, that the word *wise* is rarely used to describe children, adolescents, or even young adults (unless perhaps it is to call one of them a *wise guy*).

What does it mean to be a wise person? Wisdom is not the same as high intelligence: There are many highly intelligent people who are not wise. Paul Baltes and his colleagues define **wisdom** as a constellation of rich factual knowledge about life combined with procedural knowledge such as strategies for giving advice and handling conflicts (Pasupathi, Staudinger, & Baltes, 2001). Similarly, Robert Sternberg (2003) defines a wise person as

someone who can combine successful intelligence with creativity to solve problems that require balancing multiple interests or perspectives. Katherine Bangen and her colleagues (2013) searched through the literature for definitions of wisdom and found many variations, but most had certain features in common: “knowledge of life, prosocial values, self-understanding, acknowledgment of uncertainty, emotional homeostasis [balance], tolerance, openness, spirituality, and sense of humor” (p. 1254). The relative contribution of these factors to wisdom remains largely unknown.

Some older adults are blessed with wisdom, but the old wise person is by no means universal. Where we do see wisdom, does it arise from increasing age or from life experiences? Ursula Staudinger, Jacqui Smith, and Paul Baltes (1992) attempted to find out by interviewing young (ages 25–35) and elderly (ages 65–82) women who were clinical psychologists or similarly well-educated professionals in other fields. The goal was to assess the relative contributions of age and specialized experience to wisdom, based on the assumption that clinical psychologists gain special sensitivity to human problems from their professional training and practice.

These women were interviewed about a person named Martha, who had chosen to have a family but no career and who met an old friend who had chosen to have a career but no family. The women were asked to talk about how Martha might review and evaluate her life after this encounter. Answers were scored for qualities judged to be indicators of wisdom.

What was found? First, wisdom proved to be rare; it seems that only about 5% of the answers given by adults to problems such as these qualify as wise (Smith & Baltes, 1990). Second, expertise proved to be more relevant than age to the development of wisdom. That is, clinical psychologists, whether young or old, displayed more signs of wisdom than other women did. Older women were generally no wiser—or less wise—than younger women.

Age, then, does not predict wisdom well. Yet the knowledge base that contributes to wisdom, like other crystallized intellectual abilities, holds up well later in life (Baltes et al., 1995). Older adults, like younger adults, are more likely to display wisdom if they have life experiences (such as work as a clinical psychologist) that sharpen their insights into the human condition. The immediate social context also influences the degree to which wisdom is expressed; wiser solutions to problems are generated when adults have an opportunity to discuss problems with someone whose judgment they value and when they are encouraged to reflect after such discussions (Staudinger & Baltes, 1996). Thus, consulting with your fellow students and work colleagues and thinking about their advice may be the beginning of wisdom.

Finally, wisdom seems to reflect a particular combination of intelligence, personality, and cognitive style (Baltes & Staudinger, 2000). For example, individuals who have a cognitive style of comparing and evaluating relevant issues and who show tolerance of ambiguity are more likely to demonstrate wisdom than individuals without these characteristics. In addition, external factors influence the development of wisdom. Monika Ardelt (2000) found that a supportive social environment (loving family, good friends) during early adulthood was positively associated with wisdom 40 years later.

Our understanding of wisdom continues to evolve as new research emerges to help clarify what it is, how it develops, and how it is related to other mental abilities. It is safe to say that

research on wisdom provides further evidence that different mental faculties develop and age differently over the adult years.

Creative Endeavors

Many studies of creativity during the adult years have focused on a small number of so-called eminent creators in such fields as art, music, science, and philosophy. A major question of interest has been this: When in adulthood are such individuals most productive and most likely to create their best works? Is it early in adulthood, when they can benefit from youth’s enthusiasm and freshness of approach? Or is it later in adulthood, when they have fully mastered their field and have the experience and knowledge necessary to make a breakthrough in it? And what becomes of the careers of eminent creators in old age?

Early studies by Harvey Lehman (1953) and Wayne Dennis (1966) provided a fairly clear picture of how creative careers unfold (see also Runco, 2014, and Sternberg, 1999a). In most fields, creative production increases steeply from the 20s to the late 30s and early 40s, then gradually declines thereafter, although not to the same low levels that characterized early adulthood. Of course, there are notable exceptions. Michelangelo, for instance, was in his 70s and 80s when he worked on St. Peter’s Cathedral, and Frank Lloyd Wright was 91 when he finished the blueprint for the Guggenheim Museum in New York City. Peak times of creative achievement also vary from field to field (Csikszentmihalyi & Nakamura, 2006). For instance, productivity of scholars in the humanities (for example, historians and philosophers) continues well into old age and peaks in the 60s, possibly because creative work in these fields often involves integrating knowledge that has crystallized over years. By contrast, productivity in the arts (for example, music or drama) peaks in the 30s and 40s and declines steeply thereafter, perhaps because artistic creativity depends on a more fluid or innovative kind of thinking.

How can researchers account for changes in creative production over the adult years? One explanation, proposed long ago (Beard, 1874, in Simonton, 1984), is that creative achievement requires both enthusiasm and experience. In early adulthood, the enthusiasm is there, but the experience is not; in later adulthood, the experience is there, but the enthusiasm or vigor has fallen off. People in their 30s and 40s have it all.

Dean Simonton (1999) has offered another theory: Each creator may have a certain potential to create that is realized over the adult years; as the potential is realized, less is left to express. According to Simonton, creative activity involves two processes: ideation (generating creative ideas) and elaboration (executing ideas to produce poems, paintings, or scientific publications). After a career is launched, some time elapses before any ideas are generated or any works are completed. This would explain the rise in creative achievement between the 20s and 30s. Also, some kinds of work take longer to formulate or complete than others, which helps explain why a poet (who can generate and carry out ideas quickly) might reach a creative peak earlier in life than, say, a historian (who may need to devote years to the research and writing necessary to complete a book once the idea for it is hatched).

Why does creative production begin to taper off? Simonton (1999) suggests that older creators may simply have used up much of their stock of potential ideas. They never exhaust their creative potential, but they have less of it left to realize. Simonton argues, then,

that changes in creative production over the adult years have more to do with the nature of the creative process than with a loss of mental ability in later life. Creators who start their careers late are likely to experience the same rise and fall of creative output that others do, only later in life. And those lucky creators with immense creative potential to realize will not burn out; they will keep producing great works until they die.

What about mere mortals? Here, researchers have fallen back on tests designed to measure creativity. In one study, scores on a test of divergent thinking abilities decreased at least modestly after about age 40 and decreased more steeply starting around 70 (McCrae, Arenberg, & Costa, 1987). It seems that elderly adults do not differ much from younger adults in the originality of their ideas; the main difference is that they generate fewer of them (Jaquish & Ripple, 1981). Generally, then, these studies agree with the studies of eminent achievers: Creative behavior becomes less frequent in later life, but it remains possible throughout the adult years.

9.6

Factors that Influence IQ Scores over the Life Span

LEARNING OBJECTIVES

- Analyze the research on genetic and environmental contributions to intelligence and formulate a conclusion about how these factors contribute to our intellectual abilities.
- Critique the research on race and intelligence to reach a balanced conclusion about whether these two constructs are connected in meaningful ways.

Now that we have surveyed changes in intellectual functioning over the life span, we will address a different question: Why do children or adults who are the same age differ in IQ? Part of the answer is that they differ in the kinds of motivational and situational factors that can affect performance on a given day. Yet there are real differences in underlying intellectual ability that need to be explained. As usual, the best explanation is that genetic and environmental factors interact to make us what we are.

Genes and Environments

The pioneers of the IQ testing movement believed that individual differences in IQ exist because some people inherit “better” genes at conception than others do. This position is still held by hereditarians who draw upon twin studies and other family research to demonstrate a genetic contribution to intelligence. As you saw in Chapter 3, identical twins obtain more similar IQ scores than fraternal twins do even when they have been raised apart. Moreover, the IQs of adopted children, once they reach adolescence, are more strongly correlated with those of their biological parents than with those of their adoptive parents. Overall, most researchers find that about half of the variation in IQ scores within a group of individuals is associated with genetic differences among them. But the influence of genes on intelligence varies across the lifespan. In infancy, genes account for somewhere around 20% of the observed differences in intelligence. This figure rises to about 40% in childhood, 50% in adolescence, and roughly 60% by adulthood. By old age, it may

Checking Mastery

1. What do IQ scores predict during adulthood?
2. What are two factors that contribute to a decline in IQ scores among older adults?
3. How is wisdom different from intelligence?

Making Connections

1. As the administrator of a large health maintenance organization, would it be useful to collect information on intelligence from your clients? Why or why not?
2. In what ways are you smarter than your parents and grandparents, and in what ways are these two older generations smarter or wiser than you? What are some factors that contribute to generational differences in intelligence and age differences in wisdom?

be as high as 80%, meaning that the observed differences in intelligence among elderly adults can be largely explained by the genetic differences between them (Plomin & Deary, 2015).

What exactly does it mean to conclude that there is a genetic influence on intelligence? First, we must make clear what it does *not* mean: Genetic influence, even if it is strong, does not mean that a trait, in this case intelligence, is “set in stone” or unresponsive to the environment (see Nisbett et al., 2012). Genes need environments for expression. In studies using U.S. samples, high socioeconomic status during childhood amplifies genetic influence on intelligence during adulthood (Tucker-Drob & Bates, 2016). That is, we see greater genetic influence on intelligence among samples from more enriched socioeconomic backgrounds and less genetic influence among those from impoverished backgrounds. This relationship among SES, genes, and intelligence is not evident in samples from Western Europe and Australia, possibly because of differences in social policies that allow for greater differences in education and health care in the United States than in other Western societies. Poverty, it seems, dampens the influence of genes on intelligence. In the United States, higher socioeconomic status during childhood is associated with better education and health care, and these factors boost intelligence as well as provide the opportunity for genetic influences to be more fully expressed (Bates, Lewis, & Weiss, 2013). In countries where healthcare and social-welfare programs are available to all citizens regardless of socioeconomic status, genetic influences are evident across all socioeconomic levels (Bates et al., 2013).

How does the environment influence intelligence? Research by Arnold Sameroff and his colleagues (1993) provides a broad overview of some of the environmental factors that put children at risk for having low IQ scores—and, by implication, some of the factors associated with higher IQs. These researchers assessed the 10 risk factors shown in ●Table 9.3 at age 4 and again at age 13. Every factor was related to IQ at age 4, and most predicted IQ at age 13. In addition, the greater the number of these risk factors affecting a child, the lower his IQ, a finding confirmed by other research (Lipina & Colombo, 2009). Which risk factors children experienced was less important than how many risks were experienced. Clearly, it is not good for intellectual development to grow up in a disadvantaged home with an adult unable to provide much intellectual nurturance.

In what ways do parents and the home influence children’s intellectual development? Several of the risk factors in Table 9.3 relate to the socioeconomic status of the family environment (e.g., head of household is unemployed, mother did not complete high school, four or more children in the family). Sophie von Stumm and Robert Plomin (2015) looked at the relationship between socioeconomic status and IQ scores across childhood, from age 2 to 16. Socioeconomic status included parents’ highest level of education, their occupational status, and family income. Over the nearly 15 years of the study, socioeconomic status was fairly stable.

■ Figure 9.9 shows what the researchers found for males and females when they clustered

families into high, medium, and low socioeconomic status. Children who experience persistent (long-term) poverty average some 10–20 points below their middle-class age-mates on IQ tests. Socioeconomic status affects IQ scores as well as children’s rate of intellectual growth (von Stumm & Plomin, 2015). Thus, the cognitive development of low-SES children is slower and their endpoint is lower—on average, they end up a full standard deviation below their age peers. Otto Klineberg (1963) proposed a **cumulative-deficit hypothesis** to describe how impoverished environments inhibit intellectual growth and these negative effects accumulate over time. What if socioeconomic conditions were to improve?

■ Figure 9.9 Changes in IQ growth across childhood for boys and girls, according to SES background.

● Table 9.3 How 10 Environmental Risk Factors Affect IQ of Children at Age 4

Risk Factor	Average IQ for Children Who Experienced Risk Factor	Average IQ for Children Who Did Not Experience Risk Factor	Difference in Average IQ Depending on Whether Children Experienced or Did Not Experience Risk Factor
Child is member of minority group	90	110	20
Head of household is unemployed or low-skilled worker	90	108	18
Mother did not complete high school	92	109	17
Family has four or more children	94	105	11
Father is absent from family	95	106	11
Family experienced many stressful life events	97	105	8
Parents have rigid child-rearing values	92	107	15
Mother is highly anxious or distressed	97	105	8
Mother has poor mental health or diagnosed disorder	99	107	8
Mother shows little positive affect toward child	88	107	19

Source: Adapted from Sameroff, A. J., Seifer, R., Baldwin, A., & Baldwin, C. (1993). Stability of intelligence from preschool to adolescence: The influence of social and family risk factors. *Child Development*, 64, 80–97. Blackwell Publishing. Reprinted with permission.

The brain is responsive to environmental change—it has *neuroplasticity*. So improving the economic conditions of children’s homes can improve their IQs (Duncan, Magnuson, & Votruba-Drzal, 2015). For example, Sandra Scarr and Richard Weinberg charted the intellectual growth of children adopted before their first birthday (Scarr & Weinberg, 1983; Weinberg, Scarr, & Waldman, 1992). Many of these children came from disadvantaged family backgrounds and had biological parents who were poorly educated and somewhat below average in IQ. They were placed in middle-class homes with adoptive parents who were highly educated and above average in intelligence. Throughout childhood and adolescence, these adoptees had average or above-average scores on standardized IQ tests—higher scores than they would have obtained if they had stayed in the disadvantaged environments offered by their natural parents. Similarly, research with French children who were adopted later than infancy—around age 5—indicates that increases in IQ are much larger among children adopted into affluent homes with highly educated parents than among those adopted into disadvantaged homes (Duyme, Dumaret, & Tomkiewicz, 1999).

Andrew Dickerson and Gurleen Popli (2016) distinguish between persistent poverty and episodic, or occasional, poverty. The researchers obtained measures of cognitive development for nearly 19,000 children in the UK Millennium Cohort Study tested at ages 3, 5, and 7 years of age. For those children who experienced persistent poverty, Dickerson and Popli’s research confirms the fairly substantial negative impact of poverty on children’s cognitive development. Further, even children who experienced episodic poverty early in life continued to show some ill effects of this at age 7. The effects were not as large as for those children experiencing persistent poverty, but the early disadvantage conferred by poverty may not be completely alleviated by an improvement in economic status.

Is it possible to identify characteristics of the home environment that are more (or less) important to cognitive development? A widely used assessment of the intellectual stimulation of the home environment is the **Home Observation for Measurement of the Environment (HOME) inventory** (Bradley et al., 2001). Sample items from the preschool version of a HOME inventory include:

- Parent responds verbally to child’s vocalization or verbalizations.
- Parent does not scold, criticize, or spank child.
- Child’s play environment is safe.
- Parent provides toys or other items appropriate to facilitate learning.
- Parent talks to child while doing household chores.

It turns out that scores on the HOME can predict the IQs of African American and European American children at age 3, with correlations of about 0.50 (Bradley et al., 1989; Cleveland et al., 2000). HOME scores continue to predict IQ scores between ages 3 and 6 (Espy, Molfese, & DiLalla, 2001). Gains in intellectual performance from age 1 to age 3, as measured by habituation and speed of processing, are likely to occur among children from stimulating homes, whereas children from families with low HOME scores often experience drops in performance over the same period. These findings are consistent across numerous

countries and racial/ethnic groups, with a few exceptions (Farah et al., 2008; Lipina & Colombo, 2009).

What aspects of the home environment best predict high IQs? Studies using the HOME inventory indicate that the most important factors are parental involvement with the child and opportunities for stimulation (Gottfried et al., 1994). However, the amount of stimulation parents provide to their young children may not be as important as whether that stimulation is responsive to the child’s behavior (a smile in return for a smile) and matched to the child’s competencies so that it is neither too simple nor too challenging (Miller, 1986; Smith, Landry, & Swank, 2000). In short, an intellectually stimulating home is one in which parents are eager to be involved with their children and are responsive to their developmental needs and behavior. This may help explain why some research on intelligence finds a connection to family size and birth order, with firstborns and children from small families scoring just slightly higher (about two points) on IQ tests than later-borns and children from large families (see, for example, Zajonc, 2001a, 2001b; see also Sulloway, 2007).

Do differences in stimulation in the home really cause individual differences in IQ? Parents with greater intelligence are more likely than less intelligent parents to provide intellectually stimulating home environments for their children and to pass on to their children genes that contribute to high intelligence; that is, there is evidence of the gene–environment correlations described in Chapter 3. Maternal IQ, for example, is correlated with a child’s IQ at 3 years and is also correlated with family income and the quality of the home environment (Bacharach & Baumeister, 1998). Although a mother’s IQ is reliably associated with her children’s IQ, a father’s IQ is a less reliable predictor of his children’s IQ.

So bright children are bright, not because of the genes they inherited *or* because of the home environment their bright parents provided. Instead, they are bright because genes and environments get combined in ways that allow children with particular genetic makeups to display high intelligence under favorable environmental conditions. Overall, intellectual development

Home environments can foster intellectual development when they provide appropriate play materials, a variety of daily activities, and have parents who are responsive to children’s needs.

Hero Images/Alamy Stock Photo

seems to go best when a motivated, intellectually capable child, begging for intellectual nourishment, is fortunate enough to get it from involved and responsive adults.

Race and Ethnicity

Many studies, using samples from numerous countries, find racial and ethnic differences in IQ scores, which has sparked much controversy (see Daley & Onwuegbuzie, 2011). In the United States, for example, Asian American and European American children tend to score higher, on average, on IQ tests than African American, Native American, and Hispanic American children (Lynn, 2008b). Although some research suggests that racial differences on IQ tests have been shrinking in recent decades, other research shows little narrowing of the gap between, for example, black and white children on IQ tests (Dickens & Flynn, 2006; Murray, 2006; Yeung & Pfeiffer, 2009). Different subcultural groups sometimes show distinctive profiles of mental abilities; for example, black children often do well on verbal tasks, whereas Hispanic children, perhaps because of language differences, tend to excel on nonverbal items (Lynn, 2009; Taylor & Richards, 1991). It is essential to keep in mind that we are talking about *group averages*. Like the IQ scores of white children, those of minority children run the range from intellectually disabled to gifted. Researchers certainly cannot predict an individual's IQ merely on the basis of racial or ethnic identity. Indeed, lumping people together based on some notion of a common racial background makes little sense to many scientists who find that the variability within groups and the overlap between groups renders the group concept meaningless (Daley & Onwuegbuzie, 2011). Having said that, why do these average group differences exist? Consider the following hypotheses: bias in the tests, motivational factors, genetic differences among groups, and environmental differences among groups.

Biased Tests?

Racial differences in IQ tests may be attributable to culture bias in testing; that is, IQ tests may be more appropriate for children from white middle-class backgrounds than for those from other subcultural groups. Low-income African American children who speak a dialect of English (such as Ebonics or Black English) different from that spoken by middle-class European American children, as well as Hispanic children who hear Spanish rather than English at home, may not understand some test instructions or items. What is more, their experiences may not allow them to become familiar with some of the information called for on the tests (for example, What is a 747? Who wrote *Hamlet*?).

Minority-group children often do not have as much exposure to the culture reflected in the tests as nonminority children do. If IQ tests assess “proficiency in European American culture,” minority children are bound to look deficient (Helms, 1992). Using IQ tests designed to be fair to all ethnic groups and introducing procedures to help minority children feel more comfortable and motivated can cut the usual IQ gap between African American and European American children in half (Kaufman, Kamphaus, & Kaufman, 1985). But even though standardized IQ test items sometimes have a white middle-class flavor, group differences in IQ probably cannot

be traced solely to test bias. Culture-fair IQ tests include items that should be equally unfamiliar (or familiar) to people from all ethnic groups and social classes—for example, items that require completing a geometric design with a piece that matches the rest of the design. Still, racial and ethnic differences emerge on such tests. In addition, IQ tests predict future school achievement as well for African Americans and other minorities as they do for European Americans (Neisser et al., 1996).

Motivational Differences?

Another possibility is that minority individuals are not motivated to do their best in testing situations because they are anxious or resist being judged by an examiner who is often of a different racial/ethnic background (Huang, 2009; Ogbu, 1994; Steele, 1997). Disadvantaged children score some 7–10 points higher when they are given time to get to know a friendly examiner or are given a mix of easy and hard items so that they do not become discouraged by a long string of difficult items (Zigler et al., 1982). Even though most children do better with a friendly examiner, it seems that African American children, even those from middle-class homes, are often less comfortable in testing situations than white middle-class children are (Moore, 1986). Minority children may be less likely to see value to themselves for performing well on a test (Okagaki, 2001). And their peers may accuse (or tease) them of “acting white” if they place too much emphasis on academic success and strong test scores, values that they may associate with white culture.

Claude Steele and his colleagues have argued that the performance of African Americans is especially likely to suffer whenever negative stereotypes of their group come into play (Steele, 1997, 1999; Steele & Aronson, 1995; see also Sackett, Hardison, & Cullen, 2004). In one study, female students at Stanford University were given difficult test items. Some students were told that they were taking a test of verbal abilities and would get feedback about their strengths and weaknesses; others were told that they were going to do some verbal problems but that their ability would not be evaluated. As **Figure 9.10** shows, African American students performed poorly when they were led to believe that the test

Figure 9.10 African American students perform poorly on tests of mental abilities when they think they are taking a test that may result in their being stereotyped as unintelligent.

would reveal their level of intellectual ability, but performed more like European American students when they did not think their ability would be judged. Even being asked to identify their race in a personal information section at the start of a test of intellectual ability can undermine the performance of African American college students (Steele & Aronson, 1995).

Why? Steele concluded that African Americans perform poorly on IQ tests partly because of **stereotype threat**—fear that they will be judged to have the qualities associated with negative stereotypes of African Americans (see also Aronson et al., 1999). It is not that African Americans have internalized stereotypes and believe they are intellectually inferior, according to Steele. Instead, they become anxious and unable to perform well in testing situations that arouse concerns about being negatively stereotyped.

Gregory Walton and Steven Spencer (2009) conducted two meta-analyses of the effects of stereotype threat on test performance of thousands of students. They found substantial effects on SAT scores, the standardized test taken by many college-bound high school students. Stereotype threat seems to account for 40 points of the score gap between majority (white) and nonmajority (black and Hispanic) students. Thus, minority student performance is underestimated as a result of pervasive negative stereotypes.

On the positive side, other research has demonstrated that positive stereotypes about a group can increase the performance of members of that group. Margaret Shih and her colleagues (Shih, Pittinsky, & Ambady, 1999) gave Asian American women a math test under one of three conditions. In one, their identity as women was made noticeable; in another, their Asian American identity was made evident; and in a third condition, no identity was emphasized. Consistent with stereotypes, these women performed worse when their gender was emphasized and better when their ethnic background was emphasized, relative to the group that was not primed to think about either identity. So stereotypes can either hinder or enhance performance, depending on whether a person identifies with a group that is viewed negatively or positively on the dimension measured.

How does stereotype threat operate to potentially affect the test performance of this young African American woman?

© Superstudio/Getty Images

The effects of stereotype threat can be reduced by providing students with a mentor. Catherine Good, Joshua Aronson, and Michael Inzlicht (2003) had college students serve as mentors to seventh-graders who were likely to experience stereotype threat as a result of being female, impoverished, and a member of a minority group. The mentors encouraged students to interpret their academic troubles as a result of the transition to a new school for seventh grade. In addition, they talked about intelligence being flexible and responsive to new learning. Following such mentoring, the students performed better on standardized tests than students who did not receive mentoring. These findings provide a practical means for eliminating or reducing the negative influence of stereotype threat. Of course, eliminating the negative stereotypes that create the threat should also be a goal.

Genetic Factors?

We discussed the overall influence of genetic factors on intelligence, but is there any evidence that genetic differences *between* racial or ethnic groups account for different levels of performance? This is perhaps one of the most controversial ideas in psychology, and it has sparked much heated debate. Scholars such as Arthur Jensen (1969) and Herrnstein and Murray (1994) have suggested that IQ differences between European Americans and African Americans may be because of genetic differences between the races, and they have written books to present their positions.

However, most psychologists do not think the evidence that heredity contributes to *within-group* differences says much about the reasons for *between-group* differences. Consider this analogy from Richard Lewontin (1976): Suppose that corn seeds with different genetic makeups are randomly drawn from a bag and planted in two fields—one that has terrible soil with no nutrients and one that has rich, fertile soil. Because all the plants *within* each field were grown in the same soil, their differences in height would have to be because of differences in genetic makeup. A genetic explanation of differences would fit. But if the plants in the fertile field are generally taller than those in the nonfertile field, this *between-field* variation must be entirely because of environment. Similarly, even though genes partially explain individual differences in IQ *within* African American and European American groups, the average difference *between* the racial groups may still reflect nothing more than differences in the environments they typically experience. There is no direct evidence that differences in genetic makeup between the races account for average group differences in IQ (Neisser et al., 1996).

Environmental Influences?

It is time, then, to return to an environmental hypothesis about racial and ethnic differences in IQ. Many of the intellectual and academic differences attributed to race or ethnicity probably reflect racial and ethnic differences in socioeconomic status instead (Patterson, Kupersmidt, & Vaden, 1990). As noted earlier, placement in more advantaged homes has allowed lower-income African American children to equal or exceed the average IQ in the general population and to exceed the IQs of comparable African American children raised in more disadvantaged environments by 20 points (Moore, 1986; Scarr & Weinberg, 1983; Weinberg et al., 1992). This could not have happened if African American children were genetically deficient.

The major message of this research is that children, whatever their racial background, perform better on IQ tests when they grow up in intellectually stimulating environments with involved, responsive parents and are exposed to the “culture of the tests and the schools” (Scarr & Weinberg, 1983, p. 261). How much of the racial gap in IQ can be explained by racial differences in neighborhood and family socioeconomic conditions, mother’s education, and qualities of the home environment? Jeanne Brooks-Gunn, Pamela Klebanov, and Greg Duncan (1996) used statistical procedures to correct for these environmental differences between African American and European American children so that they could estimate what the IQ difference would be if the two racial groups had been raised in similar environments. Without any controls for environmental differences, there was an IQ gap of 18 points. The gap narrowed to 8 points when family and neighborhood income levels were controlled and was reduced to 3 points, a trivial difference, when racial differences in the provision of a stimulating home environment (HOME scores) were also controlled. In short, the fact that more African American than European American children live in poverty and have limited learning opportunities at home has a lot to do with racial difference in average IQ scores. Reducing poverty and offering more early developmental programs to offset the costs of impoverished home environments would go a long way toward eliminating racial differences in intellectual performance.

● Checking Mastery

1. How does home environment, as measured with the HOME inventory, influence IQ scores?
2. What are two hypotheses about why IQ tests yield racial/ethnic differences in scores?

● Making Connections

1. The Maori are a socioeconomically disadvantaged group in New Zealand, a country colonized by the British long ago. Maori children typically score lower on IQ tests than children of British background. Knowing what you know about minorities in the United States, what are your top two hypotheses about why Maori children perform relatively poorly, and how might you test these hypotheses?
2. What are two or three things that society—schools, local governments, and parents—can do to ensure that children born into poverty are not intellectually disadvantaged by this circumstance?
3. Considering material from this chapter as well as material from Chapter 3 on genetic influences, evaluate the relative contributions of nature and nurture to intelligence. Does one or the other have a greater contribution to intelligence? How do their effects combine? What evidence supports your position?

9.7

The Extremes of Intelligence

LEARNING OBJECTIVES

- Distinguish among different levels of intellectual disability.
- Summarize the likely causes of intellectual disability and what efforts might help reduce rates of intellectual disability.
- Explain the criteria used to identify someone as gifted.
- Trace the likely developmental path of a gifted individual through the life span.
- Compare and contrast, integrating where possible, the various theoretical perspectives on cognitive development covered in Chapters 7, 8, and now 9.

Although we have identified some of the factors that contribute to individual differences in intellectual performance, you cannot fully appreciate the magnitude of these differences without considering people at the extremes of the IQ continuum: gifted at one end and intellectually disabled at the other end.

Intellectual Disability

Intellectual disability, or mental retardation as it was called for many decades, is defined as significantly below-average intellectual functioning with limitations in areas of adaptive behavior such as self-care and social skills, originating before age 18 (see American Association on Intellectual and Developmental Disabilities., 2016; Schalock et al., 2010). An IQ score of 70–75 or lower suggests a limitation in intellectual functioning. This, along with difficulties meeting age-appropriate expectations in

important areas of everyday functioning, is indicative of intellectual disability. Thus, intellectual disability is not merely a deficiency within the person; rather, it is the product of the interaction between person and environment, strongly influenced by the type and level of supportive help the individual receives. If this sounds familiar to you, perhaps you are thinking of Fischer’s dynamic skill theory, discussed in Chapter 8, which proposed that skills can be optimized with a high level of support. A person with an IQ score of 65 in a supportive environment that is structured in ways that allow the individual to fit in and flourish may not be considered disabled in this environment. However, in an environment with different expectations and support, this same individual may be viewed as disabled.

Individuals with intellectual disability differ greatly in their levels of functioning (● Table 9.4). An adult with an IQ in the range of about 52–70 is likely to have a mental age comparable

● **Table 9.4** Levels and Characteristics of Intellectual Disability

	Level			
	Mild	Moderate	Severe	Profound
Approximate Range of IQ Scores	52–70	35–51	20–34	Below 19
Degree of Independence	Usually independent	Some independence; needs some supervision	May be semi-independent with close supervision	Dependent; needs constant supervision
Educational Achievement	Can do some academic work—usually to sixth-grade level; focus is on career	Focus is on daily living skills rather than academics; some career training	Focus is on self-care (toileting, dressing, eating) and communication skills	Focus is on self-care, mobility, and basic communication education

Source: Adapted from Carr, A. & O'Reilly, G. (2016). Diagnosis, classification, and epidemiology. In A. Carr, C. Linehan, G. O'Reilly, P. N. Walsh, & J. McEvoy (Eds.), *The Handbook of Intellectual Disability and Clinical Psychology Practice*, 2nd ed. New York, NY: Routledge.

to that of an 8- to 12-year-old child. Individuals with mild intellectual disability can learn both academic and practical skills in school, and they can potentially work and live independently as adults. Many of these individuals are integrated into regular classrooms, where they excel academically and socially relative to comparable individuals who are segregated into special classrooms (Freeman, 2000). At the other end of the continuum, individuals with IQs below 20–25 and mental ages below 3 years (“profoundly disabled”) show major delays in all areas of development and require basic care, sometimes in institutional settings. However, they, too, can benefit considerably from training.

Intellectual disability has many causes. Those who are severely and profoundly disabled are often affected by “organic” conditions, meaning that their disability is because of some identifiable biological cause associated with hereditary factors, diseases, or injuries. Down syndrome, the condition associated with an extra 21st chromosome, and phenylketonuria (PKU) are familiar examples of conditions causing intellectual disability that are associated with genetic factors (Gilissen et al., 2014; Roizen, 2013). Less common is the genetic condition that leads to Williams Syndrome, associated with IQ scores in the range of mild intellectual disability (Hodapp et al., 2011). Other forms of organic disability are associated with prenatal risk factors—an alcoholic mother, exposure to rubella, and so on (Paulson, 2013; see also Chapter 4). Because many such children are seriously delayed or have physical defects, they can often be identified at birth or during infancy and come from all socioeconomic levels. However, most cases of intellectual disability have no identifiable organic cause; they are characterized by milder symptoms and appear to result from some combination of genetic endowment and environmental factors (Batshaw, Gropman, & Lanpher, 2013). Not surprisingly, then, these children often come from poor areas, have neglectful or abusive families, and frequently have a parent or sibling who is also disabled (Batshaw et al., 2013; Zigler, 1995).

Historically, about 3% of school-age children have been classified with intellectual disability, although this rate has decreased as fewer children today are diagnosed with mild disability (Patton, 2000). Oftentimes, these children have associated impairments, such as cerebral palsy, behavioral problems, physical impairments,

or sensory disorders. As for children not diagnosed at birth, those with milder disabilities are typically diagnosed when, as toddlers, they fail to meet developmental milestones at a typical age. Once children are diagnosed, their parents experience complex reactions to their child and the disability itself (Boström, Broberg, & Hwang, 2010). Parents—mothers more so than fathers—of intellectually disabled children report higher levels of stress than parents of nondisabled children, but this stress is reduced where there are higher levels of marital and parenting satisfaction (Gerstein et al., 2009; Hill & Rose, 2009).

What becomes of these children as they grow up? Generally, they proceed along the same paths and through the same sequences of developmental milestones as other children do, although often at a slower rate (Hodapp et al., 2011). Their IQs remain low because they do not achieve the same level of growth that others do. Like nondisabled people, they show signs of intellectual aging in later life, especially on tests that require speed (Devenny et al., 1996). Individuals with Down syndrome may experience even greater intellectual deterioration later in life because they are at risk for premature Alzheimer’s disease (Roizen, 2013).

As for their outcomes in life, consider a series of follow-up studies with a group of individuals with intellectual disabilities known as the “Camberwell Cohort” for the region of England from where they were originally recruited (Beadle-Brown, Murphy, & DiTerlizzi, 2009; Beadle-Brown, Murphy, & Wing, 2005, 2006). In their 40s, about 50% lived in community group homes, 25% lived with their family, 20% lived in a larger residential facility, and the remainder had some other type of living arrangement. Social skills, important to daily interactions with others, remained largely unchanged over the 25-year period of study. But for those who, as children, started out more socially impaired than others in the sample, social impairments tended to worsen with age, possibly because social demands increased in adulthood or because support in social situations was diminished. The combination of intellectual disability and social impairment led to a poor or fair overall outcome for most of the individuals in the cohort. Not surprisingly, those who were not as intellectually disabled and did not have associated impairments had more favorable outcomes.

The results from the Camberwell Cohort suggest that overall quality of life is lower for adults diagnosed with intellectual disability early in life. However, outcomes varied and were related to severity of the disability. Other research shows a relationship between life span and intellectual disability, with shorter life-spans among those with greater intellectual disabilities (Arvio, Salokivi, & Bjelogrić-Laakso, 2016). Despite the relatively lackluster outcomes for these individuals, there are some promising findings. Fewer folks with intellectual disabilities are living in what might be considered an institutional setting; most live in the community, either in small group homes or with their family, and participate in typical community activities. This is a marked improvement from previous decades, when nearly everyone with any level of disability lived segregated from the mainstream of society, but there is room for greater improvement in the future (Beadle-Brown et al., 2016).

Giftedness

The gifted child used to be identified solely by an IQ score—one that was at least 130. Programs for gifted children still focus mainly on those with very high IQs, but there is increased recognition that some children are gifted because they have special abilities—think again of Gardner’s multiple intelligences discussed at the beginning of this chapter—rather than because they have high general intelligence. Today’s definitions emphasize that **giftedness** involves having a high IQ or showing special abilities in areas valued in society, such as mathematics, the performing and visual arts, or even leadership. Even high-IQ children are usually not equally talented in all areas. Like their average peers, high-IQ children typically have a varied profile of abilities: all may be above average, but some are higher than others (Makel et al., 2016). As they get older, they tend to pursue those areas of study and work where they have the greatest talents as well as the highest interest to them personally (Makel et al., 2016).

Joseph Renzulli (1998; Reis & Renzulli, 2011; Renzulli & Delcourt, 2013) has long argued that giftedness emerges from a combination of above-average ability, creativity, and task commitment. According to this view, someone might have a high IQ and even creative ability, but Renzulli questions whether they are truly gifted if they are not motivated to use this intelligence. Here we focus on individuals with exceptional IQs.

How early can intellectually gifted children be identified? Giftedness is usually apparent by toddlerhood, according to the Fullerton Longitudinal Study by Allen Gottfried and his colleagues (1994). They tracked a large sample of children from age 1–8, determined which children had IQs of 130 or above at age 8, and then looked for differences between these gifted children and other children earlier in life. The gifted children turned out to be identifiable as early as 18 months, primarily by their advanced language skills. Other recent research confirms that early language ability is a good, although not perfect, clue to later intellectual giftedness (Colombo et al., 2009). Gifted children were also highly curious and motivated to learn; they even enjoyed the challenge of taking IQ tests more than most children.

Linda Silverman and her colleagues at the Gifted Development Center have used the Characteristics of Giftedness Scale to

Gifted children have either high IQ scores or special abilities. This young girl is performing with the Pacific Symphony of Orange County, California.

Tony Freeman/PhotoEdit

identify gifted children (see Gifted Development Center, 2016). They have found that gifted children can be distinguished from average children by the following attributes:

- Rapid learning
- Extensive vocabulary
- Good memory
- Long attention span
- Perfectionism
- Preference for older companions
- Excellent sense of humor
- Early interest in reading
- Strong ability with puzzles and mazes
- Maturity
- Perseverance on tasks

The early emergence of giftedness is consistent with research showing a strong genetic influence on high intellect (see Brant et al., 2009; and Haworth et al., 2009). Still, prediction of giftedness is not perfect, although the prediction of nongiftedness is nearly so (Colombo et al., 2009). That is, experts are nearly always correct when they identify a child as not gifted; but among children identified early as gifted, some of these children drift out of this category as they get older (Colombo et al., 2009).

We get a richer understanding of the development of high-IQ children from a major longitudinal study launched in 1921 by Lewis Terman, developer of the Stanford–Binet test (Holahan & Sears, 1995; Oden, 1968; Terman, 1954). The participants were more than 1,500 California schoolchildren who were nominated by their teachers as gifted and who had IQs of 140 or higher. It soon became apparent that these high-IQ children (who came to be called *Termites*) were exceptional in many

other ways. For example, they had weighed more at birth and had learned to walk and talk sooner than most toddlers. They reached puberty somewhat earlier than average and had better-than-average health. Their teachers rated them as better adjusted and more morally mature than their less intelligent peers. And, although they were no more popular than their classmates, they were quick to take on leadership responsibilities. Taken together, these findings destroy the stereotype that most gifted children are frail, sickly youngsters who are socially inadequate and emotionally immature.

Another demonstration of the personal and social maturity of most gifted children comes from a study of high-IQ children who skipped high school and entered the University of Washington as part of a special program to accelerate their education (see Robinson Center, 2016). Contrary to the common wisdom that gifted children will suffer socially and emotionally if they skip grades and are forced to fit in with much older students, these youngsters showed no signs of maladjustment (see Noble & Childers, 2009). On several measures of psychological and social maturity and adjustment, they equaled their much older college classmates and similarly gifted students who attended high school. Many of them thrived in college, for the first time finding friends like themselves—friends who were like-minded rather than like-aged (Noble, Childers, & Vaughan, 2008). Other research similarly shows that acceleration through school is associated with higher academic achievement and more positive social-emotional outcomes for gifted children than lack of acceleration (Steenbergen-Hu & Moon, 2011).

What happens as gifted children move into adulthood? Most of Terman's gifted children remained as remarkable in adulthood as they had been in childhood. Fewer than 5% were rated as seriously maladjusted. Their rates of such problems as ill health, mental illness, alcoholism, and delinquent behavior were but a fraction of those observed in the general population (Terman, 1954), although they were no less likely to divorce (Holahan & Sears, 1995).

The occupational achievements of the men in the sample were impressive. In middle age, 88% were employed in professional or high-level business jobs, compared with 20% of men in the general population (Oden, 1968). As a group, they had taken out more than 200 patents and written some 2,000 scientific reports, 100 books, 375 plays or short stories, and more than 300 essays, sketches, magazine articles, and critiques. These findings of notable accomplishment are echoed in recent follow-ups of other adults identified as gifted by age 13 (see Park, Lubinski, & Benbow, 2007). What about the gifted women in Terman's study? Because of the influence of gender-role expectations during the period covered by the study, gifted women achieved less than gifted men vocationally, often interrupting their careers or sacrificing their career goals to raise families. Still, they were more likely to have careers, and distinguished ones, than most women of their generation.

Finally, the Termites aged well. In their 60s and 70s, most of the men and women in the Terman study were highly active, involved, healthy, and happy people (Holahan & Sears, 1995). The men kept working longer than most men do and stayed

involved in work even after they retired. The women, too, led exceptionally active lives. Contrary to the stereotype that gifted individuals burn out early, the Termites continued to burn bright throughout their lives.

Yet just as it is wrong to view intellectually gifted children as emotionally disturbed misfits, it is inaccurate to conclude that intellectually gifted children are models of good adjustment, perfect in every way. Some research suggests that children with IQs closer to 180 than 130 are often unhappy and socially isolated, perhaps because they are so out of step with their peers, and sometimes even have serious problems (Winner, 1996). Not all research on the profoundly gifted, as those with IQs of 180 and higher are often called, finds an unusual level of social maladjustment, however (Lubinski et al., 2001). Even within this elite group, the quality of the individual's home environment was important. The most well-adjusted and successful adults had highly educated parents who offered them both love and intellectual stimulation (Tomlinson-Keasey & Little, 1990).

Integrating Cognitive Perspectives

Our account of cognitive development over the life span is now complete. We hope you appreciate that each of the major approaches to the mind that we have considered—the Piagetian cognitive-developmental approach, Fischer's dynamic skill theory, and Vygotsky's sociocultural theory described in Chapter 7; the information-processing approach explained in Chapter 8; and the psychometric, or testing, approach, and Sternberg's triarchic model covered here—offers something of value. •Table 9.5 lists how these approaches compare on their views of intelligence.

We can summarize the different approaches to cognitive development this way: Piaget has shown that comparing the thought of a preschooler with the thought of an adult is like comparing a caterpillar with a butterfly. Modes of thought change qualitatively with age. Fischer emphasized the concept of a developmental range of skills that might result depending on level of support provided. Vygotsky has highlighted the importance of culturally transmitted modes of thinking and interactions with others. The information-processing approach has helped researchers understand thinking processes and explain why the young child cannot remember as much information or solve problems as effectively as the adult can. The psychometric approach has told researchers that, if they look at the range of tasks to which the mind can be applied, they can recognize distinct mental abilities that each person consistently displays in greater or lesser amounts. Finally, Sternberg has pushed us to look beyond traditional psychometric tests of intelligence that emphasize analytic skills valued in the classroom to consider creative and practical intelligence alongside the analytical. You need not choose one approach and reject the others. Your understanding of the mind is likely to be richer if all six approaches continue to thrive. There are truly many intelligences, and it is foolish to think that a single IQ score can describe the complexities of human cognitive development.

● **Table 9.5** Comparison of Approaches to Intelligence

	Piagetian Cognitive-Developmental Theory	Fischer's Dynamic Skill Theory	Vygotskian Sociocultural Theory	Information-Processing Approach	Psychometric Approach	Sternberg's Triarchic Model
What Is Intelligence?	Cognitive structures that help people adapt	Refining skills to optimize performance given the task and context	Tools of culture	Attention, memory, and other mental processes	Mental abilities and scores on IQ tests	Components that allow people to succeed in their lives
What Changes with Age?	Stage of cognitive development	Skill levels change	Ability to solve problems without assistance of others and with use of inner speech	Hardware (speed) and software (strategies) of the mind	Mental age (difficulty of problems solved)	Ability to respond to novel problems and automate familiar ones, adapt to current environmental demands, and select appropriate "mental tools" for solving problems
What Is of Most Interest?	Universal changes	Variability in performance	Culturally influenced changes and processes	Universal processes	Individual differences	Adapting behavior to environmental challenges

● Checking Mastery

1. How is intellectual disability defined?
2. What characterizes the typical gifted person?
3. How does the definition of intelligence vary across the various approaches presented in Chapters 7, 8, and 9?

● Making Connections

1. Should gifted, "regular," and intellectually disabled children be educated in the same classroom? What are some of the pros and cons of such integrated education for each of the three groups of children?
2. Putting together material from Chapters 7, 8, and 9, how would you describe the cognitive functioning of a typical 70-year-old person? What are the greatest cognitive strengths of older adults, what are their greatest limitations, and how much can an individual do to optimize her functioning?

Chapter Summary

9.1 Defining Intelligence and Creativity

- The psychometric, or testing, approach to cognition defines intelligence as a set of traits that allows some people to think and solve problems more effectively than others. It can be viewed as a hierarchy consisting of a general factor (*g*), broad abilities such as fluid and crystallized intelligence, and many specific abilities. The Stanford–Binet and Wechsler Scales are the most common intelligence tests and compare an individual's performance on a variety of cognitive tasks with the average performance of age-mates.
- Gardner's theory of multiple intelligences, with its focus on eight distinct forms of intelligence, offers an alternative view.

His theory includes these types of intelligence: linguistic, logical-mathematical, musical, spatial, bodily kinesthetic, interpersonal, intrapersonal, and naturalist.

- Sternberg's triarchic theory of intelligence proposes three components to intelligence. The practical component predicts that intelligent behavior will vary across different sociocultural contexts. According to the creative component, intelligent responses will vary depending on whether problems are novel or routine (automated). Finally, the analytical aspect of intelligence includes the thinking skills that a person brings to a problem-solving situation. This theory has been extended to the theory of successful intelligence, which identifies the additional factors needed to maximize your intelligence.

- Creativity is the ability to produce novel and socially valuable work. It involves divergent rather than convergent thinking and is often measured in terms of ideational fluency, the sheer number of different (including novel) ideas that a person can generate.

9.2 The Infant

- The Bayley scales include motor, mental, and behavior ratings to assess infant development. Although traditionally used as a measure of infant intelligence, they do not correlate well with later IQ scores.
- Infant measures that capture speed of information processing and preference for novelty are better at predicting later intelligence. Infants who can quickly process information are able to take in more information than those who are slower.

9.3 The Child

- During childhood, IQ scores become more stable so that scores at one point in time are generally consistent with scores obtained at a second point.
- Despite group stability, many individuals show wide variations in their IQ scores over time. Those who gain IQ points often have favorable home environments, whereas disadvantaged children often show a cumulative deficit.
- Creativity increases throughout early childhood but dips during later elementary school, possibly in response to societal expectations to conform. Creativity is associated with playfulness, openness to new experiences, and originality.

9.4 The Adolescent

- The Flynn effect describes a global increase in IQ scores over the past century that is likely the result of better nutrition, living conditions, and education.
- During adolescence, IQ scores are relatively stable and intellectual performance reaches near-adult level. IQ scores are useful for predicting the academic achievement of adolescents.
- Levels of creativity vary considerably from one individual to another. Some adolescents conform to societal norms and express little creativity, while others show a great deal of innovation.
- Adolescents with exceptional talents or creativity have both talent and motivation on the nature side and environments that foster their talents and value independence on the nurture side.

9.5 The Adult

- IQ scores are correlated with occupational status as well as health in adulthood.
- Both cross-sectional studies and longitudinal studies tend to show age-related decreases in IQ. Schaie's sequential study suggests that (1) date of birth (cohort) influences test performance, (2) no major declines in mental abilities occur until the late 60s

or 70s, (3) some abilities (especially fluid ones) decline more than others (especially crystallized ones), and (4) not all people's abilities decline.

- A few adults display wisdom, or exceptional insight into complex life problems, which requires a rich knowledge base along with particular personality traits and cognitive styles and is influenced more by experience than age.
- Creative output increases sharply from early to middle adulthood, and although it then drops somewhat, it remains above the level where it started in young adulthood. The peak period of creativity varies from one field to another. Creative output may drop-off in older adulthood because people have already generated and expressed their creative potential.

9.6 Factors That Influence IQ Scores over the Life Span

- Individual differences in IQ at a given age are linked to genetic factors and to differences in intellectually stimulating qualities of the home environment such as parental involvement and responsive stimulation.
- Social class impacts IQ scores, raising the issue of middle-class testing bias. Children who are moved from low to higher socioeconomic status homes show an increase in IQ scores.
- Racial and ethnic differences in IQ also exist, with African American and Hispanic children typically scoring, on average, lower than European American children. Motivational differences, stereotype threat, genetic factors, and environment have all been considered as contributors.

9.7 The Extremes of Intelligence

- The extremes of intelligence are represented by intellectual disability at one end of the continuum and giftedness at the other end.
- Intellectual disability is defined by deficits in adaptive behavior combined with low IQ scores. Functioning varies by level of disability and is worse when accompanied by other conditions. Most intellectually disabled adults live in the community, either in group homes or with their families.
- Giftedness has most often been defined by high IQ scores, although more recent definitions recognize special talents not measured by traditional IQ tests. Life outcomes for gifted people are generally above average.
- Six major approaches to cognitive development have been presented in Chapters 7, 8, and 9. These include Piaget's focus on qualitatively different stages of thought, Fischer's dynamic skills, and Vygotsky's emphasis on culturally transmitted modes of thought. The information-processing approach reveals how memory and problem solving are influenced by characteristics of the person such as age, and task factors such as complexity. The psychometric approach defines cognitive abilities in measurable ways, illustrating that people have more or less of distinct mental abilities. Sternberg's triarchic theory adds creative and practical intelligence to the more traditional analytic intelligence.

In her autobiography, Helen Keller, who was blind and deaf from a very young age, described the moment when she realized that everything could be named. This insight opened up the door to language, learning, and communication. “As the cool stream gushed over one hand, she [Annie] spelled into the other the word water, first slowly, then rapidly. I stood still, my whole attention fixed upon the motions of her fingers. Suddenly I felt a misty consciousness as of something forgotten—a thrill of returning thought; and somehow the mystery of language was revealed to me. I knew then that W-A-T-E-R meant the wonderful cool something that was flowing over my hand. . . . I left the well-house eager to learn. Everything had a name, and each name gave birth to a new thought. As we returned to the house every object which I touched seemed to quiver with life”(Keller, 1954, p. 36).

One of the most important milestones in development is mastering some type of language. Language, whether it is spoken or signed, allows communication with people around us. As you learned in Chapter 7, psychologist Lev Vygotsky argued that language is the primary vehicle through which adults pass culturally valued modes of thinking and problem solving to their children. He also believed that language is our most important tool of thinking.

In this chapter, we examine language skills, which become established largely through an informal education system consisting of parents, other grownups, peers, and even the media. We

also consider formal education, which uses basic language skills to cultivate the reading, writing, thinking, and problem-solving skills that allow individuals to become fully functioning members of society. However, getting the most out of education requires more than acquiring language and literacy skills. As Terrel Bell, former secretary of education, asserted: “There are three things to remember about education. The first one is motivation. The second one is motivation. The third one is motivation” (quoted in Maehr & Meyer, 1997, p. 372). Thus, we also examine achievement motivation and its relationship to education and educational outcomes.

10.1

The System of Language

LEARNING OBJECTIVES

- Describe the function of each component of a spoken language system.
- Articulate how the brain is organized to support language.
- Explain the major theoretical approaches to understanding how language develops.

Although language is one of the most intricate forms of knowledge we will ever acquire, all typically developing children master a language early in life. Indeed, many infants are talking before they can walk. Can language be complex, then? It certainly can be. Linguists (scholars who study language) define **language** as a communication system in which a limited number of signals—sounds or letters (or gestures, in the case of the sign language used by deaf people)—can be combined according to agreed-upon rules to produce an infinite number of messages. Linguists have yet to fully describe the rules of the 6,000 or so languages that exist throughout the world. To master a spoken language such as English, a child must learn basic sounds, how sounds are combined to form words, how words are combined to form meaningful statements, what words and sentences mean, and how to use language effectively in social interactions. How is this accomplished? To address this, we are guided, once again, by consideration of both nature and nurture. But first, we need to understand the basic components of language.

Basic Components

Every human language must have words (symbols) that represent the objects, people, ideas, and so on that are relevant to the community. In addition, there must be a system of rules to organize how the words are used and combined to facilitate communication among members of the community. Perhaps the most fundamental system involves **phonemes**, which are the basic units of *sound* that can change the meaning of a word. Substituting the phoneme /p/ for /b/ in the word *bit* changes the meaning of the word. Although there are 26 letters in the English alphabet, there are more phonemes than this because letters can be pronounced different ways. Trying to identify the precise number of phonemes in a language, though, is like trying to identify the exact number of colors that exist in a rainbow; there are numerous subtleties and interpretations. In addition to individual phonemes, languages

also specify how phonemes can be combined. In English, for example, we can combine /b/ and /r/ to say “brat” but we cannot combine /b/ with /m/ to produce “bmat.”

Languages also have a system for organizing the **morphemes**, the basic units of *meaning* that exist in a word. Some words consist of just one morpheme: *view*. But we can add another morpheme, *re*, and the meaning of the word changes (*review*). Add a different morpheme, *pre*, and the meaning changes again (*preview*). Morphemes are not the same as syllables: A word with multiple syllables, such as the two-syllable *apple*, consists of one morpheme because it cannot be further broken down into smaller meaningful units. To convey the meaning of what we intend when we say “apple,” we have to include both syllables.

Language allows us to generate an infinite number of new sentences to communicate with others.

WORDS AND MEANINGS/MARK SYKES/Alamy Stock Photo

An important step in language acquisition is mastering its **syntax**, the systematic rules for forming sentences. Consider these three sentences: (1) Fang Fred bit. (2) Fang bit Fred. (3) Fred bit Fang. The first violates the rules of English sentence structure or syntax, although this word order would be acceptable in German. The second and third are both grammatical English sentences, but their different word orders—determined by rules of syntax—convey different meanings. Understanding the meanings of sentences also requires knowing the **semantics** of language. To understand the sentence “Sherry was green with jealousy,” we must move beyond the literal meaning of each word, which would suggest that Sherry was the color green, to the meaning that is created when we combine these words into this particular sentence.

Finally, we must understand something of the **pragmatics** of language—rules for specifying how language is used appropriately in different social contexts. That is, children (and adults) have to learn when to say what to whom. They must learn to communicate effectively by taking into account who the listener is, what the listener already knows, and what the listener needs or wants to hear. “Give me that cookie!” may be grammatically correct English, but the child is far more likely to win Grandma’s heart (not to mention a cookie) with a polite “May I please have one of your yummy cookies, Grandma?”

In addition to these features of language, producing meaningful speech also involves **prosody**, or *how* the sounds are produced. Prosody has been called the “melody” of speech because it includes pitch or intonation, the stress or accentuation of certain syllables in a word or certain words in a sentence, and the duration or timing of speech. A child may say “dog” with little change in pitch, perhaps to make a statement meaning, “*There is a dog.*” By raising his voice at the end of the word, though, the meaning is changed to a question, “*Dog?*” A parent may produce a loud, short, “NO!” to stop a child from running into the street, but produce a long “nooo” to perhaps sarcastically make a point with a teenager. Even young infants are sensitive to the prosody of speech and can distinguish between two languages based on their rhythms (Gervain & Werker, 2013).

Thus, mastering a language includes knowing the phonemes and morphemes and how these can be combined, the syntax for turning words into sentences, the semantics for understanding the meaning of words and sentences, the pragmatics for how to best use language to suit the context and our conversational partner, and the prosody or sound features of speech.

We have now covered the basic components of language. How, though, do infants pull all of these parts together into a coherent language system? To answer this, we need to first have some understanding of how the brain processes language and then we need to consider the theoretical explanations for language.

Biology

The basics of language are supported by a brain that is uniquely structured for language. Until recently, our understanding of the brain’s role in language came from observations of individuals who had the misfortune to sustain brain damage and an associated loss of some aspect of language. From this, scientists concluded that

This infant may not understand the words her mother is speaking, but she probably gathers information from the prosody, or melody, of how the words are spoken.

Ali Russell/Alamy Stock Photo

language was largely a product of left hemisphere activity, with a region called Broca’s area associated with speech production and another region called Wernicke’s area associated with comprehension of language (see ■ **Figure 10.1**). Thanks to improved methodologies such as functional magnetic resonance imaging (fMRI) and event-related potentials (ERPs), we are beginning to craft a more precise picture of how neural activity relates to and supports language.

We have learned that human brains show remarkably consistent organization for language across the life span, with the left hemisphere showing increased activity when listening to speech and the right hemisphere showing more activity when processing the melody or rhythm of speech (Gervain & Mehler, 2010). Adults attempting to learn new words show different patterns of brain activity depending on whether they are successful or not: Those who are successful show more connectivity between the left

■ **Figure 10.1** Brain regions associated with language.

and right supramarginal gyrus (refer again to **Figure 10.1**), located in the parietal lobe, one of four main brain regions (Veroude et al., 2010). Studies using fMRI show that areas in both the left and right hemispheres are active in women's brains when processing language, whereas activity in men's brains is more typically localized in the left hemisphere (Shaywitz et al., 1995). We have also learned that Wernicke's area and Broca's area are connected with a band of fibers called the arcuate fasciculus. Typically, incoming language is processed—comprehended—in Wernicke's area and then sent to Broca's area via the connecting fibers to be turned into speech. Damage to this band of fibers can cause a type of **aphasia**, or language disorder, in which the person might hear and understand linguistic input but be unable to vocally repeat the information. Some research suggests that neurons in Broca's area are activated not only when a person produces speech but also when a person sees or hears another person speaking (Fogassi & Ferrari, 2007). This may facilitate language learning and suggests the presence of a mirror neuron system, which we discuss in more detail in Chapter 13.

Finally, there is evidence that the capacity for acquiring language has a genetic basis. Some of our linguistic competencies, including the ability to combine symbols to form short sentences, are shared with chimpanzees and other primates, suggesting that they arose during the course of evolution and are part of our genetic endowment as humans (Greenfield & Savage-Rumbaugh, 1993; Pinker, 1994). Many genes are implicated in language abilities, one of which, *FOXP2*, is associated with the motor skills necessary for speech (Hickok &

Small, 2016). Individuals whose *FOXP2* gene is damaged are unable to speak, although they may have no other limitations. Some intriguing research suggests that girls, who demonstrate advanced language skills relative to boys, have higher concentrations of *FOXP2* protein, but further research is needed to fully understand this link between sex or gender and *FOXP2* (Bowers et al., 2013).

Theories: Nature and Nurture

To understand how children manage to master the remarkable skills of language, we revisit the nature—nurture issue to frame the theoretical explanations of language development.

Nature: Innate Predispositions

On the nature side, the nativists minimize the role of the language environment and focus instead on the role of the child's biologically programmed capacities to acquire language. Noted linguist Noam Chomsky (2000) proposed that humans have a unique genetic capacity to learn language. According to this view, humans are equipped with knowledge of a **universal grammar**, a system of common rules and properties for learning any of the world's languages. Universal grammar offers a limited number of possibilities for forming language. As many as 75% of the world's languages have the basic word order of subject-verb-object (SVO; English, for example) or subject-object-verb (SOV; Japanese, for example). Another 15% have a word order that begins with a verb, whereas word order that begins with an object is quite unusual (Goodluck, 2009). Thus, most of the world's languages are based on a grammatical system that starts with a subject, followed by a verb and then an object or by an object and then a verb.

Universal grammar provides the framework for acquiring a language, but it is not language specific. Exposure to language activates the areas of the brain collectively called the **language acquisition device (LAD)**. Although LAD is not a specific structure in the brain, it is theorized to be an innate brain function that sifts through language, applies the universal rules, and begins tailoring the system to the specifics of the language spoken in the young child's environment (■ **Figure 10.2**). Infants listening to English determine that SVO is the typical grammatical sequence, whereas infants listening to Japanese detect that SOV is typical.

What evidence supports a nativist perspective on language development? First, there is what Chomsky and others have

■ **Figure 10.2** The language acquisition device (LAD).

Source: Chomsky, 1965

called the **poverty of the stimulus (POTS)**: children could not possibly acquire such an incredibly complex communication system with the limited linguistic input they receive (Berwick et al., 2011; Clark & Lappin, 2011). That is, the environmental stimulus of language input is just too impoverished to support the linguistic output that we see emerge. For example, 18-month-olds show an understanding of syntax that they could not have acquired solely from information provided to them by others; they must have inferred rules of syntax on their own (Lidz, Waxman, & Freedman, 2003). Second, children all progress through the same sequences at roughly similar ages, and they even make the same kinds of errors, which suggests that language development is guided by a species-wide maturational plan. Third, these universal aspects of early language development occur despite cultural differences in the styles of speech that adults use in talking to young children.

Other evidence for the nativist position comes from studies of second-language learning. Much research shows that young children learn their native language with ease but often struggle later to learn a second language to the same level of proficiency. Does this mean that there is a critical period for language acquisition and that the brain becomes less responsive to language learning? As noted in Chapter 6, by the time infants begin to speak at around age one, they have already become largely insensitive to sounds that are not made in their native language (see, for example, Werker, Yeung & Yoshida, 2012). This may make it more difficult to hear the nuances of speech needed to fully develop native-like mastery of another language. Consider also research with deaf children, some of whom (especially those with hearing parents) do not have an opportunity to learn any language, oral or signed, in their early years. Rachel Mayberry (2010) studied language mastery in deaf college students exposed to American Sign Language (ASL) at different ages and found that the rule “the earlier, the better” applies. Mastery of the syntax and semantics of sign language was greatest among students exposed to it in infancy or early childhood. Those who learned ASL later in their development (ages 9–16) mastered it better if they had some exposure to English early in life than if they had not been exposed to any language system before they encountered sign language. **Exploration 10.1** provides more details on what we can learn about language in general by studying language acquisition among deaf children. And in a later section of this chapter, we will consider lessons from studying individuals who acquire more than one language, either as infants or when older.

It is possible that the language-processing areas of the brain are shaped for a lifetime by early experience with language in ways that limit later learning of other languages. But it seems unlikely that there is a hard-and-fast critical period for language acquisition. Janet Werker and Richard Tees (2005) suggest that it is more accurate to say there is an “optimal period” during which languages are most easily and flawlessly acquired. And studies of brain architecture confirm that it is more appropriate to conclude that there may be a *sensitive*

period for language acquisition (Fox, Levitt, & Nelson, 2010). Perhaps the main message is that young children are supremely capable of learning languages and advancing their cognitive development in the process.

Nurture: Environment and Learning

How does the environment influence language development? It is no accident that children learn the language their parents speak, down to the regional accent. Children learn the words they hear spoken by others—even when the words are not spoken directly to them (Floor & Akhtar, 2006). For example, 18-month-olds can learn object labels and verbs by “eavesdropping” on a conversation between two adults (so be careful about what you say within earshot of toddlers). But passive exposure to language can only go so far. Young children are more likely to start using new words if they are reinforced for doing so than if they are not (Whitehurst & Idez-Menchaca, 1988). Children whose caregivers frequently encourage them to converse by asking questions, making requests, and the like are more advanced in early language development than those whose parents are less conversational (Bohannon & Bonvillian, 2017).

Learning theorists, with their focus on environment, have had an easier time explaining the development of phonology and semantics than accounting for how rules of syntax are acquired. For example, after analyzing conversations between mothers and young children, Roger Brown, Courtney Cazden,

How would learning theorists describe language acquisition that occurs through interactions such as this one, as a young boy listens to his father?

Niamh Baldock/Alamy Stock Photo

Language Acquisition among Deaf Children

Many deaf children gain their first exposure to language by learning a sign language such as American Sign Language (ASL). These are true languages: The signs are arbitrary symbols, not attempts to mimic objects and events, and they are used according to a system of grammatical rules that determines their ordering. We should be able to learn some interesting lessons about language acquisition in general, then, by studying language acquisition among deaf children.

On average, deaf children growing up in homes where sign is the native language (that is, one or both parents use sign as their primary means of communication) acquire sign language in much the same sequence and at much the same rate as hearing children acquire their native spoken language (Lederberg, Schick, & Spencer, 2013). Interestingly, deaf infants whose parents are deaf “babble” in sign language. They experiment with gestures in much

the same way that hearing infants experiment with sounds in preparation for their first meaningful communications. They sign their first meaningful single words around 12 months, use their first syntax (combinations of two signs) between 18 and 24 months, and master many rules of language, such as past tense formation, between 2 and 3 years (Mayberry & Squires, 2006). Just as hearing children have difficulty with the pronunciation of certain words and overgeneralize certain rules, deaf children make predictable errors in their signing.

The language environment experienced by deaf infants is also far more similar to that of hearing infants than you would imagine. For example, deaf mothers communicate using “child-directed signs.” They present signs at a slower pace, repeat signs more, and exaggerate their signing motions more when they talk to their infants than when they talk to their

deaf friends (Holzrichter & Meier, 2000). Moreover, just as hearing babies prefer the exaggerated intonations of child-directed speech, deaf infants pay more attention and give more emotional response when they are shown videos of infant-directed signing than tapes of adult-directed signing.

Finally, it turns out that language areas of the brain develop much the same in deaf children exposed to sign as in hearing children exposed to speech (Newman et al., 2002). In particular, reliance on areas of the left hemisphere of the cortex to process sentences is as evident among deaf children who acquired ASL early in life (that is, native signers) as among hearing individuals who acquired English early in life (native speakers). Aaron Newman and his colleagues (2002) examined brain activity during the processing of English and ASL sentences by native signers and those who acquired sign later, as a second language. Parts of the left hemisphere were activated in both groups when viewing the English sentences. A part of the right hemisphere was activated in both groups when viewing the ASL sentences. But only the native signers showed activation in a part of the right hemisphere called the angular gyrus when viewing the ASL sentences. The authors believe these findings may be evidence of a sensitive period for learning sign, similar to the sensitive period for learning a native spoken language. Early exposure to sign changes the way the brain responds when later exposed to sign language (see also Campbell, MacSweeney, & Water, 2008; Mayberry, 2010).

As you have seen, language development is sometimes delayed among deaf children of hearing parents if they cannot hear well enough to understand spoken language but are not exposed to sign language (Mayberry, 2010). Overall, then, studies of language acquisition among deaf children suggest that young humans are biologically prepared to master language and will do so if given the opportunity, whether that language is signed or spoken and whether it involves visual-spatial skills or auditory ones (see Goldin-Meadow, 2009).

This mother signs with her infant, which supports language development in much the same way as a spoken language contributes to language development among hearing infants.

Disability Images/Alamy Stock Photo

and Ursula Bellugi (1969) discovered that a mother’s approval or disapproval depended on the truth value or semantics of what was said, not on the grammatical correctness of the statement. Thus, when a child looking at a cow says, “Her cow” (accurate but grammatically incorrect), Mom is likely to provide reinforcement (“That’s right, darling”, whereas if

the child were to say, “There’s a dog, Mommy” (grammatically correct but inaccurate), Mom would probably correct the child (“No, sweetie—that’s a cow”). Similarly, parents seem just as likely to reward a grammatically primitive request (“Want milk”) as a well-formed version of the same idea (Brown & Hanlon, 1970). Such evidence casts doubt on the

idea that the major mechanism behind syntactic development is reinforcement.

Could imitation of adults account for the acquisition of syntax? The problem here is that young children produce many sentences they are unlikely to have heard adults using (“All gone cookie,” “It swam,” and so on). These kinds of sentences are not imitations. Also, an adult is likely to get nowhere in teaching syntax by saying, “Repeat after me,” unless the child already has at least some knowledge of the grammatical form to be learned (Baron, 1992; McNeill, 1970). Young children frequently imitate other people’s speech, and this may help them get to the point of producing new structures. But it is hard to see how imitation and reinforcement alone can account for the learning of grammatical rules.

Nature and Nurture Working Together

It’s now time to merge the two sides of the nature–nurture issue and construct an interactionist account of language development. Consider what Steven Pinker (1995) concludes about the importance of considering both the nature and nurture of language acquisition:

All humans talk but no house pets or house plants do, no matter how pampered, so heredity must be involved in language. But a child growing up in Japan speaks Japanese whereas the same child brought up in California would speak English, so the environment is also crucial. Thus, there is no question about whether heredity or environment is involved in language, or even whether one or the other is “more important.” Instead, language acquisition might be our best hope of finding out how heredity and environment interact. (p. 136)

Interactionists believe that both learning theorists (nurture) and nativists (nature) are correct: Children’s biologically based competencies and their language environment interact to shape the course of language development (Bloom, 1998; Bohannon & Bonvillian, 2017). They emphasize that acquisition of language skills depends on and is related to the acquisition of many other capacities: perceptual, cognitive, motor, social, and emotional. They point out that the capacity for acquiring language is not unique, as nativists who speak of universal grammar and the LAD claim (Bates, O’Connell, & Shore, 1987). It is, instead, interrelated to other developments that are taking place concurrently with language acquisition. For example, young children first begin to use words as meaningful symbols when they begin to display nonlinguistic symbolic capacities, such as the ability to use gestures (waving bye-bye), and begin to engage in pretend play (treating a bowl as if it were a hat).

The interactionists’ position is not unlike that taken by Piaget (1970). He believed that

milestones in cognitive development pave the way for progress in language development and that maturation and environment interact to guide both cognitive development and language development. Like Piaget (but unlike learning theorists), many interactionists argue that language development depends on the maturation of cognitive abilities such as the capacity for symbolic thought. However, the interactionist position also emphasizes—as Vygotsky did but Piaget did not—ways in which social interactions with adults contribute to cognitive and linguistic development. Language is primarily a means of communicating—one that develops in the context of social interactions as children and their companions strive to get their messages across (Tomasello, 2009).

Long before infants use words, Jerome Bruner (1983) says, their caregivers show them how to take turns in conversations—even if the most these young infants can contribute when their turn comes is a laugh or a bit of babbling. As adults converse with young children, they create a supportive learning environment—a *scaffold*, in Bruner’s terms, a *zone of proximal development* in Vygotsky’s—that helps the children grasp the regularities of language. For example, parents may go through their children’s favorite picture books at bedtime and ask “What’s this?” and “What’s that?” These interactions give their children repeated opportunities to learn that conversing involves taking turns, that things have names, and that there are proper ways to pose questions and give answers. When toddlers use a familiar word or phrase (“that plane”), mothers often respond with an **expansion**—a more grammatically complete expression of what the toddler stated (“Yes, that’s a loud airplane”). Adults use conversational techniques such as expansions mainly to improve communication, not to teach grammar (Penner, 1987).

When speaking to their infants, adults adjust their style of communication in ways that may facilitate acquisition of new language skills. Language researchers use the term **child-directed speech** to describe the speech adults use with infants and young children: short, simple sentences spoken slowly, in a high-pitched voice, often with much repetition, and with exaggerated emphasis on key words (Hills, 2013). For example, the mother trying to get her son to eat his peas might say, “Eat your *peas* now. Not the cracker. See those *peas*? Yes, eat the *peas*. Oh, such a good boy for eating your *peas*.” From the earliest days of life, infants seem to pay more attention to the high-pitched sounds and varied intonational patterns of child-directed speech than to the speech adults use when communicating with one another (Ma et al., 2011). This is not to say that “background speech” occurring among adults in the infant’s presence has no effect. As many a parent has learned, toddlers often pick up some of the colorful vocabulary that adults toss around thinking that sweet Suzy will not notice. She did, and it will slip out at some inopportune

Adults are not the only ones who use child-directed speech. Children also adjust their speech to their listener. How could this girl alter her speech to make it appealing and appropriate for her baby sister?

tomborro/Alamy Stock Photo

moment. Importantly, caregivers' child-directed speech occurs within a dynamic social context that helps infants and toddlers understand not only how language is used, but why it is used: to share ideas and communicate within one's social group (Golinkoff, Can, Soderstrom, & Hirsh-Pasek, 2015).

Developing language competence may be our earliest and greatest learning challenge, but it is only the beginning. There is much more to be mastered during the school years and beyond. Language lays the foundation for acquiring reading, writing, and countless other skills. But unlike language, which seems to develop effortlessly in the absence of formal education, these other skills typically require directed education. In the following sections, we look not only at language development but at education across the life span, examining changes in motivation for learning and changes in educational environments as learners get older.

10.2

The Infant

LEARNING OBJECTIVES

- Describe the typical path of language acquisition during the first 2 years.
- Identify factors that facilitate language development.
- Explain the course of early mastery motivation.
- Evaluate the components of a quality early education program.

Infants have a great deal to learn in the informal educational system of their family and neighborhoods before they enter the formal education system. In particular, they must master a language system, and most do so quickly and with little deliberate effort. Indeed, the speed with which most infants and children master language is astonishing. We trace the path to mastering language skills and then turn our attention to how infants take on mastering their environments.

Mastering Language

As you learned in Chapter 6, newborns seem to tune in to human speech immediately and show a preference for speech over non-speech sounds and for their native language, which they listened to in the womb, over other languages (Gervain & Mehler, 2010; Moon, Lagercrantz, & Kuhl, 2013). Very young infants can distinguish between phonemes such as /b/ and /p/ or /d/ and /t/ (Eimas, 1975a). Before they ever speak a word, infants are also becoming sensitive to the fact that pauses in speech fall between clauses, phrases, and words rather than in the middle of these important language units. By 7½ months, infants demonstrate **word segmentation** ability when they detect a target word in a stream of speech (see Jusczyk, Houston, & Newsome, 1999). Thus, when they hear the sentence “The cat chased the mouse,” they understand that this is not one long word but a string of five words. Word segmentation is a formidable task, but infants seem to be sensitive to a number of cues marking the boundaries between words, and this skill improves throughout the first 2 years of life (Saffran et al., 2006). One thing that helps infants with this task is the repetition of many common words throughout the days, weeks,

Checking Mastery

1. What are the basic components of language that children must master in order to communicate effectively?
2. How is the brain structured to support language skills?
3. What are the main features of the nativist and learning theories of language acquisition?

Making Connections

1. How should adults interact and talk with infants to ensure they have the best opportunities to develop a strong start with their language development?
2. What is the most compelling evidence that language is influenced by nature? And what evidence shows that it is not nature alone that determines language acquisition?

and months leading to language acquisition. By repeatedly hearing “cat” embedded in many different sentences, infants come to understand that “cat” must represent a unit that is separate from other spoken units. They are also sensitive to the stress placed on certain syllables (see Hollich, 2010). In English, for example, the first syllable of nouns is typically stressed, and infants exposed to English language learn that when they hear a stressed syllable, it probably signals the start of a word.

What about producing sounds? From birth, infants produce sounds—cries, burps, grunts, and sneezes. These sounds help exercise the vocal cords and give infants an opportunity to learn how airflow and different mouth and tongue positions affect sounds. By 5 months, infants realize that their sounds have an effect on their caregivers' behavior (Goldstein, Schwade, & Bornstein, 2009). Parents respond to as many as 50% of prelinguistic sounds as if they were genuine efforts to communicate (Goldstein et al., 2009; McCune et al., 1996). For instance, in response to her infant's hiccup sound, a mother replies, “My goodness! What's going on in there? Huh? Tell Mommy.” The mother draws her infant into a sort of dialogue. Such prelinguistic sounds, and the feedback infants receive, eventually pave the way for meaningful speech sounds (Hoff, 2014).

The next milestone in vocalization, around 6–8 weeks of age, is **cooing**—repeating vowel-like sounds such as “oooooh” and “aaaaah.” Babies coo when they are content and often in response to being spoken to in a happy voice. Do infants this age understand the words spoken to them? Not likely—they primarily respond to the intonation or “melody” of speech (Hirsh-Pasek, Golinkoff, & Hollich, 1999). Parents can say some rather nasty things to their young infants (“You're driving me nuts today!”) as

long as they say them with a happy voice, illustrating the importance of prosody.

Around 3–4 months, infants expand their vocal range considerably as they begin to produce consonant sounds. They enter a period of **babbling** between about 4 and 6 months, repeating consonant–vowel combinations such as “baba” or “dadadada,” in what Jean Piaget would call a primary circular reaction—the repeating of an interesting noise for the pleasure of making it.

Up to about 6 months, infants all over the world, even deaf ones, sound pretty much alike, but the effects of experience soon become apparent. Without auditory feedback, deaf infants fall behind hearing infants in their ability to produce well-formed syllables (Oller & Eilers, 1988). By the time infants are about 8 months old, they babble with something of an accent; adults can often tell which language infants have been listening to from the sound of their babbling (Poulin-Dubois & Goodz, 2001). These advanced babblers increasingly restrict their sounds to phonemes in the language they are hearing, and they pick up the intonation patterns of that language (Hoff, 2014; Snow, 2006). Once these intonation patterns are added to an infant’s babbles, the utterances sound a great deal like real speech until you listen closely and realize you have no idea what the infant is saying! (Hollich, 2010). We shouldn’t assume, though, that infants are as clueless as we are: What they are “saying” may make complete sense to them. As they attempt to master the semantics of language, infants come to understand many words before they can produce them. That is, *comprehension* (or reception) is ahead of *production* (or expression) in language development. Ten-month-olds can comprehend, on average, about 50 words but do not produce any of these (Golinkoff & Hirsh-Pasek, 2006). This gap between comprehension and production persists and may reflect the relative importance of understanding speech over producing speech (Bornstein & Hendricks, 2012). Research shows that early understanding of words is related to academic achievement in elementary school: The 10-month-olds who understand more words are later the children who get better grades (Hohm et al., 2007).

Shortly before speaking their first true words, as they approach 1 year, infants really seem to understand familiar words. How do they figure out what words mean? When Mom points to a small, four-legged furry animal and says, “There’s Furrball,” how do infants learn that “Furrball” refers to this particular cat and not to its movement or to its tail or to a general category of furry animals? It turns out that infants and toddlers use a variety of cues in learning to connect words with their referents—the objects, people, or ideas represented by a name. At first, 10-month-old infants rely on attentional cues such as how important an object seems to be from their perspective (Pruden et al., 2006). Thus, if their attention is captured by the ball in front of them, they may

Like many parents, this mother uses pointing and eye gaze to direct her daughter’s attention. Coupling these actions with words helps toddlers acquire the meaning of words.

Gabriel Blaj/Alamy Stock Photo

assume that mom’s verbalizations refer to this ball. By 12 months of age, though, their reliance on personal relevance is decreasing and infants begin to use social and linguistic cues to learn words.

One important social cue is **joint attention**, or social eye gaze—two people looking at the same thing. Infants listen to parents repeatedly labeling and pointing at objects, directing their gaze, and otherwise making clear the connection between words and their referents (Hollich, Hirsh-Pasek, & Golinkoff, 2000). If Mom says “cat” when both she and her child are looking at the furry animal, then this likely is the referent for the label. Importantly, early development of joint attention skills seems to pave the way for early vocabulary development (Beuker et al., 2013).

Finally, children use the process of **syntactic bootstrapping** when they use the syntax of a sentence—that is, where a word is placed in a sentence—to help determine the meaning of the word (Naigles & Swensen, 2007). In the earlier example, if mom had said, “There’s *a* furball” or “The cat is hacking up a furball” instead of the original “There’s Furrball,” the syntactic placement—how *furball* was used in the sentence—would have changed the meaning of the word.

The First Words

An infant’s first meaningful word, spoken around 1 year, is a special event for parents. First words have been called **holophrases** because a single word often conveys an entire sentence’s worth of meaning. These single-word “sentences” can serve different communication functions depending on the way they are said and the context in which they are said (Tomasello, 2009). For example, 17-month-old Shelley used the word *ghetti* (spaghetti) in three different ways over a 5-minute period. First, she pointed to the pan on the stove and seemed to be asking, “Is that spaghetti?” Later, the function of her holophrase was to name the spaghetti when shown the contents of the pan, as in “It’s spaghetti.” Finally, there was little question that she was requesting spaghetti when she tugged at her companion’s sleeve as he was eating and used the word in a whining tone.

Although there are limits to the meaning that can be packed into a single word and its accompanying intonation pattern and gestures, 1-year-olds in the holophrastic stage of language development seem to have mastered such basic language functions as naming, questioning, requesting, and demanding. When they begin to use words as symbols, they also begin to use nonverbal symbols—gestures such as pointing, raising their arms to signal “up,” or panting heavily to say “dog” (Goldin-Meadow, 2009).

What do 1-year-olds talk about? They talk mainly about familiar objects and actions—those things that they encounter every day

● **Table 10.1** Examples of Words Used by Children Younger than 20 Months

Category	Words
Sound effects	<i>baa baa, meow, moo, ouch, uh-oh, woof, yum-yum</i>
Food and drink	<i>apple, banana, cookie, cheese, cracker, juice, milk, water</i>
Animals	<i>bear, bird, bunny, dog, cat, cow, duck, fish, kitty, horse, pig, puppy</i>
Body parts and clothing	<i>diaper, ear, eye, foot, hair, hand, hat, mouth, nose, toe, tooth, shoe</i>
House and outdoors	<i>blanket, chair, cup, door, flower, keys, outside, spoon, tree, TV</i>
People	<i>baby, daddy, grandma, grampa, mommy, [child's own name]</i>
Toys and vehicles	<i>ball, balloon, bike, boat, book, bubbles, plane, truck, toy</i>
Actions	<i>down, eat, go, sit, up</i>
Games and routines	<i>bath, bye, hi, night-night, no, peek-a-boo, please, shhh, thank you, yes</i>
Adjectives and descriptors	<i>all gone, cold, dirty, hot</i>

and are important to them (● **Table 10.1**). Most research shows that the first 50 words typically consist of common nouns representing objects and people (Waxman et al., 2013). It may be easier for young children to decipher nouns and their referents in the language around them, and adults tend to use more nouns in their conversations with children (Uccelli & Pan, 2013). Another possibility, though, is that it is easy to create an image of the things represented by nouns and images to give us something tangible to remember (McDonough et al., 2011). Verbs, though, pose more of a challenge because it can be difficult to create an image for an action.

Initial language acquisition proceeds literally at one word at a time. Three or four months may pass before the child has a vocabulary of 10 words, slowly acquired one by one. There is a great deal of variability in early language acquisition: While one child may be speaking her fiftieth word as she celebrates her first birthday, another child may be reaching this milestone around the time of his second birthday (Newman & Sachs, 2012).

Then, in what is called the **vocabulary spurt**, around 18 months of age, when the child has mastered about 30–50 words, the pace of word learning quickens dramatically (Bloom, 1998; Carroll, 2008). Steven Pinker (1995), an experimental psychologist who has studied and written extensively on all aspects of language development, estimates that a new word is acquired every 2 hours during this time! At 20 months, children are producing an average of 150 words, and just 4 months later, this has doubled to 300 words (Camaioni, 2004). What makes this possible? Something called **fast mapping**, which allows children to use sentence context to help them make an educated guess about word meaning. This is a quick and efficient method of

learning new words. Although infants as young as 6 months demonstrate rudimentary fast mapping, the ability becomes much more refined between 20 and 24 months (Borgström, Torkildsen, & Lindgren, 2015). Of course, this is a simplification of what is, undoubtedly, a very complex process. Contributing to fast mapping is the greater memory capabilities of the toddler as well as the growing ability to use a word's context to decipher its meaning. Like Helen Keller with her “aha” realization that the letters being tapped on her one hand were related to the object (water) in her other hand, toddlers seem to arrive at the critical realization that everything has a name and that, by learning the names of things, they can share what they are thinking with someone else and vice versa (Bloom & Tinker, 2001). Toddlers who acquire more vocabulary during this time may be quicker information processors and this may serve them well as they move into formal schooling: Those who demonstrate larger vocabularies at age 2 enter kindergarten with higher levels of reading and math achievement than their peers with less vocabulary (Morgan et al., 2015).

With such a rapidly increasing vocabulary, it should come as no surprise that children sometimes make mistakes. Although they rarely get the meaning entirely wrong, they often use a word too broadly or too narrowly (Uccelli & Pan, 2013). One error is **overextension**, or using a word to refer to too wide a range of objects or events, as when a 2-year-old calls all furry, four-legged animals “doggie.” The second, and opposite, error is **underextension**, as when a child initially uses the word *doggie* to refer only to basset hounds like the family pet. Notice that both overextension and underextension are examples of Piaget's concept of assimilation, using existing concepts to interpret new experiences. Getting semantics right seems to be mainly a matter of discriminating similarities and differences—for example, categorizing animals on the basis of size, shape, the sounds they make, and other perceptual features (Clark & Clark, 1977). By 2½–3 years of age, these sorts of semantic errors begin to disappear from children's conversations.

But might children know more about the world than their semantic errors suggest? Yes. Two-year-olds who say “doggie” when they see a cow will point to the cow rather than the dog when asked to find the cow (Naigles & Gelman, 1995; Thompson & Chapman, 1977). Children may overextend the meaning of certain words such as *doggie* not because they misunderstand word meanings but because they want to communicate, have only a small vocabulary with which to do so, and have not yet learned to call something a “whatchamacallit” when they cannot come up with the word for it (Naigles & Gelman, 1995).

We need to be careful about applying these generalizations about early language acquisition to all children because they mask large individual differences in language development. As ■ **Figure 10.3** shows, one 24-month-old may have a vocabulary of approximately 50 words, and another may be able to produce more than 500 words (Fenson et al., 1994). What might account for these large differences in language expression? A large factor seems to be socioeconomic status of the family. A classic study by Betty Hart and Todd Risley (1995) examined how parents talked with their infants and toddlers. They found that among the poorest families in their sample, children heard about 620 words per

Figure 10.3 The range of individual differences in vocabulary size from 16 to 30 months. Each line on this figure represents the words produced by an individual child, from 16 to 30 months of age.

hour, whereas children in the wealthiest families heard more than 3 times this number of words. The researchers surmised that by the age of 4, this hourly difference would add up to a gap of approximately 30 million words. Further, they found that children who heard more words as they were growing up were the children who entered school with bigger vocabularies and higher IQ scores. In the roughly 25 years since these findings were published, much attention has been given to this gap of 30 million words between wealthy and poor families. Various programs have been developed to encourage parents in lower-income families to talk more with their infants and toddlers (see Suskind, Suskind, & Lewinter-Suskind, 2015).

Other research has disputed the size of the word gap across the range of socioeconomic statuses, but has nonetheless found some truth to the premise that parents' talk can have a powerful influence on their children's development. To try to clarify the issue, several researchers took advantage of a relatively new piece of technology that is like an exercise tracker but for language (Ramirez-Esparza, Garcia-Sierra, & Kuhl, 2014). Infants who were about 1 year old wore the small language tracker on multiple days, racking up a total of 32 hours of language for analysis. The language tracker analysis was able to distinguish who was speaking (infant or an adult), type of speech (child-directed or standard), and context (one or multiple adults). The researchers also collected a measure of word production from the infants when they were about 2 years of age.

What did the researchers find? It turns out that the sheer quantity of speech infants are exposed to did not significantly affect their later language, but that the amount of quality speech they heard was important (see also Hirsh-Pasek et al., 2015). In particular, those infants who heard more child-directed speech

from one adult at a time later produced more words than other infants. Although there were fewer lower-income parents who engaged with their infants in what the researchers defined as high-quality speech, there were certainly some who did so. The important variable did not seem to be socioeconomic status per se, but the values and beliefs that parents held regarding how to interact with their youngsters. More of the lower-income parents were unaware of the value of early stimulation for brain development and did not realize that they could make a difference in their children's lives by simply talking with them. But it takes more than awareness; it also requires time and energy, which are often less available in families where parents are working multiple jobs and worrying about safety issues. As Annette Laureau, a sociologist, has described it, middle- and upper-class families use a childrearing style of constantly cultivating their children for adulthood—in other words, very 'hands-on' with much negotiating and explaining going on between parent and child (McKenna, 2012). In contrast, lower-class families tend to use a style of 'hands-off' parenting with little negotiating and explaining. There are pros and cons of both styles, but in terms of language development, one con of the hands-off style is exposure to less child-directed speech from adults, with longer-term effects on academic achievement (see Hoff, 2013).

Telegraphic Speech

The next step in language development, normally occurring at 18–24 months of age, is combining two words into a simple sentence. Toddlers all over the world use two-word sentences to express the same basic ideas (●Table 10.2). Early combinations of two, three, or more words are sometimes called **telegraphic speech** because, like telegrams of the past where costs were minimized by eliminating unnecessary words, these sentences contain critical content words and omit frills such as articles, prepositions, and auxiliary verbs.

It is ungrammatical in adult English to say "No want" or "Where ball." However, these two-word sentences are not just random word combinations or mistakes; they reflect children's

● **Table 10.2** Two-Word Sentences Serve Similar Functions in Different Languages

Function of Sentence	Language	
	English	German
To locate or name	<i>There book</i>	<i>Buch da (book there)</i>
To demand	<i>More milk</i>	<i>Mehr Milch (more milk)</i>
To negate	<i>No wet</i>	<i>Nicht blasen</i>
To indicate possession	<i>My shoe</i>	<i>Mein Ball (my ball)</i>
To modify or qualify	<i>Pretty dress</i>	<i>Armer Wauwau (poor doggie)</i>
To question	<i>Where ball</i>	<i>Wo Ball (where ball)</i>

Source: Adapted from Slobin, 1979

developing understanding of syntax. Psycholinguists such as Lois Bloom (1998) believe it is appropriate to describe children's early sentences in terms of a **functional grammar**—one that emphasizes the semantic relationships among words, the meanings being expressed, and the functions served by sentences (such as naming, questioning, or commanding). For example, young children often use the same word order to convey different meanings. “Mommy nose” might mean “That’s Mommy’s nose” in one context, but for one 22-month-old girl one afternoon it meant “Mommy, I’ve just wiped my runny nose the length of the living room couch.” Word order sometimes does matter: “Billy hit” and “Hit Billy” may mean different things. Body language and tone of voice also communicate meanings, such as when a child points and whines to request ice cream, not merely to note its existence.

Between ages 2 and 5, children experience a dramatic increase in the number and type of sentences they produce. Consider 3-year-old Kyle’s reply to his mother after she suggests that he release a bug:

After I hold him, then I’ll take the bug back to his friends. Mommy, where did the bug go? Mommy, I didn’t know where the bug go. Find it. Maybe Winston’s on it [the family dog], Winston, get off the bug! [Kyle spots the bug and picks it up. His mother again asks him to “let the bug go back to his friends.”] He does not want to go to his friends. [Kyle drops the bug and squashes it, much to his mother’s horror.] I stepped on it and it will not go to his friends.

Compared with a child in the telegraphic stage, Kyle’s sentences are much longer and more grammatically complex, although not free of errors, and he is better able to participate in the give-and-take of conversation. Kyle has also begun to add the little function words such as articles and prepositions that are often missing in the earlier telegraphic sentences (Hoff, 2014). How do people know when children are mastering new rules? Oddly enough, their progress sometimes reveals itself in new “mistakes.” A child who has been saying “feet” and “went” may suddenly start to say “foots” and “goed.” Does this represent a step backward? Not at all. The child was probably using the correct irregular forms at first by imitating adult speech without understanding the meaning of plurality or verb tense. The use of “foots” and “goed” is a breakthrough: The child has inferred the morphological rules of adding -s to pluralize nouns and adding -ed to signal past tense. At first, however, the youngster engages in **overregularization**: overapplying the rules to cases in which the proper form is irregular. When the child masters exceptions to the rules, she will say “feet” and “went” once more.

Children must also master rules for creating variations of the basic declarative sentence; that is, they must learn the syntactic rules for converting a basic idea such as “I am eating pizza” into such forms as questions (“Am I eating pizza?”), negative sentences (“I am not eating pizza”), and imperatives (“Eat the pizza!”). The prominent linguist Noam Chomsky (1968, 1975) drew attention to the child’s learning of these rules by proposing that language be described in terms of a **transformational grammar**, or rules of

syntax for transforming basic underlying thoughts into a variety of sentence forms.

How do young children learn to phrase the questions that they so frequently ask to fuel their cognitive growth? The earliest questions often consist of nothing more than two- or three-word sentences with rising intonation (“See kitty?”). Sometimes *wh-* words such as *what* or *where* appear (“Where kitty?”). During the second stage of question asking, children begin to use auxiliary, or helping, verbs, but their questions are of this form: “What Daddy is eating?” “Where the kitty is going?” Their understanding of transformation rules is still incomplete (Tager-Flusberg & Zukowski, 2013). Finally, they learn the transformation rule that calls for moving the auxiliary verb ahead of the subject (as in the adultlike sentence “What is Daddy eating?”).

Mastery Motivation

As they are mastering language, infants are also mastering many other important tasks to prepare them for success in life. Much evidence supports the claim that infants are curious, active explorers constantly striving to understand and to exert control over the world around them. This, you should recall, was one of Piaget’s major themes. **Mastery motivation**, a striving for mastery or competence, appears to be inborn and universal and will display itself in the behavior of all typical infants without prompting from parents. We can clearly see this desire for mastery when infants struggle to open kitchen cabinets, take their first steps, or figure out how new toys work—and derive great pleasure from their efforts (Jennings & Dietz, 2003; Masten & Reed, 2002). Even so, some infants appear to be more mastery oriented than others. Given a new push toy, one baby may simply look at it, but another may mouth it, bang it, and push it across the floor (Jennings & Dietz, 2003). Why might some infants have a stronger mastery motive than others?

One possibility is that the goal itself may hold greater value to some infants: If that red ball looks highly appealing to Joanie, she may expend more time and energy to retrieve it than Naomi, who just doesn’t judge it worthy of her attention (Kenward et al., 2009). Mastery motivation also seems higher when parents frequently provide sensory stimulation designed to arouse and amuse their babies—tickling them, bouncing them, playing games of pat-a-cake, giving them stimulating toys, and so on (Busch-Rossnagel, 1997). Mastery motivation flourishes when infants grow up in a responsive environment that provides plenty of opportunities to see for themselves that they can control their environments and experience successes (Maddux, 2002; Masten & Reed, 2002). Consider the toddler who, faced with the challenge of retrieving a cookie from the kitchen counter, struggles to maneuver a chair across the room and to climb up without tipping the chair or falling off. When Mom offers to help him, he shrieks, “Me do it!” And when he does it, he feels a sense of accomplishment that increases the likelihood he will tackle future challenges. Parents who return smiles and coos or respond promptly to cries show infants they can affect people around them.

Unfortunately, infants of parents who are depressed show less interest in and persistence on challenging tasks, perhaps because

Every day, infants and young children display their innate mastery motive.

Image Source Plus/Alamy Stock Photo

their parents are not responsive to them (Sparks et al., 2012). As well, children who are raised by parents who constantly stifle their initiatives (“you will *not* move the chair across the room!”) may be less likely to take on new tasks.

An infant’s level of mastery motivation affects her later achievement behavior. Babies who actively attempt to master challenges at 6 and 12 months score higher on tests of mental development at 2 and 3 years than their less mastery-oriented peers (Jennings & Dietz, 2003; Messer et al., 1986). In sum, infants are intrinsically motivated to master challenges, but parents may help strengthen this inborn motive by stimulating their infants appropriately and responding to their actions. What about infants and toddlers who spend considerable amounts of time away from their parents? Is their motivation influenced by time spent in preschool?

Early Education

As you have seen in previous chapters, babies learn a great deal in the first few years of life. But do infants and toddlers need specific educational experiences? Despite the popular appeal of products such as *Baby Einstein* and *Baby Mozart*, many experts dispute the idea that typically developing children, raised in typical family environments, need direct instruction during their first 3 years (for example, Carlsson-Paige, 2008). And some, such as David Elkind (1987), author of *Miseducation: Preschoolers at Risk*, fear that the push for earlier education may be going too far and that young children today are not given enough time simply to be children—to play and socialize as they choose. Elkind even worries that children may lose their self-initiative and intrinsic motivation to learn when their lives are orchestrated by parents who pressure them to achieve at early ages. Is there anything to these concerns?

Some research seems to confirm Elkind’s fears. Frederick Zimmerman, Dimitri Christakis, and Andrew Meltzoff (2007; see

also Christakis, 2008) studied infants who watched *Baby Einstein* or *Brainy Baby* videos. They found, rather alarmingly, that for each hour spent watching videos, babies understood 6–8 fewer words than babies who did not watch videos. The research did not follow infants into childhood to determine if the video-watching babies later caught up to the other babies, but the findings do raise a red flag, at least with respect to early language abilities. Other research on the effects of these programs shows a similarly dismal outcome. Infants who spent 6 weeks watching *Baby Wordsmith* videos, which focus on vocabulary, demonstrated absolutely no differences in vocabulary knowledge or language development from infants who did not view this program (Richert et al., 2010; and see Chapter 1’s discussion of baby videos and language development). If educational videos are not valuable, and may even be detrimental, what about educational infant and preschool programs?

In one study, 4-year-olds in preschools with strong academic thrusts gained an initial advantage in basic academic skills such as knowledge of letters and numbers but lost it by the end of kindergarten (Hyson, Hirsh-Pasek, & Rescorla, 1991). What is more, they proved to be less creative, more anxious in testing situations, and more negative toward school than children who attended preschool programs with a social rather than academic emphasis. Similarly, Deborah Stipek and her colleagues (1995) have found that highly academic preschool programs raise children’s academic achievement test scores but decrease their expectancies of success and pride in accomplishment. So it may be possible to undermine achievement motivation by overemphasizing academics in the preschool years.

However, preschool programs that offer a healthy mix of play and academic activities in the form of guided play can be beneficial to young children (Weisberg, Hirsh-Pasek, & Golinkoff, 2013). This sort of academic skill-building may be especially helpful to disadvantaged children. This was the premise for the federally funded Head Start program, started in 1965 as part of the “War on Poverty.” The idea behind Head Start was to provide a variety of social

How would you balance structure and free play to optimize young children’s learning?

David Grossman/Alamy Stock Photo

and intellectual experiences that might better prepare disadvantaged children for school and “break the cycle of poverty.” High-quality Head Start programs provide the nutrition, health care, parent training, and intellectual stimulation that can get these children off to a good start. At first, Head Start and similar programs seemed to be a big success; children in the programs showed average gains of about 10 points on IQ tests. Unfortunately, these early gains were completely wiped out by the time children reached second or third grade (Gray, Ramsey, & Klaus, 1982; Puma et al., 2012).

But the results are not all discouraging. With more than 50 years’ worth of study, we know that the benefits of programs such as Head Start are often indirect and may not show up until much later. Consider the Abecedarian Project, a full-time educational program from infancy (starting around 4–5 months) to age 5 for children from low-income families (Campbell et al., 2001). Compared with children who did not participate, Abecedarian children showed impressive cognitive gains during and immediately after the program (■ **Figure 10.4**). But are the effects of good early educational programs truly life changing? To find out, the researchers followed-up on the Abecedarian participants at age 30 (Campbell et al., 2012). Remarkably, they were able to examine outcomes for a majority of the original participants. Those who had participated in the Abecedarian program had completed more years of education than those in the comparison group. In particular, 23% of the children who had been in the program had earned a college degree compared to only 6% in the comparison group. About 75% of the Abecedarian adults worked full-time compared to 50% of the nonparticipant adults. Despite these advantages of a high-quality preschool program, such early intervention did not “fix” everything. There were no differences, for example, between the two groups in criminal activity at age 30: In both the Abecedarian and the comparison adults, just over 25% had been convicted of a crime. Other research, though, suggests that early education programs can help reduce the number of arrests logged by age 40 (Schweinhart et al., 2005).

An alternative type of program focuses on educating parents about the importance of the early environment and the types of experiences that can be beneficial to their children. It turns out that parent training pays off. In one such program, *Born to Learn*, children displayed higher levels of mastery motivation than non-participants by 36 months of age, or even earlier—24 months—if they were from disadvantaged families (Drotar et al., 2008). In another program, the *Milwaukee Project* (Garber, 1988), full-time child care was provided for youngsters along with job and academic training for mothers. Following-up on these participants in the eighth grade showed that they remained intellectually ahead of their peers who had not participated.

■ **Figure 10.4** Cognitive growth curves as a function of preschool treatment, showing a bigger initial gain as well as a sustained advantage in cognitive growth for children in the Abecedarian program.

Source: Campbell, F. A., et al. (2001). The development of cognitive and academic abilities: Growth curves from an early childhood educational experiment. *Developmental Psychology*, 37, 231–242. Copyright © 2001, American Psychological Association.

The programs that experience greater success are those that find ways to address underlying issues, one of which is poverty. In Chapter 9, we discussed how children who grow up in poverty are likely to have lower IQ scores, on average, than their peers who did not experience poverty. It should be no surprise, then, to learn that poverty can also affect educational attainment. Early education programs may not be able to directly combat poverty, but they can address some associated factors that adversely affect academic achievement. These would include strengthening the language environment of the home, as discussed earlier in the chapter, and helping parents to understand the importance of the early environment for children’s development.

● Checking Mastery

1. Through what stages does early language acquisition progress?
2. Give an example of an overregularization of language.
3. What is mastery motivation?
4. What is one advantage and one potential disadvantage of early education programs for infants and toddlers?

● Making Connections

1. What should parents and early childhood educators look for (or listen for) to confirm that infants and toddlers are progressing typically with regard to their language acquisition at ages 1, 2, and 3?
2. Should preschool education be mandatory? At what age should formal education begin? Provide some evidence to support your answer.
3. How can parents and early childhood teachers foster mastery motivation in their children?

10.3

The Child

LEARNING OBJECTIVES

- Indicate the changes in language development that occur in childhood.
- Demonstrate understanding of different types of motivational styles by describing and giving an example of each.
- Analyze the outcomes typically associated with each motivational style.

With infancy behind them, children begin to expand their language skills and show true achievement motivation. As you'll now see, formal education uses these building blocks to develop life-long skills and knowledge.

Expanding Language Skills

School-age children improve their pronunciation skills, produce longer and more complex sentences, and continue to expand their vocabularies. The average first-grader starts school with a vocabulary of about 10,000 words and adds somewhere between 5 and 13 new words a day throughout the elementary-school years (Hoff, 2014). School-age children also begin to think about and manipulate language in ways previously impossible (Melzi & Schick, 2013). They can, for example, interpret passive sentences such as “Goofy was liked by Donald” and conditional sentences such as “If Goofy had come, Donald would have been delighted” (Boloh & Champaud, 1993; Sudhalter & Braine, 1985).

Throughout childhood, advances in cognitive development are accompanied by advances in language and communication skills. For example, as children become less cognitively egocentric, they are more able to take the perspective of their listeners (Hoff, 2014). Middle childhood also brings increased **metalinguistic awareness**, or knowledge of language as a system (Melzi & Schick, 2013). Children with metalinguistic awareness understand the concept of words and can define words (semantics). Development of metalinguistic awareness also means that children can distinguish between grammatically correct and grammatically incorrect sentences (syntax) and can understand how language can be altered to fit the needs of the specific social context in which it is used (pragmatics). Children who are **bilingual**, knowing two or more languages, have better metalinguistic skills than non-bilingual (that is, monolingual) children (Schwartz et al., 2008). Are there other benefits to being bilingual?

For starters, ongoing exposure to multiple languages alters the neural connections in the brain (Petitto et al., 2012). As monolingual infants begin to lose some sensitivity to sounds produced in other languages, bilingual and multilingual infants retain sensitivity to the wider range of sounds used in the languages they hear. This may help explain why infants and young children who are regularly exposed to multiple languages seem to acquire the multiple languages with just about as much ease as those learning a single language. There may be times when children learning two languages struggle to find the correct vocabulary word or may take slightly longer on some linguistic tasks. But, for the most part, children who are bilingual end up with more advantages than disadvantages (Bialystok, Craik, & Luk, 2012).

We have also learned that when folks who are bilingual use one of their languages, it activates the other language at the same

time (Marian & Shook, 2012). Although they may not realize that both languages are active, studies of eye movements and neuroimages of the brain indicate that both are indeed activated. Perhaps as a result of this activity, bilingual children and adults demonstrate enhanced abilities to switch back and forth between different tasks (Barac & Bialystok, 2012). Their working memory is more robust than that of monolinguals and they are also more skilled at ignoring irrelevant information and focusing on the relevant features of a task (Morales, Calvo, & Bialystok, 2013; Rubio-Fernández & Glucksberg, 2012).

Such evidence tells us that the constant juggling of two languages that bilinguals must perform strengthens the higher level executive control components of the cognitive system. Just as physical exercise affects your body's structure as well as its functioning, the early and regular mental exercise required to become bilingual affects the brain's neural wiring as well as the brain's functioning (Grady, Luk, Craik, & Bialystok, 2015; Marian et al., 2014; Wong, Yin, & O'Brien, 2016).

What's more, bilingualism seems to bolster a person's cognitive reserve (Bialystok et al., 2012). As we get older, cognitive reserve may allow us to retain our mental capabilities longer by increasing our mental processing efficiency. In one study, bilingual adults developed symptoms and were diagnosed with Alzheimer's disease 4–5 years later than monolingual adults (Alladi et al., 2013).

What if we acquire a second language later in life? The outcomes are not the same for later second language learners as for those who are exposed to a second language from birth and acquire the two languages simultaneously. For one thing, early versus later learning of a second language results in different changes in brain architecture, indicating that second language learning may follow different paths depending on the age it occurs (Jasińska & Petitto, 2013; Klein, Mok, Chen, & Watkins, 2014).

Research with native speakers of Korean or Chinese, who had come to the United States between age 3 and age 39, examined their mastery of English grammar and found that those who learned it earliest—prior to puberty—knew it best (Johnson & Newport, 1989). Among those who arrived in the United States after puberty, performance was generally poor regardless of age of arrival or number of years using English. Such findings have been used to argue that there is a sensitive period for language acquisition that ends around puberty, but other research shows that it is more one's age at the time of arrival in the United States that is related to proficiency in English as a second language (Birdsong, 1999, 2005). Although adults are generally less likely than children to attain native-like proficiency in a second language—suggesting a sensitive period—some adults do achieve

such proficiency, usually through massive effort and exposure to the second language (Birdsong, 1999).

So it seems as though it is easier to learn a second language when learning a first language during infancy, that is, to be bilingual rather than to acquire a second language later. Bilingualism also imposes some benefits that do not seem to come with later second language learning. In particular, bilinguals experience enhanced executive control and cognitive reserve. Given the benefits of bilingualism, perhaps more parents should be encouraged to brush up on their multilanguage skills in order to raise their children bilingual. When their children are old, they might appreciate having that extra cognitive reserve.

Achievement Motivation

Researchers who study achievement motivation strive to understand and explain people's behaviors in achievement situations such as those found in the classroom. Understanding what motivates students to perform (or not) can set the stage for creating conditions to foster higher levels of motivation. The importance of this should not be underestimated: Children's beliefs about their competence for various tasks predicts their performance on those tasks (Denissen, Zarratt, & Eccles, 2007).

All children occasionally experience failure in their efforts to master challenges and meet achievement standards. Why do some children persist and triumph in the face of failure, whereas others give up when they experience failure? Carol Dweck and her colleagues (for example, Dweck, 2006; Yeager, Paunesku, Walton, & Dweck, 2013; Blackwell, Trzesniewski, & Dweck, 2007) have spent over 30 years searching for answers. From this research, Dweck has concluded that it is not so much what you have—your ability, talent, or intelligence—as *how you think about what you have* (Dweck, 2006). In particular, those who have a **fixed mindset** tend to believe that “what they have” is fixed or static. Thus, they either “have” a talent or do not; they either “are” intelligent or they are not. With this sort of mindset, there is little reason to put forth great effort on a task because it cannot change a fixed trait. Students with a fixed mindset, even those who are highly talented, typically select tasks that they know will showcase their talents with little effort. They tend to avoid challenging tasks as they do not believe they can be successful on these.

In contrast, those who have a **growth mindset** believe that abilities and talent are not fixed but are malleable: They can be fostered through hard work and effort. With this sort of mindset, students are motivated to put forth effort as this will lead to learning and advancement. A growth mindset can be fostered by praising students' efforts, not just the end products of their work (Dweck, 2007; 2015). For instance, a teacher or parent might say, “That was a really hard assignment, but you kept working on it, trying different strategies, until you finished it. Way to go!” In contrast, praising students for their intelligence (“You did well on that test because you are so smart”) may lead students to think that their performance is driven by (their fixed amount of) intelligence alone and is not related to effort. What about the inevitable feedback about mistakes? Students with a fixed mindset interpret such feedback as an indication that they lack ability. Thus, when they receive low grades or a paper filled with lots of comments from

their teacher, students with a fixed mindset are more likely to feel defeated by their sense of lack of ability rather than energized to work harder and improve. Students with a growth mindset are more likely to interpret feedback about mistakes as useful information that can be used to improve for the future (Moser et al., 2011). How do some children end up with growth rather than fixed mindsets? Characteristics of children, parents, and schools all contribute to motivation style and level.

Child Contributions

Several characteristics of the child contribute to achievement levels and their motivation or mindset to succeed. First is the child's age or developmental level. By age 3, children are beginning to react differently to their successes and failures, yet they remain unrealistically optimistic about their abilities until age 7–8 (Wigfield et al., 2015). With age, children's perceptions of their academic abilities become more accurate, likely because they become better at understanding feedback—from parents, teachers, and peers—about their performance (Wigfield et al., 2015). Young children may also give up if their failures are clear-cut and they conclude they have been bad, as they equate success and failure with being a good or bad person (Burhans & Dweck, 1995; Heyman, Dweck, & Cain, 1992).

Young children are protected from damaging self-perceptions partly because they believe that ability is a changeable quality and that they can become smarter and improve their ability if they work hard. That is, they start out with a growth mindset. This view of ability encourages them to adopt **mastery goals** (also called learning goals) in achievement situations, aiming to learn new things so that they can improve their abilities (Brophy, 2010). A focus on mastery goals tends to dominate throughout the lower elementary grades (Bong, 2009).

As children age, in our society at least, they begin to see ability as a fixed trait that does not change much with effort. As a result, by late elementary and middle school, more of them have a fixed

What factors will determine whether this student remains motivated and focused on mastery goals or shifts to performance goals and possibly becomes disinterested with school?

● **Table 10.3** Comparison of Mastery and Performance Goals

Mastery Goals	Performance Goals
Ability as a changeable trait	Ability as a fixed trait
Focus on increasing competence or knowledge (“I understand this material better than I did before”)	Focus on increasing status relative to others (“I did better on this than the other students did”)
Self-regulated learning; ability to monitor understanding of material and adjust behavior (for example, effort) accordingly	Other-regulated learning; ability to monitor performance relative to peers and increase effort (approach) to outperform them or decrease effort (avoidance) to save face (to say that failures are because of a lack of effort, not incompetence)
Deep-level processing of material (for example, learning to understand)	Superficial-level processing of material (for example, memorizing for a test)
Feelings of pride and satisfaction associated with success, with failures indicating a need for more effort or different learning strategies	Feelings of anxiety and shame associated with failure; boastful feelings associated with success

Source: Adapted from Covington, 2000; Elliot & Church, 1997.

mindset and adopt **performance goals** in school; they aim to *prove* their ability rather than to *improve* it and seek to be judged smart rather than dumb (Bong, 2009; Dweck & Leggett, 1988; Erdley et al., 1997; and see ● **Table 10.3**). These changes in the understanding of ability are probably caused both by cognitive development—especially an increased ability to analyze the causes of successes and failures and to infer enduring traits from behavior—and by an accumulation of feedback in school (Stipek, 1984).

Importantly, children with growth mindsets who continue to focus on mastery or learning goals tend to do better in school than those who adopt fixed mindsets and switch to performance goals (Yeager et al., 2013). Children who focus on mastery goals do not become as disheartened by a low grade if they have nonetheless progressed in their understanding of the material. For these children, the *process* of learning is enjoyable; it helps quench their curiosity (Fisher, Marshall, & Nanayakkara, 2009). Their ability to enjoy the learning process may help explain why these children exhibit higher levels of achievement (von Stumm, Hell, & Chamorro-Premuzic, 2011). In contrast, children who focus on performance goals are more discouraged because, for them, the *outcome*—the grade—is the goal, not the process of learning. These children are more likely to report anxiety and boredom, factors that are negatively associated with achievement (Daniels et al., 2009; Pekrun, Elliot, & Maier, 2009). The two groups of children—those with mastery or learning goals and those with performance goals—even display different patterns of neurological activity in response to their performance outcomes, further evidence that these two groups are truly experiencing their successes and failures differently (Fisher et al., 2009). Importantly, the two types of goals are not mutually exclusive; that is, it is possible to be motivated by both mastery goals and performance goals (Darnon et al., 2010). What is important, though, is the predominant focus that students hold as they work to achieve their goals. As Table 10.3 illustrates, when students believe that ability is primarily a fixed entity that they either have or do not have and conclude that they lack it, they set performance goals rather than learning goals; figuring that hard work will not payoff, they run the risk of giving up in the classroom (Dweck & Leggett, 1988). Even gifted students can fall into this trap (Ablard & Mills, 1996). Evaluate your own motivation style with the exercise in **Engagement 10.1**.

In addition to their age, children’s level of intelligence, not surprisingly, contributes to their success in academics (Spinath et al., 2006). But clearly level of intelligence is just one piece of the puzzle because some students with above average intelligence do not do particularly well in school and others exceed expectations based solely on their IQ scores. It turns out that both motivation and achievement levels are higher when children value a subject—they believe it is important and they are interested in a subject (Spinath et al., 2006). Think of this in relation to your own learning and motivation and you will likely recognize that you try harder and perform better when something is important and interesting to you.

Parent Contributions

Parents can foster their children’s achievement motivation by stressing and reinforcing the *process* of learning rather than emphasizing the product (Dweck, 2015). They can also emphasize the learning opportunities provided by making mistakes. Consider research by Kyla Haimovitz and Carol Dweck (2016). Over several studies, they demonstrated that parents tend to hold mindsets about *failure* as either debilitating or enhancing. Children pick up on these parental mindsets about failure and these help shape children’s own mindsets about intelligence. In particular, parents who view failures as debilitating tend to have children with fixed mindsets about their intelligence. As we have already learned, fixed mindsets are not as productive as growth mindsets. Instead, individuals who believe intelligence is influenced by effort—how hard they work—are more likely to show improvement following mistakes than individuals who believe that intelligence is a fixed trait.

In their review of research on achievement motivation, Allan Wigfield, Jacquelynne Eccles, and their colleagues (2015) concluded that three aspects of parenting style can influence children’s motivation:

1. Providing an appropriate balance of structure for daily activities, without being controlling, overly prescriptive, or holding unrealistic expectations;
2. Offering consistent and supportive responses to children’s activities and behaviors;
3. Presenting opportunities for children to observe healthy responses to life’s challenges from the adults in their lives.

What's Your Motivation Style?

Indicate whether you agree (A) or disagree (D) with each of the following statements, as they pertain to your typical approach or thoughts about learning and coursework.

- 1. I read the chapter because the material was interesting to me.
- 2. I read the chapter because the instructor said there would be a quiz on the material.
- 3. I often look up some additional information related to the course material so that I can better understand what is discussed in class or presented in the textbook.
- 4. I feel good when I am able to convey my understanding of the material on the exam.
- 5. I need to earn a B+ or higher in this class to maintain my scholarship.
- 6. I want to get an A on this test to show the professor that I'm good.
- 7. I want to get an A on all the quizzes this semester because then I will be exempt from taking the final exam.
- 8. As long as I pass this class, I'll be happy because I know I've learned something new from a really challenging professor.
- 9. I like to see how others in the class score on the assignments so I can get an idea of how well I'm doing.
- 10. I don't really care how other people in the class score because their performance is unrelated to my learning.

- 11. I get bored and frustrated when the instructor spends time on easy material and quizzes us on stuff that seems obvious.
- 12. I get frustrated when the instructor goes over difficult material that is going to be hard to study to earn a good grade.
- 13. There is nothing I like more than a good challenging homework assignment that makes me think harder or differently.
- 14. I like getting a homework assignment that is easy and fairly mindless to complete. I know I can get it done and the instructor will be happy with my answers.
- 15. I usually find that I can master a task or material by working really hard on it.
- 16. If I cannot solve a task right away, I usually stop working on it because I'm not going to be able to solve it.

Scoring: Count the number of "Agree" answers to these questions: 1, 3, 4, 8, 10, 11, 13, 15. Count the number of "Disagree" answers to these questions: 2, 5, 6, 7, 9, 12, 14, 16. If the number of "Agree" answers to the first set (1, 3, 4, 8, 10, 11, 13, 15) is higher than the number of "Disagree" answers to the second set (2, 5, 6, 7, 9, 12, 14, 16), then you focus more on learning or mastery goals. You are more interested in mastering material for the sake of learning than for the sake of grades. If, on the other hand, the number of your "Disagree" answers to the second set of questions is higher than the number of "Agree" answers to the first set, then you focus more on performance goals. You are motivated to perform well and earn good grades. According to the text, which of these motivation styles—mastery versus performance—ultimately leads to a deeper and richer understanding of material? What could you do to shift from one style to the other?

Thus, parents should provide a safe, structured environment that encourages children to challenge themselves with new tasks or set higher goals for those tasks already familiar to them. Children who are encouraged and supported in a positive manner are likely to enjoy new challenges and feel confident about mastering them.

School Contributions

How do schools affect achievement? Nearly every school asserts that the major goal of classroom instruction is improvement of children's learning. Many of these same schools, however, are structured in ways that focus on the external rewards that students can earn (such as grades or stickers). As a result, they may encourage children, either deliberately or inadvertently, to set performance goals rather than mastery or learning goals. Many classrooms are competitive places where students try to outdo each other to earn the best grades and gain teacher recognition. Students receive a grade (good or bad), indicating their performance on a test or project, and that is the end of it. If they did not fully learn the material, they are given no opportunity to do so: They learn that the grade, not learning, is the goal.

What if schools downplayed the competitive race for the best grades in class? Consider some research by Elaine Elliott and Carol Dweck (1988). They asked fifth-graders to perform a novel

task. The students were led to believe that they had either low or high ability and were warned that they would soon be performing similar tasks that would prove difficult. Half the children worked under a performance goal (not unlike the goals emphasized in many classrooms): They were told that their performance would be compared with that of other children and evaluated by an expert. The remaining children were induced to adopt a learning or mastery goal: Although they would make some mistakes, they were told, working at the tasks would "sharpen the mind" and help them at school.

As expected, the only children who became frustrated and gave up were those who believed they had low ability and were pursuing a performance goal. For them, continuing to work on the difficult task meant demonstrating again that they were stupid. By contrast, even "low ability" students who pursued a mastery goal persisted despite their failures and showed remarkably little frustration, probably because they believed they could grow from their experience. Perhaps, then, teachers undermine achievement motivation by distributing gold stars and grades and frequently calling attention to how students compare with one another (Brophy, 2010). Children might be better off if teachers nurtured their intrinsic motivation to master challenges and structured their classrooms to emphasize mastery rather than performance goals (Murayama & Elliot, 2009). Then, slower learners could

view their mistakes as a sign that they should change strategies to improve their competencies rather than as further proof that they lack ability.

In a fascinating study, Harvard economist Roland Fryer, Jr. (2011) spent millions of dollars to learn whether students could be bribed into earning higher standardized test scores. He enlisted school districts in three major cities and used a different set of incentives in each location. In Chicago, ninth-graders could earn up to \$2,000 per year by getting paid \$50 for each A test grade, \$35 for each B grade, and \$20 for each C grade. Students in New York City were paid for completing assignments throughout the term. In Dallas, second-graders were paid \$2 every time they read a book and completed a quiz on their reading.

The results may surprise you. The program was a bust in Chicago and New York City: Students earned lots of money for getting good grades on tests throughout the year but showed no

improvement on standardized tests given at the end of the school year. The program that proved to have the biggest bang for the bucks was the one in Dallas that paid the least and targeted, not grades, but a behavior that all children could already perform and could control—their reading. Young students who were paid for reading books and answering quiz questions significantly improved their standardized reading comprehension scores. We still need to see how students in the various groups perform over time—and ensure that rewarding activities such as reading books does not eventually undermine intrinsic motivation for reading. But the results suggest that rewarding children not for the final products of their work (that is, the grades) but for the steps that contribute to the final product can have a positive effect on their performance. Fryer and others involved in the study found that students who had the opportunity to earn the most money for high test scores were very excited by this prospect but did not know how to go about achieving it. Instead of bribing students for the grades they earn, it might be better to encourage students to involve themselves in behaviors they can control that contribute to greater engagement with the course material. Ultimately, this is what will lead to greater achievement gains.

Finally, schools can help students develop growth mindsets through fairly simple interventions. In one program, researchers developed a workshop on mindset and study skills for minority and low-income students. Over the course of eight sessions, “students learned to think of their brains as muscles that get stronger as you exercise them. Students visualized new neuronal connections growing as they completed hard math problems” (Yeager et al., 2013, p. 8). Another group of students participated in a workshop on study skills, but without the focus on mindset. Math scores before and after the intervention were tracked for both groups and the results were quite remarkable (Blackwell, Trzessniewski, & Dweck, 2007). Math scores of both groups were nearly identical prior to the intervention, but deviated significantly after the training. Those with the mindset training showed upward progress, whereas those without the mindset training showed declining progress, despite receiving study skills training.

To recap what you have learned so far, children approach achievement tasks with either a fixed or growth mindset, based on how they view their abilities: unchangeable or malleable. As they age, children are more likely to believe that ability is a stable trait and shift from focusing on mastery goals to focusing on performance goals. These changes, brought about by both cognitive development and feedback in school, may make them more vulnerable to “failure syndrome,” a tendency to give up at the first obstacle they encounter (Brophy, 2010). Yet some children remain far more motivated to succeed in school than others, and parents and schools have a lot to do with that.

Learning to Read

Perhaps children’s most important achievement in school is acquiring the ability to read. Mastery of reading paves the way for mastering other academic skills. Skilled readers consume more printed material than unskilled readers, giving them an advantage in other academic areas that increasingly rely on reading skills over the school years (Sparks, Patton, & Murdoch, 2013;

Students who are given external rewards for good performance in the classroom or on tests may end up losing their intrinsic motivation for learning.

Marmaduke St. John/Alamy Stock Photo

Stanovich, 1986). Unlike language acquisition, a natural learning task that typically requires no formal education, reading acquisition usually requires direct instruction. Fortunately, the brain seems to be structured to support the acquisition of reading skills (Dehaene, 2009). How, though, do children master this complex and important skill?

Mastering the Alphabetic Principle

Before children can read, they must understand the **alphabetic principle**—the idea that the letters in printed words represent the sounds in spoken words in a systematic way (Lonigan, 2015). According to Linnea Ehri (1999), this is a four-step process, as follows:

- **Prealphabetic phase:** Children memorize selected visual cues to remember words. They can “read” text that they have memorized during previous readings. A picture on a page in a favorite book, for instance, triggers a child to recall the words she has often heard her mother read when they turned to this page.
- **Partial alphabetic phase:** Children learn the shapes and sounds of letters. They begin to connect at least one letter in a word—usually the first—to its corresponding sound. For example, they recognize the curved shape of the letter C and begin to associate this with a particular sound. Not surprisingly, children typically recognize the initial letter of their first name before other letters (Treiman & Broderick, 1998).
- **Full alphabetic phase:** Children know all the letters and make complete connections between written letters and their corresponding sounds. To do this, they rely on **phonological awareness**—the sensitivity to the sound system of language that enables them to segment spoken words into sounds or phonemes (Carroll et al., 2003). Children who have phonological awareness can recognize that *cat* and *trouble* both have the phoneme /t/ in them, can tell you how many distinct sounds there are in the word *dark*, and can tell you what will be left if you take the /f/ sound out of *fat*. Children can decode words never before seen by applying their knowledge of phonetics.
 - **Table 10.4** shows what happened when a third-grade boy with poor phonological awareness tried to read the sentence, “A boy said, ‘Run, little girl.’” He ended up with an incorrect interpretation (“A baby is running little go”) and lost the intended meaning of the sentence, illustrating the importance of phonological awareness.
- **Consolidated alphabetic phase:** Children are able to group letters that regularly occur together into a unit. For instance, the letter sequence *ing*, which frequently appears at the end of

Repeatedly reading the same story fosters vocabulary and deepens children’s understanding of the story content.

imageBROKER/Alamy Stock Photo

verbs, is perceived as a single unit rather than as three separate letters. This grouping speeds the processing of the multisyllabic words that older children are increasingly exposed to in their books.

Thus, the basic components of literacy include mastering a language system, understanding connections between sounds and their printed symbols (the alphabetic principle), and discriminating phonemes that make up words (phonological awareness). How does the child pull all this together into reading?

Emergent Literacy

Several factors influence **emergent literacy**—the developmental precursors of reading skills in young children (Whitehurst & Lonigan, 1998). Emergent literacy includes knowledge, skills, and attitudes that will facilitate the acquisition of reading ability. Children with greater working memory and attention control demonstrate a higher degree of reading readiness than other children, suggesting that activities strengthening these skills can help foster reading achievement (Welsh et al., 2010). One way to do this is through reading storybooks to preschoolers (Evans & Shaw, 2008). Repetitious storybook reading enhances children’s vocabulary and

• **Table 10.4** One Boy’s Misreading of the Sentence “A Boy Said, ‘Run, Little Girl.’”

Words in Target Sentence	Strategies Employed by Reader	Words “Read”
A	Sight word known to reader	A
boy	Unknown; uses beginning <i>b</i> to guess <i>baby</i>	baby
said, “Run,	<i>Said</i> unknown; jumps to the next word (<i>run</i>), which he recognizes, then uses the <i>s</i> in <i>said</i> and his knowledge of syntax to generate <i>is running</i>	is running
little	Sight word known to reader	little
girl	Unknown; uses beginning <i>g</i> to guess <i>go</i>	go

Source: Adapted from Ely, 2001

allows them to see the connection between printed and spoken words. Importantly, parents should read *with* their child rather than to their child, meaning they should actively involve their child in the activity rather than having the child remain the passive recipient (Phillips, Norris, & Anderson, 2008). With each successive reading, parents who ask increasingly complex questions about the text can move their child from a superficial to a deeper understanding (van Kleeck et al., 1997). Even older children benefit from reading the same book on multiple occasions (Faust & Glenzer, 2000) and from shared reading with a parent (Clarke-Stewart, 1998). Parents, with their greater mastery of reading, can help their fledgling readers develop an understanding of printed words. If you think of this in Vygotsky's framework, it is an example of parent and child operating in the zone of proximal development.

Rhyming stories and games can help foster phonological awareness. For this reason, listening to books with a rhyming structure (for example, Dr. Seuss's *The Cat in the Hat*) can benefit children. Young children's sensitivity to rhyme (for example, *cat-sat*) helps predict their later reading success (Bryant, 1998; Goswami, 1999).

By assessing preschool children's emergent literacy skills, parents and early childhood educators can develop a fairly accurate idea of what children's later reading skills will be. In particular, differences among children in knowledge of letters (for example, knowing the alphabet), phonological awareness, and word segmentation skills predict later differences in their reading ability (Carroll et al., 2003; Kendeou et al., 2009). In addition, semantic knowledge as reflected in children's ability to retrieve words, provide word definitions, and assign meaning to the printed symbols that represent words predicts later reading ability (Kendeou et al., 2009; Roth, Speece, & Cooper, 2002). This suggests that parents can help children get a head start on reading by encouraging activities such as rhyming, repeating the ABCs, and defining words.

Skilled and Unskilled Readers

After children have received reading instruction, why are some children quick, advanced readers but others struggle to master the most basic reading material? For starters, skilled readers have a solid understanding of the alphabetic principle—the notion that letters must be associated with phonemes. Thus, when they see the letter *b*, they know the sound that it represents. A large body of research also confirms that reading ability is influenced by a child's level of phonological awareness (see Lonigan, 2015). Children with higher levels of phonological awareness usually become better readers than children with lower levels of phonological awareness.

But there is more to being a skilled reader than connecting letters with sounds. Analyses of eye movement patterns show that unskilled readers skip words or parts of words, whereas skilled readers' eyes hit all the words (Perfetti, 1999). Skilled readers spend less time looking at the printed words than less-skilled readers, and their eyes are also less likely to skip back to a previous word in the sentence (Valle et al., 2013). In other words, their eye movements suggest that they are faster information processors. Speed of information processing influences performance on a variety of tasks and is important from infancy through old age.

Some children have serious difficulties learning to read, even though they have normal intellectual ability and no sensory impairments or emotional difficulties that could account for their problems. These children have **dyslexia**, or a reading disability. A minority have the kind of visual perception problem that used to be seen as the heart of dyslexia; they cannot distinguish between letters with similar appearances, or they read words backward (*top* might become *pot*). However, it is now clear that the difficulties of most dyslexic children involve auditory perception more than visual perception (see, for example, Temple et al., 2000).

Specifically, children who become dyslexic readers often show deficiencies in phonological awareness well before they enter school (Bruck, 1992; Melby-Lervåg, Lyster, & Hulme, 2012). There is even evidence that the brains of dyslexic children respond differently than those of other children to speech sounds soon after birth; functional imaging of the brain shows that this distinctive pattern of neural activity is still evident when the children are later diagnosed as having dyslexia (see, for example, Caylak, 2009; Shaywitz et al., 2001). This suggests that a perceptual deficit may develop during the prenatal period of brain development. Because dyslexic children have difficulty analyzing the sounds in speech, they also have trouble detecting sound–letter correspondences, which in turn impairs their ability to recognize printed words automatically and effortlessly (Bruck, 1990). They must then devote so much effort to decoding the words on the page that they have little attention to spare for interpreting and remembering what they have read. Dyslexic children continue to perform poorly on tests of phonological awareness and tests of word recognition as adolescents and adults, even if they have become decent readers (Bruck, 1990, 1992; Shaywitz et al., 1999). It is now clear that dyslexia is a lifelong disability, not just a developmental delay that is eventually overcome.

Let's broaden our attention now from effective reading instruction to effective education. How well are schools doing at educating children? What factors contribute to effective schools, and in doing so, presumably contribute to more effective learning by children?

Effective Schools, Effective Learning

Some schools seem to do a better job than others—they graduate a higher percentage of students or have a higher percentage of students at or above the proficient level in one or more subjects. Why? To understand why some schools seem more effective than others, we must consider characteristics of the students, characteristics of the teachers and school settings, as well as the interaction between student and environment.

Student Characteristics

Over the years, some scholars have argued that a school's effectiveness is only as good as what it has to work with—the students it takes in. We know there are genetic differences among children and these differences contribute to differences in aptitude among them. As you learned in Chapters 3 and 9, IQ scores have a genetic component, and children with higher

IQs attain higher grades throughout their 12 years of school. Schools cannot eliminate these genetic differences among children, but they can influence (that is, raise) overall levels of academic achievement. In addition, academic achievement, on average, tends to be higher in schools with a preponderance of economically advantaged students; children are better able to make academic progress in school when they come from homes that are stocked with computers, books, and intellectually stimulating toys (Portes & MacLeod, 1996). However, this does not mean that schools are only as good as the students they serve. Many schools that serve disadvantaged populations are highly effective at motivating students and preparing them for jobs or further education. To really determine a school's effectiveness, researchers need to look at how students change from before to after they receive instruction (Zvoch & Stevens, 2006).

This was, in large part, the goal of the federally mandated *No Child Left Behind* (NCLB) in the United States—to ensure that children, regardless of how high or low they score at the start, improve their performance after each year of instruction. After nearly 20 years, though, studies examining the influence of the controversial NCLB law have found mixed results. According to a Brookings Institution report, math performance of disadvantaged children improved in elementary school, although not by as much as had been hoped (Dee & Jacob, 2010). Reading performance remained fairly stable from before to after implementation of NCLB.

Studies of effective learning environments provide another illustration of the interaction of nature and nurture. High-achieving parents pass their genes to their children, providing genetic potential for high achievement to their children (Rutter & Maughan, 2002). These same high-achieving parents are likely to select schools with strong academic reputations, often by choosing to live in a neighborhood served by a “good” school district. This is an example of a passive gene–environment correlation, described in Chapter 3, in which children are influenced by their parent's genes directly through genetic transmission and indirectly through the environments their parents create for them.

Teacher and School Characteristics

Andrew Wayne and Peter Youngs (2003) reviewed research on the relationship between teacher characteristics and student achievement. They found that student achievement scores rose with increases in the quality of their teachers' undergraduate institutions and their teachers' licensure examination scores. Other research similarly finds that higher cognitive skills of teachers in their content area translates into better student performance (Hanushek, Piopiunik, & Wiederhold, 2014; Kunter et al., 2013; Sadler et al., 2013). Perhaps the most intriguing findings about teacher effectiveness come from statistical analyses conducted by William Sanders, who found that students who are

lucky enough to get the best teachers 3 years in a row achieve as much as 50 points higher on standardized tests than students who are unfortunate enough to get the worst teachers 3 years in a row (Sanders & Horn, 1995; Sanders & Rivers, 1996). What is an effective teacher? According to Sanders, effectiveness can be defined by how far teachers can advance their students each year. Eric Hanushek reached a similar conclusion after finding that students with the best teachers advance 1.5 years in 1 school year, whereas students with the worst teachers advance only half a year over the course of the school year (see Hanushek, Rivkin, & Kain, 2005). These effects are cumulative and long-lasting: A student with the best teachers 2 years in a row progresses the equivalent of 3 years, whereas the student with the worst teachers 2 years in a row progresses just 1 year and will be 2 years behind the other student in achievement level. Ultimately, a person's earnings over their lifetime may be impacted by whether they had teachers who were highly effective, average, or below average (see ■ Figure 10.5).

What might be going on in the classrooms of the students who show the most progress each year? The collection of research shows that in effective classrooms, teachers:

- Strongly emphasize academics. They demand a lot from their students, expect them to succeed, regularly assign homework, and work hard to achieve their objectives in the classroom (Hoy, 2012).
- Create a task-oriented but comfortable atmosphere. For example, they waste little time starting activities or dealing with distracting discipline problems, provide clear instructions and feedback, and encourage and reward good work.
- Manage discipline problems effectively. For instance, they enforce the rules on the spot rather than send offenders to the principal's office, and they avoid the use of physical punishment.

■ **Figure 10.5** As this striking analysis by economist Eric Hanushek shows, having a more effective teacher can make a big difference, especially in larger classes.

Source: Hanushek, E. A. (2011). The economic value of higher teacher quality. *Economics of Education Review*, 30, 466–479.

- Foster an atmosphere of social cohesion in the classroom so that everyone—students, teachers, and aides—feel as though they have a stake in the group and its success (Hoy, 2012).

Student-Environment Interaction

Finally, characteristics of the student and characteristics of the learning environment often interact to affect student outcome. This is an example of the concept of goodness of fit—an appropriate match between the person’s characteristics and her environment (see Chapter 11). Many educational institutions seem to be based on the assumption that one teaching method, organizational system, or philosophy of education will prove superior for all students, regardless of their ability levels, learning styles, personalities, and cultural backgrounds. This assumption is often wrong. Instead, many educational practices are highly effective with some kinds of students but ineffective with other students. The secret is to find an appropriate match between the learner and the teaching method.

In a good illustration of goodness of fit between learners and environments, highly achievement-oriented students adapt well to unstructured classrooms in which they have a good deal of choice, whereas students who are less achievement oriented often do better with more structure (Peterson, 1977). Sometimes an alternative teaching method works as well as a traditional one for highly capable students but only one of these methods suits less capable students. In one study, for example, highly distractible students got more from computer-assisted instruction than from a teacher’s presentation of the same material, whereas more

attentive students benefited equally from both methods (Orth & Martin, 1994). Finally, students tend to have more positive outcomes when they and their teacher share similar backgrounds and students feel as though they are understood and valued by their teacher (Wigfield et al., 2015). Evidence of the importance of the fit between student and classroom environment implies that educational programs are likely to be most effective when they are highly individualized—tailored to suit each student’s developmental competencies and needs.

● Checking Mastery

1. What is the difference between a mastery (or learning) goal and a performance goal?
2. What is one characteristic that differentiates a skilled reader from a less-skilled reader?
3. What are three factors that characterize an effective learning environment?

● Making Connections

1. Using the material on effective learning environments, evaluate your high school and indicate ways it could improve to become a highly effective learning environment.
2. Unlike most of his peers, Johnny, age 7, is not yet reading despite having the usual classroom instruction. What might account for Johnny’s trouble with reading?

10.4

The Adolescent

LEARNING OBJECTIVES

- Explain why levels of academic achievement decline in adolescence and provide two methods to stop this decline.
- Describe the main findings of cross-cultural research on math performance and delineate steps to improve math scores in countries near or below average relative to other countries.
- Analyze the pros and cons of employment during high school.
- Indicate conditions that contribute to a smooth transition for teens completing high school and moving on to college or work.

Adolescents make critical decisions about such matters as how much time to devote to studying, whether to work part-time after school, whether to go to college, and what to be when they grow up. They become more capable of making these educational and vocational choices as their cognitive and social skills expand; in turn, the choices they make shape their development. But many of them lose interest in school when they leave elementary school.

Declining Levels of Achievement

You might think that adolescents would become more dedicated to academic success once they begin to realize that they need a good education to succeed in life. But consider what Deborah Stipek (1984) concluded after reviewing studies on the development of achievement motivation from early childhood to adolescence:

On the average, children value academic achievement more as they progress through school, but their expectations for success and self-perceptions of competence decline, and their affect toward school becomes more negative. Children also become increasingly concerned about achievement outcomes and reinforcement (for example, high grades) associated with positive outcomes and less concerned about intrinsic satisfaction in achieving greater competence. (p. 153)

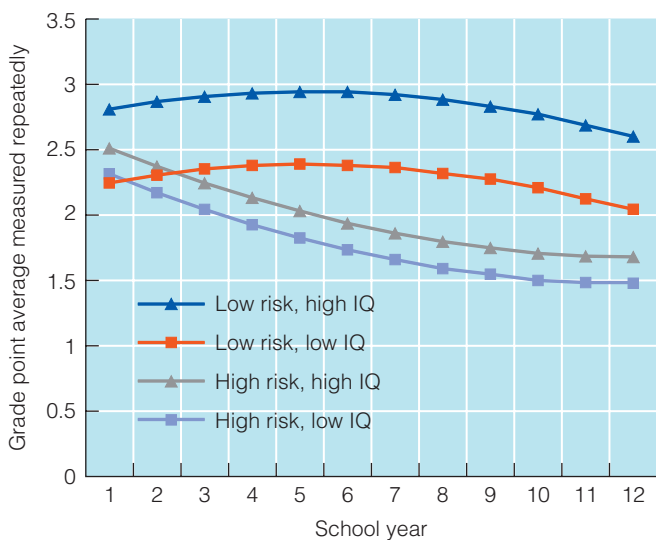

Many of the negative trends Stipek describes become especially apparent as young adolescents make the transition from elementary school to middle school (typically grades 6–8) or junior high school (grades 7–9). At this critical juncture, achievement motivation, self-esteem, and grades may all

By adolescence, some students have little motivation to achieve in the classroom. How can this be prevented?

decline. ■ **Figure 10.6** shows the academic trajectories for four groups of students studied by Leslie Gutman and his colleagues: those with high and low IQ scores who had either many or few risk factors (Gutman, Sameroff, & Cole, 2003). Risk factors included minority group status, low maternal education and mental health, stressful life events, large family size, and father absence. Students with more risk factors showed a steady decline in academic achievement throughout their schooling, regardless of whether they began with high or low IQ scores. Students with few risk factors showed a slight increase in achievement until around grade 6 or 7, at which time achievement began to drop slowly. Boys show greater declines in motivation and school interest than girls (Dotterer, McHale, & Crouter, 2009).

■ **Figure 10.6** Grade point average from 1st grade to 12th grade for students with high and low risk and IQ.

Source: Gutman, L. M., Sameroff, A. J., & Cole, R. (2003). Academic growth curve trajectories from 1st grade to 12th grade: Effects of multiple social risk factors and preschool child factors. *Developmental Psychology, 39*, 777–790. Copyright © 2003 by the American Psychological Association.

What might explain these discouraging trends? To answer this question, we’ll first examine what is going on at the individual level, and then consider family and peer influences before ending with a look at the wider context of school and society.

At the individual level, children become increasingly capable of analyzing the causes of events, interpreting feedback from teachers, and inferring enduring traits such as high or low ability from their behavior (Stipek & Mac Iver, 1989). The result is that they view their strengths and weaknesses more realistically—and lose some of their high academic self-esteem and high expectancies of success (Stipek & Mac Iver, 1989; Wigfield et al., 1997). Those who manage to maintain an emphasis on mastery or learning goals attain higher grades in high school than those who do not (Gutman, 2006). Students who believe that success is a matter of luck have lower grades than students without this attributional style (House, 2006).

Fortunately, higher levels of academic achievement can be promoted by continuing to emphasize a growth mindset throughout adolescence (e.g., Wiersema et al., 2015). Parents can help their teens to appreciate learning for learning’s sake and not over-emphasize the importance of grades. Middle-school students who are encouraged to assume responsibility for their learning and decision-making are more likely to complete high school and continue their education than their classmates who place greater value on grades than on learning (Tenenbaum et al., 2007). Adolescents’ achievement motivation is also affected by the increasing importance of the peer group, which at times seems to undermine parents’ and teachers’ efforts to encourage school achievement. Peer pressures that undermine achievement motivation tend to be especially strong for many lower-income males and for minority students (Véronneau et al., 2008). In particular, African American and Hispanic peer cultures in many low-income areas actively discourage academic achievement, whereas European American and especially Asian American peer groups tend to value and encourage it (Steinberg, Dornbusch, & Brown, 1992). High-achieving African American students in some inner-city schools risk being rejected by their African American peers if their academic accomplishments cause them to be perceived as “acting white” (Fordham & Ogbu, 1986). They may feel that they have to abandon their cultural group and racial identity to succeed in school, and this takes a psychological toll (Arroyo & Zigler, 1995; Ogbu, 2003). Some students may disengage from academics to preserve their cultural identity with a group that has historically not always been treated fairly by the educational system (Ogbu, 2003). Although African American parents are as likely as European American parents to value education and to provide the kind of authoritative parenting that encourages school achievement, their positive influences are sometimes canceled out by negative peer influences (Steinberg et al., 1992).

For those African American teens who belong to a supportive peer group, academic achievement is strengthened (Gutman et al., 2002). In addition, African American teens who strongly value their ethnic group membership and have positive beliefs about how society views African Americans tend to have more positive beliefs about education (Chavous et al., 2003). But even

a strong ethnic identity may not be able to overcome the subtle and negative effects of the discrimination still experienced by many minority students in the classroom that erodes their self-confidence and lowers their motivation (Thomas et al., 2009).

It is also possible that some of the decline in the achievement motivation of adolescents may reflect a poor fit between person and environment. Adopting a goodness-of-fit explanation, Jacquelynne Eccles and her colleagues (Eccles, Lord, & Midgley, 1991; Eccles et al., 1993) argue that the transition to middle school or junior high school is likely to be especially difficult because young adolescents are often experiencing major physical and psychological changes at the time they are switching schools. For example, girls who were reaching puberty when they were moving from sixth grade in an elementary school to seventh grade in a junior high school were more likely to experience drops in self-esteem and other negative changes than girls who remained in a K–8 school during this vulnerable period (Simmons & Blyth, 1987).

Could it be that more adolescents would remain interested in school if they did not have to change schools when they are experiencing pubertal changes? This idea became an important part of the rationale for shifting from junior high schools, in which students transitioned between the sixth and seventh grades, to middle schools where the transition occurs between the fifth and sixth grades. Research conducted in Germany, where the transition to a new school happens even earlier—after fourth grade, prior to pubertal changes for most students—helps answer this question (Arens et al., 2013). Students, both boys and girls, experienced lowered self-perceptions, including perceptions of their academic competence, following the school transition. This suggests that the school transition itself can be challenging, apart from whether pubertal changes are occurring at the same time.

The transition to middle or junior high school often involves going from a small school with close student–teacher relationships, a good deal of choice regarding learning activities, and reasonable discipline to a larger, more bureaucratized environment in which student–teacher relationships are impersonal, good grades are more emphasized but harder to come by, opportunities for choice are limited, assignments are not as intellectually stimulating, and discipline is rigid—all when adolescents are seeking more rather than less autonomy and are becoming more rather than less intellectually capable (Eccles et al., 1993; Hill & Tyson, 2009). Giving students a sense of ownership and some degree of control in their learning helps maintain their interest and motivation (Tsai et al., 2008; Valiente et al., 2008).

Other research shows the importance of having the right balance between challenge and support. David Shernoff and his colleagues (2016) looked at engagement of high school students in relation to what they called the complexity of the learning environment. Complexity is to the extent to which a class challenges students but also provides support to meet those challenges. In those classrooms where teachers require higher level thinking, students rise to the challenge if teachers also provide the environment needed for concentration and a means for capturing students' interest and enjoyment in the subject matter. Thus, the material may be hard to understand at first, but the teacher is able to make it interesting to students. When we are interested

in something, we can be highly motivated to learn it even when the process of learning is hard. Those students fortunate enough to have teachers who are able to lead them through this interesting challenge *enjoy* learning. They will be more likely to take on challenges in the future.

The message? Declines in academic motivation and performance are not inevitable during early adolescence. Students may indeed form more realistic expectancies of success as their growing cognitive abilities allow them to use the increasingly informative feedback they receive from teachers. Experiencing pubertal changes at the same time as other stressful changes and needing to downplay academics to gain popularity may also hurt school achievement. However, educators can help keep adolescents engaged in school by creating school environments that provide a better fit to the developmental needs and interests of adolescents. Whether they are called middle schools or junior high schools, such schools should provide warm, supportive relationships with teachers, intellectual challenges, and increased opportunities for self-direction (Eccles et al., 1993). Parents can also help by remaining supportive and involved in their child's education throughout the middle-school years rather than pulling back (Hill & Tyson, 2009).

Cross-Cultural Differences

Mathematics, reading, and writing are considered basic skills important for success in many industrialized nations. By looking at cross-national educational outcomes, we may be able to learn how to optimize achievement. Every 4 years, the Trends in Mathematics and Science Study (TIMSS) is conducted with fourth- and eighth-graders from around the world (TIMSS, 2016).

■ **Figure 10.7** shows average mathematics achievement scores of eighth-grade students in various countries. Students in the United States score above the international average but significantly below achievement levels in nations such as Singapore, Japan, and Korea. When researchers looked at the best students—those in the top 10% of all eighth-graders surveyed in the 48 nations—only 7% of U.S. students met the criteria in math compared to nearly half of eighth-graders in Chinese Taipei, Singapore, and the Republic of Korea. What might account for these international differences in achievement? Are students in some nations simply more intelligent than students in other nations?

Consider some research by Amy Hsin and Yu Xie (2014). They were interested in whether the observed gap between Asian American and white students, shown in ■ **Figure 10.8**, was attributable to socioeconomic factors, cognitive ability, or greater work ethic and motivation. They discovered that socioeconomic status of the family could not entirely account for the gap as there was a mix of SES backgrounds sprinkled across the range of low to high academic achievers (see Lee & Zhou, 2014a). There also did not seem to be significant differences in cognitive ability that could explain the widening gap in academic achievement over the years. Instead, Hsin and Xie's (2014) research pointed to a difference in work ethic and motivation as the likely explanation for the gap. They had access to data collected from children in kindergarten through twelfth grade. As ■ **Figure 10.9** shows, they found a difference in academic effort between Asian and white

students, as assessed by teacher ratings, but no gap in cognitive ability. Thus, Asian Americans do not do better than white students because they are smarter but because they work harder. Why? Hsin and Xie (2014) found that Asian Americans are less likely to believe ability is fixed or inborn and more likely to hold a growth mindset. Asian Americans also reported feeling greater pressure from their parents to succeed academically.

From this and other research, we can draw the following conclusions about cross-cultural differences in academic achievement:

- Asian parents are strongly committed to the educational process and communicate their high expectations to their students. In addition to parental expectations, societal stereotypes of the smart, high-achieving Asian student also serve to motivate Asian American students to work hard to live up to these expectations, which Jennifer Lee and Min Zhou (2014b) refer to as “stereotype promise.”
- Asian parents, teachers, and students all share a strong belief that hard work or effort will pay off in better academic performance (that is, they have a growth mindset and set what Dweck calls learning goals), whereas Americans tend to put more emphasis on ability as a cause of good or poor performance. The result may be that Americans give up too quickly on a child who appears to have low intellectual ability. In doing so, they may help create a case of learned helplessness.
- Asian students spend more time being educated. They attend school more days of the year and their school day is often longer than that of American students (Stevenson, Lee, & Stigler, 1986). When they are in school, Asian students spend more time on-task: They spend about 95% of their time engaged in activities such as listening to the teacher and completing assignments, whereas American students spend only about 80% of their time on-task. This additional time on academics extends outside the classroom and regular school hours as well. Asian students, especially Japanese students, are assigned and complete considerably more homework than American students (Verma & Larson, 2003).

This cross-cultural research and comparison of Asian American and European American students carries an important message: The secret of effective learning is to get teachers, students, and parents working together, to set high achievement goals, and to invest the day-by-day effort required to attain those goals. Many states and local school

Figure 10.9 On this chart, the blue bars show the influence of cognitive ability on the Asian-White gap in academic achievement, and the red bars show the influence of academic effort. Clearly, academic effort has a larger impact on this gap than does cognitive ability.

Source: Hsin, A., & Xie, Y. (2014). Explaining Asian Americans' academic advantage over whites. *Proceedings of the National Academy of Sciences*, 111, 8416–8421.

districts have begun to respond to evidence that American schools are being outclassed by schools in other countries by strengthening curricula, tightening standards for teacher certification, and raising standards for graduation and promotion from grade to grade.

Pathways to Adulthood

In the United States, approximately 4 out of 5 students graduate from high school “on time,” or in four years (National Center for Education Statistics, 2013). But if we look closer, we see some disparities across racial/ethnic groups with Black, Hispanic, and American Indians/Alaskan Native students less likely to complete high school than white or Asian students. To some extent, the educational paths and attainments of adolescents are set long before they enter high school. Because many individuals' IQ test scores remain stable from childhood on, some children enter adolescence with more aptitude for schoolwork than others do (see Chapter 9). Moreover, some students have more achievement motivation than others. Clearly, a bright and achievement-oriented student is more likely to obtain good grades and go on to college and is less likely to drop out of school than a student with less ability and less desire to achieve. By early elementary school, and sometimes even before they enter school, future dropouts are often identifiable by such warning signs as low IQ and achievement test scores, poor grades, aggressive behavior, low socioeconomic status, and troubled homes (Bierman et al., 2013; Ensminger & Slusarcick, 1992). Among middle-school students, those who regularly smoke cigarettes, drink alcohol, and engage in sexual activity are more likely to drop out of high school than their peers who do not engage in such problem behaviors (Hawkins, Jaccard, & Needle, 2013). Perhaps not surprisingly, students who are victims of bullying also have higher dropout rates (Cornell et al., 2013). Employment during high school may also affect success, which is considered in **Exploration 10.2**. But it is often

not just a single factor that leads students to drop out or fail out of school. Instead, there is often a combination of two or more factors that place students at risk for failure (Lucio, Hunt & Bornovalova, 2012).

Those who graduate from high school stand a chance of being among the nearly 40% of Americans who complete 4 years of college or more (National Center for Education Statistics, 2013). These youth, in turn, are likely to have higher career aspirations and to end up in higher status occupations than their peers who do not attend college or do not even finish high school (McCaul et al., 1992). If their grades are good, they are likely to perform well in those jobs and advance far in their careers (Roth et al., 1996). In a real sense, then, individuals are steered along “high success” or “low success” routes starting in childhood. Depending on their own decisions and family, peer, and school influences, adolescents are more distinctly “sorted” in ways that will affect their adult lifestyles, income levels, and adjustment. Meanwhile, high school dropouts not only have less successful careers but also miss out on the beneficial effects that every year of schooling has on intellectual functioning (Ceci & Williams, 1997). In addition, they experience more psychological problems than those who stay in school (Kaplan, Damphousse, & Kaplan, 1994).

Graduation from high school is an important milestone for most teens and helps set the stage for a successful transition to adulthood.

Hill Street Studios/Sarah Golonka/Blend Images/Alamy Stock Photo

Combining Work and School

High school students who work long hours in rather mindless jobs may also be disengaged from their school work.

RosalreneBetancourt 1/Alamy Stock Photo

Laurence Steinberg and his associates have conducted numerous studies to understand how students who work during high school might be advantaged or disadvantaged relative to their nonworking classmates (Greenberger & Steinberg, 1986; Steinberg & Dornbusch, 1991; Steinberg, Fegley, & Dornbusch, 1993). On the positive side, working students seem to gain knowledge about work, consumer issues, and financial management and sometimes about greater self-reliance. However, high school students who worked 20 or more hours a week had lower grade-point averages than students who did not work or who worked only 10 or fewer hours per week (Steinberg & Dornbusch, 1991). Working students were also more likely than nonworkers to be disengaged from school—bored and uninvolved in class, and prone to cut class and spend little time on homework. In addition, the more adolescents worked, the more independent they were of parental control, the more likely they were to be experiencing psychological distress (anxiety, depression, and physical symptoms such as headaches), and the more frequently they used alcohol and drugs and engaged in delinquent acts.

(2003, 2011) have found: Not-yet-employed students who want to work long hours tend to be disenchanting with school, have low grades, and are more likely to use alcohol and cigarettes. Once they start working, the disenchantment and problem behaviors are exacerbated (Bachman et al., 2003, 2011). Similarly, longitudinal research on adolescents and work confirms that academically struggling students are the ones likely to work more hours (Warren, LePore, & Mare, 2000).

But the negative outcomes associated with working in high school are not entirely attributable to preexisting characteristics of these teens. Bachman and his colleagues (2011) found some negatives of work even when they attempted to control for a variety of preexisting problem behaviors among the teens who worked the most hours during high school. Notably, teens who worked the most were less likely to have completed college when the researchers followed up with them when they were 29–30 years of age.

Somewhat surprisingly, the teens who were most disadvantaged by working long hours during high school were whites, especially whites from high socioeconomic

backgrounds, and Asian Americans, relative to Hispanic and African Americans. The latter two groups tend to have more trouble finding employment during high school, so perhaps those who managed to find work are a unique group, for example, more hard working. And whites from higher socioeconomic homes who work long hours while in high school are probably also an unusual group.

When all the research is examined as a package, the findings suggest that working while attending high school is often more detrimental than beneficial. Much depends on the nature of the work adolescents do (Taylor et al., 2012). For those lucky teenagers who land a part-time job that offers them an opportunity for self-direction or decision making, and draws on academic skills such as reading and mathematics, they may be building valuable skills that will serve them in their future full-time jobs (Greenberger & Steinberg, 1986). Unfortunately, part-time jobs held by teenagers are generally lower-level, unskilled positions that can erode mastery motivation (Call, Mortimer, & Shanahan, 1995; Shanahan et al., 1991).

Over the past 10–15 years, the percentage of teens working during high school has declined (Baum & Ruhm, 2014; Staff et al., 2014). Many of the “teen jobs” such as flipping burgers at fast-food restaurants have increasingly gone to adults, including older adults returning to the work force to make ends meet following the 2008–2009 recession. Following the recession, more teens are working informally as babysitters and grass mowers, and they are less likely to be working long—20 plus—hours. In sum, there is no clear answer on whether part-time work during high school will prove to be an opportunity for growth or a tedious distraction from schoolwork, so parents should help teens consider all the pros and cons and discuss how they might gain value even if they end up in a job that is not especially challenging.

● Checking Mastery

1. What are two reasons why achievement motivation may decline during adolescence?
2. Why might students in Asian schools outperform many other students in science and math?
3. What is one advantage and one disadvantage of working while in high school?

● Making Connections

1. Research shows that achievement motivation and grades often drop as students move through middle school and high school. Develop a program to combat this trend, keeping in mind that students of different backgrounds may lose motivation for different reasons.
2. After finishing up ninth grade, your teenager says he wants to work for the next 3 years while in high school. What advice will you give him?

10.5

The Adult

LEARNING OBJECTIVES

- Describe language changes in adulthood.
- Explore the achievement motivations of adults.
- Explain the challenges for adults who struggle with literacy.
- Outline pros and cons of continuing education for adults.

The lives of adults are dominated by work—paid or unpaid, outside the home or within the home. We consider, first, how language and achievement motivation change during this period of life. We also examine the educational options available to adults and the benefits of lifelong education.

Language

What happens to language skills during adulthood? Adults simply hold onto the knowledge of phonology they gained as children, although elders can have difficulty distinguishing speech sounds (such as /b/ from /p/) if they have hearing impairments or deficits in the cognitive abilities required to make out what they hear (Thornton & Light, 2006). Adults also retain their knowledge of grammar or syntax. Older adults tend to use less complex sentences than younger adults do, however. Also, those with memory difficulties may have trouble understanding sentences that are highly complex syntactically (for example, “The children warned about road hazards refused to fix the bicycle of the boy who crashed”); they may not be able to remember the beginning of the sentence by the time they get to the end (Kemtes & Kemper, 1997; Stine, Soederberg, & Morrow, 1996).

Meanwhile, knowledge of the semantics of language, of word meanings, often expands during adulthood, at least until people are in their 70s or 80s (Obler, 2013; Schaie, 1996). After all, adults gain experience with the world from year to year, so it is not surprising that their vocabularies continue to grow and that they enrich their understandings of the meanings of words. However, older adults more often have the “tip-of-the-tongue” experience of not being able to recall the name of an object (or especially a person’s name) when they need it (Thornton & Light, 2006). This problem is a matter of not being able to retrieve information stored in memory rather than a matter of no longer knowing the words. In order to maintain fluency in the face of these retrieval problems, older adults speak a little more slowly and plan their

choice of words further in advance than when they were younger (Spieler & Griffin, 2006).

Adults also refine their pragmatic use of language—adjusting it to different social and professional contexts (Obler, 2013). Physicians, for example, must develop a communication style that is effective with their patients. Partners who have been together for years often develop a unique way of communicating with one another that is distinctly different from how they communicate with others. Overall, command of language holds up well in later life unless the individual experiences major declines in cognitive functioning (Kemper & Mitzner, 2001; Stine et al., 1996).

Achievement Motivation

The level of achievement motivation that we acquire in childhood and adolescence carries into adulthood to influence our decisions and life outcomes (Włodkowski, 1999). For instance, women who have a strong need to achieve are more likely than less achievement-oriented women to work outside the home (Krogh, 1985). Adults with strong achievement needs are also likely to be more competent workers than adults who are less interested in mastering challenges (Helmreich, Sawin, & Carsrud, 1986; Spence, 1985).

What happens to achievement motivation in later life? Adults, at least those who are in “learner mode” and are taking classes, often score higher than adolescents and young adults on mastery or learning goals (Eppler & Harju, 1997). As we learned earlier in this chapter, those pursuing mastery goals may be more motivated to learn than those who adopt performance goals. In related research, adult learners rated their class experiences as more enjoyable than their younger counterparts (Remedios & Richardson, 2013). Those who enjoy their classroom experience are likely paying more attention and gaining more from their experience than those who do not find the experience especially enjoyable. Despite the sharp rise in adult learners in recent years,

there is very little research on this group of learners, so we don't have a deep understanding of what motivates them or how to best foster a continued love of learning.

What about motivation in the main sphere of many adults' lives—the workplace? Motivation levels do seem to decline, but certainly this is not universal (Ackerman & Kanfer, 2004). This may reflect a “top of the ladder” effect, as many older adults may be in one of the highest positions in their workplace or may believe they are as high as they are going to get (or want to get). Other research suggests that this is not so much a decline in motivation but a *shift* in motivation from extrinsic to intrinsic (Inceoglu, Segers, & Bartram, 2012). Early in our careers, we may be more strongly motivated by external factors such as new titles and increased pay. At the other end of our careers, we may care more about doing work that is personally satisfying.

There is evidence that women's achievement motivation declines fairly steeply with age (see Mellinger & Erdwins, 1985). However, this age trend pertained mainly to career-related motivation and an interest in striving for success in competitive situations. Women's motivation in other areas remained high. Many women have traditionally set aside career-achievement goals after they have children and make nurturing those children their priority (Krogh, 1985). However, highly educated women often regain a strong motive to achieve outside the home once their children are older and they can invest more energy in outside work. Thus, women are especially likely to be motivated to achieve career success when they have the educational background that would allow them to pursue attractive career goals and when they are not pursuing family-related goals.

Overall, adults' achievement-related motives are far more affected by changes in work and family contexts than by the aging process (Filipp, 1996). Adults of different ages are often more alike than they are different, and different people tend to retain their characteristic levels of achievement motivation over the years, much as they retain many personality traits (Stevens & Truss, 1985). There is little evidence that elderly adults inevitably lose their motivation to pursue important goals. Moreover, those elders who have a strong sense of purpose and direction and feel they are achieving their goals enjoy greater physical and psychological well-being than those who do not (Hooker & Siegler, 1993; Rapkin & Fischer, 1992; Reker, Peacock, & Wong, 1987). Throughout the life span, then, setting and achieving goals are important.

Literacy

Literacy is the ability to use printed information to function in society, achieve goals, and develop one's potential. Few adults are completely illiterate, but many adults do not have functional literacy skills despite years of formal education. According to the National Institute of Literacy, 14% of adults in the United States are below a basic literacy rate, which is roughly equivalent to a third-grade or lower reading ability (U.S. Department of Education, 2015). Such an adult could probably find an expiration date on a driver's license and sign a form but would have trouble filling out an application or reading a simple book to a child. Although one-quarter of this group consists of immigrants learning English

as a second language, most individuals in this group are U.S.-born citizens and nearly two-thirds did not finish high school.

Another 29% of adults have just rudimentary, or basic, literacy skills, allowing them to perform simple literacy tasks such as using a television guide or comparing prices on two receipts, but limiting their abilities to consult reference information online or in texts. Approximately half of the adults demonstrated proficient, or higher, levels of literacy. Literacy contributes to economic security through occupational advancement. Nearly half of the adults with the lowest literacy scores live in poverty, whereas few adults with the highest literacy scores do (Bowen, 1999). Improving the literacy skills of impoverished adults, however, does not automatically raise them out of poverty. For many low-income and functionally illiterate adults, other obstacles must be overcome, including addiction, discrimination, and disabilities (Bowen, 1999).

Programs to raise the literacy level of adults are rarely successful. Several factors limit the success of such programs. For one thing, despite having limited literacy skills, many of these adults (75%) reported that they could read or write “well” or “very well”—attitudes that must make it difficult to motivate them to improve their literacy skills. Second, adults do not stay in literacy programs long enough to make improvements (Amstutz & Sheared, 2000). The dropout rate is as high as 70%–80%, and many leave in the first weeks of the program (Quigley & Umland, 2000). Adults who do not persist report that the programs are boring and do not meet their needs (Imel, 1996; Kerka, 1995; Quigley, 1997). Materials, for example, are often geared toward children, not adults who have families, jobs, and different interests than children do.

Continuing Education

As noted earlier, an increasing number of adults are seeking education beyond basic literacy skills. In 2011, 33% of all college students were 25 years or older, and a full 50% of students attending college part-time were over the age of 25 (National Center for Education Statistics, 2013). The number of “older” adults attending college is expected to increase as the overall population ages. Whether we call them adult learners, nontraditionals, returning students, mature students, or lifelong learners, these adults represent a diverse group. They bring different work and life experiences to the classroom, and they report a variety of reasons for enrolling in postsecondary education (Ross-Gordon, 2011).

Many “traditional” students (17- to 24-year-olds) are motivated to attend college by external expectations, but older students are often motivated by internal factors (Ross-Gordon, 2011). Women are more likely to return to the classroom for personal enrichment or interest, whereas men are more likely to take classes required or recommended for their work (Sargant et al., 1997). Both men and women today sometimes find that they need further education in order to become employable as the job market changes. The internal motivation of adult students often leads to deeper levels of processing information (Harper & Kember, 1986). In other words, returning students may put forth greater effort to truly understand material because they want to learn and want (or need) to use the material. Traditional students who do not have

Many older adults remain motivated to learn and seek challenging experiences.

De Visu/Alamy Stock Photo

the benefit of experience may learn the material necessary to do well on an examination but may not process the material in ways that will lead to long-term retention.

Although it is tempting to conclude that there are only positive outcomes associated with continued education, there are a few drawbacks. Mainly, it is often difficult for adults already busy with jobs and family to find the time to take classes, at least those offered in traditional classrooms. Successful continuing education programs are those that have met the needs of adult learners by scheduling classes at convenient times and being flexible to accommodate the lifestyles of their adult learners. Yet the benefits of lifelong education typically outweigh drawbacks. For instance, continued education allows adults to remain knowledgeable and competitive in fields that change rapidly. Adults who return to school for bachelor's or master's degrees can also advance their careers, particularly if their education and work are closely related (Senter & Senter, 1997). Finally, you learned in Chapter 5 that higher education is associated with maintaining or improving physical and mental health.

In this and previous chapters, you have examined a great deal of material on thinking and learning across the life span. How can principles of cognitive development be used to improve education for all ages? Before closing this chapter, we summarize, in **Application 10.1**, what theorists Piaget and Vygotsky contribute to education and what research on information processing, intelligence, and perception suggests about optimal learning environments.

● APPLICATION 10.1

What Can Theory and Research Contribute to Education?

To help you appreciate the practical implications for school reform and school achievement of the material in Chapters 6 through 9, we provide the following recommendations based on the research and theories discussed in these chapters:

Piaget

- Provide opportunities for independent, hands-on interaction with the physical environment, especially for younger children.
- With the child's current level of understanding in mind, create some disequilibrium by presenting new information slightly above the child's current level. Children who experience disequilibrium—cognitive discomfort with their understanding (or lack of understanding)—will work to resolve it, achieving a higher level of mastery of the material.
- Encourage interaction with peers, which will expose children to other perspectives and give them an opportunity to reevaluate and revise their own view.

Vygotsky

- Provide opportunities for children to interact with others who have greater mastery of the material—an older peer, teacher, or parent. These more advanced thinkers can help “pull” children to a level of understanding they would be unable to achieve on their own.
- Encourage students, especially young ones, to talk to themselves as they work on difficult tasks. Such private speech can guide behavior and facilitate thought.
- Present challenging tasks, but do not expect students to complete such tasks successfully without guidance. With support, students can accomplish more difficult tasks than those they would be able to achieve independently.

Research on Information Processing

- Provide opportunities for rehearsal and other memory strategies to move information into long-term memory. Realize that young children do not spontaneously use

memory strategies but often can use them when prompted.

- Structure assignments so that retrieval cues are consistent with cues present at acquisition to facilitate retrieval of information from long-term memory.
- Enable learners to develop a knowledge base and expertise in domains of study. When beginning a new lesson, start with and build on what students already know.
- Assess the knowledge and strategies required to solve assigned problems; then determine which aspects of a task pose difficulties for learners and target these for further instruction.
- Be aware that well-learned and frequently repeated tasks become automatized over time, freeing information-processing capacity for other tasks.

Research on Intelligence

- Realize that individual differences in intelligence have implications for the classroom. Students at both ends of the continuum

(continued)

● APPLICATION 10.1

What Can Theory and Research Contribute to Education? *(continued)*

may need special educational services to optimize their learning.

- Recognize that although IQ scores do a reasonably good job of predicting achievement in the classroom, such tests have weaknesses that limit their usefulness, especially in assessing members of minority groups.

Research on Sensory and Perceptual Abilities

- Test all children early and regularly for sensory and perceptual problems that might limit their ability to benefit from regular classroom instruction.
- Be aware of developmental differences in attention span. Clearly, a young child will

not be able to attend to a task for as long as a teenager.

- Minimize distractions in the learning environment. Younger students have trouble “tuning out” background noise and focusing on the task at hand.

● Checking Mastery

1. How might men’s and women’s achievement motivation change during adulthood?
2. Why is literacy important to adults and are literacy programs successful?

● Making Connections

1. If you find that one of your parents (or spouse) is going through a midlife “career slump,” what might you do to foster a higher level of achievement motivation during this stage of his or her life?
2. Based on what you have learned in this and previous chapters about memory, thinking, problem solving, and language skills, how would you teach older adult students versus students of traditional high school or college age?

Chapter Summary

10.1 The System of Language

- The complex process of language acquisition appears to occur effortlessly through an interaction of inborn readiness and a normal language environment.
- To acquire language, children must master phonology (sound), semantics (meaning), and syntax (sentence structure). They must also learn how to use language appropriately (pragmatics) and how to understand prosody.
- Theories of language development include learning theories, nativist theories, and interactionist theories. The interactionist view emphasizes the child’s biologically based capacities and experience conversing with adults who use child-directed speech and strategies such as expansion that simplify the language-learning task.

10.2 The Infant

- Infants are able to discriminate speech sounds and progress from crying, cooing, and babbling to one-word holophrases (at 12 months) and then to telegraphic speech (at 18 months).

- During the preschool years, language abilities improve dramatically, as illustrated by overregularizations and new transformation rules.
- Precursors of achievement motivation can be seen among infants who strive to master their environments. Mastery motivation is fostered by a responsive environment that provides plenty of opportunities for infants to learn that they can control their environments and experience successes.
- Early education can help prepare disadvantaged children for formal schooling, but an overemphasis on academics at the expense of exploration and play may hinder young children’s development.

10.3 The Child

- School-age children and adolescents refine their language skills and become less egocentric communicators.
- During childhood, some children develop higher levels of achievement motivation than others; they tend to have a growth mindset rather than a fixed mindset regarding abilities, and they set learning goals rather than performance goals in the classroom.
- To read, children must master the alphabetic principle and

develop phonological awareness so that they can grasp letter-sound correspondence rules. Emergent literacy activities such as listening to storybooks facilitate later reading. Compared with unskilled readers, skilled readers have better understanding of the alphabetic principle and greater phonological awareness.

- Learning is influenced by characteristics of students and their teachers. Students perform best when (1) they are intellectually capable and motivated; (2) their teachers create a motivating, comfortable, and task-oriented setting and involve parents in their children's schooling; and (3) there is a good fit between children's characteristics and the kind of instruction they receive.

10.4 The Adolescent

- Achievement motivation and grades tend to drop during adolescence for a variety of reasons, including cognitive growth, family characteristics, peer pressure, and a poor fit between the student and the school.
- Middle school and high school include a greater focus on mathematics education. U.S. students score close to the international

average but below several other countries in math. Cross-cultural research suggests that the success of Asian schools is rooted in more class time spent on academics, more homework, more parent involvement, more peer support, and a stronger belief that hard work pays off.

10.5 The Adult

- Language skills remain fairly stable throughout adulthood, unless there are substantial sensory impairments or cognitive declines.
- Level of achievement carries over from adolescence into adulthood. There may be some decline in achievement motivation among women who set aside career goals to raise children, but career goals reemerge as their children age, especially among women with higher levels of education.
- Some adults, despite years of education, have not acquired the skills of functional literacy. Literacy programs have had minimal success in improving literacy rates.
- Adults increasingly are seeking continued educational opportunities for both personal and work-related reasons.

In her memoir *My Beloved World* (2013), Supreme Court Justice Sonia Sotomayor describes her humble beginnings: growing up in a poor, Puerto Rican section of New York City as a child with diabetes, an alcoholic father who died when she was only 9, and an overworked and emotionally distant mother (see Barnes, 2013). Not being sure she could count on her parents and fearing that she would die young, she learned to give herself insulin injections at age 7 and developed a strong independent streak and a drive to succeed that contributed to her later success in law. She had doubts about whether she was as capable as her classmates at Princeton but concluded that some of her deficiencies in knowledge were the product of her background and that she could overcome them through hard work. She also says this about herself: “I think my life approach is never to look at the negative of what I’m experiencing but also always trying to see its positive” (Barnes, 2013, p. C3).

Sonia Sotomayor, by writing her autobiography, created a life story that defines her as a unique person who overcame challenges and self-doubts and rose to a position of prominence. How would you tell your life story? Who are you and what is unique about you?

This chapter is about the self and the personality and the ways in which personalities, and our perceptions of those personalities, change—and remain the same—over the life span. It is, in other words, about the issue of continuity (consistency or stability) and discontinuity (change) in human development (see Chapter 2). It is also about influences on and implications of our self-concepts and personalities. We begin our inquiry by clarifying some terms used in describing the personality and the self and then briefly compare theoretical perspectives on the self and personality.

Sonia Sotomayor’s life story involved turning experiences of poverty, childhood diabetes, and an alcoholic father into an independence and drive that propelled her to the Supreme Court of the United States.

11.1

Conceptualizing the Self and Personality

LEARNING OBJECTIVES

- Define and give examples of the aspects of personality called dispositional traits, characteristic adaptations, and narrative identity.
- Distinguish among self-concept, self-esteem, and identity.
- Compare how psychoanalytic, trait, and social learning theorists view personality and its development.

Basic Concepts

Personality is often defined as an organized combination of attributes, motives, values, and behaviors unique to each individual. Pause for a moment: How would you describe your own personality? One way we describe our own and other people’s personalities is in terms of relatively enduring **dispositional traits** such as extraversion or introversion, independence or dependence, and the like. We invite you to complete the brief personality scale in **Engagement 11.1** to get a feel for describing your own personality in terms of dispositional traits.

As Dan McAdams and Jennifer Pals (2006; and see McAdams, 2013) argue, though, at least two other aspects of personality besides traits deserve attention. People also differ in **characteristic adaptations**, more situation-specific and changeable ways in which people adapt to their roles and environments. Characteristic adaptations include motives, goals, plans, schemas, self-conceptions, developmental issues and concerns, and coping mechanisms. Did any of these characteristic adaptations come to mind when you thought about your own personality?

A third aspect of personality is **narrative identities**, unique and integrative life stories that we construct about our pasts and futures to give ourselves an identity and our lives meaning (as Sonia Sotomayor has done in her memoir). In a study of narrative identity, you might be asked to picture your life as a book, outline the major scenes and turning points that have defined who you

are, and lay out your dreams and fears for the future (McAdams, 2008, 2011). McAdams and Pals believe that both biological factors, including a “human nature” shared by fellow humans and individual genetic makeup, and cultural and situational influences help shape all three aspects of personality: dispositional traits, characteristic adaptations, and narrative identities.

When you describe yourself, you may not be describing your personality so much as revealing your **self-concept**—your perceptions, positive or negative, of your unique attributes and traits as a person. We all know people who seem to have unrealistic self-conceptions—the fellow who thinks he knows it all (but doesn’t) or the woman who believes she is a dull plodder (but is actually brilliant). A closely related aspect of self-perception is **self-esteem**—your overall evaluation of your worth as a person, high or low, based on all the positive and negative self-perceptions that make up your self-concept. Self-concept is about “what I am,” whereas self-esteem concerns “how good I am” (Harter, 1999, 2012). We will examine both, as well as how adolescents pull together their various self-perceptions to form an **identity**—an overall sense of who they are, where they are heading, and where they fit into society.

Theories of Personality

We can gain a sense of issues in understanding the development of the self and personality by contrasting the very different views offered by psychoanalytic theory, trait theory, and social learning theory.

● ENGAGEMENT 11.1

A Brief Personality Scale

Here are several personality traits that may or may not apply to you. Write a number from 1 to 7 next to each statement to indicate the extent to which you agree or disagree with that statement. You should rate the extent to which the pair of traits applies to you, even if one characteristic applies more strongly than the other.

- | | |
|--------------------------------|----------------------|
| 1 = Disagree strongly | 5 = Agree a little |
| 2 = Disagree moderately | 6 = Agree moderately |
| 3 = Disagree a little | 7 = Agree strongly |
| 4 = Neither agree nor disagree | |

I see myself as:

- _____ Extraverted, enthusiastic
- _____ Critical, quarrelsome
- _____ Dependable, self-disciplined
- _____ Anxious, easily upset
- _____ Open to new experiences, complex
- _____ Reserved, quiet
- _____ Sympathetic, warm
- _____ Disorganized, careless
- _____ Calm, emotionally stable
- _____ Conventional, uncreative

To score yourself, reverse the scoring of items marked below with *R* so that a score of 1 becomes 7, 2 becomes 6, 3 becomes 5, 4 stays 4, 5 becomes 3, 6 becomes 2, and 7 becomes 1. Then add the pair of scores listed here for each of the Big Five personality dimensions:

- | | |
|--|---------------------------|
| Extraversion | Item 1 + item 6R = _____ |
| Agreeableness | Item 2R + item 7 = _____ |
| Conscientiousness | Item 3 + item 8R = _____ |
| Low neuroticism (high emotional stability) | Item 4R + item 9 = _____ |
| Openness to experience | Item 5 + item 10R = _____ |

To help you see roughly where you stand on the Big Five personality dimensions, the average sums for each pair of two items for a sample of 1813 college students tested by Samuel Gosling and colleagues (2003) were 8.88 for extraversion, 10.46 for agreeableness, 10.80 for conscientiousness, 9.66 for low neuroticism (high emotional stability), and 10.76 for openness to experience.

Bear in mind that this scale is much shorter than standard measures of the Big Five personality dimensions. It may not provide an accurate reading of your personality, but it will acquaint you with the trait approach to studying personality and with the Big Five personality dimensions as well.

Source: Reprinted from Gosling, S. D., Rentfrow, P. J., & Swann, W. B. (2003). A very brief personality scale. *Journal of Research in Personality, 37*, 525, with permission from Elsevier, © 2003.

Psychoanalytic Theory

Psychoanalytic theorists generally use in-depth interviews and similar techniques to get below the surface of the person and her behavior and understand the inner dynamics of personality. As you will recall from Chapter 2, Sigmund Freud believed that children progress through universal stages of psychosexual development, ending with the genital stage of adolescence. Freud did not see psychosexual growth continuing during adulthood. Indeed he believed that the personality was formed during the first 5 years of life and showed considerable continuity thereafter. Anxieties arising from harsh parenting or other unfavorable early experiences in the family, he said, would leave a permanent mark on the personality and reveal themselves in adult personality traits.

The psychosocial theory of personality development formulated by neo-Freudian Erik Erikson, also introduced in Chapter 2, will be highlighted in this chapter. Like Freud, Erikson concerned himself with the inner dynamics of personality and proposed that people undergo similar personality changes at similar ages as they confront the challenges associated with different stages of development (Erikson, 1963, 1968, 1982). However, Erikson placed more emphasis on social influences beyond parents such as peers, teachers, and cultures; the rational ego and its adaptive powers; and possibilities for overcoming the effects of harmful early experiences. Most importantly, he saw the potential for personal growth and change throughout the life span.

Trait Theory

The approach to personality that has most strongly influenced efforts to study it is trait theory, based on the *psychometric approach* that guided the development of intelligence tests (see Chapter 9). According to trait theorists, personality is a set of dispositional trait dimensions along which people can differ. To identify distinct trait dimensions, researchers administer personality scales to people and use the statistical technique of factor analysis to identify groupings of personality scale items that are correlated with each other but not with other groupings of items. Trait theorists assume that personality traits are quite consistent across situations and relatively enduring. Like psychoanalytic theorists, then, they expect to see carryover in personality over the years; unlike psychoanalytic theorists, however, they do not believe that the personality unfolds in a series of stages.

How many personality trait dimensions are there? Many scholars now agree that human personalities can best be described in terms of a five-factor model—with five major dimensions of personality that have come to be known as the **Big Five** (Digman, 1990; McCrae & Costa, 2003, 2008). The Big Five personality dimensions—openness to experience, conscientiousness, extraversion, agreeableness, and neuroticism—are described in ● **Table 11.1**. If you took and scored the short personality scale in Engagement 11.1, you got a rough sense of where you fall on these Big Five trait dimensions.

● **Table 11.1** The Big Five Personality Dimensions

Dimension	Basic Definition	Key Characteristics
Openness to experience	Curiosity and interest in variety vs. preference for sameness	Openness to fantasy, esthetics, feelings, actions, ideas, values
Conscientiousness	Discipline and organization vs. lack of seriousness	Competence, order, dutifulness, striving for achievement, self-discipline, deliberation
Extraversion	Sociability and outgoingness vs. introversion	Warmth, gregariousness, assertiveness, activity, excitement seeking, positive emotions
Agreeableness	Compliance and cooperativeness vs. suspiciousness	Trust, straightforwardness, altruism, compliance, modesty, tender-mindedness
Neuroticism	Emotional instability vs. stability	Anxiety, hostility, depression, self-consciousness, impulsiveness, vulnerability

As a mnemonic device, notice that the first letters of the five dimensions spell *ocean*.

Source: Adapted from Costa & McCrae, 1992.

The Big Five appear to be both genetically and environmentally influenced and emerge in childhood (McCrae & Costa, 2008). The Big Five also seem to be universal; they capture the ways in which people all over the world describe themselves and other people (Heine & Buchtel, 2009; McCrae, 2004). This is true even though levels of Big Five traits differ from culture to culture (for example, Europeans appear to be more extroverted on average than Asians or Africans) and even though traits may be expressed differently in different cultures (as when a Chinese extravert smiles warmly at seeing an old friend but an American extravert grins and gives the friend a big bear hug). You will soon learn more about the development of these dispositional trait dimensions.

Social Learning Theory

Finally, social learning (or social cognitive) theorists such as Albert Bandura (1986; and see Chapter 2) and Walter Mischel (1973; Mischel & Shoda, 2008) not only reject the notion of universal stages of personality development but also question the existence of enduring personality traits that show themselves across a variety of situations and over long stretches of the life span. Instead, they

emphasize that people’s behavior is influenced by the situations they are in and changes if their environments change and different behaviors are modeled and reinforced.

From the social learning perspective, personality boils down to a set of behavioral tendencies shaped by interactions with other people in specific social situations. Because social context is so powerful, consistency in personality over time is most likely if the person’s social environment remains the same. Thus, if Rick the rancher continues to run the same ranch in the same small town for a lifetime, he might stay the “same old Rick.” However, most of us experience new social environments as we grow older. Just as we behave differently when we are in a library than when we are in a bar, we become “different people” as we take on new roles, develop new relationships, or move to new locations. Different situation, different personality.

Armed with basic concepts and a sense of the strikingly different perspectives that psychoanalytic, trait, and social learning theorists take on personality (see ● Table 11.2 for a summary), we will now explore continuity and discontinuity in self-conceptions and personality traits across the life span.

● **Table 11.2** Perspectives on Personality

Perspective	Theorists	Themes
Psychoanalytic theory	Sigmund Freud and Erik Erikson	Personality as inner qualities that develop in a stagelike manner. Freud believed the personality was formed in first 5 years of life, whereas Erikson saw growth and change continuing through adulthood.
Trait theory	Paul Costa and Robert McCrae	Personality as a set of dispositional traits (the Big Five) that are enduring over time and consistent across situations.
Social learning theory	Albert Bandura and Walter Mischel	Personality as behavior that is influenced by situational factors and changes if the environment changes. We should not expect universal stages of personality development or enduring traits.

● Checking Mastery

1. What is the difference between a dispositional trait and a characteristic adaptation? Give an example of each.
2. What is the difference between self-esteem and self-concept?
3. Why do social learning theorists think trait theorists are wrong about personality?

● Making Connections

1. Using the concepts of dispositional traits, characteristic adaptations, and narrative identities, the three aspects of personality highlighted by McAdams and Pals, do an analysis of the main features of your own personality. What are your prominent dispositional traits and characteristic adaptations, and what is the plot of your narrative identity or life story?
2. Think about two people you know well and list for each of them five traits that you believe capture their personalities well. Now look at the Big Five trait dimensions in Table 11.1 and see if you can match the traits you see in these individuals to the Big Five personality dimensions. Based on this analysis, do you agree that the Big Five dimensions capture the main ways in which humans differ—or do you believe that something is missing from the Big Five? Why?

11.2

The Infant

LEARNING OBJECTIVES

- Explain how we come to know ourselves in the first 2 years of life.
- Summarize two approaches to describing infants' temperaments and the role of goodness of fit in the development of temperament.

When do infants display a sense of themselves as distinct individuals? Do they have unique personalities?

The Emerging Self

Infants may be born without a sense of self, but they quickly develop an implicit, if not conscious, sense of self. It is based in their perceptions of their bodies and actions and grows out of their interactions with caregivers (Rochat, 2010; Rochat & Striano, 2000; Trevarthen, 2011). The capacity to differentiate self from world becomes more apparent by around 2 or 3 months of age, when infants display a sense of agency—a sense that they can cause things to happen in the world. For example, 2-month-old infants whose arms are connected by strings to audiovisual equipment delight in producing the sight of a smiling infant's face and the theme from *Sesame Street* by pulling the strings (Lewis, Alessandri, & Sullivan, 1990). When the strings are disconnected and the infants can no longer produce such effects, they pull harder and become frustrated and angry. Over the first 6 months of life, then, infants discover properties of their physical selves, distinguish between themselves and the rest of the world, and discover that they can act upon other people and objects.

In the second half of their first year, infants realize that they and their companions are separate beings who have different perspectives and on occasion can share perspectives (Goodvin, Thompson, & Winer, 2015). Thus a 9-month-old infant may point to a toy and look toward her companion to focus his attention on the same toy. You may recall from Chapter 7 that this breakthrough is called *joint attention*, or the sharing of perceptual experiences by infants and their caregivers from about 9 months of age on.

Around 18 months, infants experience an even more amazing breakthrough in the development of the self when they recognize themselves visually as distinct individuals. How do we know this? Michael Lewis and Jeanne Brooks-Gunn (1979) used an ingenious technique first used with chimpanzees to study **self-recognition**—the ability to recognize oneself in a mirror or

photograph. Mother daubs a spot of rouge or lipstick on an infant's nose and then places the infant in front of a mirror. If the infant has some mental image of his own face and recognizes his mirror image as himself, he should soon notice the red spot and reach for or wipe his own nose or turn to a companion and point to his own nose rather than touch the nose of the mirror image or look behind the mirror to find this interesting new playmate.

When infants 9–24 months old were given this mirror test, the youngest infants showed no self-recognition: They seemed to treat the image in the mirror as if it were “some other baby” and sometimes touched the mirror. Some 15-month-olds recognized themselves, but only starting at 18 months of age did most infants pass the test, showing clear evidence of self-recognition.

As babies get to know themselves better, they also form a **categorical self**; that is, they classify themselves into social categories based on age, sex, and other visible characteristics, figuring out what is “like me” and what is “not like me” and recognizing that they are babies, not adults, and boys or girls. By 18–24 months, then, most infants have an awareness of who they are—at least as a physical self with a unique appearance and as a categorical self. They now begin to use their emerging language skills to talk about themselves by name and to construct stories about events in their lives (Goodvin et al., 2015).

Cognitive, Social, and Cultural Influences

What contributes to self-awareness in infancy? First, self-recognition depends on *cognitive development* and requires the maturation of certain areas of the brain (Bertenthal & Fischer, 1978; Lewis & Carmody, 2008). For example, intellectually disabled children are slow to recognize themselves in a mirror but can do so once they have attained a mental age of around 18 months (Hill & Tomlin, 1981).

Second, self-awareness depends on *social interaction*. Chimpanzees who have been raised without contact with other chimps fail to recognize themselves in a mirror as normal chimps do (Gallup, 1979). Human children's early responsiveness to other people is linked to their later self-recognition (Kristen-Antonow

Does this boy know that he is the fascinating tot in the mirror? Probably not. Most infants do not master self-recognition until they are 18 months old.

Joseph Pobereskin/Getty Images

et al., 2015). And human toddlers who have formed secure attachments to their parents are better able to recognize themselves in a mirror and know more about their names and genders than do toddlers whose relationships are less secure (Pipp, Easterbrooks, & Harmon, 1992). Throughout life, we forge our self-concepts from the information and feedback we receive from interacting with other people (Harter, 2012).

Third, the *cultural context* may influence the emergence of self-awareness. In studying cultural influences on mirror self-recognition, researchers have focused primarily on how much a culture emphasizes individuality. Joscha Kärtner and his colleagues (2012) expected that self-awareness might develop more rapidly in **individualistic cultures**—cultures that emphasize autonomy and encourage children to pursue their own goals as individuals—than in **collectivist cultures**—cultures that emphasize relatedness to others and subordinating individual goals to the goals of the group (see Triandis, 1989, 1995). Parents in individualistic cultures would be likely to help children get to know themselves and their preferences and assert themselves, whereas parents in collectivist cultures would not call attention to the

child as an individual and would instead socialize their children to be sensitive to others and respectful of their elders.

The researchers compared the development of mirror self-recognition in two individualistic cultures (urban Germany and urban India) and two collectivist ones (rural India and the Nso culture in rural Cameroon, Africa). Sure enough, almost all toddlers in the individualistic/urban cultures recognized themselves in a mirror by 18 or 19 months (for example, touched the mark that had been placed on their face), whereas only a minority of those in the collectivist/rural cultures did. In earlier work (Keller et al., 2005), these researchers had discovered that urban German mothers engaged in more face-to-face interaction with and were more responsive to their 3-month-old babies' actions than rural Nso mothers. Moreover, this maternal responsiveness to the infant as an individual was correlated with later self-recognition.

Yet other researchers are not so sure the mirror self-recognition task is equally valid in all cultures. Tanya Broesch and her colleagues (2011), testing children in several different cultures, found that only 2 of 82 Kenyan children ranging in age from 18 to 72 months touched the mark that had been put on their face during the mirror self-recognition task; instead, they froze and stared at the mirror. The researchers were convinced that most of these children knew who they were but simply did not know how to react in this unusual situation or did not think they had permission to touch or remove the mark. So, we cannot be certain yet how to explain earlier emergence of mirror self-recognition skills in individualistic cultures than in collectivist cultures. Nonetheless, we can conclude that cognitive development, social interaction, and cultural context all influence the development of self-awareness.

Implications of Self-Recognition

Achieving conscious self-awareness is an exciting breakthrough that paves the way for other critical social and emotional developments. Toddlers who recognize themselves in the mirror are more able than those who do not to:

- Talk about themselves and to assert their wills (DesRosiers et al., 1999)
- Experience self-conscious emotions such as pride upon mastering a new toy or embarrassment if asked to show off by dancing or singing for strangers (Lewis et al., 1989; and see Chapter 14)
- Understand other people—for example, empathize with peers in distress (Eisenberg, Spinrad, & Sadovsky, 2006; Taumoepeau & Reese, 2014)
- Coordinate their own perspectives with those of other individuals—for example, cooperate with peers to achieve common goals such as retrieving toys from containers (Brownell & Carriger, 1990).

Temperament

Although it takes infants some time to become aware of themselves as individuals, they have distinctive personalities from the first weeks of life. The study of infant personality has centered on **temperament**—early, genetically based but also environmentally influenced tendencies to respond in predictable ways to events

that serve as the basis for later personality (see Chen & Schmidt, 2015; Rothbart, 2011; Shiner et al., 2012). Learning theorists have tended to view babies as “blank slates” who can be shaped in any number of directions by their experiences. However, it is now clear that babies are not blank slates—that they differ from the start in basic response tendencies.

Easy, Difficult, and Slow-to-Warm-Up Temperaments

One of the first attempts to characterize infant temperaments was the influential work of Alexander Thomas, Stella Chess, and their colleagues (Chess & Thomas, 1999; Thomas & Chess, 1977, 1986). These researchers gathered information about nine dimensions of infant behavior, including typical mood, regularity or predictability of biological functions such as feeding and sleeping habits, tendency to approach or withdraw from new stimuli, intensity of emotional reactions, and adaptability to new experiences and changes in routine. Based on the overall patterning of these temperamental qualities, most infants could be placed into one of three categories:

- **Easy temperament.** Easy infants are even tempered, typically content or happy, and open and adaptable to new experiences such as the approach of a stranger or their first taste of strained plums. They have regular feeding and sleeping habits, and they tolerate frustrations and discomforts.
- **Difficult temperament.** Difficult infants are active, irritable, and irregular in their habits. They often react negatively (and vigorously) to changes in routine and are slow to adapt to new people or situations. They cry frequently and loudly and often have tantrums when they are frustrated by such events as being restrained or having to live with a dirty diaper.
- **Slow-to-warm-up temperament.** Slow-to-warm-up infants are relatively inactive, somewhat moody, and only moderately regular in their daily schedules. Like difficult infants, they are slow to adapt to new people and situations, but they typically

Because temperament is genetically based, identical twins often react similarly to new experiences.

leungchopan/Shutterstock.com

respond in mildly, rather than intensely, negative ways. For example, they may resist cuddling by looking away from the cuddler rather than by kicking or screaming. They eventually adjust, showing a quiet interest in new foods, people, or places.

Of the infants in Thomas and Chess’s longitudinal study of temperament, 40% were easy infants, 10% were difficult infants, and 15% were slow-to-warm-up infants. The remaining third could not be placed in only one category because they shared qualities of two or more categories.

Thomas and Chess went on to conduct a longitudinal study of continuity and discontinuity in temperament from infancy to early adulthood (Chess & Thomas, 1984; Thomas & Chess, 1986). Difficult infants who had fussed when they could not have more milk often became children who fell apart when they could not work mathematics problems correctly. By adulthood, however, an individual’s adjustment had little to do with her temperament during infancy, suggesting a good deal of discontinuity over this long time span (Guerin et al., 2003).

Surgency/Extraversion, Negative Affect, and Effortful Control

Mary Rothbart and her colleagues (Putnam, Gartstein, & Rothbart, 2006; Rothbart, 2007, 2011; Rothbart, Ahadi, & Evans, 2000; Rothbart & Derryberry, 2002) have gone in a different direction and have defined infant temperament in terms of dimensions rather than types such as easy or difficult babies. They have also considered not only infants’ reactivity to experiences, as Thomas and Chess did, but also their capacity for self-regulation. That is, they have focused on how easily infants become emotionally aroused and how able they are to control or regulate their arousal. Rothbart became interested in temperament in part because her two sons were so different. For example, the first liked to be rocked or handed a pacifier when he was distressed, but the second son found these tactics upsetting; he preferred low levels of stimulation and wanted to lie quietly by himself to calm himself down (Rothbart, 2011).

Rothbart and her colleagues have identified at least three major dimensions of temperament, each made up of more specific dimensions. The first two are evident from infancy on; the third, effortful control, emerges more clearly in toddlerhood and early childhood and continues to develop into adulthood:

- **Surgency/extraversion**—the tendency to actively, confidently, and energetically approach new experiences in an emotionally positive way (rather than to be inhibited and withdrawn). Surgent/extraverted babies are eagerly and actively engaged in life; they enjoy interacting with people and smile and laugh a lot.
- **Negative affectivity**—the tendency to be sad, fearful, easily frustrated, irritable, and difficult to soothe (as opposed to laid back and adaptable).
- **Effortful control**—the ability to focus and shift attention when desired, inhibit responses, and appreciate low-intensity activities such as sitting on a parent’s lap. Perhaps you remember the children’s game, “Simon Says.” Effortful control is

illustrated by being able to inhibit hand clapping when the command is “Clap your hands” rather than “*Simon says* clap your hands.” At age 3, only 22% can inhibit forbidden actions like this; by age 4, 90% can (Rothbart, 2011). This rapid development of self-control at around age 3 is followed by more rapid growth in adolescence (Eisenberg et al., 2014).

A number of frameworks have been devised to characterize and measure infant temperament (see Chen & Schmidt, 2015). Thomas and Chess pioneered the study of temperament with their easy, difficult, and slow-to-warm-up temperament types. Today, Rothbart’s dimensions of temperament have become especially influential because they have been well-researched and because they share similarities with the Big Five dimensions used to describe adult personality (Rothbart, 2011). Perhaps you have noticed yourself that surgency/extraversion matches up well with the Big Five’s extraversion dimension, negative affectivity with neuroticism, and effortful control with conscientiousness (Rothbart, 2011).

Goodness of Fit

Differences in temperament are rooted in part in genetically based differences in levels of certain neurotransmitters in the brain (Chen & Schmidt, 2015; Saudino & Wang, 2012). However, prenatal influences such as maternal stress and substance use also help shape it (Huizink, 2012; see Chapter 4). And the postnatal environment then helps determine how adaptive particular temperamental qualities are and whether they persist or change (Bates, Schermerhorn, & Petersen, 2012; Rothbart, 2011). In short, genes and environment interact to influence the development of temperament (Saudino & Micalizzi, 2015).

Thomas and Chess must have appreciated this when they called attention to the **goodness of fit** between child and environment—the extent to which the child’s temperament is compatible with the demands and expectations of the social world to which she must adapt (Thomas & Chess, 1977). Consider Carl, one of the children studied by Thomas and Chess. Early in life, Carl was clearly a difficult child: “Whether it was the first bath or the first solid foods in infancy, the beginning of nursery and elementary school, or the first birthday parties or shopping trips, each experience evoked stormy responses, with loud crying and struggling to get away” (Chess & Thomas, 1984, p. 188). Carl’s mother became convinced that she was a bad parent, but his father accepted and even delighted in Carl’s “lusty” behavior. He

Temperamentally difficult children may remain so if there is a “bad fit” between them and an impatient parent.

LoisjoyThurstun/BubblesPhotolibrary/Alamy Stock Photo

patiently and supportively waited for Carl to adapt to new situations. As a result, Carl did not develop serious behavioral problems as a child and became a well-adjusted adult after weathering some difficulties when he started college.

If the fit between Carl’s difficult temperament and his parents’ demands and expectations had been poor—for example, if his parents had been impatient, angry, and overly demanding instead of sensitive—Carl might have been headed for serious problems (Guerin et al., 2003; Leerkes, Blankson, & O’Brien, 2009). Similarly, shy, inhibited children are likely to remain inhibited if their parents are either overprotective or angry and impatient, but can overcome their inhibition if their parents create a “good fit” by preparing them for potentially upsetting experiences and making firm but reasonable demands that they cope (Kagan, 1994).

The moral for parents is clear: Get to know your baby as a person, and allow for his personality quirks. Training parents of irritable, difficult babies in how to interpret their infants’ cues and respond sensitively and appropriately to them can produce calmer infants who cry less and become less irritable preschoolers (van den Boom, 1995; Crockenberg & Leerkes, 2003). Infants’ temperaments and their parents’ parenting reciprocally influence one another, of course (Bates et al., 2012; Chen & Schmidt, 2015). Sensitive parenting can make a difficult baby less difficult, but a difficult baby can also make a sensitive parent less sensitive.

● Checking Mastery

1. What important breakthrough in the development of the self occurs at around 18 months of age, and what influences when it happens?
2. How might Mary Rothbart describe Serena, a child whom Thomas and Chess would classify as an easy baby?

● Making Connections

1. The mirror test has become the main way of assessing self-awareness in infants. What do you see as the strengths and limitations of this approach? Can you think of other ways to assess infant self-awareness?
2. Gracie the toddler throws fits when her routines are changed, a stranger comes to visit, or she is asked to try something new and unfamiliar. Using the two different systems for analyzing temperament, help her parents understand her temperament and, more importantly, what they can do to help her become as well adjusted as possible.

11.3

The Child

LEARNING OBJECTIVES

- Summarize how children’s self-concepts typically change as they get older.
- Explain the multidimensional nature of self-esteem and the factors that contribute to its being high or low.
- Assess the implications of personality in early childhood for later personality and adjustment.

Children’s personalities continue to form, and children acquire much richer understandings of themselves as individuals, as they continue to experience cognitive growth and interact with other people during the preschool and school years.

Elaborating on a Sense of Self

Once toddlers begin to talk, they can and do tell us about their emerging self-concepts. Parent–child conversations that focus on children’s experiences and the emotions associated with them help young children pull together what they know of themselves into a self-concept (Goodvin et al., 2015). The preschool child’s emerging self-concept is concrete and physical (Damon & Hart, 1988; Harter, 2012). Asked to describe themselves, preschoolers note their physical characteristics, possessions, physical activities and accomplishments, and preferences. One exuberant 3-year-old described herself this way:

I’m 3 years old and I live in a big house with my mother and father and my brother, Jason, and my sister, Lisa. I have blue eyes and a kitty that is orange and a television in my own room. I know all of my ABC’s, listen: A B, C, D, E, F, G, H, J, L, K, O, M, P, Q, X, Z. I can run real fast. I like pizza and I have a nice teacher at preschool. I can count up to 100, want to hear me? I love my dog Skipper. (Harter, 2012, p. 29)

Few young children mention their psychological traits or inner qualities. At most, young children use global terms such as *nice* or *mean* and *good* or *bad* to describe themselves and others (Livesley & Bromley, 1973). Children note their psychological and social qualities more by around age 8, thanks in part to cognitive growth (Harter, 2012). First, they describe their enduring qualities using personality trait terms such as *funny* and *smart* and *honest* (Harter, 2012; Livesley & Bromley, 1973). Second, children form social identities, defining themselves in terms of their identifications with social groups (“I’m a Kimball, a second-grader at Brookside School, a Brownie Scout”; Damon & Hart, 1988). Third, they become more capable of **social comparison**—of using information about how they compare with others to characterize and evaluate themselves (Frey & Ruble, 1985; Pomerantz et al., 1995). The preschooler who said she could hit a baseball becomes the elementary school child who says she is a better batter than her teammates.

Preschool children typically think they are quite wonderful, even in the face of compelling evidence that they have been outclassed by other kids (Butler, 1990; Diehl et al., 2011). By first grade, children are not only very interested in social comparisons

but also more aware of their implications. They glance at each other’s papers, ask “How many did you miss?” and say things like “I got more right than you did” (Frey & Ruble, 1985; Pomerantz et al., 1995). As they get older, children learn to be more diplomatic about what they say when they outperform others, but they increasingly use social comparisons to get a more accurate sense of their strengths and weaknesses (Diehl et al., 2011).

Self-Esteem

As children amass a range of perceptions of themselves and engage in social comparisons, they begin to evaluate their worth.

Changes in Self-Esteem

Susan Harter (2003, 2012) has developed self-perception scales for use with different age groups and has found that self-esteem becomes more differentiated or *multidimensional* with age. Preschool children distinguish only two broad aspects of self-esteem: their competence (both physical and cognitive) and their personal and social adequacy (for example, their social acceptance). By mid–elementary school, children differentiate among five aspects of self-worth:

- scholastic competence (feeling smart or doing well in school)
- social acceptance (being popular or feeling liked)
- behavioral conduct (staying out of trouble)
- athletic competence (being good at sports)
- physical appearance (feeling good-looking)

When Harter’s scale was given to third- through ninth-graders, even third-graders showed that they had well-defined senses of where they stood, high or low, in each of these five areas. As children get older, they also integrate their self-perceptions in these distinct domains to form an overall sense of self-worth (Harter, 2012; Marsh & Ayotte, 2003). Meanwhile the accuracy of their self-evaluations increases steadily (Harter, 2012; Marsh, Craven, & Debus, 1999). For example, those with high scholastic self-esteem are more likely than those with low scholastic self-esteem to be rated as intellectually competent by their teachers, and those with high athletic self-esteem are frequently chosen by peers to be on sports teams (Harter, 2012).

At the same time, children are forming an ever grander sense of what they “should” be like—an **ideal self**. With age, the gap between the real self and the ideal self increases; older children therefore run a greater risk than younger children do of thinking that they fall short of what they should be (Glick & Zigler, 1985; Oosterwegel & Oppenheimer, 1993). Social comparisons that do not always come out well, a widening gap between the real self

and the ideal self, and a tendency for parents and teachers to “raise the bar” and give older children more critical feedback than they give younger children all contribute to a decrease in average self-esteem from early to middle childhood (Harter, 2012).

Influences on Self-Esteem

Why do some children develop higher self-esteem than others? Three influences stand out (Harter, 2012). First, *genetic makeup* is part of the answer; surprising as it may seem, level of self-esteem is a heritable characteristic, influenced by genes as well as by unique or nonshared experiences (Kamakura, Ando, & Ono, 2007; Svedberg et al., 2014). Second, some children display more *competence* than others; they experience more success and come out better in social comparisons as a result. Thus, putting the basketball in the basket more often than the other kids do tells you that you are good at basketball, and doing well in school has a positive effect on academic self-concept (Guay, Marsh, & Boivin, 2003; Marsh & Craven, 2006).

Third, even when two children are equally competent and do equally well in social comparisons, *social feedback* from parents, teachers, and peers can make a big difference in their self-perceptions. Parents are especially important. Children with high self-esteem tend to be securely attached to parents who are warm and democratic (Arbona & Power, 2003; Coopersmith, 1967). These parents frequently communicate approval and acceptance rather than saying, through words, looks, or actions, “Why can’t you be better?” (Doyle et al., 2000). The parents’ democratic approach also gives their children a sense that their opinions matter. The relationship between high self-esteem and warm, democratic parenting holds up in a variety of ethnic groups and cultures (Scott, Scott, & McCabe, 1991; Steinberg, Dornbusch, & Brown, 1992). High self-esteem, in turn, is positively correlated with good adjustment in childhood (Coopersmith, 1967; Harter, 2012).

Self-esteem is based in part on demonstrating competence and coming out well in social comparisons.

Alistair Berg/Stone+/Getty Images

Should we do all we can to boost children’s self-esteem, then? Some observers believe that American parents and educators go overboard in trying to make all children feel good about themselves by handing out stickers, stars, and shouts of “Good job!” at every turn (Damon, 1994; Harter, 2012). Self-esteem means little, they argue, unless it grows out of a child’s real achievements. Indeed, giving children an inflated and unrealistic sense of their worth is likely to do more harm than good. One team of researchers, for example, found that if children who are low in self-esteem are given exaggerated praise (“You made an incredibly beautiful drawing!”), it causes them to shy away from challenges, possibly because they believe they will be judged by impossibly high standards (Brummelman et al., 2014). So, it will probably not work in the long run to tell children that they are the greatest when they can see for themselves that they are not. However, helping children succeed at important tasks can boost their self-esteem, and higher self-esteem can then help fuel future achievements (Marsh & Craven, 2006).

The Developing Personality

The early response tendencies called temperament are elaborated into a predictable personality during childhood, which then predicts later personality and adjustment (Shiner & Caspi, 2012). As noted earlier, some of the dimensions of early temperament studied by Mary Rothbart are related to Big Five personality traits (Hagekull & Bohlin, 1998; Rothbart, 2011; Shiner & Caspi, 2012). Consider self-control or self-regulation in childhood. It is an outgrowth of Rothbart’s effortful-control dimension of temperament, is linked to the Big Five dimension of conscientiousness later in life, and is associated with a range of good developmental outcomes (Eisenberg et al., 2014; Rueda, 2012). Self-controlled children do well in school, are socially and morally mature, and have fewer adjustment problems than their less self-controlled peers. They even go on to become adults who are healthier, more successful in their careers, more financially stable, and less likely to get into trouble with substance use and crime (Daly et al., 2015; Moffitt et al., 2011; and see Chapter 13). These highly self-regulated, conscientious individuals are able to focus on their long-term goals, act responsibly to pursue them, and resist temptations (such as that party down the hall) that might distract them.

Despite such evidence of continuity between early temperament and later personality, however, we must reject Freud’s view that the personality is mostly formed by age 5. Personalities change in response to parenting, cultural pressures, and life events, and the aspects of personality that best characterize young children are sometimes different than the Big Five dimensions that fit adolescents and adults so well (Soto & Tackett, 2015). As a result, correlations between early childhood traits and adult traits are usually quite small. Some dimensions of personality do not fully “gel” until the elementary school years, when children’s traits begin to predict their adolescent and adult personality and adjustment much better (McAdams & Olson, 2010; Tackett et al., 2008). Other aspects of personality do not seem to stabilize until adolescence or even adulthood, as we will see later. So the roots of adult personality can be found in childhood, but it takes many years for a personality to fully form.

● Checking Mastery

1. What are three major ways in which the self-description of 9-year-old Alonzo might differ from that of his brother, 4-year-old Jamal?
2. What are three main reasons that Lisa may have higher self-esteem than Lula?

● Making Connections

1. Some educators believe that nurturing high self-esteem in all children is critical; they favor giving all children lots of positive feedback and sparing them from failure experiences so that they will feel competent. What are the pros and cons of doing this, and what does research say about it?
2. Revisit the Big Five personality dimensions in Table 11.1. If you wanted to determine whether these trait dimensions are evident at age 2 or 3, how would you go about doing so?

11.4

The Adolescent

LEARNING OBJECTIVES

- Discuss how self-descriptions and self-esteem typically change between childhood and adolescence.
- Explain how identity formation in adolescence has been studied and what has been learned about progress in such key areas as ethnic identity and vocational identity.
- Identify and illustrate the major influences on the achievement of identity.

Perhaps no period of the life span is more important to the development of the self than adolescence. Adolescence is truly a time for “finding oneself,” as research on adolescent self-conceptions, self-esteem, and identity formation illustrates.

Self-Concept

Some years ago, Raymond Montemayor and Marvin Eisen (1977) learned a great deal about the self-concepts of children and adolescents in grades 4–12 by asking students to write 20 different answers to the question “Who am I?” How would you answer that question? And, looking at **Engagement 11.2**, how would you describe the developmental trends evident there in the answers given by a 9-year-old, an 11½-year-old, and a 17-year-old?

Self-descriptions change considerably between childhood and adolescence (Damon & Hart, 1988; Harter, 2012). Self-conceptions become:

- *less physical and more psychological* (contrast “I have brown eyes” with “I am lonely” in Engagement 11.2).
- *less concrete and more abstract*, thanks to cognitive development (contrast “I love! sports” with “I am a truthful person” or the even more abstract “I am a pseudoliberal”).
- *more differentiated*; for example, the child’s “social self,” which reflects perceived acceptance by others, splits into three distinct aspects in adolescence: acceptance by the larger peer group, acceptance by close friends, and acceptance by romantic partners (Harter, 2012); adolescents also appreciate that they are different “selves” in different social contexts (Diehl et al., 2011; Harter & Monsour, 1992).
- *more integrated and coherent*; thus, adolescents can notice and integrate discrepant self-perceptions, perhaps explaining that they are happy in some situations and grumpy in others because they are moody or because they are happier around people who accept them than around people who are critical of them (Harter & Monsour, 1992).

● ENGAGEMENT 11.2

How Do Self-Conceptions Change with Age?

What do these three answers to the question, “Who am I?” say about how self-conceptions change with age? Come to your own conclusions and then compare them to those in Section 11.4.

9-year-old: My name is Bruce C. I have brown eyes. I have brown hair . . . I have great! eye sight. I have lots! of friends. I live at . . . I have an uncle who is almost 7 feet tall. My teacher is Mrs. V. I play hockey! I’m almost the smartest boy in the class. I love! food . . . I love! school.

11½-year-old: My name is A. I’m a human being . . . a girl . . . a truthful person. I’m not pretty. I do so-so in my studies. I’m a very good cellist. I’m

a little tall for my age. I like several boys . . . I’m old fashioned. I am a very good swimmer . . . I try to be helpful . . . Mostly I’m good, but I lose my temper.

17-year-old: I am a human being . . . a girl . . . an individual . . . I am a Pisces. I am a moody person . . . an indecisive person . . . an ambitious person. I am a big curious person . . . I am lonely. I am an American (God help me). I am a Democrat. I am a liberal person. I am a radical. I am conservative. I am a pseudoliberal. I am an Atheist. I am not a classifiable person (i.e., I don’t want to be). (Montemayor & Eisen, 1977, pp. 317–318)

- *more reflected upon*; adolescents become more self-aware, think more about the self, and sometimes become painfully self-conscious (Harter, 2012); for example, adolescents are more likely than either children or adults to show signs of self-consciousness such as embarrassment, along with heightened activity in social and emotional processing centers of the brain, when they are told they are being observed (Somerville et al., 2013).

In sum, from childhood to adolescence and over the course of adolescence, self-understandings become more psychological, abstract, differentiated, integrated, and reflected upon. Many adolescents even become sophisticated personality theorists who reflect for hours upon the workings of their own personalities and those of their companions.

Self-Esteem

Self-esteem tends to decrease from childhood to early adolescence (Robins et al., 2002). This may happen because adolescents are learning more about their strengths and weaknesses, and also because their bodies are changing, they typically change schools, and they face many social pressures. This early adolescent dip in self-esteem affects only some teens, though. It seems to be most common among white females, especially those facing multiple stressors at once—for example, entering middle school, coping with pubertal changes, beginning to date, and so on (Gray-Little & Hafdahl, 2000; Simmons et al., 1987).

In the end, though, adolescence is not as hazardous to self-esteem as most people believe. Although some adolescents do experience dips in self-esteem in early adolescence, most maintain moderate or high levels of self-esteem over the adolescent years or emerge from this developmental period with higher self-esteem than they had at the start (Erol & Orth, 2011; Morin et al., 2013). It matters: As adults, adolescents with high self-esteem tend to have better physical and mental health, better career and financial prospects, and less involvement in criminal behavior than adolescents with low self-esteem (Trzesniewski et al., 2006).

Forging an Identity

Erik Erikson (1968) characterized adolescence as a critical period in the lifelong process of forming an identity as a person—a time for the psychosocial conflict of **identity versus role confusion**. The concept of *identity*, as noted at the start of the chapter, refers to a definition of who you are, where you are going, and where you fit into society. To achieve a sense of identity, adolescents

Adolescents sometimes experiment with a variety of looks in their search for a sense of identity.

XiXinXing/Shutterstock.com

must integrate their self-perceptions into a coherent sense of self. The search for identity involves grappling with many important questions: What kind of career do I want? What religious, moral, and political values can I really call my own? Who am I as a man or woman and as a sexual being? Where do I fit in?

If you have struggled with such issues, you can appreciate the uncomfortable feelings that adolescents may experience when they cannot seem to work out a clear sense of who they are. Erikson believed that many young people experience a full-blown and painful “identity crisis.” After all, adolescents’ bodies are changing and they must therefore revise their body images and come to think of themselves as sexual beings; their new cognitive abilities allow them to think systematically about hypothetical possibilities, including ideal selves and possible future selves; and society pressures them to “grow up—to decide what they want to do in life and to get on with it. According to Erikson (1968), our society supports youths by allowing

them a **moratorium period**—a time during the high school and college years when they are relatively free of responsibilities and can experiment with different possibilities to find themselves. But complex societies like ours also make establishing an identity hard by giving youths a huge number of options and encouraging them to believe they can be anything they want to be.

Developmental Trends

James Marcia (1966) expanded on Erikson’s theory and stimulated much research on identity formation by developing an interview procedure to assess where an adolescent is in the process of identity formation. Adolescents are classified into one of four identity statuses (*statuses*, not stages) based on their progress toward an identity in each of several domains (for example, occupational, religious, and political-ideological). The key questions are whether an individual has experienced a *crisis* (or has seriously grappled with identity issues and explored alternatives) and whether he has achieved a *commitment* (that is, resolved the questions raised and settled on an identity). On the basis of crisis and commitment, the individual is classified into one of the four identity statuses shown in **Figure 11.1**.

When do we achieve a sense of identity? Philip Meilman’s (1979) study of college-bound boys between 12 and 18, 21-year-old college males, and 24-year-old young men gives us some answers (**Figure 11.2**). Most of the 12- and 15-year-olds were in either the identity diffusion status or the identity foreclosure status. At these ages, many adolescents simply have not yet thought

		Commitment?	
		No Commitment Made	Commitment Made
Crisis?	No Crisis Experienced	Diffusion Status The individual has not yet thought about or resolved identity issues and has failed to chart directions in life. Example: "I haven't really thought much about religion, and I guess I don't know what I believe exactly."	Foreclosure Status The individual seems to know who he or she is but has latched onto an identity prematurely with little thought. Example: "My parents are Baptists, and I'm a Baptist; it's just the way I grew up."
	Crisis Experienced	Moratorium Status The individual is experiencing an identity crisis, actively raising questions, and seeking answers. Example: "I'm in the middle of evaluating my beliefs and hope that I'll be able to figure out what's right for me. I've become skeptical about some of what I have been taught and am looking into other faiths for answers."	Identity Achievement Status The individual has resolved his/her identity crisis and made commitments to particular goals, beliefs, and values. Example: "I really did some soul-searching about my religion and other religions, too, and finally know what I believe and what I don't."

■ **Figure 11.1** The four identity statuses as they apply to religious identity.

■ **Figure 11.2** Percentage of subjects in each of James Marcia's four identity statuses as a function of age. Note that only 4% of the 15-year-olds and 20% of the 18-year-olds had achieved a firm identity.

Source: From Meilman, P.W. (1979). Cross-sectional age changes in ego identity status during adolescence. *Developmental Psychology*, 15, 230–231.

about who they are (the **diffusion status**, with no crisis and no commitment). Other adolescents have made commitments, may say things like "I'm going to be a doctor like my dad," and appear to have their acts together. However, it becomes apparent that

they have never thought through on their own what suits them best or investigated alternatives; they have simply accepted identities suggested to them by their parents or other people (the **foreclosure status**, involving a commitment without a crisis).

As Figure 11.2 indicates, progress toward identity achievement becomes more evident starting at age 18. More individuals begin to fall into the **moratorium status**. Now they are experiencing a crisis or actively exploring identity issues; now they may be questioning their religious upbringing, experimenting with drugs, changing majors or relationships, or putting outrageous postings on Facebook, all to find themselves. If they can not only raise questions but answer them, they will move to the **identity achievement status**. About 20% of the 18-year-olds, 40% of the college students, and slightly more than half of the 24-year-olds in Meilman's study had achieved a firm identity based on a careful weighing of alternatives. Females progress toward achieving a sense of identity at about the same rate as males do (Kroger, 2007).

Judging from such research, identity formation *takes a long time*. Many young men and women do not raise identity questions or reach the identity achievement status until their late teens or early 20s, during the period of emerging adulthood. Some adults continue in a moratorium status for years; others reopen the question of who they are and recycle through the identity statuses after thinking they had all the answers earlier in life (Anthis & LaVoie, 2006; Kroger, 2007). Even in late adulthood, some adults are reworking and strengthening their identities (Zucker, Ostrove, & Stewart, 2002).

Identity formation not only takes a long time but *occurs at different rates in different domains of identity*. For example, Sally Archer (1982) assessed the identity statuses of 6th- to 12th-graders

in four domains: occupational choice, gender-role attitudes, religious beliefs, and political ideologies. Only 5% of the adolescents were in the same identity status in all four areas. In short, identity formation takes a long time, can be revisited after adolescence, and occurs at different rates in different domains.

Constructing Narrative Identities

Some researchers have taken a different approach to studying identity formation and examined adolescents' *narrative identities*, or life stories (McAdams, 2008, 2011; McAdams & McLean, 2013). A life story, much like an identity in Erikson's sense, tells "who I am, how I came to be, and where my life is going in the future" (McAdams, 2005, p. 241). The process of constructing a meaningful life story begins in childhood but becomes very important during late adolescence and emerging adulthood.

Developing a life story is correlated with making progress through Marcia's identity statuses toward identity achievement (McLean & Pratt, 2006). Life stories then become an important element of our adult personalities and are revised over the years and reflected upon in old age (Birren & Schroots, 2006; McAdams & McLean, 2013). People whose life stories feature overcoming adversity and achieving redemption—for example, people who gain a powerful sense of the meaning of life after almost dying of a drug overdose or after working their way out of poverty to become a Supreme Court justice—tend to have high well-being and good adjustment (McAdams & McLean, 2013).

Developing a Positive Ethnic Identity

An important aspect of identity development is forging an **ethnic identity**—a sense of personal identification with an ethnic group and its values and cultural traditions (Phinney, 2006; Spencer, Swanson, & Harpalani, 2015; Santos & Umaña-Taylor, 2015). Although everyone has an ethnic and racial background, members of minority groups tend to put more thought than majority group adolescents into defining who they are ethnically or racially. Multiracial or multiethnic youth may have even more reason to think about their ethnic identity; they may be pressed to identify with only one group (for example, to identify as Black rather than Asian when they have both a Black and an Asian parent) and may need to learn how to shift from one identity to another, depending on who they are with (Gaither, 2015). By contrast, white adolescents in the United States often do not even think of themselves as having a race or ethnicity (Bracey, Bamaca, & Umaña-Taylor, 2004).

The process of forming an ethnic identity begins in infancy as babies notice visible differences among people. Three-month-old Caucasian infants already prefer to look at other Caucasian babies rather than at babies from other ethnic backgrounds (Kelly et al., 2005). African babies show a similar preference for African faces, though not if they grow up among Caucasians, suggesting that babies form these preferences based on the faces they see most often (Bar-Haim et al., 2006).

During the preschool years, children learn about different racial and ethnic categories and gradually become able to classify themselves correctly (Spencer & Markstrom-Adams, 1990).

For example, Mexican American preschool children may learn behaviors associated with their culture, such as how to give a Chicano handshake; by about age 8, they may know what ethnic labels apply to them and understand that their ethnicity will last a lifetime (Bernal & Knight, 1997). During elementary school, children learn a lot more about their ethnic group and can talk about it in terms of qualities such as language, physical appearance, heritage, and status in society (Rogers et al., 2012).

In forming a positive ethnic identity, adolescents seem to work through the same identity statuses as they do in forming a vocational or religious identity (Douglass & Umaña-Taylor, 2015; Seaton, Scottham, & Sellers, 2006). School-age children and young adolescents say either that they identify with their racial or ethnic group because their parents and others in their ethnic group influenced them to do so (foreclosure status) or that they have not given it much thought (diffusion status). In their mid- to late teens or early 20s, more minority youths move into the moratorium and achievement statuses (Phinney, 2006; Seaton et al., 2006).

What helps adolescents form a positive ethnic identity? It helps when their parents socialize them regarding their race or ethnicity by teaching them about their group's cultural traditions, preparing them to live in a culturally diverse society, and even preparing them to deal with prejudice, at least as long as it is done in a way that does not breed anger and mistrust (Douglass & Umaña-Taylor, 2015; Hughes et al., 2006; Umaña-Taylor & Guimond, 2010).

Once formed, a positive ethnic identity has many benefits (Spencer et al., 2015). It can protect adolescents from the damaging effects of racial or ethnic discrimination (Neblett, Rivas-Drake, & Umaña-Taylor, 2012), boost their overall self-esteem (Umaña-Taylor, Gonzales-Backen, & Guimond, 2009), and contribute to academic achievement and good adjustment (Laursen & Williams, 2002; Mandara et al., 2009). Overall, most minority adolescents cope well with the special challenges they face in identity formation. They settle their questions of ethnic identity,

Establishing a positive ethnic identity is more central for minority adolescents than for white ones.

resolve other identity issues around the same ages that European American youth do (Markstrom-Adams & Adams, 1995), and wind up feeling at least as good about themselves (Gray-Little & Hafdahl, 2000).

Vocational Identity and Choice

I wanted to be a firefighter, then I touched a spark. I'm too afraid. I wanted to be a teacher, then I babysat for a 4-year-old. I'm too impatient. I wanted to be a model, then I looked in the mirror. I'm too short.

I know, I know—I can be anything I want when I am all grown up. But I am rapidly approaching all grown up and I see less of what I can be and more of what I cannot be. (Kelly Witte, *The Washington Post*, April 2, 2006, p. D1)

Vocational identity is another important aspect of identity, one with implications for adult career development. How do we choose career paths? Children younger than about age 10 actively explore vocational possibilities but their choices often reflect fantasy rather than reality; they may want to be zookeepers, professional basketball players, firefighters, rock stars, or whatever else strikes them as glamorous and exciting (Ginzberg, 1972, 1984; Hartung, Porfeli, & Vondracek, 2005). Children make important progress, though, by narrowing their ideas about future careers to those consistent with their emerging self-concepts—as humans rather than as lions or ninja turtles, as males or females, and so on (Gottfredson, 1996; Luke & Redekop, 2014). From an early age, for instance, boys choose traditionally masculine occupations, and girls choose traditionally female occupations, setting themselves on paths to traditional gender-stereotyped careers (Hartung et al., 2005; Schuette, Ponton, & Charlton, 2012; Weisgram, Bigler, & Liben, 2010). Elementary school children also learn about the prestige or social status associated with different careers; they may begin to prefer the idea of being a surgeon to the idea of being a car mechanic (Gottfredson, 1996).

Like teenager Kelly Witte, quoted in the beginning of this section, adolescents become more realistic, begin to weigh factors other than their wishes, and make preliminary vocational choices. According to theorist Eli Ginzberg (1972, 1984), they consider their *interests* (“Would I enjoy counseling people?”), their *capacities* (“Am I skilled at relating to people?”), and their *values* (“Is it really important to me to help people, or do I value power or money more?”).

As they get still older, adolescents also begin to take into account the realities of the job market and the physical and intellectual requirements for different occupations, and they begin serious preparation for chosen occupations (Ginzberg, 1984; Hirschi & Vondracek, 2009; Walls, 2000). By late adolescence or emerging adulthood, they may consider the availability of job openings in a field such as school counseling, the years of education required, the work conditions, and other relevant factors.

The main developmental trend evident in vocational choice, then, is *increasing realism with age*—a shift from the child's

fantasies to informed choice based on knowledge of both the self and the world of work. As adolescents narrow career choices in terms of both personal factors (their own interests, capacities, and values) and environmental factors (the realities of the job market), they seek the vocation that best suits them.

According to influential vocational theorist John Holland (1985, 1996), vocational choice is just this: a search for an optimal fit between one's personality and an occupation (see also Wilson & Hutchison, 2014). Holland's pioneering work led many who study vocational development and adjustment to emphasize the importance of **person-environment fit**, a concept much like the *goodness of fit* concept discussed earlier that concerns the match between personality and environment, in this case work environment (Su, Murdock, & Rounds, 2015).

You may well have taken a vocational interest inventory guided by Holland's theory of vocational development (if not, and if you would like to do so, go to the U.S. Department of Labor's Interest Profiler website at www.mynextmove.org/explore/ip). Holland identified six personality types, each suited to a different cluster of occupations:

- *investigative* types who enjoy learning, solving problems, and working creatively with ideas (for example, scientists)
- *social* types who like interacting with and helping other people (for example, teachers and counselors)
- *realistic* types who favor practical work with concrete objects (for example, car mechanics, construction workers)
- *artistic* types who are nonconforming and want to express themselves creatively (for example, artists, musicians)
- *conventional* types who prefer order, structure, and predictability (for example, librarians, accountants)
- *enterprising* types who seek to influence others and attain status (for example, sales people, entrepreneurs, leaders of organizations)

Unfortunately, youth from lower-income families, especially minority group families, may face limited vocational opportunities and discrimination. They may aim high at first but, as they become more aware of constraints on their success, lower their career aspirations and aim toward the jobs they think they can get rather than the jobs that interest them most or fit best with their personalities (Armstrong & Crombie, 2000; Hartung et al., 2005; Phillips & Pittman, 2003).

Similarly, the vocational choices of females have been and continue to be constrained by traditional gender norms (Weisgram et al., 2010). Young women who have adopted traditional gender-role attitudes and expect to marry and start families early in adulthood sometimes set their educational and vocational sights low, choosing careers they think will make it easier for them to combine work and family (Bleske-Rechek et al., 2011; Mahaffy & Ward, 2002). More young women today than ever, though, aspire toward high-status and male-dominated occupations.

Those adolescents who do as Erik Erikson and vocational theorist John Holland advise—explore a range of possible occupations, then make informed choices—are more likely than those who do not to choose careers that fit their personalities (Grotevant &

Cooper, 1986). In turn, a good person-environment fit between personality and vocation predicts greater job satisfaction, better performance, and a higher likelihood of staying in the job, in support of Holland's theory of vocational development (Nye, Su, Rounds, & Drasgow, 2012; Spokane, Meir, & Catalano, 2000). The saving grace is that those who do not explore thoroughly enough as adolescents have plenty of time to change their minds as adults.

Influences on Identity Formation

Taking everything into consideration, an adolescent's progress toward achieving identity in various domains is a product of at least five factors:

- **Cognitive development.** Adolescents who have achieved solid mastery of formal-operational thought, who think in complex and abstract ways, and who actively seek relevant information when they face decisions are more likely than other adolescents to raise and resolve identity issues (Berzonsky & Kuk, 2000; Waterman, 1992).
- **Personality.** Adolescents who explore and achieve identity tend to score low in neuroticism and high in openness to experience and conscientiousness (Ozer & Benet-Martinez, 2006). That is, they are emotionally stable, curious, and responsible.
- **Quality of relationship with parents.** Youths who get stuck in the diffusion status of identity formation and drift for years are sometimes neglected or rejected by their parents and emotionally distant from them. Adolescents in the foreclosure status are often extremely close to parents who are loving but overly protective and controlling; these adolescents have few opportunities to make decisions and may never question their parents' ideas about what they should be. Adolescents in the moratorium and identity achievement statuses generally have warm and democratic parents, the same kind of parents who foster high self-esteem (Grotevant & Cooper, 1986; Emmanuelle, 2009; Kroger, 2007).

In traditional societies, teens do not explore a variety of careers in order to choose the best fit. Instead, they simply learn to do whatever adults in their society do.

sutiporn/Shutterstock.com

- **Opportunities for exploration.** Adolescents who attend college are exposed to diverse ideas and are encouraged to think through issues independently and explore different possibilities. College provides the kind of moratorium period with freedom to explore that Erikson felt was essential to identity formation (Kroger, 2007).
- **Cultural context.** The cultural and historical context influences identity formation. Think about some of the difficulties faced by gay adolescents living in Western societies today in forming their sexual identities. Now think about how much harder it was a few decades ago in Western societies when being gay was more stigmatized—or how hard it must be today in a number of Middle Eastern and African societies where homosexuality is viewed as a sickness, a sin, or a crime—sometimes a crime punishable by death. Consider too that the very idea that adolescents should forge a personal identity after carefully exploring options may well be most relevant in modern, industrialized Western societies (Côté & Levine, 2016; Flum & Blustein, 2000). Teens in more traditional societies centered around farming, fishing, or herding may simply adopt the adult roles most adults in their culture adopt, without much soul-searching or experimentation; that is, identity foreclosure may be the most adaptive path to adulthood in such cultures (Côté & Levine, 2016).

Overall, in Western industrialized societies anyway, the adolescent who is able to raise serious questions about identity and answer them is likely to be better off for it. Identity achievement is associated with psychological well-being and high self-esteem, complex thinking about moral and social issues, a willingness to accept and cooperate with other people, better mental health, and a variety of other psychological strengths (Waterman, 1992; Waterman et al., 2013).

Checking Mastery

1. How are 17-year-old Tom's self-descriptions likely to differ from those of his 9-year-old brother Ben?
2. College student Kwan is in the foreclosure status with respect to vocational identity, whereas his roommate Min is in the diffusion status. What does each status mean, and what kind of parenting might give rise to it?
3. What besides warm, democratic parenting is likely to foster identity achievement?

Making Connections

1. Write three brief descriptions of yourself to show how you might have answered the question "Who am I?" at age 4, age 8, and age 18. What developmental changes in self-conceptions do your self-descriptions illustrate?
2. Analyze your own, current identity statuses in the areas of vocational, ethnic, and religious identity and what you perceive to be the major influences on these aspects of identity.

11.5

The Adult

LEARNING OBJECTIVES

- Discuss age and gender differences in self-esteem across the life span and strategies that aging adults use to maintain self-esteem, as well as how self-conceptions differ in individualistic and collectivist cultures.
- Referring to the two different senses of continuity or discontinuity in personality, summarize what we know about continuity and discontinuity in the Big Five trait dimensions over the adult years.
- Analyze the extent to which research supports Erikson's stages of adult development and Levinson's concept of midlife crisis.
- Summarize the typical course of career development and the factors that would enable older workers to adjust well to retirement and have a successful aging experience.

We enter adulthood having gained a great deal of understanding of what we are like as individuals—but we are far from done developing. Both self-conceptions and personalities change, and both can affect and be affected by the careers that adults establish and end.

Self-Concepts and Self-Esteem

Adults differ greatly in their self-perceptions and levels of self-esteem. To what extent do age, gender, and cultural context contribute to this variation?

Age and Gender Differences

It is commonly believed that adults gain self-esteem as they cope successfully with the challenges of adult life but then lose it as aging, disease, and losses of roles and relationships take their toll in later life. Is there truth to this view? A large Internet survey of more than 300,000 people ages 9–90 conducted by Richard Robins and his colleagues (2002) suggests there is. On average, self-esteem tends to be relatively high in childhood, to drop in adolescence, to rise gradually through the adult years until the 50s and 60s, and then to drop in late old age, as shown in **Figure 11.3**. The same pattern is seen in longitudinal studies (Orth, Robins, & Widaman, 2012; Orth, Trzesniewski, & Robins, 2010). Longitudinal studies also tell us that adults' rankings within a group in level of self-esteem remain quite stable over the years (Orth & Robins, 2014).

As Figure 11.3 also shows, males often display higher self-esteem than females in early adulthood but gender differences fade in old age. We know less about racial and ethnic differences. Black and white adults generally have similar levels of self-esteem but blacks tend to show more of an increase in early adulthood and more of a decline in late adulthood, possibly because they experience steeper declines in financial well-being and health (Orth & Robins, 2014).

Do these age and gender differences apply across cultures? Both the rise in self-esteem from adolescence to middle age and the finding that males have higher self-esteem than females were indeed evident across cultures when Wiebke Bleidorn and his colleagues (2016) examined the responses of almost one million

Figure 11.3 Self-esteem dips in early adolescence and rises during the adult years until it declines in very old age. Males have higher scores than females except in childhood and late old age. The lines graph mean, or average, self-esteem for the various age groups shown; the triangles (for males) and circles (for females) plot mean self-esteem at particular ages in the various studies summarized in this meta-analysis.

Source: From Robins, R. W., et al. (2002). Global self-esteem across the life span, *Psychology and Aging*, 17, 423–434.

respondents in 48 nations to an online self-esteem scale. So, we know that these trends are not peculiar to the United States. They may reflect biological universals such as hormonal changes or cultural universals such as the entry of adults worldwide into roles as workers and parents during early adulthood or cross-cultural similarities in gender roles (Bleidorn et al., 2016). There were differences across societies in the size of age and gender differences, however.

In adulthood, as in childhood and adolescence, self-esteem matters: It is associated with relationship and job satisfaction, health, and happiness. Moreover, it appears to be more the cause of these good life outcomes than the consequence

of them (Orth & Robins, 2014). How, then, can older adults maintain positive self-images as long as possible, even as they experience some of the difficulties and losses that may come with aging? Reducing the gap between the ideal and real self, changing one's goals and standards of self-evaluation, making social comparisons to other old people, and avoiding negative self-stereotyping can all help.

Reducing the Gap between Ideal and Real Self Comparing young, middle-aged, and elderly adults, Carol Ryff (1991) found that self-ratings of the present self changed little across the adult years, but that older adults scaled down their visions of what they could ideally be. As a result, their ideal and present selves converged. Notice, then, that the gap between the ideal self and the real self that opens up during childhood, widens during adolescence, and gives us a sense of falling short, apparently closes again in later life, helping us maintain self-esteem.

Adjusting Goals and Standards of Self-Evaluation People's goals and standards often change with age so that what seem like losses or setbacks to a younger person may not be perceived as such by an older adult. A 40-year-old may be devastated at being passed over for a promotion, whereas a 60-year-old nearing retirement may not be bothered at all (Carstensen & Freund, 1994). And, for the older adult with a disability, walking a mile may be as much a triumph as running a mile might have been earlier in life (Rothermund & Brandtstädter, 2003b). As our goals and standards change over the life span, we apply different measuring sticks in evaluating ourselves and do not mind failing to achieve goals that are no longer realistic or important.

Comparing to Other Older Adults Older adults are also able to maintain self-esteem by making social comparisons primarily to other older adults who have the same kinds of chronic diseases and impairments they have rather than to younger adults (Brandtstädter & Greve, 1994; Helgeson & Mickelson, 2000). Indeed, if they really want to feel good about themselves, they can strategically select worse-off peers to judge themselves against, making what are called downward social comparisons, as in, “My mind’s a lot sharper than poor Bessie’s is” (Bauer, Wrosch, & Jobin, 2008; Frieswijk et al., 2004).

Not Internalizing Ageist Stereotypes Finally, older adults are likely to maintain self-esteem better if they can resist applying negative stereotypes of aging people to themselves. Negative stereotypes breed the prejudice and discrimination against older people we call **ageism**. Ageism shows up in everything from patronizing an elderly customer in a restaurant (“How are we doing, dear?”) to discriminating against older adults in hiring.

Becca Levy (2003, 2009) argues that stereotypes of old people, which we learn in childhood, can result in **self-stereotyping** when we reach old age. Although we hold a few positive stereotypes of older people (they are wise, agreeable, and kindly), negative stereotypes of older adults (they are sick, fragile, forgetful, incompetent, and so on) far outnumber positive ones and show

up in a variety of cultures (see Chan et al., 2012; Miche, 2015). These negative stereotypes are reinforced over the years and are available to be applied to the self once people begin to think of themselves as “old.” This may be why so many aging adults go to great lengths to deny that they are old! If they can avoid identifying with their age group, they are likely to feel younger than they actually are, perceive more time ahead of them, and enjoy higher self-esteem (Weiss & Lang, 2012; Weiss & Freund, 2012; Westerhof, Whitbourne, & Freeman, 2012).

But eventually, when aging adults can deny their years no longer, they apply the “old” label to themselves and run the risk of negatively stereotyping themselves and suffering as a result (Levy, 2009; Rothermund & Brandtstädter, 2003a). In one demonstration of how negative self-stereotyping can hurt the performance of elderly adults (Hausdorff, Levy, & Wei, 1999), words reflecting either negative or positive stereotypes of aging were flashed rapidly on a computer screen to elderly adults so that the words were perceived but below the level of awareness. After this priming experience, these adults were asked to walk down a hall wearing measuring devices on their feet that registered how rapidly and sprightly (how long they kept their feet off the ground) they walked. Older adults primed with positive stereotypes of aging clocked faster speeds and more foot-off-the-floor time than older adults who were exposed to negative stereotypes and shuffled along like “old” people. As Chapter 8 revealed, Levy (1996) has also found that priming older adults with words such as *senile* results in poorer memory performance than priming them with words such as *wise*.

By contrast, resisting taking negative stereotypes of aging to heart—for example, disagreeing with statements such as “Things keep getting worse as I get older”—is positively associated with good health and longevity (Levy, Slade, and Kasl, 2002; Levy et al., 2009), fewer signs of psychological disorder (Levy, Pilver, & Pietrzak, 2014), and even fewer signs of the brain changes associated with Alzheimer’s disease at autopsy (Levy et al., 2016). These studies and others suggest that ageist stereotypes can do real damage to those older adults who identify themselves as “old” and then apply old-age stereotypes to themselves and that older adults are better off if they can resist this self-stereotyping (Hess, 2006; Hummert, 2015; Kotter-Grühn, 2015). **Application 11.1** asks what else can be done to combat ageist stereotypes.

In sum, self-esteem appears to rise in early and middle adulthood and to drop off in old age. Older adults can maintain self-esteem, however, by bringing their ideal selves into line with their real selves, adjusting their goals and standards of self-evaluation, making social comparisons with other older people, and not applying negative stereotypes of old people to themselves.

Cultural Differences

Self-conceptions in adulthood show the imprint not only of age and gender but also of culture. Recall that in an *individualistic culture*, individuals are socialized to put their own goals ahead of their social group’s goals, whereas in a *collectivist culture*, people give group goals and relationships higher priority than personal goals. North American and Western European societies typically

● APPLICATION 11.1

Combating Negative Stereotypes of Aging

Frail, forgetful, lonely? What other negative stereotypes pop into your head when you think about “old people.” As you have seen, negative stereotypes of older adults can damage their self-perceptions, functioning, and longevity if they are internalized and applied to the self through self-stereotyping. So how might we as a society combat these ageist stereotypes and the harm they do?

Intervention might need to begin in childhood, as that is when we first learn ageist stereotypes (Kotter-Grühn, 2015). For example, intergenerational programs in which retired adults work with children in the schools not only help children learn but also improve their attitudes toward older people (Cummings, Williams, & Ellis, 2003).

Efforts to combat ageism need to be aimed at seniors too, though. If it’s all in their heads, it makes sense to change their negative views of aging (Kotter-Grühn, 2015). For example, activating positive stereotypes of aging before older people perform tasks can boost their cognitive performance (Levy, 2003) and physical functioning (Levy et al., 2014), at least temporarily. Moreover, telling older adults who just had their handgrip strength measured that they did much better than most people their age makes them feel younger and even makes them do better on a second test of handgrip strength (Stephan et al., 2013). Moreover, the activity levels and rated health of nursing home residents can be boosted by convincing them that the difficulties in

physical functioning they are experiencing are due to the nursing home environment (slippery tile floors, for example) rather than to aging (Rodin & Langer, 1980).

Other studies suggest that older adults may feel younger and even live longer if they minimize cues to their own aging—for example, by dyeing their hair or socializing or even living with people younger than themselves (Hsu, Chung, & Langer, 2010). Our society’s overvaluing of youthfulness may be part of what needs changing, however. Interventions like this could backfire if they only end up reinforcing negative views of aging (Kotter-Grühn, 2015).

Ultimately, broader societal change is needed. People in some countries (China and Japan, for example) have more positive views of old age and grant elders more respect than people the United States do (Levy & Langer, 1994). Possibly more positive views of aging can be promoted through social policies, media campaigns, and education and training programs (Braithwaite, 2002; Ferrario et al., 2008). While they are waiting for broad social change, older adults may be best off if they simply become more aware of the incorrectness of many negative stereotypes of old people and

What stereotypes do you have of elderly people—and to what extent do they believe the stereotypes apply to them?

Golden Pixels/Alamy Stock Photo

their potentially damaging effects, resist taking them personally, and avoid blaming every memory lapse or stumble on the ravages of old age.

have an individualistic orientation, whereas many societies in Latin America, Africa, and East Asia are primarily collectivist.

Hazel Markus and her colleagues have carefully studied the meanings of self in the United States and Japan (Cross, 2000; Markus, 2004; Markus, Mullally, & Kitayama, 1997; and see Heine & Buchtel, 2009). They have found that being a person in the United States (an individualistic culture) means being independent and different from other people, whereas being a person in Japan (a collectivist culture) means being interdependent with others. Thus, when asked to describe themselves, American adults talk about their unique personal qualities but Japanese adults more often refer to their social roles and social identities and mention other people (for example, “I try to make my parents happy”).

In addition, Americans describe their generalizable personality traits—traits they believe they display in most situations and relationships. By contrast, Japanese adults describe their behavior in specific contexts such as home, school, or work and often describe themselves differently depending on the social situation or context they are talking about. Interestingly, the Japanese language has no word to refer to *I* apart from social context (Cross, 2000). In short, Americans think like trait theorists and feel they have an inner self that is consistent across situations and over time, whereas Japanese people seem to adopt a social learning theory perspective on personality and see situational influences on behavior as powerful (Heine & Buchtel, 2009; Tafarodi et al., 2004).

Finally, Americans are more obsessed with self-esteem and show more self-enhancing biases when they evaluate themselves, believing they are above average (Harter, 2012). Japanese and other East Asian adults are more modest and self-effacing. They readily note their inadequacies and a desire to overcome them, seem reluctant to call attention to ways in which they are better than other people or even to make social comparisons, and are not as concerned with bolstering their self-esteem (Harter, 2012; Heine & Buchtel, 2009; also see ● **Table 11.3** for a summary of these differences).

Differences in self-descriptions between individuals in individualistic and collectivist cultures can be detected as early as age 3 or 4 (Wang, 2004, 2006). American children talk about their preferences, characteristics, and feelings, whereas Chinese children describe themselves in terms of social roles and social routines such as family dinners. They are a good deal more modest, too, saying things like “I sometimes forget my manners.” Parents probably help create these cultural differences through everyday conversations. For example, American mothers tell stories in which their children are the stars, whereas Chinese mothers talk about the experiences of the family as a group (Wang, 2004). Perhaps as a result, as American children become adolescents, they put less emphasis on their relationships with their parents in their self-definitions, whereas Chinese students continue to see their relationships with their parents as an integral part of who they are (Pomerantz, Qin, Wang, & Chen, 2009).

Cross-cultural studies of individualistic and collectivist cultures challenge the Western assumption that a person must individuate himself from others. In much of the world, it’s about “self-in-relation-to-others,” not about being a unique self distinct from others (Shweder et al., 2006). These studies even suggest that commonly used methods for studying the self and personality—asking people who they are, having them respond to global self-esteem scales, and giving them personality scales about how

they *generally* behave across social contexts—may be culturally biased. It is wise to remind ourselves, then, that the self is culturally defined.

Continuity and Discontinuity in Personality

As we now turn to personality development during adulthood, we must ask two questions:

- Do *individual* adults retain their rankings on trait dimensions compared with others in a group over the years?
- Do *average* scores on personality trait measures increase, decrease, or remain the same as age increases?

Do People Retain Their Rankings?

Paul Costa, Robert McCrae, and their colleagues have closely studied personality change and continuity by giving adults from their 20s to their 90s Big Five personality tests and administering these tests repeatedly over the years (McCrae & Costa, 2003, 2008). They have found a good deal of *consistency in rankings within a group*, as indicated by high correlations between scores on the same trait dimensions at different ages. In other words, the person who tends to be extraverted as a young adult is likely to be extraverted as an elderly adult, and the introvert is likely to remain introverted over the years. Similarly, the adult who shows high or low levels of neuroticism, conscientiousness, agreeableness, or openness to new experiences is likely to retain that ranking when compared with peers years later. Correlations between personality trait scores on two occasions 20–30 years apart average about 0.60 across Big Five personality dimensions, suggesting consistency in personality over time but also room for change (McCrae & Costa, 2003; Morizot & Le Blanc, 2003).

The tendency to be consistent increases with age. Analyzing many studies, Brent Roberts and Wendy DelVecchio (2000) found that the average correlation between scores at two testings increased quite steadily from infancy and early childhood to late adulthood, as shown in ■ **Figure 11.4**. Personalities are still forming in childhood and even adolescence and young adulthood; after around age 50, they are quite consistent (Lodi-Smith, Turiano, & Mroczek, 2011; Roberts & DelVecchio, 2000).

Do Mean Personality Scores Change?

But do most people change in similar ways over the years? You may be consistently more extraverted than your best friend over the years, and yet both of you could, along with others, become less extraverted from age 20 to age 70. This second major type of continuity in personality, *stability in the mean level of a trait*, is relevant when we ask whether there is growth in personality after adolescence or whether there is truth to stereotypes of older adults.

McCrae, Costa, and their colleagues (2000) have examined age-group differences in scores on the Big Five personality dimensions in countries as diverse as Turkey, the Czech Republic, and

● **Table 11.3** Views of the Self in Individualistic and Collectivist Cultures

Individualistic (e.g., United States)	Collectivist (e.g., Japan)
Separate	Connected
Independent	Interdependent
Emphasis on uniqueness	Emphasis on group memberships and similarities to others
Traitlike (personal qualities transcend specific situations and relationships)	Flexible (different in different social contexts)
Self-enhancing: Need for self-esteem results in seeing self as above average	Self-effacing: Self-critical, aware of inadequacies

Japan. They and other researchers have discovered a shift toward maturity in which people become more emotionally stable (less neurotic), more cooperative and easy to get along with, and more disciplined and responsible from adolescence to middle adulthood (see also Lodi-Smith et al., 2011; Roberts, Walton, & Viechtbauer, 2006; Roberts, Donnellan, & Hill, 2013). This shift toward greater emotional stability, agreeableness, and conscientiousness with age has come to be called the **maturity principle**.

Because this personality maturation shows up across cultures, Robert McCrae and Paul Costa (2008) concluded that it was probably built into the human species by evolution. Others believe that the maturity principle depends on more experience, especially entering roles that require responsible behavior—for example starting work, marrying, becoming a parent. If so, there should be differences across societies in the ages at which maturational changes in personality occur that can be linked to the ages at which adolescents and young adults enter key adult roles (Bleidorn, 2015).

To sort out this nature-nurture issue, Wiebke Bleidorn and his colleagues (2013) analyzed data from an online Big Five personality inventory completed by almost 900,000 young people ranging in age from 16 to 40 in 62 countries. The shift toward greater emotional stability, agreeableness, and conscientiousness was evident across cultures, suggesting that there could well be something universal and possibly biologically based about it. Yet the size of the shift was larger in some cultures than in others,

and it occurred earlier in cultures where the transition to work occurred early than in cultures where the work transition occurred later. The ages of typical transitions to marriage and parenthood in a culture did not make as much difference. Overall, then, this research and other studies like it suggest that both nature and nurture may be behind the maturation principle of personality development (Bleidorn, 2015).

What personality changes can people expect later—from middle age to old age? Not as many. So much for the accuracy of many stereotypes of older people. Activity level—the tendency to be energetic and action oriented, an aspect of extraversion—begins to decline in people’s 50s and continues declining through the 80s and 90s (McCrae & Costa, 2003). Otherwise, few consistent changes in personality in later life have been detected. Either we will remain much the same or we will change in response to life experiences but in our own ways and at our own times (Helson, Jones, & Kwan, 2002; but see Kandler et al., 2015).

Overall, most evidence points to (1) a good deal of cross-age consistency, more with age, in people’s rankings compared with other people on Big Five personality trait dimensions, as indicated by correlations; (2) personality growth from adolescence to middle adulthood in the form of the maturity principle (greater average emotional stability, conscientiousness, and agreeableness); and (3) little systematic personality change from middle adulthood to later adulthood except for a decreased activity level.

Why Do People Change or Remain the Same?

What makes personalities remain stable over the years? Here are a few ideas (see Roberts, Wood, & Caspi, 2008). First, *genetic makeup* contributes to continuity (Borkenau et al., 2001; Krueger & Johnson, 2008). Second, *lasting effects of childhood experiences*

Research on changes in personality during adulthood suggests that both the father and grandfather in this family may be more mature (emotionally stable, agreeable, and conscientious) than their son/grandson.

Ariel Skelley/Blend Images/Getty Images

may contribute. Third, traits tend to remain stable when people's *environments remain stable*; playing consistent social roles like mother or engineer may breed consistency in personality (Roberts, Wood, & Caspi, 2008). Fourth, *gene–environment correlations* can promote continuity. That is, genetic endowment may influence the kinds of experiences we have, and those experiences, in turn, may strengthen our genetically based predispositions through a kind of snowball effect (Caspi, 1998; Roberts & Caspi, 2003; also see Chapter 3). Thus, an extravert's early sociability will elicit friendly responses from others, cause her to seek out social activities, and in the process strengthen her initial tendency to be extraverted—while the introvert seeks and experiences an environment that reinforces introversion.

What, then, might cause the significant changes in personality that some adults experience? *Biological factors* such as disease and dementia can certainly contribute. The nervous system deterioration associated with Huntington's disease or Alzheimer's disease, for example, can cause affected individuals to become moody, irritable, and irresponsible (McCrae & Costa, 2003). Adult personalities also change in response to *changes in the environment*, including major life events, changes in social and

vocational roles, and psychotherapy (Lüdtke, Roberts, Trautwein, & Nagy, 2011; Sutin et al., 2010).

Finally, change is more likely when there is a *poor person–environment fit* (Roberts & Robins, 2004). For example, Florine Livson (1976) discovered that independent women who did not have traditionally feminine traits experienced more personality change during midlife than traditional women who fit the stereotypically feminine roles of wife and mother better. Bothered by the mismatch between their personalities and their traditionally feminine roles, the nontraditional women redirected their lives in their 40s, expressed their masculine sides more, and experienced better psychological health by their 50s (see also Livson, 1981; Weiss, Freund, & Wiese, 2012). For both men and women, a poor person–environment fit prompts personality change. The role of fit to one's culture in personality development and change over the life span is examined in **Exploration 11.1**.

Thus, genes, lasting effects of early childhood experiences, stable environments, and gene–environment correlations all contribute to the continuity seen in adult personality. Change in personality becomes more likely if people's biologies

● EXPLORATION 11.1

Personality and Culture: The Importance of Fit

The goodness of fit concept developed by Thomas and Chess to understand infant temperament and the person–environment fit concept used by John Holland and others to understand vocational development also help us think about personality development in its cultural context. Adults in some cultures, for example, value emotional expressiveness and assertiveness in children, whereas adults in other cultures want their children to be quiet, respectful, and self-controlled (Chen & Schmidt, 2015). These sorts of differences in cultural values translate into differences in personality development as children try to meet adults' expectations. They can also spell trouble for the child whose biologically based temperament is a poor fit to her cultural setting. So, for example, a difficult temperament tends to be maladaptive in many cultural environments (Thomas & Chess, 1977). Yet a difficult temperament proved very adaptive for Masai babies in East Africa during a famine: Their lusty crying got them more attention from caregivers (DeVries, 1984).

Another wonderful illustration of the importance of person–environment fit comes from

research by Xinyin Chen and his colleagues on the implications of shyness for children in Eastern and Western cultures (see Chen, Cen, Li, & He, 2005; Chen, Wang, & Wang, 2009; Chen, Yang, & Fu, 2012). In North America's individualistic culture, where autonomy and initiative are highly valued, shyness can be a disadvantage. It is sometimes linked to poor functioning at school and in social relationships, low self-esteem, and even depression. In China's collectivist culture, by contrast, the personality of the shy child has traditionally been prized and predicts good adjustment. Shy children are appropriately humble, do not call attention to themselves, and try to fit in rather than stand out. Interestingly, although shyness continues to be an asset in rural China today, it has become correlated with poor rather than good adjustment in urban areas of China. Why the change? Western capitalism has rapidly taken hold in China's cities and a more forceful, outgoing, and enterprising personality is now valued.

Finally, consider an intriguing study of adult personality and culture. Derya Güngör and colleagues (2013) gave personality scales to three

groups of young mothers: Japanese women living in Japan, European-American women living in the United States, and Japanese-American immigrants who had lived in the United States for an average of 5–6 years. The Japanese-American immigrants had a Big Five personality profile somewhere between that of the Japanese women and the European-American women, suggesting that their personalities may have changed to fit in better with their new American cultural setting. Their personalities were especially likely to be more American and less Japanese to the extent that they became highly acculturated to the United States and took on more American habits, friends, language usage, and so on.

We see, then, that an individual's historical and cultural environment, by influencing which personality traits are most valued, influences which traits are reinforced and strengthened and which prove most adaptive over the life span (Chen & Schmidt, 2015; Rothbart, 2011). We also learn that personality is not set in stone by genetic makeup; rather, it is malleable and can change shapes to achieve a better fit to its cultural environment (Güngör et al., 2013).

or environments change or if there is a poor fit between their personalities and lifestyles. All things considered, the forces for continuity are often stronger than the forces for change, perhaps in part because we want to retain our identities as individuals and because we keep building the same niches for ourselves even when we move, change jobs, or make other life changes (Roberts et al., 2008).

Personality and Adjustment

When all is said and done, personality has a tremendous impact on life-span development. Personal strengths such as emotional stability and conscientiousness are correlated with good physical and mental health (Kern & Friedman, 2010; Hampson & Friedman, 2008; Lucas & Diener, 2008). Moreover, personality affects how we react to and cope with life events. For example, highly agreeable people are able to adjust better than most people to becoming disabled (Boyce & Wood, 2011), and people high in emotional stability (low in neuroticism) handle the deaths of loved ones better (Robinson & Marwit, 2006). Personality—not only self-rated personality but personality as judged by friends—even predicts longevity (Jackson et al., 2015). In these and other ways, personality plays a critical role in adjustment throughout the life span.

Eriksonian Psychosocial Growth

The trait approach to studying personality focuses on enduring dispositional traits and probably reveals the most stable aspects of personality. We get a sense of much more growth and change from research inspired by Erikson’s psychoanalytic theory of psychosocial development through the life span. Erikson’s stages of psychosocial development are outlined in ● **Table 11.4** (see also Chapter 2). Both maturational forces and social demands, Erikson believed, push humans everywhere through these eight psychosocial crises. Later conflicts may prove difficult to resolve if early conflicts were not resolved successfully. For development to proceed optimally, a healthy balance between the terms of each conflict must be struck; if this happens, the individual gains a particular “virtue,” or psychosocial strength. Consider briefly how the self and personality unfold prior to adulthood according to Erikson before examining his adult stages.

The Path to Adulthood

During Erikson’s first psychosocial conflict **trust versus mistrust**, infants learn to trust other people if their caregivers are responsive to their needs; otherwise, the balance of trust versus mistrust will tip in the direction of mistrust. Erikson believed that infants come to recognize that they are separate from their caregivers. Indeed, as you saw earlier in this chapter, infants begin to distinguish self from other as early as the first 2 or 3 months of life.

Toddlers acquire an even clearer sense of themselves as individuals as they struggle with the psychosocial conflict of **autonomy versus shame and doubt**. According to Erikson, they assert that they have wills of their own. Consistent with this view, toddlers recognize themselves in a mirror and lace their speech with “me” around 18–24 months of age. Some “terrible twos” also make “no” their favorite word—a clear signal that they are now in charge.

Four- and five-year-olds who have achieved a sense of autonomy then enter Erikson’s stage of **initiative versus guilt**. They develop a sense of purpose by devising bold plans and taking great pride in accomplishing the goals they set (“I did it!”). As you have seen, preschoolers define themselves in terms of their physical activities and accomplishments. A sense of initiative, Erikson believed, paves the way for success when elementary school children face the conflict of **industry versus inferiority** and focus on mastering important cognitive and social skills. As you have seen, elementary school children engage in more social comparison than younger children and are likely to acquire a sense of industry rather than inferiority if those comparisons turn out favorably.

According to Erikson, children who successfully master each of these childhood psychosocial conflicts gain new ego strengths. Moreover, they learn a good deal about themselves and position themselves to resolve the adolescent crisis of **identity versus role confusion**, Erikson’s fifth stage, which was discussed in some detail earlier in this chapter.

What happens to adolescents with newfound identities during the adult years? Erikson thought that stagelike changes in personality—and exciting possibilities for personal growth—continue during adulthood through psychosocial crises focused on intimacy versus isolation, generativity versus stagnation, and

● **Table 11.4** The Eight Stages of Erikson’s Psychosocial Theory

Stage	Age Range	Central Issue	Virtue or Strength
1. Trust vs. mistrust	Birth–1 year	Can I trust others?	Hope
2. Autonomy vs. shame and doubt	1–3 years	Can I act on my own?	Will
3. Initiative vs. guilt	3–6 years	Can I carry out my plans successfully?	Purpose
4. Industry vs. inferiority	6–12 years	Am I competent compared with others?	Competence
5. Identity vs. role confusion	12–20 years	Who am I and where am I going?	Fidelity
6. Intimacy vs. isolation	20–40 years	Am I ready for a committed relationship?	Love
7. Generativity vs. stagnation	40–65 years	Have I given something to future generations?	Care
8. Integrity vs. despair	65 years and older	Has my life been meaningful?	Wisdom

integrity versus despair. In a longitudinal study of college students from their college years to their 40s and 50s, Susan Whitbourne and her colleagues (Whitbourne, Sneed, & Sayer, 2009) assessed progress in resolving all eight of Erikson's issues. They found steady growth even in qualities like trust and autonomy that are associated with the childhood stages, along with especially rapid growth in qualities related to the adult conflicts centering on intimacy, generativity, and integrity. So, as Erikson maintained, there is most certainly psychosocial growth throughout the life span.

Early Adult Intimacy

As Erikson saw it, early adulthood is a time for dealing with the psychosocial conflict of **intimacy versus isolation**. A person must achieve a sense of individual identity before becoming able to commit himself to a shared identity with another person. The young adult who has no clear identity may be threatened by the idea of entering a committed, long-term relationship and being “tied down,” or he may become overdependent on a romantic partner as a source of identity.

Does identity indeed pave the way for genuine intimacy? To find out, Susan Whitbourne and Stephanie Tesch (1985) measured identity statuses and intimacy statuses among college seniors and 24- to 27-year-old alumni from the same university. College graduates had progressed farther than college seniors in resolving intimacy issues. In addition, the college graduates who had achieved a sense of identity were more likely than those who had not to be capable of genuine and lasting intimacy. Specifically, they were more often in relationships in which they and their partners had close involvement in each other's lives, open communication about their feelings, and a long-term commitment to one another.

As Erikson theorized, then, we must know ourselves before we can truly love another person. Yet Erikson believed that women resolve identity questions when they choose a mate and fashion an identity around their roles as wife and mother-to-be. Is this old-fashioned view correct? Only for some women, especially those who develop in a sociocultural context with traditional gender-role expectations (Dyk & Adams, 1990; George, Helson, & John, 2011; Kroger, 2007). Other women, also influenced by traditional gender-role expectations, resolve intimacy issues before identity issues: They marry and have children and, only after the children are older, ask who they

are as individuals and pursue careers that suit their personalities (George et al., 2011). Still other women, especially those with less traditional gender-role orientations, follow the identity-before-intimacy route that characterizes most men, settling on a career first, thinking about a serious relationship later (Dyk & Adams, 1990). Today, more and more women are following this identity-before-intimacy path (Beyers & Seiffge-Krenke, 2010), further evidence that development is shaped by its historical and cultural context.

Midlife Generativity

What does psychosocial development look like in middle age? George Vaillant (1977), a psychoanalytic theorist, conducted an in-depth longitudinal study of mentally healthy Harvard men from college to middle age and a similar longitudinal study of blue-collar workers (Vaillant, 1983, 2012; Vaillant & Milofsky, 1980). Vaillant found support for Erikson's view that the 20s are a time for intimacy issues. He found that in their 30s, men shifted their energies to advancing or consolidating their careers and were seldom reflective or concerned about others. In their 40s, though, many men became concerned with Erikson's issue of **generativity versus stagnation**. This psychosocial conflict involves gaining the capacity to generate or produce something that outlives you and to care about the welfare of future generations. It is realized through such activities as parenting, teaching, mentoring, and leading (de St. Aubin, McAdams, & Kim, 2004; Slater, 2003).

Vaillant's 40-something men expressed more interest in passing on something of value to their own children, to younger people at work, or to their communities. They were growing as individuals, often becoming more caring and self-aware as they entered their 50s. One of these men expressed the developmental progression Vaillant detected perfectly: “At 20 to 30, I think I learned how to get along with my wife. From 30 to 40, I learned how to be a success in my job. And at 40 to 50, I worried less about myself and more about the children” (1977, p. 195).

Middle-aged men and women are more likely than young adults to have achieved a sense of generativity (de St. Aubin et al., 2004; McAdams, Hart, & Maruna, 1998). Moreover, those adults who have attained identity and intimacy are more likely than other adults to achieve generativity as well, as Erikson would predict (Christiansen & Palkovitz, 1998). The middle-age conflict of generativity versus stagnation may

Early adulthood is the time, according to Erik Erikson, for deciding whether to commit to a shared identity with another person—for resolving the conflict of intimacy versus isolation.

Reminiscence and life review can help older adults achieve a sense of integrity.

Masterfile

play out differently in different cultural contexts; for example, for Mexican-American parents with a collectivist orientation it may center on relationships with children, whereas for Anglo-Americans it may more often center on individual contributions such as book writing or community service (de St. Aubin & Bach, 2015). Either way, research supports Erikson's view that both women and men are capable of impressive psychosocial growth during middle adulthood.

Old-Age Integrity

Elderly adults, according to Erikson, confront the psychosocial issue of **integrity versus despair**. They search for a sense of meaning in their lives that will help them face the inevitability of death. If they constructed a life story or narrative identity during their early adult years, they may work on accepting it in old age as the only life they could have led (McAdams, 2011; McAdams & Adler, 2006). Those older adults who achieve integrity tend to be well-adjusted people who think in mature and complex ways and have a sense of great well-being (Hearn et al., 2012; James & Zarrett, 2005; Torges, Stewart, & Duncan, 2008).

Noted gerontologist Robert Butler (1963) proposed that older adults engage in a process called **life review**, in which they reflect on unresolved conflicts of the past to come to terms with themselves, find new meaning and coherence in their lives, and prepare for death (see also Haber, 2006; Webster & Haight, 2002). Elders who engage in life review display a stronger sense of integrity and better overall adjustment and well-being than those who do not reminisce much or who mainly stew about unresolved regrets (Bohlmeijer et al., 2007; Wong & Watt, 1991). Finding that life review can be beneficial, Butler and other gerontologists have turned it into a therapy approach in which elderly adults reconstruct and reflect on their life stories, sometimes with the

help of photo albums and other memorabilia (Haight & Haight, 2007; Kunz & Soltys, 2007).

On balance, Erikson's view that humans experience psychosocial growth throughout the life span is well supported by research. Erikson's childhood stages capture important milestones in the development of the self, and there is support for his idea that achieving a sense of identity in adolescence paves the way for forming a truly intimate relationship in early adulthood, gaining a sense of generativity in middle adulthood, and resolving the issue of integrity versus despair through life review in later adulthood.

Midlife Crisis?

Midlife is when you reach the top of the ladder and find that it was against the wrong wall. (Joseph Campbell, cited in S. Weiss, 2008)

This quotation captures the essence of midlife crisis. But where in all the evidence of stability and change in personality traits over the adult years and of psychosocial growth through Erikson's stages is the midlife crisis that many people believe is a standard feature of personality development in middle age? Although Erikson, and Vaillant after him, saw few signs of a midlife crisis, another psychoanalytic theorist, Daniel Levinson (1986, 1996; Levinson et al., 1978) did. He proposed a stage theory of adult development based on intensive interviews with 40 men and later reported that it applied to a sample of women he interviewed as well (Levinson, 1996).

Levinson claimed that adults worldwide go through a repeated process of first building a "life structure," or overall pattern of living, and then questioning and altering it during a transition period every 7 years or so. He believed that the transition period from age 40 to age 45 is an especially significant transition, a time of **midlife crisis** in which a person questions his life structure and raises unsettling issues about where he has been and where he is heading. Most middle-aged adults Levinson interviewed did not seek divorces, quit their jobs, buy red sports cars, or behave like lovesick adolescents, as popular images of the midlife crisis would have it. However, most did seem to experience a significant psychological crisis in their early 40s.

In support of Levinson, many researchers agree that middle age is often a time when people confront important issues like aging, evaluate their lives, and revise their goals (Freund & Ritter, 2009; Hermans & Oles, 1999; McAdams & Adler, 2006). There is even intriguing evidence that life satisfaction shows a U-shaped pattern over the adult years, decreasing from early adulthood to a low in middle adulthood and then increasing from middle adulthood to old age (Cheng, Powdhavee, & Oswald, 2016). In addition, some middle-aged adults change in response to life events. So it was for K., a woman who was thrown off balance in her 40s by her father's death, her mother's stroke, her husband's leaving her, and a layoff from work and who told herself that "at least she had so many troubles that she couldn't dwell on all of them at once" (Rauch, 2014, p. 92).

In the end, though, there is not much support for Levinson's claim that adults universally experience a genuine psychic crisis in the narrow age range of 40 to 45 (Freund & Ritter, 2009; Hedlund & Ebersole, 1983; Vaillant, 1977). It seems sounder to call what many middle-aged adults experience *midlife questioning*, to recognize that it can occur in response to life events at a variety of ages, and to appreciate that it is usually not a true psychological crisis. The cultural context also must be considered: Midlife may be viewed more positively in a culture like Japan where people believe that we become wiser and more capable as we age than in a youth-oriented culture like the United States where middle age may be viewed as the beginning of decline (Menon, 2015).

Vocational Development and Adjustment

Although Levinson's concept of midlife crisis is not well supported, he was right to emphasize that adults revise important life decisions as they develop. To illustrate, consider adult vocational development, an outgrowth and expression of an individual's self-concept and personality (George et al., 2011; Judge & Bono, 2001). After much experimenting in early adulthood, people settle into chosen occupations in their 30s and strive for success. Ultimately, they prepare for the end of their careers, make the transition into retirement, and attempt to establish a satisfying lifestyle during their "golden years."

Establishing a Career

Early adulthood is a time for exploring vocational possibilities, launching careers, making tentative commitments, revising them if necessary, seeking advancement, and establishing yourself firmly in what you hope is a suitable occupation. This often takes time and involves lots of false starts and job changes.

To illustrate, Susan Phillips (1982), using data from a longitudinal study of males tracked from adolescence to age 36, examined whether men's decisions about jobs at different ages were tentative and exploratory (for example, "to see if I really liked that kind of work") or more final (for example, "to get started in a field I wanted [to enter]"). The proportions of decisions that were predominantly exploratory were 80% at age 21, 50% at age 25, and 37% at age 36. From age 21 to age 36, then, young adults progressed from wide-open exploration of different career possibilities to tentative or trial commitments to a stabilization of their choices. Even in their mid-30s, however, about a third of adults were still exploring what they wanted to be when they grew up! A recent longitudinal study of Americans born from 1957 to 1964 confirms this, showing that the average worker held almost 12 jobs from age 18 to age 48 (Bureau of Labor

Statistics, 2015). Nearly half of these were held from age 18 to 24; job change declined with age but was still happening in people's 40s. This picture of frequent job change was very similar for men and women.

After their relatively unsettled 20s and decision-making 30s, adults often reach the peaks of their careers in their 40s (Simonton, 1990). They often have major responsibilities and define themselves in terms of their work. Personality is an important influence on how successful a person becomes. Vocational success is consistently correlated with Big Five qualities such as conscientiousness, agreeableness, extraversion, and emotional stability (Ozer & Benet-Martinez, 2006; Sackett & Walmsley, 2014). Person-environment fit can be critical too: People tend to perform poorly and become open to leaving their jobs when the fit between their personality and aptitudes and the demands of their job or workplace is poor (Hoffman & Woehr, 2006; Nye et al., 2012).

Gender is another significant influence on vocational choice and development. Although women are entering a much wider range of fields today and aiming higher than they were a few decades ago, most administrative assistants, teachers, and nurses are still women, and overall working women still earn less than men. Although gender discrimination is a contributor, gender differences in vocational success and earnings also arise because traditional gender-role norms have led many women to subordinate career goals to family goals. Women are more likely than men to interrupt their careers, drop down to part-time work, take less demanding jobs, and turn down promotions that would require transferring to a new location so that they can have and raise children (Biemann, Zacher, & Feldman, 2012; Kirchmeyer, 2006; Moen, 1992). In the process, women have ended up with lower odds of rising to higher paid, more responsible positions.

Since the recession of 2008, many adults have experienced the stress that accompanies unemployment.

Frances Roberts/Alamy Stock Photo

So, although we make preliminary vocational choices as adolescents, we remain open to making new choices as young and even middle-aged adults and take some time to settle on careers that fit our personalities and gender roles. Meanwhile, our vocational experiences affect our personalities (Wille, Beyers, & De Fruyt, 2012). For instance, people whose work is complex and intellectually challenging become able to handle intellectual problems more adeptly and self-confidently (Kohn & Schooler, 1982; Schooler, Mulatu, & Oates, 1999). Mentally challenging work even appears to help people maintain good cognitive functioning when they reach old age (Then et al., 2015). Attaining a responsible position at work can also make people more conscientious and emotionally stable (Roberts et al., 2008). In the end, person–environment fit and the dynamic, reciprocal influences of personality on career and of career on personality shape adult vocational development (Hesketh, Griffin, & Loh, 2011; Wille et al., 2012).

Job Loss and Unemployment

How are adults affected when they suddenly lose their jobs? As we continue to live with the effects of the global economic recession that began in 2008, this is an especially important question to ask. Because work is such a central part of adulthood, job loss and unemployment can threaten adults’ identities, disrupt their goals, and lower their self-esteem (Brand, 2015; Price, Friedland, & Vinokur, 1998). Moreover, job loss is likely to be accompanied by a cascade of other stressors such as the need to apply for unemployment benefits, alter routines, move to cheaper housing, or borrow money. It can, as a result, have negative effects on both physical and mental health (Brand, 2015; Feldman & Ng, 2013;

Howe et al., 2012). In the long run, one instance of unemployment may not have much lasting effect. However, after they have retired, adults who had repeated periods of unemployment experience more depression and anxiety symptoms and have lower life satisfaction than those who managed to stay employed during their adult years (Zenger, Brähler, Berth, & Stöbel-Richter, 2011).

Unemployment also affects the individual’s whole family (Brand, 2015). Not only may job losers become angry and depressed, but their partners may too, and the quality of the couple’s relationship may suffer (Howe, Levy, & Caplan, 2004). When economic hardship causes parents to be depressed and to fight with one another, parenting often deteriorates. As a result, children’s behavior problems tend to increase while their performance in school and their well-being suffer (Brand, 2015; Conger et al., 1992; and see Chapter 15). In sum, the whole family may need help coping with job loss.

The Aging Worker

Many people believe that adults become less able or less motivated to perform well on the job as they approach retirement. As it turns out, the job performance of workers in their 50s and 60s is largely similar overall to that of younger workers (Rhodes, 1983). Judging from a meta-analysis of multiple studies (Ng & Feldman, 2008), age is largely unrelated to quality of task performance and creativity on the job. Older workers actually outperform younger workers in areas such as good citizenship and safety and have fewer problems with counterproductive behavior such as aggression, substance use, tardiness, and absenteeism. Most negative stereotypes of older workers are baseless (Ng & Feldman, 2012).

Why is the performance of older workers not hurt by some of the age-related physical and cognitive declines described earlier in this book? First, these declines typically do not become significant until people are in their 70s and 80s, long after they have retired, and even then they do not affect everyone. The “older” workers in most studies are mainly middle-aged adults in their 40s, 50s, and 60s. Second, older workers have often accumulated a good deal of on-the-job expertise that helps them continue to perform well (Hansson et al., 1997).

Third and finally, the answer may lie in the strategies that aging adults use to cope with aging. Gerontologists Paul and Margaret Baltes (1990) theorized that older people can best cope with aging through the strategy of *selective optimization with compensation* (SOC) (Baltes & Baltes, 1990; Lang, Rohr, & Williger, 2011; and see Chapter 8). Using SOC, an overworked 60-year-old lawyer might, for example, avoid spreading herself too thin by focusing on her strongest specialty area and delegating other types of assignments to younger workers (selection); put a lot of time into staying up-to-date in her main area of specialization (optimization); and make up for her failing memory by taking more notes at meetings (compensation). For pianist Arthur Rubenstein,

Figure 11.5 Male and female labor force participation by age group in the United States in 2014. Labor force participation increases in people’s 20s, peaks in their late 20s through 40s, and declines steeply starting at age 55. Most adults are out of the labor force by age 65–69. Men’s participation is higher than women’s, especially during the child-rearing years, but the gender gap is much narrower than it used to be.

Source: U.S. Department of Labor, U.S. Bureau of Labor Statistics; Table 3.3, Civilian labor force participation rates by age, sex, race, and ethnicity. www.bls.gov/emp/ep_table_303.htm.

maintaining excellence in old age meant playing fewer different pieces (selection), practicing them more (optimization), and compensating for loss of speed by increasing the contrast between the slower and faster parts of a piece to make the faster parts sound faster (Baltes, Lindenberger, & Staudinger, 2006).

The federal government may have recognized that older workers are generally effective workers when it raised or eliminated mandatory retirement ages, increased the age of eligibility for receiving Social Security, and, through the Age Discrimination in Employment Act, protected workers age 40 and older from age discrimination in hiring and retention (Hansson et al., 1997). But job applicants in their 60s, especially women, are still discriminated against by employers, even when they have the same credentials as younger applicants (Neumark, Burn, & Button, 2015), and older workers still have more difficulty than younger ones getting rehired after losing a job (Wanberg et al., 2016). So, much remains to be done to combat ageism in the workplace and to meet the needs of those who have the desire and ability to continue working well into old age (see Hedge, Borman, & Lammlein, 2006).

Retirement

A century ago in North America, most working adults continued working as long as they were able, as people in many traditional societies today do. The introduction of Social Security in 1934, affluence, and the increased availability of private pension plans changed that, making it financially possible for more men and women to retire and to do so earlier. And they have! As shown in **Figure 11.5**, the labor force participation of men and women increases in early adulthood, plateaus, and then starts decreasing steeply in people's late 50s. As of 2014, around half of adults were out of the labor force by age 62–64, over two-thirds were out by age 65–69, and over 90% were out by age 75 and older. From the 1960s to the 1990s, the average age of retirement dropped from over 67 to 62. However, it has been inching up again since the mid-1990s. In 1991, only about 1 in 10 workers intended to keep working beyond age 65; now almost 4 in 10 do (Reid, 2015). Why the recent rise in the retirement age? Today's older workers are healthier and want to keep contributing, mandatory retirement policies are gone, economic uncertainty and rising health care costs make people feel they need or want to continue working for financial reasons, and the age of eligibility for full Social Security benefits has increased (Song & Manchester, 2009; Toossi, 2012).

Retirement is not a single event; it is a process that often plays out over a number of years. While some workers do retire “cold turkey” all at once, many others retire gradually, cutting back their work hours, becoming self-employed, taking part-time “bridge” jobs between full-time work and retirement, and sometimes cycling in and out of retirement multiple times before they settle into full retirement (Calvo, Haverstick, & Sass, 2009; Zissimopoulos & Karoly, 2009).

How do people adjust to the final chapter of the work life cycle? They face two main challenges: adjusting to the loss of their work role and developing a satisfying and meaningful lifestyle in retirement (van Solinge & Henkens, 2008). Robert Atchley (1976) proposed that adults progress through phases as they make the transition from worker to retiree. The process of adjustment begins with a *preretirement phase* in which workers nearing

retirement gather information and plan for the future (Ekerdt, Kosloski, & DeViney, 2000). Discussing retirement with one's spouse and working out a financial plan during the preretirement phase are likely to pay off in greater well-being after retirement (Noone, Stephens, & Alpass, 2009).

Just after they retire, according to Atchley, workers often experience a *honeymoon phase* in which they relish their newfound freedom; they head for the beach, golf course, or camp grounds and do all the projects they never had time to do while they worked. Then, according to Atchley, many enter a *disenchantment phase* as the novelty wears off; they feel aimless and sometimes unhappy. Finally, they move to a *reorientation phase* in which they begin to put together a realistic and satisfying lifestyle.

Consider Don, a businessman who retired early at age 58. In the first weeks, he took trips and renovated his house: “That was great—I loved it.” But after some months of this fun and of taking on more volunteer consulting jobs than he intended, he was reassessing how he wanted to spend his time and worrying that his money might not last: “Here I am over a year down the road and I don't like where I am. I don't think I've got my life coursed out correctly.” After a few more months, he felt he'd worked out a lifestyle that suited him.

Research offers some support for Atchley's view of the adjustment process. For example, David Ekerdt and his colleagues (Ekerdt, Bossé, & Levkoff, 1985) found that (1) men who had been retired only a few months were in a honeymoon period, highly satisfied with life and optimistic about the future, (2) men who had been retired 13–18 months were rather disenchanting, and (3) men who had been retired for longer periods were relatively satisfied. Yet not everyone fits this pattern; for example, almost half of retirees in one study adjusted easily and within a month to retirement, whereas one in five found it took much longer and was challenging (van Solinge & Henkens, 2008).

After retirees have adjusted to retirement, are they better or worse off than they were before they retired? Negative images of the retired person abound; the retiree supposedly ends up feeling old, useless, bored, sickly, and dissatisfied. Yet research shows that retirement has surprisingly few effects on adults (Hansson et al., 1997; Palmore et al., 1985). Retirement's most consistent effect is to reduce the individual's income (Palmore et al., 1985). This is a problem in that many people, especially women and minorities, have very little saved up for retirement, whether because their earnings were low when they worked, they did not save enough, they were not eligible for pensions, or other reasons (Copeland, 2014; Rhee, 2013a, 2013b). For example, three out of four Black households and four out of five Latino households with adults in the 25–64 age range have less than \$10,000 in retirement savings, compared to about half of white households (Rhee, 2013a).

However, apart from experiencing a drop in income, retired people fare well. They generally do not experience a decline in health simply because they retire. Poor health more often causes retirement than retirement causes poor health. Similarly, retirement does not typically diminish cognitive functioning (Coe et al., 2012), or cause a deterioration of people's social networks and social interactions, lower people's life satisfaction, or undermine their mental health (Palmore et al., 1985).

In sum, retirees are likely to experience an initial adjustment process, sometimes involving preretirement and then honeymoon, disenchantment, and reorientation phases. They then usually adapt successfully to retirement and to the drop in income that it typically involves. Yet there are huge differences in how it goes. What makes for a good adjustment? According to research (Bender, 2012; Palmore et al., 1985; Wang, Henkens, & van Solinge, 2011; Wong & Earl, 2009), good long-term adjustment to retirement is most likely among adults who:

- retire voluntarily rather than involuntarily and feel in control of their retirement decision
- enjoy good physical and mental health
- have positive personality traits such as agreeableness and emotional stability
- have the financial resources to live comfortably
- are married or otherwise have strong social support

Personality and Successful Aging

What lifestyle decisions make not only for a successful transition to retirement but also for a happy and fulfilling old age? Several theories have been offered about the best path to a satisfying old age (Stowe & Cooney, 2015). Some have emphasized the value of staying highly active (Havighurst, Neugarten, & Tobin, 1968). Others have argued that our needs change in later life and we want to disengage from society—retire from work, drop out of some activities, build a more relaxed lifestyle (Cumming & Henry, 1961). After reading this chapter, we hope you can appreciate that there is no one path to successful aging that fits all.

We must take the role of personality into consideration. A good fit between the individual's lifestyle and the individual's needs, preferences, and personality seems to be the real secret to successful aging (Fry, 1992; Seleen, 1982). Energetic and outgoing Linda may want to maintain her active lifestyle in old age by being highly involved in church activities and family affairs, whereas Albert, who always found work to be stressful and annoying, may like nothing better than to disengage by fishing the day away. Linda might be delighted but Albert might be miserable if made to participate in a retirement community's sing-alongs and skits. In sum, the key to successful aging can be found in the person–environment fit concept that helps explain adjustment throughout the life span.

Some seniors believe that the key to successful aging is a highly active lifestyle, but what suits one type of person may not suit others.

● Checking Mastery

1. Identify two different senses in which there could be continuity in the Big Five dimension of conscientiousness from age 40 to age 50.
2. According to Erikson, when and how might an adult gain a sense of generativity?
3. Who theorizes that adults experience a true midlife crisis in their early 40s, and what does research say about that?
4. What are three factors likely to make retirement a negative experience?

● Making Connections

1. After reading this chapter, what makes you optimistic that you may well be a better person at age 50 than you are now? Cite specific findings.
2. If you were counseling adults in their 50s about retirement, what would you say?

Chapter Summary

11.1 Conceptualizing the Self and Personality

- Personality is an organized combination of attributes unique to the individual. McAdams and Pals describe personality in terms of three aspects: dispositional traits, characteristic adaptations, and narrative identities. Self-concept is an individual's perceptions of those attributes; self-esteem is one's overall evaluation of self-worth; and identity is a coherent self-definition.
- Psychoanalytic theorists such as Erikson maintain that we all experience stagelike personality changes at similar ages; trait theorists believe that aspects of personality such as the Big Five trait dimensions are expressed across situations and are enduring, and social learning theorists maintain that people can change in any number of directions at any time if their social environments change.

11.2 The Infant

- Early in their first year, infants sense that they are separate from the world around them and develop a sense of agency; at around 18 months, possibly later in collectivist cultures, they display mirror self-recognition and form a categorical self based on age and gender.
- Infants differ in temperament: in easy, difficult, or slow-to-warm-up temperament (Thomas and Chess), and in surgency/extraversion, negative affectivity, and effortful control (Rothbart). Temperament is influenced by genes and goodness of fit with the environment, and some dimensions of temperament match up with Big Five personality dimensions.

11.3 The Child

- Whereas the self-concepts of preschool children are focused on physical characteristics and activities, 8-year-olds describe their inner psychological traits and social ties and evaluate their competencies through social comparison.
- Children are most likely have high self-esteem when they have the genes for it, are competent, receive positive feedback in social comparisons, and have warm, democratic parents.
- Links between temperament in early childhood and later personality and adjustment are evident, but some personality traits do not gel until middle childhood or even later.

11.4 The Adolescent

- During adolescence, self-concepts become more psychological, abstract, differentiated, integrated, and reflected upon; self-esteem dips for some but mainly holds steady or increases over adolescence.
- In resolving Erikson's conflict of identity versus role confusion, many college-age youths progress from the diffusion or

foreclosure to the moratorium and identity achievement statuses, at different rates in different domains. Analyzing life stories, or narrative identities, is another approach to studying identity.

- Developing a positive ethnic identity is more central to minority than to majority group adolescents and has many benefits.
- Vocational choices become increasingly realistic from childhood through adolescence; the choices made by low-income youth and females are sometimes constrained, but as John Holland theorized, a good person–environment fit between personality and vocation predicts good vocational outcomes.
- Cognitive development, personality, parenting, opportunities for exploration, and culture all influence identity development.

11.5 The Adult

- Although self-esteem typically rises through middle age and declines in late old age, older adults can maintain self-esteem by converging their ideal and real selves, changing their standards of self-evaluation, comparing themselves with other aging adults, and resisting ageist self-stereotyping. Self-conceptions differ in individualistic cultures and collectivist cultures.
- Individuals' rankings on the Big Five dimensions of personality, as indicated by correlations, become more stable with age; at the same time, a shift called the maturity principle from adolescence to middle age, evident across cultures, brings higher levels of emotional stability, conscientiousness, and agreeableness. In later adulthood few changes other than a decline in activity level are consistently observed.
- Stability of personality may be caused by genes, early experience, stable environments, and gene–environment correlations; personality change may result from biological or environmental changes or a poor person–environment fit, including a poor fit to one's culture.
- Consistent with Erikson's psychosocial theory, resolution of early conflicts paves the way for achieving intimacy in early adulthood, generativity in middle age, and integrity through life review in old age.
- Daniel Levinson's theory that adults experience a midlife crisis in their early 40s is not well supported, but young adults do engage in much career exploration and questioning before they settle down in their 30s and achieve peak success in their 40s. Older workers are generally as effective as younger workers, in part because they use selective optimization with compensation (SOC) to cope with aging.
- Retiring workers may experience preretirement, honeymoon, disenchantment, and reorientation phases, and a drop in income, but little change in health, social involvement, or psychological well-being. However, several factors influence adjustment to retirement.
- When explaining successful aging in general, it is useful to consider person–environment fit.

Changes in Gender Roles
Changes in Sexuality

Many of us have grown up taking our sex and gender for granted and living comfortably in our assigned category: male–female, boy–girl, man–woman. But are sex and gender really so simple that they can be captured with two distinct categories? Consider Kathryn who, at age 2, told her parents that she was a boy (see Dvorak, 2012). She was so determined that she was a boy and so unhappy about being viewed as a girl that her parents took her to a psychologist for advice. After much thought, they allowed their child to begin living as a boy, changed his name, shopped for “boy” clothes and toys, and referred to their child with masculine pronouns. The family’s decision to allow their child to make this change was influenced, in part, by another family whose son, “Will,” struggled throughout childhood with his male sex and gender, firmly believing that he was a girl (Dvorak, 2012). He threatened suicide at age 6 and was taken to therapists who concluded that the child “was probably just gay.” It wasn’t until their child was a teenager that the family finally capitulated and allowed “him” to live as “her,” but then felt great remorse for forcing the male gender on their child for so long, leading to a childhood of misery.

● ENGAGEMENT 12.1

Test Your Understanding of Sex and Gender

Which of the following are “real” sex differences or accurate characterizations of gender? Mark each statement true or false. Answers are printed upside down; they will be clarified in the main text.

1. _____ Males are more aggressive than females.
2. _____ Gender identity is determined by whether a person is born with male or female genitals.
3. _____ Sexual orientation can be changed with counseling.
4. _____ Females have stronger verbal abilities than males.

5. _____ Androgynous people have a mix of both feminine and masculine traits.
6. _____ Gender identity is determined by parenting styles.
7. _____ Gender stereotypes represent the roles associated with men and women in society.
8. _____ Men typically score higher than women on standardized tests of mathematical ability.

Answers: 1-T, 2-F, 3-F, 4-T, 5-T, 6-F, 7-T, 8-T.

As illustrated by these two examples of **transgender** children—individuals who identify with a gender other than their biological one—sex and gender may not be as simple as we try to make them. These are not new issues. Among many Native American cultures, there has long been a third gender category (“two spirits”) for those individuals who do not neatly fit into the male or the female category (Bonvillain, 2012). Similarly, in India, the term *hijras* is used to describe third-sex individuals, often individuals with biologically male or ambiguous genitalia who dress in ways that appear feminine but do not view themselves as either male or female. And in Sulawesi, an island in Indonesia, as many as five gender categories are recognized to capture the diversity of this characteristic (Davies, 2007). Clearly, there is much more complexity than the dichotomy of male-female, man-woman, suggests.

Gender matters. It used to be that the first question asked following a birth was whether the baby was a boy or girl. With today’s technology, this question is often posed as soon as a pregnancy is announced and the answer to this question begins to influence how we think of the developing child. In most cases, as children develop, girls discover that they are girls and many acquire a taste for wearing pink clothes and playing with dolls, while boys discover that they are boys and often wrestle each other on the lawn. As an adult, you may define yourself partly in terms of roles or activities that highlight gender, such as mother, boyfriend, husband, wife, and so on. In short, being female or male is a highly

Indian *hijras*, “neither women nor men,” challenge the concept that gender can be fully characterized by two distinct categories of women and men.

PawelBienkowski/photos/Alamy Stock Photo

important aspect of the self throughout the life span. Before you read any further, try the quiz in **Engagement 12.1** to see if you know which of the many beliefs we hold about males and females have some truth to them.

12.1 Sex and Gender

LEARNING OBJECTIVES

- Distinguish between the concepts of sex and gender.
- Explore the emergence of gender stereotypes and explain the two main gender roles.
- Evaluate whether it makes more sense to talk about gender differences or gender similarities.

Chances are good that sex and gender have influenced several characteristics that make you the unique person that you are, from your physical characteristics and abilities, to some of the roles you play in society, to some of your psychological characteristics. When we talk about your **biological sex**, we mean those physical

characteristics that define male and female, whereas **gender** incorporates all those features that a society associates with or considers appropriate for men and women. For example, females menstruate as a result of their hormonal and physiologic makeup, making this a component of their biological sex. Males typically

have larger bones and muscle mass than females, another biological sex difference. Consider, though, that women as a group earn less money than men. This is not a sex difference but a gender difference because it arises from societal forces that have created different expectations and outcomes for males and females in the workforce. To understand how sex and gender might influence your life, let us consider some of the obvious physical differences before examining the psychological correlates of gender.

The physical differences between most males and most females are undeniable. A zygote that receives an X chromosome from each parent is a genetic (XX) female, whereas a zygote that receives a Y chromosome from the father is a genetic (XY) male. In rare cases of sex chromosome abnormalities (see Chapter 3), this is not the case; a girl may have only one X chromosome or a boy may have three sex chromosomes (XYY or XXY). Chromosomal differences result in different prenatal hormone balances in males and females, and hormone balances before and after birth are responsible for the fact that males and females have different genitalia. Males typically grow to be taller, heavier, and more muscular than females, although females may be the hardier sex in that they live longer and are less susceptible to many physical disorders (but see Van Oyen et al., 2013 for a discussion of how longer life span may come at the cost of living with greater infirmities). As you will see later in the chapter, some theorists argue that biological differences between males and females are responsible for psychological and social differences.

There is, however, much more to being a man or woman than the biological features that define one's sex. Virtually all societies expect the two sexes to take on different **gender roles**—the patterns of behavior that females and males should adopt in a particular society (for example, the roles of wife, mother, and woman for females and of husband, father, and man for males). Characteristics and behaviors viewed as desirable for males or females are specified in *gender-role norms*—society's expectations or standards concerning what males and females *should be* like. Each society's norms generate **gender stereotypes**, overgeneralized and largely inaccurate beliefs about the characteristics of all males and all females (Halim & Ruble, 2010). For example, when trying to decide who should drive to a friend's house in an unfamiliar location, John may say to his new girlfriend, "I'll drive because you women always get lost," to which she replies, "Well, unlike you guys, at least women stop to ask for directions." They have both applied stereotypes about a group to an individual member of the group. The reality is that this particular woman may be a superb navigator and John may be highly likely to stop and ask for directions. Where did such gender stereotypes come from and is there any truth behind them?

Gender Roles and Stereotypes

Many stereotypes originate with a grain of truth, and in the case of gender stereotypes, the grain may be the physical makeup of males and females. One clear physical difference between the sexes is women's ability to bear and nurse children. As a result, women have adopted the role of childbearer and nurturer and this role has shaped the gender-role norms that prevail in many societies, including our own. At the heart of the nurturer gender role is

communality (or communion), an orientation that emphasizes connectedness to others and includes traits of emotionality and sensitivity to others (Abele & Wojciszke, 2014; Best & Williams, 1993). Girls who adopt communal traits will presumably be prepared to play the roles of wife and mother—to keep the family functioning and to raise children successfully. By contrast, the central aspect of the masculine gender role is **agency**, an orientation toward individual action and achievement that emphasizes traits of dominance, independence, assertiveness, and competitiveness. Boys have been encouraged to adopt agentic traits to fulfill the traditionally defined roles of husband and father, which involve providing for the family and protecting it from harm. Taking this one step further, Baron-Cohen (2003) claims that men's focus on work, achievement, and independence stems from the male brain's tendency to **systemize**, or analyze and explore how things work. Communion and agency have long been viewed as two fundamental psychological dimensions of human nature that are widespread across a variety of cultures (Abele & Wojciszke, 2014).

With gender-role norms in many cultures mandating that females play a communal role and males play an agentic role, stereotypes have arisen saying that females possess communal traits and males possess agentic traits (Williams & Best, 1990). If you are thinking that these stereotypes have disappeared as attention to women's rights has increased and as more women have entered the labor force, think again. Although some changes have occurred, children, adolescents, and adults still endorse many traditional stereotypes about men and women (see Sczesny et al., 2008). Boys are more likely than girls to endorse traditional stereotypes, perhaps because stereotypes about males (such as "independent") tend to be more positive than the stereotypes about females (for example, "dependent") (Rowley et al., 2007).

Moreover, males and females continued to describe themselves differently after gender roles changed dramatically during the 20th century. When Jean Twenge (1997) analyzed studies conducted from 1970 to 1995 in which standard scales assessing gender-relevant traits had been administered, she found that men and women in the mid-1990s described themselves more similarly than men and women did 20 years previously, largely because modern women saw themselves as having more agentic traits. In the 20 years since this analysis, women have continued to identify about the same as before with masculine traits, but their identification with feminine traits has declined (Donnelly & Twenge, 2016). Traditional feminine gender roles just do not seem to resonate with most of today's young women. Most millennials, male and female, embrace egalitarian views about the roles for men and women (Donnelly & Twenge, 2016).

Gender Differences or Similarities?

Much research has attempted to answer the question of whether there are meaningful behavioral or psychological differences based on one's sex or gender. Although differences in some areas have been identified, other areas show no gender differences. Early research on gender seemed focused on trying to reveal differences of any size or value, and psychological differences between men and women were emphasized (see, for example,

Tannen, 1991). More recently, Janet Hyde (2005, 2007, 2014) and others have proposed that it is more appropriate to focus on gender similarities. They advance a **gender similarities hypothesis**, which states that “males and females are similar on most, but not all, psychological variables. That is, men and women, as well as boys and girls, are more alike than they are different” (Hyde, 2005, p. 581). As you review the following research on gender, try to evaluate for yourself whether there are more gender similarities or differences, and where there are differences, decide whether they are large and meaningful or negligible and unimportant. Also keep in mind that these are *group differences*, and even when research shows that women score higher (or lower) than men on average, there will be individual women who score lower (or higher) than individual men. With this in mind, here is what the research shows:

- There are fairly large differences in how most men and most women perceive themselves in terms of gender identity. In particular, *most men hold a masculine gender identity, whereas most women have a feminine gender identity* (Hines, 2015).
- *Boys and girls engage in different play activities*. These differences seem to arise from a combination of hormone-driven preferences and a society that promotes the “genderization” of children throughout their development (Berenbaum & Meyer-Bahlburg, 2015; Hines, 2015).
- *Females sometimes display greater verbal abilities than males, but on most verbal tasks the difference is small*. One verbal task where females consistently outperform males is reading (Organisation for Economic Co-operation and Development [OECD], 2012). This difference is observed in many different countries, and the size of the difference is often quite large.
- *Males outperform females on many tests of spatial ability*, especially three-dimensional mental rotations, starting in childhood and persisting across the life span. Training in the form of

Suppose you are asked to imagine how this fruit bowl would appear from a different perspective. How quickly and accurately can you mentally rotate the image in your mind and determine the appearance of the fruit from another viewpoint? Historically, males have demonstrated greater mental rotation skills than females.

Alexey Stioip/Alamy Stock Photo

playing action video games can reduce or eliminate the gender difference on most spatial tasks (Feng, Spence, & Pratt, 2007). It may also be the case that it is having a masculine gender identity, something males have more than females, that leads to the apparent gender difference on mental rotation tasks (Reilly & Neumann, 2013).

- Historically, males outperformed females on standardized tests of mathematical ability, but this male advantage has been shrinking in the United States and many other countries: *Females and males perform similarly on most but not all standardized math tests, and females obtain slightly higher math grades in the classroom than males* (Else-Quest, Hyde, & Linn, 2010; Lachance & Mazzocco, 2006). In some countries (such as Austria, Chile, Germany, and Japan), there is a male advantage in math, perhaps reflecting different educational opportunities for males and females in these countries (OECD, 2012). In a handful of countries, females score higher than males (for example, Qatar and Jordan). Thus, in most cases there are not significant gender differences in math performance, but in those cases where there is a difference, it typically is in favor of males. Interestingly, males express more positive attitudes about math than females do, and this more positive outlook may create more opportunities for males to gain experience and comfort with math; for example, they may be more likely to sign up for higher level math classes than females do (Else-Quest et al., 2010). A notable exception to the disappearing gender differences in this area is the College Board SAT Mathematics test, on which males continue to score approximately 30 points higher than females (College Board, 2012). Among the top scorers on the SAT-Math test, males outnumber females by a ratio of 2 to 1.

Boys and girls often display traditional gender roles in their pretend play.

Angela Wayne/Alamy Stock Photo

- *Girls display greater memory ability than boys.* Some studies show that this is a general or overall advantage (Johnson & Bouchard, 2007), whereas other research suggests that female’s memory advantage is in specific areas such as remembering object locations. Other research shows that females excel at recalling verbal information, as well as faces, particularly female faces (see Herlitz & Lovén, 2013). Finally, listen to your female friends if they tell you something smells bad, because women also show an advantage over men when it comes to recognizing familiar odors (Herlitz & Rehnman, 2008).
- *Males engage in more physical and verbal aggression than females, starting as early as 17 months* (Baillargeon et al., 2007; Burton, Hafetz, & Henninger, 2007; Buss & Perry, 1992). Across 21 diverse countries, teachers in nearly all the countries report that boys are more aggressive than girls (Rescorla et al., 2007; but see Kim, Kim, & Kamphaus, 2010). Sex differences are more obvious for physical aggression than for other forms of aggression. For example, at 17 months, for every one girl who is physically aggressive there are five boys who display frequent physical aggression (Baillargeon et al., 2007). Males also commit more serious and more physically violent crimes (Barash, 2002). Some research shows that females tend to specialize in subtle, indirect, and relational forms of aggression, such as gossiping about and excluding others (Crick & Bigbee, 1998; Murray-Close, et al., 2016).
- Even before birth and throughout childhood, *boys are more physically active* than girls (Almli, Ball, & Wheeler, 2001); they fidget and squirm more as infants and run around more as children. In 19 out of 21 countries studied by Leslie Rescorla and colleagues (2007), teachers report that boys are more hyperactive than girls.
- *Both males and females report that females are more nurturant and empathic.* Sex differences in behaviors are small but show females empathizing more than males (Baron-Cohen, 2003; Van der Graaff et al., 2014).
- *Females are more prone to develop anxiety disorders, depression, and eating disorders* (American Psychiatric Association [APA], 2013). In contrast, *males are more likely to display antisocial behaviors and drug and alcohol abuse and are more frequently diagnosed with autism* (APA, 2013).
- *Males use computers more than females do and express greater confidence in their computer abilities* (Li & Kirkup, 2007; Misa, 2010). These findings do not tell us, though, whether there are gender differences in computer ability.

What have you concluded from this collection of research on gender? Are males and females different in meaningful ways or are differences trivial, as would be predicted by the gender similarities hypothesis? To help answer this, consider that if we ordered people based on degree of aggressiveness from most aggressive to the least aggressive person in a group, only 5% of the observed differences could be attributed to whether a person is male or female (Hyde, 1984). It is worth repeating the point we made earlier: *Average* levels of a behavior such as aggression may be noticeably different for males and females, but within each sex there are both extremely aggressive and extremely nonaggressive

individuals. Therefore it is impossible to predict accurately how aggressive a person is simply by knowing that person’s biological sex. Gender differences in most other abilities and personality traits are similarly small.

If, as we have just seen, females and males are more psychologically similar than different, then why do unfounded stereotypes persist? Partly because we, as the holders of male—female stereotypes, are biased in our perceptions. We are more likely to notice and remember behaviors that confirm our beliefs than to notice and remember exceptions, such as independent behavior in a woman or emotional sensitivity in a man (Martin & Halverson, 1981).

In addition, Alice Eagly’s (2012) **social-role theory** suggests that differences in the roles that women and men play in society do a lot to create and maintain gender stereotypes. For example, men have traditionally occupied powerful roles in business and industry that require them to be dominant and forceful. Women have more often filled the role of homemaker and therefore have been called upon to be nurturant and sensitive to their children’s needs. As a result, we begin to see men as dominant or agentic by nature and women as nurturant or communal by nature. We lose sight of the fact that the differences in the social roles they play cause men and women to behave differently; it is not all “by nature.” Individuals even perceive themselves differently depending on which of their roles they are considering: more agentic when thinking of their work role and more communal when thinking of their family role (Uchronski, 2008). Might gender differences in behavior be minimized or reversed if women ran companies and men raised children?

According to Alice Eagly’s social-role theory, this man would be perceived as nurturant, warm, and caring because he has assumed the role of caregiver.

Olesia Bilkei/Shutterstock.com

Some research suggests that this may be the case. Both men and women rate male and female homemakers as equally communal (Bosak, Sczesny, & Eagly, 2008). Thus, men who are in the role of homemaker are perceived as being just as caring and affectionate as women in this role. Still, women presented in employee roles are not always judged as equally agentic as men in employee roles. This may be a result of continued gender segregation of the workforce, with far more women in such occupations as nurse and teacher and far more men in occupations such as plumber, corporate executive, and construction worker. Thus, conjuring up the role of employee for men and women may lead not to a single image of what this role involves but to multiple images based on existing gender differences in types of work (Bosak et al., 2008).

Although psychological gender differences are often small, it still makes a difference in society whether a person is male or female. First, gender norms and stereotypes, even when they are unfounded, affect how we perceive ourselves and other people. As long as people expect females to be less competent in math than males, for example, females may lack confidence in their abilities and perform less competently (Eccles, Jacobs, & Harold, 1990). This was the conclusion reached by Zachary Estes and Sydney Felker (2012) in their research on mental rotation ability: Gender differences on this task were eliminated when males and females had the same confidence levels.

In addition, even though males and females are similar psychologically, they are steered toward different roles in society. In childhood, girls and boys conform to their gender roles by segregating themselves by biological sex and developing different interests and play activities (Maccoby, 1998). As adolescents and adults, males and females pursue different vocations and lifestyles. Although more women are entering male-dominated fields today than in the past, they are underrepresented in many traditionally male-dominated fields, and men rarely enter female-dominated fields (Bureau of Labor Statistics, U.S. Department of Labor, 2016). Occupations therefore remain highly gender segregated.

For instance, the top five occupations held by U.S. women continue to be secretary, nurse, teacher, cashier, and nursing or health aide. More men are sharing child-rearing and household responsibilities with their partners, but many couples still divide the labor along traditional lines, so that the woman is primarily responsible for child care and housework and the man is primarily responsible for income and money management (Austin Institute, 2014). When we think about who asks whom out on a date, who stays home from work when a child has an ear infection, or who does the laundry, we must conclude that, despite significant social change, traditional gender roles are alive and well.

● Checking Mastery

1. What is the central feature of agency and of communion?
2. What are four differences between males and females, two that favor females and two that favor males, and how large or meaningful are these differences?
3. How does Eagly's social-role theory explain gender differences?

● Making Connections

1. What roles do you play as a result of your biological sex? For example, are you a son or a daughter? How do these roles influence your behavior? Would you, for instance, behave any differently if you were a son rather than a daughter (or vice versa)?
2. Your grandmother strongly believes that boys and girls (and men and women) are quite different. Sometimes, she is even bothered by some of your behaviors because she doesn't believe you are behaving like a "proper" young woman or man. How did her thinking about gender become so entrenched, and what could be done to soften her views?

12.2

The Infant

LEARNING OBJECTIVES

- Describe how infants may be treated differently based on their biological sex and indicate how this may lead to gender differences.
- Explain what infants know about gender as a social category.

At birth there are few differences, other than the obvious anatomical ones, between males and females. Male newborns tend to be somewhat more irritable than females, and female newborns are more alert than males (Boatella-Costa et al., 2007). But overall, differences between males and females at birth are small and inconsistent. Nonetheless, it does not take long after newborns are labeled as girls or boys for gender stereotypes to affect how they are perceived and treated—and for infants to notice that males and females are different.

Differential Treatment

When the baby is still in the hospital delivery room or nursery, parents tend to use masculine terms when talking to or about their

infant son (such as “big guy” or “tiger”) and to comment on the strength of his cries, kicks, and grasps. Female infants are more likely to be labeled “sugar” or “sweetie” and to be described as soft, cuddly, and adorable (see Leaper, 2013; 2015). Even when objective examinations reveal no such differences between boys and girls at birth, adults perceive boys as strong, large featured, and coordinated and view girls as weaker, finer featured, and more awkward (Rubin, Provenzano, & Luria, 1974). Soon boys and girls are decked out in either blue or pink and provided with “sex-appropriate” hairstyles, toys, and room furnishings (Pomerleau et al., 1990).

In an early study of the effects of gender stereotyping, college students watched a videotape of a 9-month-old infant who was introduced as either “Dana,” a girl, or as “David,” a boy (Condry

Take a look at this baby boy and write down a few adjectives describing what you think he might have been feeling or thinking at the time this photo was taken. Now suppose you learn that this “boy” is actually a girl. Do the adjectives still seem to fit? Do any of them reflect gender stereotyping?

Pavel Galkevich/Alamy Stock Photo

& Condry, 1976). Students who saw “David” interpreted his strong reaction to a jack-in-the-box as anger, whereas students who watched “Dana” concluded that the same behavior was fear. A similar study found that college students rated babies introduced as males as stronger and more “masculine” than babies introduced as females (Burnham & Harris, 1992). Although stereotyping of boys and girls from birth could be partly the effect of differences between the sexes, it may also be a cause of such differences. This was the conclusion from a longitudinal study of young children’s aggressive behavior: Those children whose fathers held strong gender stereotypes were more often subjected to physical control by their parents, which later led to higher levels of aggression from the children (Endendijk et al., 2017).

Early Learning

Yet infants are not merely the passive targets of other people’s reactions to them; they are actively trying to get to know themselves and the social world around them. Several studies have examined visual tracking of objects by infants at various ages. It turns out that throughout much of infancy, males spend more time looking at a truck whereas females spend more time looking at a doll (Alexander, Wilcox, & Woods, 2009; Jadva, Hines, & Golombok, 2010). This suggests a rudimentary recognition of gender-stereotypic information. At around 3–4 months of age, infants can distinguish between male and female faces (Quinn et al., 2002). By the end of the first year, babies look longer at a male (or female) face when they hear a male (or female) voice than when they hear a voice that does not match the gender of the face, demonstrating cross-modal association of gender-related information (Fagot & Leinbach, 1993; Poulin-Dubois & Serbin, 2006). By 24 months, they look longer at males and females performing gender-inconsistent activities (such as a man putting on makeup) than those performing activities consistent with gender

stereotypes (such as a man mowing the grass; Hill & Flom, 2007). Their response shows that they recognize something incongruent or odd about males and females engaged in activities inconsistent with gender stereotypes.

As they begin to categorize other people as males and females, they also figure out which of these two significant social categories they belong to. By 18 months, most toddlers seem to have an emerging understanding that they are either like other males or like other females, even if they cannot verbalize it (Martin, Ruble, & Szkrybalo, 2002). Girls as young as 24 months understand which activities are associated with males and which ones are more typical of females (Poulin-Dubois et al., 2002; see also Serbin, Poulin-Dubois, & Eichstedt, 2002). Boys, however, do not show the same understanding until at least 6 months later. Almost all children give verbal proof that they have acquired a basic sense of **gender identity**, or an awareness that they are either a boy or a girl, by age 2½ to age 3 (see Leaper, 2015).

As they acquire their gender identities, boys and girls also begin to behave differently. At an early age, boys usually prefer trucks and cars to other playthings, whereas girls of this age would rather play with dolls and soft toys (Berenbaum et al., 2008). Many 18- to 24-month-old toddlers are not interested in playing with toys regarded as appropriate for the opposite sex—even when there are no other toys to play with (Caldera, Huston, & O’Brien, 1989). As they approach age 2, then, infants are already beginning to behave in ways considered gender appropriate in our society.

The Beginnings of a Sexual Self

Sigmund Freud (see Chapter 2) made the seemingly outrageous claim that humans are sexual beings from birth onward. We are born, he said, with a reserve of sexual energy redirected toward different parts of the body as we develop. Freud may have been wrong about some things, but he was right that infants are sexual beings.

Young children tend to be comfortable with their bodies and are curious about how they work and how they compare to other bodies. Most societies, though, impose restrictions on nakedness and discourage children from expressing too much curiosity about bodies, which adults interpret as sexual expressions.

Andrew Holt/Alamy Stock Photo

Babies are biologically equipped at birth with male or female chromosomes, hormones, and genitals. Moreover, young infants in Freud's oral stage of development appear to derive pleasure from sucking, mouthing, biting, and other oral activities. But the clincher is this: Both male babies and female babies have been observed to touch and manipulate their genital areas, to experience physical arousal, and to undergo what appear to be orgasms (see Galenson, 2015).

What should you make of these infant behaviors? Infants feel body sensations, but they are hardly aware that their behavior is "sexual" (Crooks & Baur, 2017). Infants are sexual beings primarily in the sense that their genitals are sensitive and their nervous systems allow sexual responses. They are also as curious about their bodies as they are about the rest of the world (Schuhrke, 2000). They enjoy touching all parts of their body, especially those that produce pleasurable sensations, and are likely to continue touching themselves unless reprimands from parents or other grownups

discourage this behavior, at least in public (Thigpen, 2009). From these early experiences, children begin to learn what human sexuality is about and how the members of their society regard it.

● Checking Mastery

1. What is gender identity, and what evidence shows understanding of this concept during infancy?

● Making Connections

1. Think of someone who recently became a new parent. In what ways has this person's thinking, and the thinking of his or her surrounding social network, already been shaped by knowing the biological sex of the baby? What is the baby's world like—can you tell by looking at its room or clothes whether it is a boy or girl?

12.3

The Child

LEARNING OBJECTIVES

- Analyze how children acquire gender stereotypes and how they are influenced by these stereotypes.
- Explain how children acquire a solid understanding of gender identity.
- Describe typical gendered behaviors that we can expect to see throughout childhood.
- Summarize and evaluate the usefulness of each theory of gender-role development.
- Outline children's understanding of sex and reproduction.

Much of the action in gender-role development takes place during the toddler and preschool years. Having already come to understand their basic gender identity, young children rapidly acquire gender stereotypes, or beliefs about what groups of males and females are supposedly like, and gender-typed behavioral patterns, or tendencies to favor "gender-appropriate" activities and behaviors over those typically associated with the other sex. Through the process of **gender typing**, children not only become aware that they are biological males or females but also acquire the motives, values, and patterns of behavior that their culture considers appropriate for members of their biological sex. Through the gender-typing process, for example, Susie may learn a gender-role norm stating that women should strive to be good mothers and gender-role stereotypes indicating that women are more skilled at nurturing children than men are. As an adult, Susan may then adopt the traditional communal role by switching from full-time to part-time work when her first child is born and devoting herself to the task of mothering.

It would be a mistake, then, to attribute any differences that we observe between girls and boys (or women and men) solely to biological causes. They could just as easily be caused by differences in the ways males and females are perceived and raised.

Acquiring Gender Stereotypes

As early as 2–3 years of age, children seem to understand society's gender stereotypes and act in gendered ways. Judith Blakemore

(2003) showed pictures of toys to 3- to 11-year-olds and asked them whether boys or girls would usually play with each toy. Toys included masculine-stereotyped ones (for example, GI Joe dolls) and feminine-stereotyped ones (for example, Barbie dolls). Even the youngest children (3 years) knew that girls, but not boys, play with Barbie dolls and vice versa for GI Joes. They also recognized that boys and girls differ in clothes and hairstyles. By age 5–6, girls show a preference for feminine toys and boys show a preference for masculine toys (Li & Wong, 2016). In addition, boys seem to hold more gender-stereotypical toy preferences than girls (Cherney, Harper, & Winter, 2006).

Over the next several years, children acquire considerably more "knowledge" about the toys and activities considered appropriate for girls or boys (Blakemore, 2003; Serbin, Powlishta, & Gulko, 1993). In one study, for instance, researchers (Levy, Sadovsky, & Troseth, 2000) asked 4- and 6-year-olds whether men or women would be better in two masculine-stereotyped occupations (car mechanic and airplane pilot) and two feminine-stereotyped occupations (clothes designer and secretary). Children believed that men would be more competent than women as mechanics and pilots, whereas women would make better designers and secretaries. Boys and girls also expressed positive emotions at the thought of growing up and holding gender-stereotypical occupations. They reacted negatively, however, when asked to consider holding gender-counterstereotypic occupations.

How seriously do children take the gender-role norms and stereotypes that they are rapidly learning? It depends on how old

they are. Robin Banerjee and Vicki Lintern (2000) tested the rigidity of 4- to 9-year-olds' gender-stereotypic beliefs with four brief stories in which characters had either gender-stereotypic interests (for example, a boy named Tom who was best friends with another boy and liked playing with airplanes) or gender-counterstereotypic interests (for example, a boy named John who was best friends with a girl and liked playing with doll carriages). Children were then asked whether the target child would like to play with dolls, play football, skip, or play with toy guns.

Younger children (4- and 6-year-olds) were considerably more rigid in their beliefs than older children; they did not believe boys would want to play with dolls or skip (stereotypic girl activities) or girls would want to play with footballs or toy guns (stereotypic boy activities). Some children seem particularly offended when peers step outside of traditional gender-stereotypic behaviors and will act as “enforcers” of gender-stereotyped behaviors, telling boys, “You shouldn't be playing with that doll” or telling girls, “That game is for boys” (see Martin & Ruble, 2010). Rigidity about gender stereotypes is especially high during the preschool years (around ages 4–7), but then decreases over the elementary school years (Conry-Murray, Kim, & Turiel, 2015; Ruble et al., 2007). Using fMRI scans, Eva Telzer and her colleagues (2015) were able to demonstrate different patterns of brain activity in the amygdala as children of various ages viewed same- or opposite-sex faces. The amygdala of young children (4–7 years) seemed to register differences between viewing same-sex and opposite-sex faces, whereas 10- to 12-year-old children did not show this same reaction. The researchers believe that the pattern of findings reflects the “cootie effect,” the dislike that young boys and girls often seem to harbor toward members of the “other” sex.

Research with children of different ethnic backgrounds also shows strong adherence to gender-typed behavior in the preschool-age group (Halim et al., 2013). Similar findings also emerged from a longitudinal study of gender stereotypes. Hanns Trautner and his colleagues (2005) followed the same group of children from age 5 through age 10 to see if children who held rigid beliefs about gender stereotypes at age 5 remained unshakable in these beliefs over the next 5 years. As **Figure 12.1** shows, peak levels of rigidity occurred between ages 5 and 7, followed by significant relaxation of beliefs from age 7 to 10.

Why? The younger children are in the process of acquiring a clear understanding that their biological sex will remain constant, making them intolerant of anyone who violates traditional gender-role standards. These norms now have the force of absolute moral laws and must be obeyed: Boys must not play with dolls. Eleanor Maccoby (1998) suggests that young children may exaggerate gender roles to cognitively clarify these roles. However, once their gender identities are more firmly established, children can afford to be more flexible in their thinking about what is “for boys” and what is “for girls.” They still know the stereotypes but no longer believe the stereotypes are “written in stone” (Martin et al., 2002). Other research suggests that children's rigidity about gender-role violations depends on how essential a behavior is to children's understanding of gender identity (Blakemore, 2003). Thus, children believe it would be bad for boys to wear dresses because dresses are strongly associated with the feminine gender role. But if boys wanted to play with a toy kitchen, this would not

Figure 12.1 Once gender identities are clearly established, usually by age 7, children become much more open about gender behaviors, as illustrated by the sharp increase in number of flexible responses to questions about what is “acceptable” behavior for boys and girls.

be too bad because, although the toy kitchen may be associated with the feminine gender role, it is not considered an essential aspect of the feminine gender role (Blakemore, 2003).

Gender-Typed Behavior

Finally, children rapidly come to behave in “gender-appropriate” ways. As you have seen, preferences for gender-appropriate toys are detectable in infancy. Apparently, babies establish preferences for “boys’ toys” (such as action figures and building toys) or “girls’ toys” (such as dolls and stuffed animals) even before they have established clear identities as males or females or can correctly label toys as “boy things” or “girl things” (Cherney & London, 2006; Fagot, Leinbach, & Hagan, 1986). In childhood, preference for gender-congruent toys and activities is still evident, although occasionally both boys and girls choose “boys’ toys” more than “girls’ toys” (Cherney, 2005; Martin & Dinella, 2012). Their leisure activities also differ, with boys spending more time playing sports and video/computer games than girls (Cherney & London, 2006). And it turns out that gender-typed behavior in

childhood—as early as age 3—is consistent with later gender-typed behavior (Golombok et al., 2012). Thus, boys and girls who display feminine or masculine behaviors at age 3 continue to have feminine or masculine preferences in adolescence.

Children begin to favor same-sex playmates as early as 30–36 months of age (see, for example, Howes, 1988; Martin, Fabes, & Hanish, 2014). During the elementary school years, boys and girls develop even stronger preferences for peers of their own sex and show increased **gender segregation**, separating themselves into boys’ and girls’ peer groups and interacting far more often with their own sex than with the other sex (Halim & Ruble, 2010). Gender segregation occurs in a variety of cultures, including Botswana, Kenya, India, and the Philippines, and it increases with age (Bock, 2005; Leaper, 1994; Whiting & Edwards, 1988). At age 4½, children in the United States spend three times more time with same-sex peers than with peers of the other sex; by age 6½, they spend 11 times more time (■ **Figure 12.2**; Maccoby & Jacklin, 1987). This is partly because of incompatibilities between boys’ and girls’ play styles. Boys are too rowdy, domineering, and unresponsive to suit the tastes of many girls, so girls gravitate toward other girls and develop a style of interacting among themselves different from the rather timid style they adopt in the company of boys (Maccoby, 1998; Pellegrini et al., 2007).

But there is more to gender segregation than different activity levels of boys and girls (Martin et al., 2013). Preschool girls who are just as active as boys often start the school year playing with boys but end up in gender-segregated groups as they progress through the year in preschool (Pellegrini et al., 2007). Socialization pressures seem to encourage these active girls to drift away from the boys and create their own playgroup, separate from the active boys and the less-active girls. In an analysis of gender segregation, Carol Martin and her colleagues (2013) found that the

What percentage of boys versus girls are likely to receive boxing gloves to play with? Chances are good that most of these purchases are made for boys and not girls. What traits are likely to be encouraged by such play, and what message is conveyed to children by such gendered gifts?

■ **Figure 12.2** Do children prefer playmates of their own sex? Apparently so. Both boys and girls spend more time playing with same-sex peers, especially at age 6.

Source: Reprinted from Maccoby, E. E., & Jacklin, C. N. (1987). Gender segregation in childhood. In H. W. Reese (Ed.), *Advances in child development and behavior* (Vol. 20). Copyright © 1987 with permission from Elsevier.

gender of potential playmates, and not the activity of the playmates, is the primary criterion for selecting playmates.

Some research suggests that children who insist most strongly on clear boundaries between the sexes and avoid consorting with the opposite sex tend to be socially competent and popular, whereas children who violate gender segregation rules tend to be less well-adjusted and run the risk of being rejected by their peers (Rieger & Savin-Williams, 2012). But other research challenges these findings (Martin et al., 2012). Nonconforming children do seem to have fewer peer interactions, which means they have fewer socialization opportunities. Importantly, though, their more limited socialization does not seem to lead to problem behavior as earlier research suggested (Martin et al., 2012).

Boys face stronger pressures to adhere to gender-role expectations than girls do, which may help explain why they develop stronger gender-typed preferences at earlier ages (Banerjee & Lintern, 2000; O’Brien et al., 2000). Just ask your female classmates if they were tomboys when they were young; you are likely to find that somewhere between one-third and one-half readily acknowledge that they were “tomboys” or had masculine interests (Bailey, Bechtold, & Berenbaum, 2002; Martin & Dinella, 2012). But we challenge you to find many male classmates who willingly admit they were “sissies” or had feminine interests in their youth. Even when the label is changed (for example, to “mama’s boy”), and the traits associated with the label are positive (for example, “well-mannered”), people still believe that it is not desirable for boys to behave in gender nonconforming ways (Coyle, Fulcher, & Trübtschek, 2016).

We have now surveyed some major milestones in gender-role development. Now comes the most intriguing question about gender-role development in childhood and adolescence: How can it be explained?

Explaining Gender-Role Development

There are numerous theories about the development of gender roles. We will once again use the framework of the nature–nurture issue to organize these theories into those that emphasize biological factors, those that emphasize the environment and socialization, and then those that attempt to integrate these factors.

Influence of Nature

On the nature side, how might genetic and hormonal factors influence one’s gender-role development? To start, most of us receive either the standard male pattern of sex chromosomes (XY) or the female pattern of sex chromosomes (XX). These set the stage for various other events to unfold:

1. If certain genes on the Y chromosome are present, a previously undifferentiated tissue develops into testes as the embryo develops; otherwise, it develops into ovaries.
2. The testes of a male embryo normally secrete more of the male hormone testosterone, which stimulates the development of a male internal reproductive system, and another hormone that inhibits the development of female organs. Without these hormones, the internal reproductive system of a female will develop from the same tissues.

3. Three to four months after conception, secretion of additional testosterone by the testes normally leads to the growth of a penis and scrotum. If testosterone is absent (as in typically developing females), or if a male fetus’s cells are insensitive to the male sex hormones he produces, female external genitalia (labia and clitoris) will form.
4. The relative amount of testosterone alters the development of the brain and nervous system. For example, it signals the male brain to stop secreting hormones in a cyclical pattern so that males do not experience menstrual cycles at puberty.

According to the **biosocial theory** of gender-role development, proposed by John Money and Anke Ehrhardt (1972), these early biological developments influence how people react to a child, and these social reactions have much to do with children’s assuming gender roles. Parents and other people label and begin to react to children on the basis of the appearance of their genitalia. If children’s genitals are atypical and they are mislabeled as members of the other sex, this incorrect label will affect their future development. For example, the biosocial theory predicts that if a biological male were consistently labeled and treated as a girl, he would, by about age 3, acquire the gender identity of a girl. Finally, biological factors reenter the scene at puberty when large quantities of hormones are released, stimulating the growth of the reproductive system and the appearance of secondary sex characteristics. These events, combined with a person’s earlier self-concept as a male or female, provide the basis for adult gender identity and role behavior. The complex series of critical points in biological maturation and social reactions to biological changes that Money and Ehrhardt (1972) propose is diagrammed in **Figure 12.3**. But how much is nature, and how much is nurture?

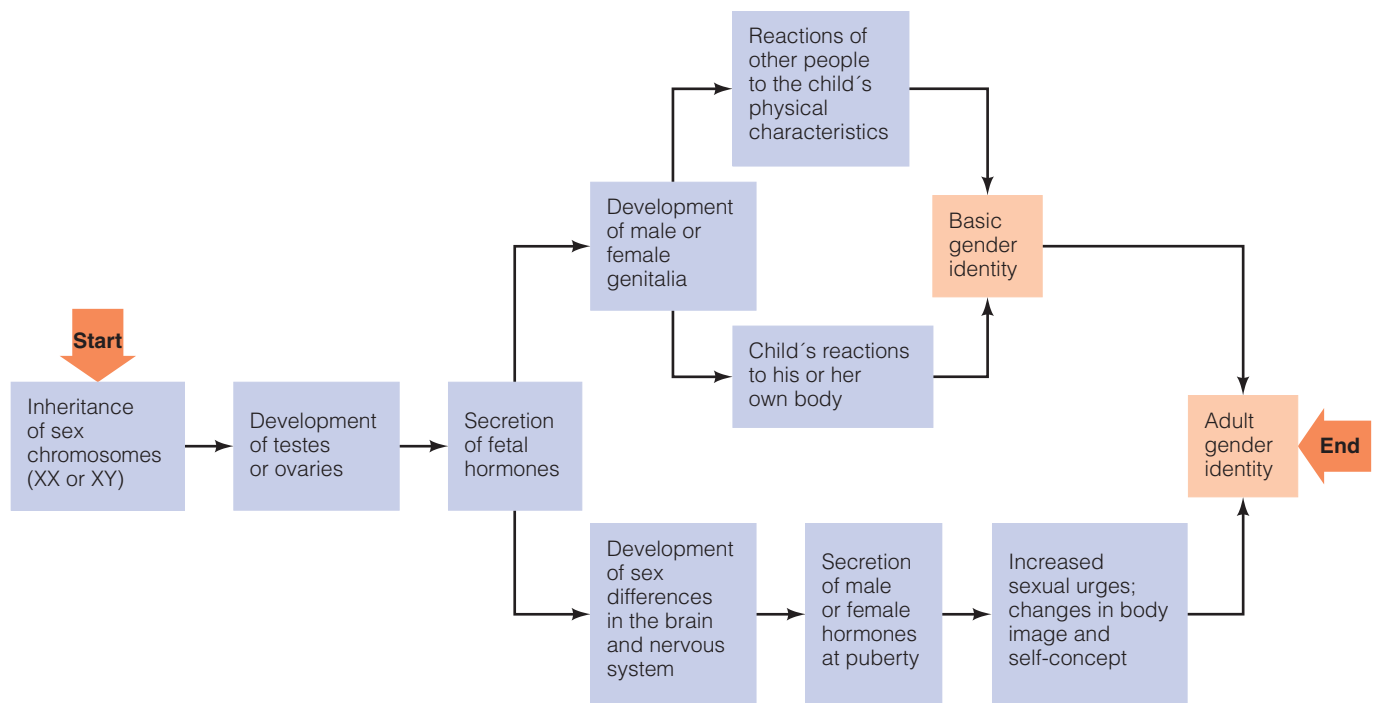

Figure 12.3 Critical events in John Money and Anke Ehrhardt’s biosocial theory of gender typing.

Source: From Money, J., & Ehrhardt, A. (1972). *Man and woman, boy and girl*. Baltimore, MD: Johns Hopkins University Press. Reprinted by permission.

Biological influences on development are evident in studies of children exposed to the “wrong” hormones prenatally. For instance, consider the consequences to offspring of mothers who, in past decades, were given drugs containing progestins to help prevent miscarriages (Brunskill, 1992). The drugs were converted by the mother’s body into the male hormone testosterone and, depending on the dose and timing, ended up masculinizing female fetuses so that, despite their XX genetic endowment and female internal organs, they were born with external organs that resembled those of a boy (for example, a large clitoris that looked like a penis and fused labia that resembled a scrotum). Several of these **androgenized females**—girls prenatally exposed to excess androgens—were recognized as genetic females, underwent surgery to alter their genitals, and were then raised as girls. When compared with their sisters and other girls, it became apparent that many more androgenized girls were tomboys and preferred boys’ toys and vigorous activities to traditionally feminine pursuits (Money & Ehrhardt, 1972; see also Meyer-Bahlburg et al., 2006). As adolescents, they began dating somewhat later than other girls and felt that marriage should be delayed until they had established their careers. A relatively high proportion (37%) described themselves as homosexual or bisexual (Money, 1985; see also Dittman, Kappes, & Kappes, 1992). Androgenized females also tend to perform better than most other females on tests of spatial ability, further evidence that early exposure to male hormones has “masculinizing” effects on a female fetus (Hines, Constantinescu & Spencer, 2015).

In addition, male exposure to testosterone and other male hormones may be part of the reason males are more likely than females to commit violent acts (Rubinow & Schmidt, 1996).

Brothers, yet very different personalities, as reflected here in how they are dressed. According to the biosocial theory, what factors influence children’s acquisition of gender-typed behaviors?

Maria Teijeiro/Getty Images

Evidence from experiments conducted with animals is quite convincing. For example, female rhesus monkeys exposed prenatally to the male hormone testosterone often threaten other monkeys, engage in rough-and-tumble play, and try to “mount” a partner as males do at the beginning of a sexual encounter (Young, Goy, & Phoenix, 1964; Wallen, 1996). Men with high testosterone levels tend to have high rates of delinquency, drug abuse, abusiveness, and violence, although nature interacts with nurture so that these links between testosterone and antisocial behavior are not nearly as evident among men high in socioeconomic status as among men low in socioeconomic status (Dabbs & Morris, 1990). Note, however, that these are correlational studies showing an association between testosterone and aggression; they do not show us the direction of the relationship. Indeed, being in an aggressive situation may raise testosterone levels (Batinos, 2012; Sapolsky, 1998). Because testosterone levels rise as a result of aggressive and competitive activities, it has been difficult to establish unambiguously that high concentrations of male hormones cause aggressive behavior in humans (Archer, 1991). Still, much evidence suggests that prenatal exposure to male or female hormones has lasting effects on the organization of the brain and, in turn, on sexual behavior, aggression, cognitive skills such as spatial abilities, and other aspects of development (Auyeung et al., 2012; Rubinow & Schmidt, 1996). Yet biology does not dictate gender-role development. Instead, gender-role development evolves from the complex interaction of biology, social experience, and the individual’s behavior.

Influence of Nurture

The environment and socialization may influence gender roles in a variety of ways. Here, we consider ways in which the social environment of the child may push him or her into certain roles as well as ways in which children may socialize themselves to assume certain gender roles. We look first at social learning theories and then consider cognitive theories.

Social Learning Theory. Social learning theorists argue that children learn masculine or feminine identities, preferences, and behaviors through two processes introduced in Chapter 2. First, through *differential reinforcement*, children are rewarded for sex-appropriate behaviors and are punished for behaviors considered more appropriate for members of the other sex. Second, through *observational learning*, children adopt the attitudes and behaviors of same-sex models. In this view, children’s gender-role development depends on which of their behaviors people reinforce or punish and on what sorts of social models are available. Change the social environment and you change the course of gender-role development.

Parents use differential reinforcement to teach boys how to be boys and girls how to be girls (Lytton & Romney, 1991). By the second year of life, parents are already encouraging sex-appropriate play and discouraging cross-sex play, before children have acquired solid gender identities or display clear preferences for male or female activities (Fagot & Leinbach, 1989). By 20–24 months, daughters are reinforced for dancing, dressing up (as women), following their parents around, asking for help, and playing with dolls; they are discouraged from manipulating objects, running, jumping, and climbing. By contrast, sons are not encouraged to

pursue such “feminine” behavior as playing with dolls or seeking help and they receive more positive responses from their parents when they play with “masculine” toys such as blocks, trucks, and push-and-pull toys (Blakemore, 2003; Fagot, 1978; Fagot, Leinbach, & O’Boyle, 1992). Mothers and fathers may also discipline their sons and daughters differently, with fathers more likely to use physical forms of discipline (such as spanking) than mothers and mothers more likely to use reasoning to explain rules and consequences (Conrade & Ho, 2001; Russell et al., 1998). In addition, boys end up on the receiving end of a spanking more often than girls do (Day & Peterson, 1998). Some of this differential treatment is influenced by multiple factors, including children’s birth order and gender composition of siblings (Crouter, Whiteman, & Osgood, 2007). For instance, being the youngest daughter with only brothers as siblings leads to a different set of experiences in the family than being the youngest brother with only sisters as siblings.

In research by Barbara Morrongiello and Kerri Hogg (2004), mothers were asked to imagine how they would react if their 6- to 10-year-old son or daughter misbehaved in some way that might be dangerous (for example, bicycling fast down a hill they had been told to avoid). Mothers reported that they would be angry with their sons but disappointed and concerned with their daughters for misbehaving and putting themselves in harm’s way. Boys will be boys, they reasoned, but girls should know better. To prevent future risky behaviors, mothers said they would be more rule-bound with their daughters but would not do anything different with their sons. After all, they reasoned, there is no point in trying to prevent these risky behaviors in boys because it is “in their nature.” Girls’ behavior, on the other hand, can be influenced, so mothers may believe that it is worth enforcing an existing rule or instituting a new one. It’s not just mothers: Other research shows that fathers are more protective of their preschool-aged daughters than their preschool-aged sons (Hagan & Kuebli, 2007).

Does the “gender curriculum” in the home influence children? It certainly does. Parents who show the clearest patterns of differential reinforcement have children who are relatively quick to label themselves as girls or boys and to develop strongly sex-typed toy and activity preferences (Fagot & Leinbach, 1989; Fagot et al., 1992). Fathers play a central role in gender socialization; they are more likely than mothers to reward children’s gender-appropriate behavior and to discourage behavior considered more appropriate for the other sex (Leve & Fagot, 1997; Lytton & Romney, 1991). This may reflect fathers’ use of more explicit—directly stated—gender stereotypes about how boys and girls should act, whereas mothers are less likely to explicitly express gender stereotypes (Endendijk et al., 2013). Thus, fathers may overtly state their gender stereotypes (for example, “guys shouldn’t wear jewelry”), whereas mothers may be unconsciously influenced by implicit stereotypes without directly stating these stereotypes (for example, throwing away a brochure for a math camp, assuming a daughter will not be interested in this). Fathers, then, may be an especially important influence on the gender-role development of both sons and daughters.

Could differential treatment of boys and girls by parents also contribute to gender differences in ability? Possibly so. Jacqueline Eccles and her colleagues (1990) have conducted several studies to determine why girls tend to shy away from math and science courses and are underrepresented in occupations that

involve math and science (see also Benbow & Arjmand, 1990). They suggest that parental expectations about gender differences in mathematical ability become self-fulfilling prophecies. The plot goes something like this:

- Parents, influenced by societal stereotypes about gender differences in ability, expect their sons to outperform their daughters in math and expect their sons will be more interested in math and science than their daughters (Tenenbaum & Leaper, 2003).
- Parents attribute their sons’ successes in math to ability but credit their daughters’ successes to hard work. Perhaps as a result of this, fathers talk differently to their sons and daughters when discussing science with them (Tenenbaum & Leaper, 2003). With their sons, they use more scientific terms, provide more detailed explanations, and ask more abstract questions than with their daughters. These differences reinforce the belief that girls lack mathematical talent and turn in respectable performances only through plodding effort.
- Children begin to internalize their parents’ views, so girls come to believe that they are “no good” in math. Girls report that they are less competent and more anxious about their performance than boys (Pomerantz, Altermatt, & Saxon, 2002).
- Thinking they lack ability, girls become less interested in math, are less likely to take math courses, and are less likely to pursue career possibilities that involve math after high school.

In short, parents who expect their daughters to have trouble with numbers may get what they expect. The negative effects of low parental expectations on girls’ self-perceptions are evident regardless of their performance. Indeed, girls feel less competent than do boys about math and science even when they outperform the boys (Pomerantz et al., 2002). Girls whose parents are nontraditional in their gender-role attitudes and behaviors do not show the declines in math and science achievement in early adolescence that girls from more traditional families display, so apparently the chain of events Eccles describes can be broken (Updegraff, McHale, & Crouter, 1996).

Social learning theorists also emphasize that *observational* learning contributes in important ways to gender typing. Children see which toys and activities are “for girls” and which are “for boys” and imitate individuals of their own sex. Around age 6 or 7, children begin to pay much closer attention to same-sex models than to other-sex models; for example, they will choose toys that members of their own sex prefer even if it means passing up more attractive toys (Frey & Ruble, 1992). Children who see their mothers perform agentic tasks and their fathers perform household and child care tasks tend to be less aware of gender stereotypes and less gender typed than children exposed to traditional gender-role models at home (Sabattini & Leaper, 2004; Turner & Gervai, 1995). Similarly, boys with sisters and girls with brothers have less gender-typed activity preferences than children who grow up with same-sex siblings perhaps, as you learned earlier, because socialization within the family is affected by both the gender composition and the ages of siblings (Colley et al., 1996; Endendijk et al., 2013; Rust et al., 2000).

Not only do children learn by watching the children and adults with whom they interact, but they also learn from the media—radio,

television, movies, video games—and even from their picture books and elementary school texts. Although sexism in children’s books has decreased over the past 50 years, male characters are still more likely than female characters to engage in active, independent activities such as climbing, riding bikes, and making things, whereas female characters are more often depicted as passive, dependent, and helpless, spending their time picking flowers, playing quietly indoors, and “creating problems that require masculine solutions” (Crabb & Marciano, 2011; Diekmann & Murnen, 2004). Several analyses of children’s books show continued gender-stereotypic representations of men and women in these books (Adams, Walker, & O’Connell, 2011; Anderson & Hamilton, 2007; DeWitt, Cready, & Seward, 2013). Although discouraging, the reality is that these gender-stereotypic portrayals in children’s books largely mirror the continued gender-stereotypic roles in real life.

In recent decades, blatant gender stereotyping of television characters has decreased but not disappeared. Male characters still dominate on many children’s programs, prime-time programs, and advertisements (Matthes, Prieler, & Adam, 2016; Ganahl, Prinsen, & Netzley, 2003; Glascock, 2001; Smith et al., 2010). Similarly, among the top 100 films of 2014, 75% of the main characters were male, 13% were comprised of a group with both males and females, and only 12% were females (Lauzen, 2015). Children who watch a large amount of television are more likely to choose gender-appropriate toys and to hold stereotyped views of males and females than their classmates who watch little television (Signorielli & Lears, 1992).

Perhaps the strongest traditional gender stereotypes are found in video games, which males play at a much higher rate than females (Ogletree & Drake, 2007). College students, both male and female, report that female video game characters are portrayed as helpless and sexually provocative, in contrast to male characters who are portrayed as strong and aggressive (Ogletree & Drake, 2007). Men do not find these stereotypes as offensive as women do, perhaps because men already hold more traditional gender stereotypes than women (Brenick et al., 2007).

To recap, there is much evidence that both differential reinforcement and observational learning contribute to gender-role development. However, social learning theorists often portray children as the passive recipients of external influences: Parents, peers, television and video game characters, and others show them what to do and reinforce them for doing it. Perhaps this perspective does not put enough emphasis on what children contribute to their own gender socialization. Youngsters do not receive gender-stereotyped birthday presents simply because their parents choose these toys for them. Instead, parents tend to select gender-neutral and often educational toys for their children, but their boys ask for trucks and their girls request tea sets (Alexander, 2003; Robinson & Morris, 1986; Servin, Bohlin, & Berlin, 1999).

Cognitive Theories. Cognitive theories offer a different perspective on gender-role socialization, placing greater emphasis on children’s active involvement in acquiring gender roles.

To begin, Kohlberg (1966a) proposed a cognitive theory of gender typing with two major themes:

- Gender-role development depends on stage-like changes in cognitive development; children must acquire certain

Children may learn societal gender-typed behavior by watching and imitating role models.

Blend Images/Alamy Stock Photo

understandings about gender before they will be influenced by their social experiences.

- Children engage in self-socialization; instead of being the passive targets of social influence, they actively socialize themselves.

Kohlberg suggests that children *first* understand that they are girls or boys and *then* actively seek same-sex models and a range of information about how to act like a girl or a boy. To Kohlberg, it is not “I’m treated like a boy; therefore, I must be a boy.” It is more like “I’m a boy, so now I’ll do everything I can to find out how to behave like one.” Or, as May Ling Halim and Diane Ruble (2010) explain, the theory “views children as internally, self-initiated ‘gender detectives’—agents who actively construct the meaning of gender categories, rather than as passive recipients of external gender socialization agents” (p. 495).

What understandings are necessary before children will teach themselves to behave like boys or girls? Kohlberg believes that children everywhere progress through the following three steps as they acquire **gender constancy**, or understanding that our genders remain the same throughout our lives and despite superficial changes in appearance.

1. Basic gender identity is established by age 2 or 2½, when children can recognize and label themselves as males or females (Campbell, Shirley, & Caygill, 2002; Zosuls et al., 2009).
2. Somewhat later—around age 3—children acquire **gender stability**—that is, they come to understand that gender identity is stable over time. They know that boys invariably become men and girls grow up to be women.
3. The gender concept is complete, somewhere between age 5 and age 7, when children achieve **gender consistency** and realize that their sex is also stable across situations. Now children know that their sex cannot be altered by superficial changes such as dressing up as a member of the other sex or engaging in cross-sex activities.

Research shows that toddlers often do lack the concepts of gender stability and gender consistency; they often say that a boy could

become a mommy if he really wanted to or that a girl could become a boy if she cut her hair and wore a football uniform (Warin, 2000). But as they acquire gender stability, they often become rather rigid in their gender behaviors (Halim, 2016; Halim et al., 2014). It is at this point that many girls succumb to “pink frilly dress” or “PFD syndrome,” the strong desire to wear pink frilly dresses and embrace all that is pink (see Halim and Ruble, 2010; Halim et al., 2014). Doing so may help these young ‘gender detectives’ solidify their new understanding of themselves as girls. Boys seem to go through a similar stage where they adhere to all things boy-like (for example, clothing with action figures or camouflage) and, just as importantly for boys, avoid all things girl-like such as pink frilly dresses (Halim et al., 2014).

As children enter Piaget’s concrete-operational stage of cognitive development and come to grasp concepts such as conservation of liquids, they also realize that gender is conserved—remains constant—despite changes in appearance. Gender constancy is demonstrated by very few 3- to 5-year-olds, about half of 6- to 7-year-olds, and a majority of 8- to 9-year-olds (Trautner, Gervai, & Nemeth, 2003). In support of Kohlberg’s theory, Jo Warin (2000)

The “PFD” (pink frilly dress) phase.

Andrea Jones Images/Alamy Stock Photo

found that children who have achieved the third level of understanding display more gender-stereotypic play preferences than children who have not yet grasped gender consistency.

Not all research supports this view of gender-role development. In one study, children who had acquired only the first step in the process—applying gender labels to themselves—began to engage in more gender-typed play, which, according to Kohlberg’s model, shouldn’t occur until after the third step (Zosuls et al., 2009). Other research similarly shows that children need not reach the concrete operations stage to understand gender stability and consistency if they have sufficient knowledge of male and female anatomy to realize that people’s genitals make them male or female (Bem, 1989). Children who have younger siblings often arrive at this understanding earlier than children with only older siblings or those without siblings (Karniol, 2009). The most controversial aspect of Kohlberg’s cognitive-developmental theory, however, has been his claim that only when children fully grasp that their biological sex is unchangeable, around age 5 to age 7, do they actively seek same-sex models and attempt to acquire values, interests, and behaviors consistent with their cognitive judgments about themselves. Although some evidence supports some aspects of Kohlberg’s version of cognitive-developmental theory, this chapter shows that children learn many gender-role stereotypes and develop clear preferences for same-sex activities and playmates long before they master the concepts of gender stability and gender consistency and then, according to Kohlberg, attend more selectively to same-sex models (Halim & Ruble, 2010). It seems that only a rudimentary understanding of gender is required before children learn gender stereotypes and preferences.

Martin and Halverson (1981, 1987) have proposed a somewhat different cognitive theory, an information-processing one that overcomes the key weakness of Kohlberg’s theory. Like Kohlberg, they believe that children are intrinsically motivated to acquire values, interests, and behaviors consistent with their cognitive judgments about the self. However, Martin and Halverson argue that self-socialization begins as soon as children acquire a basic gender identity, around age 2 or age 3. According to their schematic-processing model, children acquire **gender schemata** (plural of schema)—organized sets of beliefs and expectations about males and females that influence the kinds of information they will attend to and remember.

First, children acquire a simple in-group–out-group schema that allows them to classify some objects, behaviors, and roles as appropriate for males and others as appropriate for females (cars are for boys, girls can cry but boys should not, and so on). Then they seek more elaborate information about the role of their own sex, constructing an own-sex schema. Thus, a young girl who knows her basic gender identity might first learn that sewing is for girls and building model airplanes is for boys. Then, because she is a girl and wants to act consistently with her own self-concept, she gathers a great deal of information about sewing to add to her own-sex schema, largely ignoring any information that comes her way about how to build model airplanes (■ Figure 12.4).

Consistent with this schema-processing theory, children appear to be especially interested in learning about objects or activities that fit their own-sex schemata. For instance, in one study, elementary-school-aged children who perceived themselves as gender typical

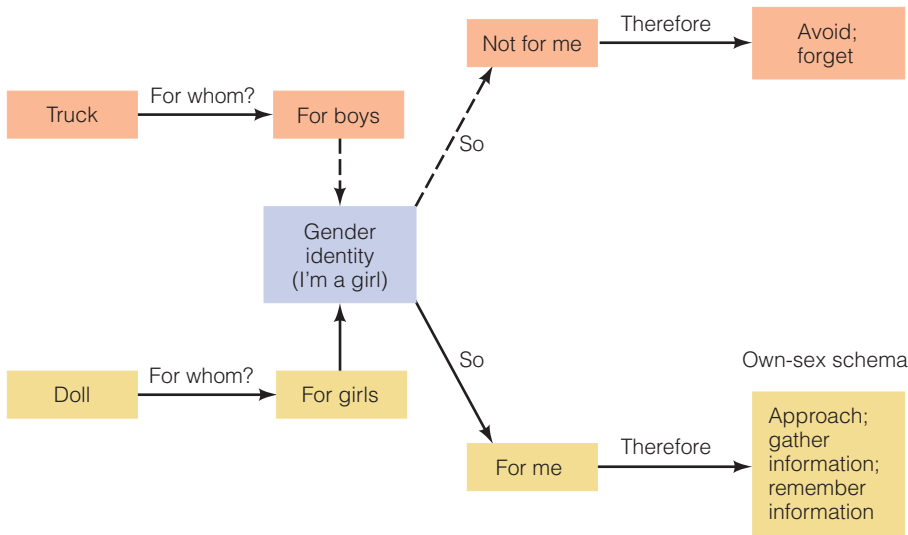

Figure 12.4 Gender schema theory in action. A young girl classifies new information according to an in-group–out-group schema as either “for boys” or “for girls.” Information about boys’ toys and activities is ignored, but information about toys and activities for girls is relevant to the self and is added to an even larger own-sex schema.

Source: Adapted from Martin & Halverson, 1987.

showed greater interest in gender-typical activities than in gender atypical ones (Patterson, 2012). In another study, 4- to 9-year-olds were given boxes of gender-neutral objects (hole punches, burglar alarms, and so on) and were told that some objects were “girl” items and some were “boy” items (Bradbard et al., 1986). Boys explored boy items more than girls did, and girls explored girl items more than boys did. A week later, the children easily recalled which items were for boys and which were for girls; they had apparently sorted the objects according to their in-group–out-group schemata. In addition, boys recalled more in-depth information about boy items than did girls, whereas girls recalled more than boys about these same objects if they had been labeled girl items. If children’s

information-gathering efforts are guided by their own-sex schemata in this way, you can easily see how boys and girls might acquire different stores of knowledge as they develop.

Once gender schemata are in place, children will distort new information in memory so that it is consistent with their schemata (Liben & Signorella, 1993; Martin & Halverson, 1983). For example, Martin and Halverson (1983) showed 5- and 6-year-olds pictures of children performing gender-consistent activities (for example, a boy playing with a truck) and pictures of children performing gender-inconsistent activities (for example, a girl sawing wood). A week later, the children easily recalled the sex of the actor performing gender-consistent activities; when an actor expressed gender-inconsistent behavior, however, children often distorted the scene to reveal gender-consistent behavior (for example, by saying that it was a boy, not a girl, who had sawed wood). This research gives some insight into why inaccurate gender stereotypes persist. The child who believes that women cannot be doctors may be introduced to a female doctor but may remember meeting a nurse instead and continue to state that women cannot be doctors. Even adults have trouble suppressing gender stereotypes and are influenced by their gender stereotypes when reading and interpreting text (Oakhill, Garnham, & Reynolds, 2005). To learn whether researchers have had any success in changing gender-role attitudes and behavior, check out the material in

Nature and Nurture Working Together

The biosocial, social learning, and cognitive perspectives all contribute to our understanding of sex differences and gender-role development (● Table 12.1). The biosocial model offered by Money and Ehrhardt notes the importance of biological

● **Table 12.1** An Integrative Overview of the Gender-Typing Process

Developmental Period	Events and Outcomes	Pertinent Theory or Theories
Prenatal period	The fetus develops male or female genitalia, which others will react to once the child is born.	Biosocial
Birth to 3 years	Parents and other companions label the child as a boy or a girl; they begin to encourage gender-consistent behavior and discourage cross-sex activities. As a result of these social experiences and the development of basic classification skills, the young child acquires some gender-typed behavioral preferences and the knowledge that he or she is a boy or a girl (basic gender identity).	Social learning
3–6 years	Once children acquire a basic gender identity, they begin to seek information about sex differences, form gender schemata, and actively try to behave in ways viewed as appropriate for their own sex.	Gender schema
7 to puberty	Children finally acquire the concepts of gender stability and consistency, recognizing that they will be males or females all their lives and in all situations. They begin to look closely at the behavior of same-sex models to acquire attributes consistent with their firm self-categorization as male or female.	Cognitive developmental
Puberty and beyond	The biological changes of adolescence, with social pressures, intensify gender differences and stimulate formation of an adult gender identity.	Biosocial, Social learning, Gender schema, Cognitive developmental

developments that influence how people label and treat a child. Yet socialization agents are teaching children how to be girls or boys well before they understand that they are girls or boys. Differences in social learning experiences may also help explain why, even though virtually all children form gender concepts and schemata, some children are far more gender typed than others in their preferences and activities (Serbin et al., 1993).

How children are labeled and treated by society can affect their gender development. For instance, some androgenized females were labeled as boys at birth and raised as such until their underlying condition was detected. Money and Ehrhardt (1972) report that the discovery and correction of this condition (by surgery and relabeling as a girl) caused few adjustment problems if the change took place before 18 months. After age 3, though, sexual reassignment was exceedingly difficult because these genetic females had experienced prolonged masculine gender typing and had already labeled themselves as boys. These findings led Money and Ehrhardt to conclude that there is a critical period between 18 months and 3 years for the establishment of gender identity when the label society attaches to the child is likely to stick.

Some research seems to support Money and Ehrhardt's emphasis on the importance of societal reactions to biological

sex in shaping gender identity. A review of research in which infants were presented to some people as boys but to others as girls showed that, to some extent adults, and to a large extent children, interacted differently with the infants based on whether they believed the infants were male or female (Stern & Karraker, 1989). One implication of these findings is that older siblings may be especially important in communicating gender messages to infants. In other research, mothers were asked to estimate how their 11-month-old infants would perform on several crawling tasks (Mondschein, Adolph, & Tamis-LeMonda, 2000). Mothers over-estimated their infant sons' abilities and under-estimated their infant daughters' abilities. The researchers proceeded to test crawling ability of the infants and found no differences between males and females, showing that mothers had preconceived ideas of motor skills of baby boys and girls.

Other research, though, calls into question whether early socialization in reaction to biological sex is as powerful as Money and Ehrhardt proposed. Consider an unusual study of a group of 18 biological males in the Dominican Republic who had a genetic condition that made their cells insensitive to the effects of male hormones (Imperato-McGinley et al., 1979; see also Herdt & Davidson, 1988). They had begun life with ambiguous genitals,

● APPLICATION 12.1

Changing Gender-Role Attitudes and Behavior

Some people believe that the world would be a better place if boys and girls were no longer socialized to adopt traditional masculine or feminine roles, interests, and behaviors. Children of both sexes would then have the freedom to be androgynous; women would no longer suffer from a lack of assertiveness in the world of work, and men would no longer be forced to suppress their emotions. Just how successful are efforts to encourage more flexible gender roles?

In several projects designed to change gender-role behavior, children have been exposed to nonsexist films, encouraged to imitate models of cross-sex behavior, reinforced by teachers for trying cross-sex activities, and provided with nonsexist educational materials (Katz, 1986; Katz & Walsh, 1991). For example, Rebecca Bigler and Lynn Liben (1990) reasoned that if they could alter children's gender stereotypes, they could head off the biased information processing that stereotypes promote. They exposed 6- to 11-year-olds to a series of problem-solving discussions emphasizing that (1) the most important considerations in deciding who could perform well in such traditionally masculine or feminine occupations as construction worker and beautician

are the person's interests and willingness to learn and (2) the person's gender is irrelevant. Compared with children who received no such training, program participants showed a clear decline in occupational stereotyping, especially if they had entered the study with firm ideas about which jobs are for women and which are for men. Moreover, this reduction in stereotyping brought about the predicted decrease in biased information processing: Participants were more likely than nonparticipants to remember counterstereotypic information presented to them in stories (for example, recalling that the garbage collector in a story was a woman).

Yet many efforts at change that work in the short run fail to have lasting effects (see Vogel & Wänke, 2016). Children who are encouraged to interact in mixed-sex groups revert to their preference for same-sex friends as soon as the program ends (Lockheed, 1986; Serbin, Tonick, & Sternglanz, 1977). Why is it so difficult to change children's thinking? Perhaps because children are groomed for their traditional gender roles from birth and are bombarded with traditional gender-role messages every day. A short-term intervention project may have little chance of succeeding in this larger context.

Other research shows that it is often difficult to change the gender schemata we have constructed. Farah Hughes and Catherine Seta (2003) gave fifth-graders descriptions of men and women behaving in ways inconsistent with traditional gender stereotypes. The children were then asked to rate the likelihood that another man or woman would behave in gender-inconsistent ways. Despite being exposed to a model of gender-stereotype inconsistent behavior, children believed that the other man (although not the other woman) would behave in a gender-consistent manner. The authors interpret this in terms of gender schema theory and children's desire to maintain their stereotypic gender schemata by countering an inconsistent piece of information with a highly consistent one. It also illustrates that simply exposing children to models of people who defy gender stereotypes is not going to miraculously lead to changes in the way children think about gender-stereotypic behavior: Men should still behave in masculine ways, women in feminine ways, although, consistent with other research presented in this chapter, Hughes and Seta found that women were given more flexibility than men to express both their feminine and masculine sides.

were mistaken for girls, and so were labeled and raised as girls. However, under the influence of male hormones produced at puberty, they sprouted beards and became entirely masculine in appearance. How, in light of Money and Ehrhardt's critical-period hypothesis, could a person possibly adjust to becoming a man after leading an entire childhood as a girl?

Amazingly, 16 of these 18 individuals seemed able to accept their late conversion from female to male and to adopt masculine lifestyles, including the establishment of heterosexual relationships. One retained a female identity and gender role, and the remaining individual switched to a male gender identity but still dressed as a female. This study also casts doubt on the notion that socialization during the first 3 years is critical to later gender-role development. Instead, it suggests that hormonal influences may be more important than social influences. It is possible, however, that Dominican adults, knowing that this genetic disorder was common in their society, treated these girls-turned-boys differently from other girls when they were young or that these youngsters recognized on their own that their genitals were not normal (Ehrhardt, 1985). As a result, these "girls" may never have fully committed themselves to being girls.

What studies such as these of individuals with genital abnormalities appear to teach us is this: We are predisposed by our biology to develop as males or females; the first 3 years of life are a sensitive period perhaps, but not a critical period, for gender-role development; and both biology and social labeling contribute to gender-role development. Thus, we must respect the role of genes and hormones in gender-role development but also view this process from a contextual perspective and appreciate that the patterns of male and female development that we observe in society today are not inevitable. In another era, in another culture, the process of gender-role socialization could produce different kinds of boys and girls.

Childhood Sexuality

Although boys and girls spend much of their time in gender-segregated groups, most are nonetheless preparing for the day they will participate in sexual relationships with the other sex. They learn a great deal about sexuality and reproduction, continue to be curious about their bodies, and begin to interact with the other sex in ways that will prepare them for dating in adolescence.

Understanding Sex and Reproduction

With age, children learn that sexual anatomy is the key differentiator between males and females, and they acquire a more correct and explicit vocabulary for discussing sexual organs (Gordon, Schroeder, & Abrams, 1990). Children's understandings of where babies come from proceeds through a sequence consistent with Piaget's cognitive-developmental stages (Bernstein & Cowan, 1975; see Chapter 7). Accordingly, young children with their pre-operational reasoning seem to assume either that babies are just there all along or that they are somehow manufactured, much as toys might be. According to Jane, age 3½, "You find [the baby] at a store that makes it . . . Well, they get it and then they put it in the tummy and then it goes quickly out" (p. 81). Another preschooler, interpreting what he could of an explanation about reproduction from his mom, created this scenario (author's files):

The woman has a seed in her tummy that is fertilized by something in the man's penis. (*How does this happen?*) The fertilizer has to travel down through the man's body into the ground. Then it goes underground to get to the woman's body. It's like in our garden. (*Does the fertilizer come out of his penis?*) Oh no. Only pee-pee comes out of the penis. It's not big enough for fertilizer.

As these examples illustrate, young children construct their own understandings of reproduction well before they are told the "facts of life." Consistent with Piaget's theory of cognitive development, children construct their understanding of sex by assimilating and accommodating information into their existing cognitive structures. Some children as young as age 6 know that sexual intercourse plays a role in the making of babies, but their understanding of just how this works is limited (Caron & Ahlgrim, 2012). By age 12, most children have integrated information about sexual intercourse with information about the biological union of egg and sperm and can provide an accurate description of intercourse and its possible outcomes. Thus, as children mature cognitively and as they gain access to information, they are able to construct ever more accurate understandings of sexuality and reproduction.

Sexual Behavior

According to Freudian theory, preschoolers in the phallic stage of psychosexual development are actively interested in their genitals and seek bodily pleasure through masturbation, but school-age children enter a latency period during which they repress their sexuality and turn their attention instead to schoolwork and friendships with same-sex peers. It turns out that Freud was half right and half wrong.

Freud was correct that preschoolers are highly curious about their bodies, masturbate, and engage in both same-sex and cross-sex sexual play (see Kellogg, 2009). Between ages 2 and 5, interest increases and at least half of all children engage in sexual play (playing doctor or house), and sexual exploration such as looking at and touching genitals—their own, a peer's, or a younger sibling's (Kellogg, 2009; Larsson & Svedin, 2002). Freud was wrong, though, to believe that such activities occur infrequently among school-age children. Elementary school age children in Freud's latency period may be more discreet about their sexual experimentation than preschoolers, but they have by no means lost their sexual curiosity. Surveys show, for example, that about two-thirds of boys and half of girls have masturbated by age 13 (Janus & Janus, 1993; Larsson & Svedin, 2002) and are beginning to engage in "light" sexual activities (holding hands, kissing) with other young teens (Williams, Connolly, & Cribbie, 2008).

Gilbert Herdt and Martha McClintock (2000) have gathered evidence that age 10 is an important point in sexual development, a time when many boys and girls experience their first sexual attraction (often to a member of the other sex if they later become heterosexual or to a member of their own sex if they later become gay or lesbian). This milestone in development appears to be influenced by the maturation of the adrenal glands (which produce male androgens). It comes well before the maturation of the sex organs during puberty and therefore challenges the view of Freud (and many of the rest of us) that puberty is the critical time

in sexual development. As Herdt and McClintock note, our society does little to encourage fourth-graders to have sexual thoughts, especially about members of their own sex, so perhaps a hormonal explanation of early sexual attraction makes more sense than an environmental one (see also Halpern, 2006).

Sexual Abuse

Children's sexual activity with their peers is typically absent or, at most, exploratory ("I'll show you mine if you show me yours."). Some children, unfortunately, are victims of sexual abuse by, in most cases, someone older than themselves. By the end of childhood, 27% of females and 5% of males have experienced sexual assault or sexual abuse (Finkelhor et al., 2014). Clearly, sexual abuse is a serious and widespread social problem. Sadly, only one out of every four abused children tells someone about the abuse within the first 24 hours and one in four remains silent, never telling anyone about their painful experience (Kogan, 2004).

What is the effect of sexual abuse on the survivor? Kathleen Kendall-Tackett, Linda Williams, and David Finkelhor (1993) offer a useful account, based on their review of 45 studies. No single distinctive "syndrome" of psychological problems characterizes abuse survivors. Instead, they may experience any number of problems commonly seen in emotionally disturbed individuals, including anxiety, depression, low self-esteem, aggression, acting out, withdrawal, and school learning problems. Roughly 20%–30% experience each of these problems, and boys seem to experience the same types and degrees of disturbance as girls do.

Many of these aftereffects boil down to lack of self-worth and difficulty trusting others (Freyd et al., 2005; Putnam, 2003). A college student who had been abused repeatedly by her father and other relatives wrote this about her experience (author's files):

It was very painful, emotionally, physically, and psychologically. I wanted to die to escape it. I wanted to escape from my body I developed a "good" self and a "bad" self. This was the only way I could cope with the experiences I discovered people I trusted caused me harm It is difficult for me to accept the fact that people can care for me and expect nothing in return I dislike closeness and despise people touching me.

Two problems seem to be especially linked to being sexually abused. First, about a third of survivors engage in sexualized behavior, acting out sexually by putting objects in their vaginas, masturbating in public, behaving seductively, or if they are older, behaving promiscuously (Kendall-Tackett et al., 1993). One theory is that this sexualized behavior helps survivors master or control the traumatic events they experienced (Tharinger, 1990). Second, about a third of survivors display the symptoms of **posttraumatic stress disorder**. This clinical disorder, involving nightmares, flashbacks to the traumatizing events, and feelings of helplessness and anxiety in the face of danger, affects some soldiers who have experienced combat and other survivors of extreme trauma (Kendall-Tackett et al., 1993).

In a few children, sexual abuse may contribute to severe psychological disorders, yet about a third of children seem to experience no psychological symptoms (Kendall-Tackett et al., 1993;

Putnam, 2003). Some of these symptomless children may experience problems in later years. Nevertheless, some children are less severely damaged and more able to cope than others are.

Which children have the most difficulty? The effects of abuse are likely to be most severe when the abuse involved penetration and force and occurred frequently over a long period, when the perpetrator was a close relative such as the father, and when the child's mother did not serve as a reliable source of emotional support (Beitchman et al., 1991; Kendall-Tackett et al., 1993; Trickett & Putnam, 1993). Children are likely to recover better if they have high-quality relationships with their mother and friends (Adams & Bukowski, 2007; Aspelmeier, Elliott, & Smith, 2007). Psychotherapy aimed at treating the anxiety and depression many survivors experience and teaching them coping and problem-solving skills so that they will not be revictimized can also contribute to the healing process (Cuevas et al., 2010; Finkelhor & Berliner, 1995).

Finally, not all sex abuse offenders fit the stereotype of an adult who is an obvious pervert. Some offenders are themselves juveniles taking advantage of peers or somewhat younger children (Finkelhor, 2009). With appropriate and timely intervention and education, they can learn acceptable behaviors that reduce the likelihood of continued offending. Education can also prepare children to respond to inappropriate advances in ways that derail the possibility of an offense occurring. This three-pronged approach—working with the survivors, the offenders, and all children on prevention of sexual abuse—may be behind a recent decline in reports of childhood abuse (Finkelhor et al., 2010).

● Checking Mastery

1. At what age are children likely to be most concerned about adhering to traditional gender-role behaviors? Why?
2. What are two factors that contribute to gender segregation during childhood?
3. What are gender schemas, and what role do they play in gender typing?
4. What are some of the long-term effects of childhood sexual abuse?

● Making Connections

1. Jen and Ben are fraternal twins whose parents are determined that they should grow up having no gender-stereotypic attitudes or behaviors. Nonetheless, when the twins are only 4, Jen wants frilly dresses and loves to play with her Barbie doll, and Ben wants a machine gun and loves to pretend he's a football player and tackle people. Each seems headed for a traditional gender role. Which of the theories in this chapter do you think explains this best, which has the most difficulty explaining it, and why did you reach these conclusions?
2. Boys and girls have sometimes been characterized as living in two different worlds. Thinking about your own childhood, how was your world similar to or different from that of your other-sexed siblings (if any) and friends?
3. After reviewing the theories of gender-role development, where do you stand on the relative contributions of biology and environment to one's gender-role identity?

12.4

The Adolescent

LEARNING OBJECTIVES

- Describe the typical path of gender-role development in adolescence.
- Discuss the emergence of sexual identity and indicate where paths may diverge for those with heterosexual, homosexual, transgender, and/or bisexual identities.
- Analyze the evolution of sexual morality that has led to the current perspectives on sexual morality among adolescents.
- Outline the typical pattern of adolescent sexual behaviors and note factors that influence sexual behaviors of males and females.

After going their separate ways in childhood, boys and girls come together in the most intimate ways during adolescence. How do they prepare for the gender roles that will likely characterize their adulthood?

Adhering to Gender Roles

As you learned in the prior section, young elementary school children are highly rigid in their thinking about gender roles, whereas older children think more flexibly, recognizing that gender norms are not absolute, inviolable laws. Curiously, adolescents again seem to become highly intolerant of certain role violations and stereotyped in their thinking about the proper roles of males and females in adolescence. They are more likely than somewhat younger children to make negative judgments about peers who violate expectations by engaging in cross-sex behavior or expressing cross-sex interests (Alfieri, Ruble, & Higgins, 1996; Sigelman, Carr, & Begley, 1986).

Consider what Trish Stoddart and Elliot Turiel (1985) found when they asked children ages 5–13 questions about boys who wear a barrette in their hair or put on nail polish and about girls who sport a crew haircut or wear a boy’s suit. Both the kindergartners and the adolescents judged these behaviors to be wrong, whereas third-graders and fifth-graders viewed them far more tolerantly. Like the elementary school children, eighth-graders clearly understood that gender-role expectations are just social conventions that can easily be changed and do not necessarily apply in all societies. However, these adolescents had also begun to conceptualize gender-role violations as a sign of psychological abnormality and could not tolerate them.

Increased intolerance of deviance from gender-role expectations is tied to a larger process of **gender intensification**, in which gender differences may be magnified by hormonal changes associated with puberty and increased pressure to conform to gender roles (Boldizar, 1991; Galambos, Almeida, & Petersen, 1990). According to this process, boys begin to see themselves as more masculine and girls emphasize their feminine side. There is some support for this, at least in terms of higher levels of “femininity” reported by teen girls than by boys (Priess, Lindberg, & Hyde, 2009). When it comes to “masculinity,” though, teen boys and girls report roughly the same levels.

When gender intensification does occur, it is largely related to peer influence and the growing importance of dating. Adolescents increasingly find that they must conform to traditional

gender norms to appeal to the other sex. A girl who was a tomboy and thought nothing of it may find that, as a teenager, she must dress and behave in more “feminine” ways to attract boys and must give up her tomboyish ways (Burn, O’Neil, & Nederend, 1996; Carr, 2007). A boy may find that he is more popular if he projects a more sharply “masculine” image. Social pressures on adolescents to conform to traditional roles may even help explain why sex differences in cognitive abilities sometimes become more noticeable as children enter adolescence (Hill & Lynch, 1983; Roberts et al., 1990). It should be noted that the social pressure to conform to gender stereotypes does not need to be real—adolescents’ *perceptions* of their peers’ thoughts and expectations can affect their behaviors and lead to gender intensification (Pettitt, 2004). Later in adolescence, teenagers again become more comfortable with their identities as men and women and more flexible in their thinking.

Not Adhering to Gender Roles: Transgender Youth

Navigating the many changes of adolescence can be challenging for all youth, but they can be especially difficult for those who are transgender or are exploring their gender identity. We introduced two transgender children in this chapter’s opener and gave a general definition of transgender. It is important to keep in mind that the concept of transgender is multifaceted and means different things to different people. It could mean an individual who was assigned as a male at birth who later perceives herself as a girl. Growing into adulthood, this individual may present as a woman who may be sexually attracted to women or to men or to others regardless of the others’ gender identity. Clearly, there are many variations within the transgender label (Levitt & Ippolito, 2014).

A solid majority (2 out of every 3) transgender youth report bullying, harassment, and verbal abuse by not only their peers, but in some cases by their own parents (Grossman, D’Augelli, & Frank, 2011). Those who have support from family and/or peers benefit from this, but it does not eliminate the harmful effects of bullying and other abuse directed towards them (Mustanski, Newcomb, & Garofalo, 2011). Heidi Levitt and Maria Ippolito (2014) analyzed interviews with transgender people and concluded that transgender identity development was a balancing act. That is, in acknowledging their transgender identity, people considered how to balance their internal feelings about their gender with what they believed would be the external consequences

of their life as a transgendered person. Importantly, there is no single path or outcome that is right for everyone; it is very much a personal journey that depends on the resources and characteristics of each individual. Still, there have been attempts to characterize the process of adopting a transgender identity. Here, we consider a five-stage process articulated by Walter Bockting and Eli Coleman (2016). Their five stages are:

1. Pre-coming out
2. Coming out
3. Exploration
4. Intimacy
5. Identity integration

We have learned that society sends powerful messages about how boys and girls should act to fit into the binary categories of boy–girl and man–woman to which most societies adhere. During the pre-coming out stage, children begin to feel confused as they realize they do not fit nicely into the two big gender categories that everyone else seems to embrace and expect of them. Depending on their age and developmental stage, children may not understand what they are feeling and may not be able to verbalize their feelings. In a world where they are presented with limited options—act like a boy if assigned as a male at birth or act like a girl if assigned as a female at birth—children who have transgender feelings may feel quite baffled. They are often bullied for being different or not conforming to societal norms.

During the second stage, coming out, individuals begin to acknowledge to selves and others that they do not fit the standard gender identities and are, instead, transgender. This realization can occur at any time across the life span, although most

transgender adults acknowledge feeling different from others from a young age (Grossman et al., 2005).

With the realization of one’s transgender identity comes a phase of exploration, or learning as much as possible and, in a sense, testing the boundaries of what this new identity means. During this stage, most individuals conduct a great deal of research and give considerable thought to how to best live as transgender, trying to answer questions about name, clothing, surgery, hormones, and even which bathroom to use.

Following exploration of “how to be” transgender, the next stage is to navigate intimacy in one’s new identity. Bockting and Coleman (2016) note that transgender men seem to have an easier time with this stage than transgender women. Whether male or female, the ease of developing positive intimate relationships is influenced by one’s sexual orientation. Those whose sexual orientation is heterosexual have a smoother path than those with a homosexual orientation, as is the case with non-transgender youth.

Finally, there is identity integration, which Bockting and Coleman (2016) describe as a union of one’s public and private selves. This integration promotes living comfortably as one’s true self, whatever that means to the individual. Among children who have transitioned from a traditional gender identity to transgender, research indicates that their gender perceptions of self are much like those of non-transgendered children of their expressed gender (Olson, Key, & Eaton, 2015). In other words, a transgender girl (a child assigned as male at birth but now living as a girl) thinks of herself very much like girls who were assigned female at birth and whose gender identity is consistent with this sex assignment.

Just as transgender children need time, resources, and support to navigate to the identity that best suits them, so do their parents and friends. Even the most supportive parents can often feel overwhelmed with trying to understand the changes in their child and answer the inevitable questions from other family members, school officials, and others who knew their child prior to transitioning. Parents identify accurate medical information and professional support among their top needs as they try to support their child and make informed decisions (Riley et al., 2011). At school, transgender youth should be protected from discrimination by the federal law known as Title IX (see U.S. Department of Education, Office for Civil Rights, 2016). Many schools have had to scramble to make accommodations for male-to-female and female-to-male transgender students who want to be educated in a safe and welcoming environment, regardless of their gender status.

Attaining Sexual Maturity

Although infants and children are sexual beings, sexuality assumes far greater importance once sexual maturity is achieved. Adolescents must incorporate into their identities as males or females concepts of themselves as sexual males or females. Moreover, they must figure out how to express their sexuality in relationships. As part of their search for identity, teenagers raise questions about their sexual attractiveness, their sexual values, and their goals in close relationships. They also experiment with sexual behavior—sometimes with good outcomes, sometimes with bad ones. And what do the teens’ parents think of this burgeoning sexuality? As

Sinikka Elliott (2012) describes in her book, *Not My Kid*, parents believe that other teenagers are sexual beings and may be trying to lure their innocent child into sexual exploits, but their child is not yet sexual or is far too young for such matters. As you will see, however, it is not the case that only *other* adolescents are interested in sexual activity!

Sexual Orientation

Part of establishing a sexual identity, part of an individual's larger task of resolving Erikson's conflict of identity versus role confusion, is becoming aware of one's **sexual orientation**—that is, preference for sexual partners of the same or other sex, or both. Sexual orientation exists on a continuum, with many experts now recognizing five classifications of sexual identity: heterosexual, mostly heterosexual, mostly homosexual, homosexual, or bisexual (Vrangalova & Savin-Williams, 2012). Most adolescents establish a heterosexual sexual orientation without much soul-searching, what Elizabeth Morgan (2012) refers to as “commitment with passive exploration.” For youths attracted to members of their own sex, however, the process of accepting that they have a homosexual, mostly homosexual, or bisexual orientation and establishing a positive identity in the face of societal attitudes that may be negative or ambivalent can be difficult. Many have an initial awareness of their sexual preference before reaching puberty but do not accept being gay or lesbian, or gather the courage to “come out,” until their mid-20s (Savin-Williams, 2001). Among 17- to 25-year-olds with same-sex attractions in one study, fewer than half had told both their parents and about one-third had not told either parent about their sexual orientation (Savin-Williams & Ream, 2003). Those who had disclosed to one or both parents did so around age 19. By this age, most are out of high school and have achieved some independence from their parents, which may give them the confidence to share this information. In recent years, coming out as gay or lesbian has become, if not easy, then perhaps easier than it was for previous generations (Savin-Williams & Cohen 2015). Teens who have disclosed their same-sex orientation to someone report higher levels of self-esteem and overall well-being than other teens who have not done so (Kosciw, Palmer, & Kull, 2015). Those who come out may feel more comfortable with their identity and have the personal resources to manage the stresses that accompany coming out.

Experimentation with homosexual activity is fairly common during adolescence, but few adolescents become part of the estimated 5–6% of adults who establish an enduring homosexual or bisexual sexual orientation (Savin-Williams & Ream, 2007). Contrary to societal stereotypes of gay men as effeminate and lesbian women as masculine, gay and lesbian individuals have the same range of psychological and social attributes that heterosexual adults do. Knowing that someone prefers same-sex romantic partners reveals no more about his or her personality than knowing that someone is heterosexual.

For the most part, sexual orientation is stable across the life span, at least for those individuals who identify themselves as 100% heterosexual or 100% homosexual (Mock & Eibach, 2012; Savin-Williams, Joyner, & Rieger, 2012). For individuals who identify as bisexual, there is less stability over time, with only one in four remaining in this category over time. Ritch Savin-Williams and colleagues (2012) report that females who initially

According to a 2013 Gallup poll, 3.5% of the U.S. population self-identifies as lesbian, gay, bisexual, or transgender.

Jari Hindstroem/Shutterstock.com

identified as bisexual are most likely to later identify as “mostly heterosexual,” whereas males who initially identify as bisexual are much more variable in their identity at later points in time. In longitudinal research with women, Lisa Diamond (2008) found that orientation as lesbian or bisexual was relatively enduring over a 10-year period, although women often defied attempts to be defined exclusively by a single sexual orientation. Many preferred to be unlabeled, perhaps reflecting an openness to changes in sexual orientation or an attraction to the person without regard to that person's biological sex (see Diamond, 2008).

What influences the development of sexual orientation? Part of the answer lies in the genetic code. Twin studies have established that identical twins are more alike in sexual orientation than fraternal twins (see Ngun & Vilain, 2014; Pillard & Bailey, 1998). As **Table 12.2** reveals, however, in as many as two-thirds of identical twin pairs, one twin is homosexual or bisexual but the other is heterosexual. Thus, although more identical twins than fraternal twins are concordant (alike) for sexual orientation, the majority of identical twins are still not concordant—they are dissimilar—for sexual orientation. This means that environment contributes at least as much as genes to the development of sexual orientation (Bailey, Dunne, & Martin, 2000; Kendler et al., 2000).

Looking at childhood behaviors, research shows that many gay men and lesbian women expressed strong cross-sex

● **Table 12.2** Percentage of Twins Who Are Concordant (Alike) for Nonheterosexual Sexual Orientation

Identical twins	32%
Same-sex fraternal twins	13%
All fraternal twins (same and other sex)	8%

Source: Adapted from Kendler, K. S., Thornton, L. M., Gilman, S. E., & Kessler, R. C. (2000). Sexual orientation in a U.S. national sample of twin and nontwin sibling pairs. *American Journal of Psychiatry*, 157, 1843–1846, Figure 2.

Note: Nonheterosexual is any sexual orientation other than heterosexual (that is, includes homosexual and bisexual). Higher rates of similarity for identical twin pairs than for fraternal twin pairs provide evidence of genetic influence on nonheterosexuality.

interests when they were young, despite being subjected to the usual pressures to adopt a traditional gender role (Bailey et al., 2000; Golombok et al., 2012; Lippa, 2008). For example, as **Figure 12.5** shows, Richard Lippa (2008) found that homosexual adults—both male and female—were significantly more likely than heterosexual adults to recall **childhood gender nonconformity (CGN)**. CGN, or not adhering to the typical gender-role norms expected for members of one’s assigned gender group, is also more common for females than males.

Still, it is important to note that sexual orientation is every bit as heritable among gay men who were typically masculine boys and lesbian women who were typically feminine girls as among those who showed early gender nonconformity (Bailey & Pillard, 1991; Bailey et al., 1993). Although it might be tempting to infer sexual orientation from early childhood behaviors, all we really know is that *some* gay and lesbian adults knew from an early age that traditional gender-role expectations did not suit them, but others did not.

What environmental factors may help determine whether a genetic predisposition toward homosexuality is actualized? We do not know yet, although we can reject the old psychoanalytic view that male homosexuality stems from having a domineering mother and a weak father (LeVay, 1996). Growing up with a gay or lesbian parent also seems to have little effect on later sexual orientation (Patterson, 2004). We can also rule out the shared family environment: In a fairly large analysis of the same-sex behavior of nearly 4,000 pairs of identical and fraternal twins, researchers concluded that the shared environment contributed next to nothing to the concordance of twins’ sexual orientation (Långström et al., 2010). Instead, genetics played a role and was stronger for males than females.

A more promising hypothesis is that hormonal influences during the prenatal period influence sexual orientation (Ellis et al., 1988; Meyer-Bahlburg et al., 1995). For example, androgenized females are more likely than other women to adopt a lesbian or

bisexual orientation, suggesting that high prenatal doses of male hormones may predispose at least some females to homosexuality (Dittman et al., 1992; Money, 1988). Later-born males with older brothers may be more prone to a homosexual orientation because, according to one theory, their mother produces anti-male antibodies that accumulate over the course of each pregnancy with a male (see Blanchard & Lippa, 2007). However, this does not explain why some firstborn males or males without older brothers develop a homosexual orientation (see Gooren, 2006). Another possibility is that nature and nurture interact: Biological factors may predispose an individual to have certain traits, which in turn influence the kinds of social experiences the person has, which in turn shape her sexual orientation (Byne, 1994). However, even the experts cannot yet clearly define which factors in the prenatal or postnatal environment contribute, with genes, to a homosexual orientation.

Beliefs about Sexuality

Whatever their sexual orientation, adolescents establish beliefs about what is and is not appropriate sexual behavior. The sexual beliefs of adolescents changed dramatically during the 20th century, especially during the 1960s and 1970s, yet at least some of the old values have endured (Caron & Moskey, 2002). Several generalizations emerge from the research on sexual beliefs.

First, many adolescents—approximately three out of four—have come to believe that sex with affection in the context of a committed relationship is acceptable (Caron & Moskey, 2002). They no longer buy the traditional view that premarital intercourse is always morally wrong (● **Table 12.3**). Brooke Wells and Jean Twenge (2005) analyzed 530 studies of sexual behavior and attitudes, spanning a period of over 50 years. They found that the percentage of men who approved of premarital sex jumped from 40% to 79%, but the change in women’s attitudes was even more dramatic, going from 12% to 73% who approved of premarital sex. However, adolescents do not all go so far as to approve of casual or “nonromantic” sex, although males have somewhat more permissive attitudes about this than females (see Olmstead et al., 2013). Consistent with this, most adolescents believe that partners should be in a long-term romantic relationship or feel a close emotional involvement with each other (Caron & Moskey, 2002). Most adolescents—both male and female—report that their first sexual relationship was with someone with whom they were romantically, not casually, involved (Ryan, Manlove, & Franzetta, 2003; Williams & Russell, 2013). On average, teens wait about 5 months before having sex with a romantic partner. Even adolescents who have sex with a nonromantic partner report that there were emotional and social components to the relationship (Williams & Russell, 2013). Thus, casual sex is not the norm among young teenagers.

Teens who go off to college may find casual sexual encounters somewhat more normative in this context. The typical **hookup** is a casual, often brief, sexual encounter between two people who have often just met at a party and have little expectation of forming a romantic relationship. Males and females are similar in their descriptions of what transpires during a typical hookup, but women express a wider range of mostly negative emotional reactions to hooking up (Lyons et al., 2014; Uecker, Pearce, & Andercheck, 2015). Women with higher rates of casual

sex—hookups—are more likely to experience depression relative to those having no or little casual sex (Welsh, Grello & Harper, 2006). In contrast, men with higher rates of casual sex have some of the lowest levels of depression. Women are also more likely than men to experience guilt and remorse following casual sex (Fielder & Carey, 2010; Owen et al., 2010). These differences may be explained, at least in part, by the next finding.

A second generalization is that the **double standard** has declined but not disappeared over the years (Kreager & Staff, 2009; Peterson & Hyde, 2010). According to the double standard, sexual behavior that is viewed as appropriate, and even good, for males is considered inappropriate or bad for females; there is one standard for males, another for females. In the “old days,” a young man was expected to obtain some sexual experience, and gained respect from peers for his sexual exploits (“he’s a stud”). In contrast, a young woman was expected to remain a virgin until she married and was viewed negatively for engaging in sexual behaviors (“she’s a slut”). Teens and young adults still tend to believe that a woman who has many sexual partners is more immoral than an equally promiscuous man (Boislard, van de Bongardt, & Blais, 2016). In part, the double standard for male–female sexuality may persist because it fits entrenched societal expectations, even though actual sexual behaviors of males and females are more similar than different. Males are more likely than females to retain the double standard, although both males and females believe women should be more careful with casual sexual encounters out of fear that women may experience social stigma or be subjected to various rape myths (Conley, Ziegler, & Moors, 2013; Rudman, Fetterolf, & Sanchez, 2013). The persistence of the double standard may help explain why males report primarily positive feelings from casual hookups, whereas females report mostly negative feelings from these encounters.

A third generalization that emerges from research on sexual beliefs is that adolescents are confused about sexual norms. Adolescents continually receive mixed messages about sexuality (Ponton, 2001). They are encouraged to be popular and attractive to the other sex, and they watch countless television programs and movies that glamorize sexual behavior. The more sexualized content they watch, the more likely they are to be sexually active themselves (Chandra et al., 2008). Yet many adolescents are told to value virginity and to fear and avoid pregnancy, bad reputations, and AIDS and other sexually transmitted infections (STIs). Adults often tell teens that they are too young to engage in sexual activity, yet they make teens feel ashamed or embarrassed about masturbating (Halpern et al., 2000; Ponton, 2001).

Finally, today’s adolescents are more tolerant or open-minded of a variety of sexual behaviors and orientations. Homosexual orientation may not be normative, but it is certainly more widely accepted today than it was in previous generations. Nearly half of adults today agree that “same-sex sexual activity is not wrong at all,” compared to only about 12% of adults 40 years earlier (Twenge, Sherman, & Wells, 2016). The standards for males and females are now more similar, and adolescents tend to agree that sexual intercourse in the context of emotional involvement is acceptable; but teenagers still must forge their own codes of behavior, and they differ widely in what they decide.

Sexual Behavior

If beliefs about sexual behavior have changed over the years, has sexual behavior itself changed? In short, yes. Today’s teenagers are involved in more intimate forms of sexual behavior at earlier ages than adolescents of the past were. Rates of sexual activity climbed in the 1960s and continued to climb through the 1980s before leveling off and then declining somewhat from the mid-1990s on

(Martinez & Abma, 2015). For instance, the percentage of 15–19 year old males who have ever had sex declined from 60% in 1988 to 42% in 2008 (Martinez & Abma, 2015). Over this same 20-year period, the percentage of females who ever had sexual intercourse dipped from 51% to 43%, nearly identical to the male rate. By age 20, 75% of young adults report having had sexual intercourse, and by age 24, 85% report having had sexual intercourse (Chandra, Mosher, Copen, & Sionean, 2011; Meschke et al., 2000).

Rates of sexual activity depend greatly on how sexual activity is defined. What constitutes “having sex”? Virtually all college students—both male and female—agree that penile–vaginal intercourse is having sex, but in a 2007 survey only 20% of college students agreed that they had “had sex” when they engaged in oral–genital stimulation (Hans, Gillen, & Akande, 2010). Perhaps this is why there are higher rates of **oral sex** than intercourse among today’s high school students (Prinstein, Meade, & Cohen, 2003). If their cognitive schema of having sex does not include oral sex (or anal sex for some teens), they can engage in oral sex without feeling they are really having sex. Consequently, as many as 40% of college students who label themselves virgins report giving or receiving oral sex, and some of these have had three or more oral sex partners (Chambers, 2007).

Interestingly, today’s teens rate oral sex as less intimate than intercourse, the opposite of what many from their parents’ generation believe (Chambers, 2007). This may help explain the rise in oral sex among teenagers. Another reason is teens’ inaccurate perception that oral sex is safer than vaginal penetration. Although oral sex without intercourse may sharply reduce pregnancy rates, it does not prevent transmission of STIs unless partners consistently use protection. Unfortunately, many teens lack knowledge about how to protect themselves during oral sex (Brady & Halpern-Fisher, 2007; Chambers, 2007). In addition to possible health consequences, there may be emotional consequences for teens who engage in oral sex. Teens who engage only in oral sex (without intercourse) report less positive feelings about themselves and their relationship than other sexually active teens (Brady & Halpern-Fisher, 2007).

Becoming sexually active is a normal part of development, but parents and society often express concerns about teens becoming sexually active when they are too young, because early sexual activity is associated with risky behaviors that can lead to unwanted pregnancies and STIs. Just a year or two can make a big difference in whether or not teens take precautions to reduce risks: Among teens who start having intercourse at age 17 or younger, 82% of males and 77% of females report using contraception when they became sexually active (Martinez & Abma, 2015). But among those teens who start having intercourse at ages 18–19, they are significantly more likely (99% males and 93% females) to report using contraception when they have sex.

Jessica Siebenbruner and her colleagues (2007) studied the antecedents of early sexual behavior among three groups of 16-year-olds who had previously been evaluated on a variety of measures at ages 6, 9, 12, and 13. The researchers distinguished among three groups on the basis of self-reported sexual behaviors at age 16: sexual abstainers who had not yet had sexual intercourse, low risk-takers who reported having five or fewer sexual partners and always using contraception, and high risk-takers who reported having six or more sexual partners and inconsistently

using contraception. The researchers wanted to know whether they could predict which of these three groups a teen would end up in at age 16 based on information collected at the earlier ages.

Several findings emerged from this research. High-risk sexual behavior at age 16 seemed to be part of a general pattern of problem behavior that started at birth with a mother who was unmarried (Siebenbruner et al., 2007). Unwed mothers tend to be younger, less educated, and more likely to experience economic hardships. High-risk teens grew up in homes that were characterized as less emotionally responsive, and they were rated by teachers as engaging in more externalizing behaviors at ages 9 and 12. In these respects, the high-risk teens were different from both the low-risk teens and the abstainers throughout childhood.

By contrast, the low-risk teens and the abstainers were similar throughout childhood, yet began to diverge in early adolescence. At age 13, low-risk teens *looked* more mature than abstainers and were more involved in romantic relationships. They were also somewhat more likely to drink alcohol at age 16 than the abstainers. Their mature appearance may have led others to respond to them differently, leading them to romantic relationships, sexual involvement, and alcohol use at an earlier age than their peers who appeared less mature. These findings suggest that parents who are concerned about early involvement in sex should be on the alert for problem behaviors during childhood, provide an emotionally responsive home environment, and talk to their teens about how their appearance may influence how others perceive and treat them.

Some teens seem headed for engaging in riskier sexual behaviors than other teens. M. Lynne Cooper (2010) evaluated the sexual behaviors of nearly 2,000 young adults and found that numerous factors, including within-person factors, situational factors, and interactions of the two, contribute to the chances of engaging in risky sex. Within-person factors associated with more risky sexual behaviors included low levels of impulse control and communal-ity, high levels of being adventurous, and a tendency towards negative emotionality (a tendency to feel anxious and depressed and react poorly to stressful situations). Situations involving sex with a new partner were associated with drinking more alcohol and choosing a riskier partner but also with a greater likelihood of using a condom. Research consistently shows that alcohol use is associated with riskier sexual behaviors. Compared with adults, teens and young adults from minority groups, especially males, are more likely to engage in risky sex practices, with potentially life-altering consequences (see Espinosa-Hernandez & Lefkowitz, 2009; Lee & Hahm, 2010). **Exploration 12.1** examines the concerning issue of sexual assault on college campuses, which is often accompanied by alcohol or drug use by one or both parties.

Although most adolescents seem to adjust successfully to becoming sexually active, there have also been some casualties among those who are psychologically unprepared for sex or who end up with an unintended pregnancy or an STI. Sexually active adolescent couples often fail to use contraception, partly because they are cognitively immature and do not take seriously the possibility that their behavior could have unwanted long-term consequences (Loewenstein & Furstenberg, 1991). Although condom use has increased over past decades, it is still lower than health-care professionals would like to see. In addition, adolescent

● EXPLORATION 12.1

Sexual Assaults on College Campuses

One in five, or 20%: That's how many women in college report that they have been sexually assaulted (Krebs et al., 2007). **Sexual assault** refers to unwanted and nonconsensual sexual contact or behavior (Krebs et al., 2016). It includes rape and attempted rape, as well as unwanted fondling, touching, kissing, and other nonconsensual contact with your body. The figure in this box tells an important story: Women are most likely to experience a sexual assault during the first month or two of their first year in college (Krebs et al., 2016).

According to this same survey (Krebs et al., 2016), a majority of women tell a friend, roommate, or family member, but do not report the incident to a school official or to law enforcement. Reasons for not making an official report include not wanting to make a “big deal” out of it and concern that others will blame them for what happened.

Women report a variety of problems in the aftermath of a sexual assault, including trouble with friends and roommates, withdrawal from classes, and even thoughts about dropping out or transferring schools (Jordan, Combs, & Smith, 2014; Krebs et al., 2016).

What factors contribute to the incidence of sexual assaults on college campuses? Alcohol consumption, especially excessive episodic consumption (binge drinking), is common by both parties involved in the sexual assault (Fedina, Holmes, & Backes, 2016; White & Hingson, 2014). A culture of “hooking up” can also contribute to the likelihood of perpetrating a sexual assault or experiencing one (Sutton & Simons, 2015). Fraternity and athletic subcultures on college campuses may also encourage attitudes and behaviors that promote sexual misconduct.

There are actions that individuals can take to reduce personal risk, and there are

programs that schools can implement to decrease the sexual assaults on their campuses and to promote healthy behaviors. For one, intervention programs that teach

students how they can intervene when one of their friends appears at-risk for inappropriate behavior have been effective (Coker et al., 2015). These “bystander intervention” programs are designed to empower peers to take action if they witness risky behavior. Other programs focus on fostering clearer communication about issues of consent. One such promising program is *RealConsent*, which consists of six 30-minute online, interactive modules on various aspects of sexual relationships. In one study, researchers were able to randomly assign male college students to complete either the *RealConsent* program or a different web program on general health promotion (Salazar et al., 2014). Six months after completing the webinars, the *RealConsent* students showed more positive behaviors (for example, intervening when someone else was at risk) and fewer negative behaviors (for example, less often being involved in sexual violence) than students in the control group. In addition, the *RealConsent* students reported greater knowledge of effective consent and healthier attitudes about women and relationships (for example, less hostility toward women and more empathy toward victims).

Comprehensive reviews of dozens of studies of sexual assault prevention identify several important features needed for program success (White House Task Force to Protect Students from Sexual Assault, 2014). These features focus on four important elements: characteristics of the individuals involved, their relationships with others, their physical environments, and the broader social and cultural contexts in which they function (DeGue, 2014; DeGue et al., 2012). Short, one-time programs are largely ineffective in making measurable and lasting changes to behavior. Working effectively with potential perpetrators of sexual violence requires programming that gets at some of the underlying risk factors, such as the individual's beliefs about women and the messages they receive from the culture around them about acceptable behaviors. Although the number of sexual assaults on college campuses is high, there are many promising signs that individuals and institutions are no longer willing to stand by silently and permit this problem to continue. With increasing numbers of institutions implementing aggressive prevention programs, the payoff is likely to be fewer and fewer college students who experience sexual assaults.

couples who are in long-term, monogamous relationships often stop using condoms because they no longer fear transmission of human immunodeficiency virus (HIV) or other STIs.

Sexual behaviors are also shaped by the social and cultural contexts in which children develop. For example, research shows that teens are less likely to use condoms if their friends report engaging in sex without condoms (Henry et al., 2007). Conversely, teens are more likely to use condoms if they believe their friends are using

condoms. Examining the larger cultural context, Eric Widmer and his colleagues (Widmer, Treas, & Newcomb, 1998) found wide variations in sexual beliefs across the 24 countries that they studied. These prevailing cultural beliefs, whether conservative, permissive, or somewhere in the middle, influence how teens construct their individual sexual identities. Teens growing up in cultures with more permissive attitudes about sexuality are likely to interpret their own behaviors differently than teens growing up in cultures with largely

Becoming sexually active is a normal part of development, occurring during adolescence for some and adulthood for others.

Daniel Vrabec/Alamy Stock Photo

conservative beliefs. Thus, sexual behavior is not driven simply by the surge in hormones that accompanies puberty; it is mediated by social context and by the personal beliefs that are constructed in response to physical changes and cultural beliefs.

For the adolescent who gives birth, the consequences of teenage sexuality can include an interrupted education, a low income, and a difficult start for both her and her child (see Hoffman & Maynard, 2008). This young mother's life situation and her child's developmental status are likely to improve later, especially if she goes back to school and limits her family size, but she is likely to remain economically disadvantaged compared with her peers who postpone parenthood until their 20s or later (Hoffman & Maynard, 2008). Fortunately, after increasing for many years, rates of teenage pregnancy have begun to decline in recent years (Kost, Henshaw, & Carlin, 2010).

In addition to unplanned pregnancy, poorly planned sexual activity can have health consequences, namely STIs. ● **Table 12.4** provides an overview of STIs that can result from inconsistent or

● **Table 12.4** Sexually Transmitted Infections (STIs) with Their Cause, Symptoms, and Treatment

STI	Cause and Treatment	Symptoms and Side Effects
<i>Chlamydia</i> : Highest rates among 15- to 19-year-olds, followed by 20- to 24-year-olds	Caused by bacteria; can be treated and cured with antibiotics	Few or no symptoms; when present, symptoms include slight discharge from vagina or penis, burning with urination, and lower abdominal pain. If left untreated, it can result in pelvic inflammatory disease, which is associated with infertility.
<i>Trichomoniasis</i> : Highest rates among women aged 30 and older	Caused by a parasite; can be treated and cured with antibiotics	Few or no symptoms; when present, symptoms include irritation or itching of the genital area, painful urination and intercourse, and possibly lower abdominal pain.
<i>Gonorrhea</i> : Highest rates among adolescents and young adults	Caused by bacteria; can be treated and usually cured with antibiotics, although some strains have become resistant	Few or no symptoms; when present, symptoms include genital discharge and painful urination. Gonorrheal infections can also invade the mouth and throat through oral sex with an infected partner, or the anus and rectum through anal sex with an infected partner. Can lead to infertility if untreated.
<i>Genital Herpes</i> : Incidence increases across age groups, peaking in middle adulthood	Caused by herpes simplex virus; can be treated but not cured	Symptoms include genital discharge, itching or burning, and painful blisters in the genital and anal regions. Although blisters may disappear in 2–3 weeks, the underlying virus that causes genital herpes remains and can cause symptom recurrence at any time. On average, infected persons have four occurrences per year.
Genital Warts: Highest rates among those in their early 20s	Caused by human papillomavirus (HPV); can be treated with surgery or cauterization of warts but may recur if immune system does not completely eliminate virus	Symptoms include small painless bumps on the vagina, cervix, or vulva (females) and penis (males); the anus and mouth may also be affected. If left untreated, the growths can grow into a larger clump of warts resembling cauliflower. Some strains of HPV are associated with cervical cancer, and a vaccine has been developed to prevent HPV.
<i>Syphilis</i> : Highest rates among 20-somethings	Caused by <i>Treponema pallidum</i> bacteria, which is highly contagious; can be treated in early stages with antibiotics	Symptoms emerge in stages: The first symptom is typically one or more ulcerlike sores around the genitals, although these sores, called chancres, can also appear in the mouth or anal area depending on point of contact with an infected person. This is followed by a body rash and flulike symptoms, which may last for several weeks. The underlying bacteria can remain dormant for years, or it can resurface in the lungs, heart, or brain. Can cause brain disease, dementia, or blindness if left untreated.

Sources: Adapted from Centers for Disease Control and Prevention (CDC). (2012d, December). *Sexually transmitted disease surveillance*, 2011. inadequate safe-sex practices. Sadly, few adolescents are doing what they would need to do to protect themselves from STIs: abstaining from sex or using a condom *every* time. No wonder many educators are calling for stronger programs of sex education and distribution of free condoms at school. There is little chance of preventing the unwanted consequences of teenage sexuality unless more adolescents either postpone sex or practice safer sex.

One encouraging finding is that teens who feel close to their parents, especially their mothers, and who report having closer parental supervision are more likely to delay initiating sexual activity (L'Engle & Jackson, 2008). Parents who have clear household routines, monitor their teens, and establish strong relationships with their sons and daughters tend to have adolescents who delay sex or avoid casual sex (Manlove et al., 2012). Parent–teen communication about sexuality can also delay the age of first intercourse, particularly when mothers (rather than fathers) have the conversation and point out the negative consequences of having sex at an early age (Widman et al., 2016). Unfortunately, many parents do not communicate clearly or regularly with their teens about matters of sexuality (Guilamo-Ramos et al., 2008). In a survey of mothers of at-risk urban middle-school students, those who thought that a conversation about sex would embarrass their teen or felt unsure of what to say or how to initiate such a conversation tended not to talk to their teen about sex. In contrast, mothers who thought that talking about sex would encourage their teen to think more maturely, believed it wouldn't be too embarrassing, thought they would be able to answer their teen's questions, and felt comfortable with themselves and with the idea of talking about sex were more likely to have such conversations (Guilamo-Ramos et

al., 2008; Pluhar, Dilorio, & McCarty, 2008). This suggests that successful sex education programs need to reach out to parents and help educate parents as well as their teens.

Another encouraging finding is that educational programs that emphasize abstinence can be effective (Jemmott, Jemmott, & Fong, 2010). Such programs can encourage young adolescents to delay sexual intercourse. Importantly, when teens who participate in abstinence-only programs have intercourse, they are just as likely to use a condom as teens who participate in alternative educational programs focusing on safe sex (Jemmott et al., 2010). This is good news for those who worry that focusing on abstinence may not provide teens with sufficient knowledge about safe sex.

● Checking Mastery

1. What do we know about the sexual beliefs of many of today's teens?
2. Are there differences in sexual behavior of males and females?
3. What factors likely contribute to one's sexual orientation?

● Making Connections

1. What factors are likely to influence the age at which young people today become sexually active?
2. If you wanted to delay the age of first intercourse, what would be two ways to do this?

12.5

The Adult

LEARNING OBJECTIVES

- Explore changes in gender roles across adulthood.
- Evaluate the pros and cons of androgyny.
- Indicate how women and men have managed to integrate the various roles of adulthood: career, relationships, and parenting.
- Discuss changes in sexual behaviors and sexuality throughout adulthood.

You might think that once children and adolescents have learned their gender roles, they simply play them out during adulthood. Instead, as people face the challenges of adult life and enter new social contexts, their gender roles and their concepts of themselves as men and women change. So, too, do their sexual behaviors and their perceptions of their own sexuality.

Changes in Gender Roles

Although males and females fill their agentic or communal roles throughout their lives, the specific content of those roles changes considerably over the life span. The young boy may act out his agentic role by playing with trucks or wrestling with his buddies; the grown man may play his role by holding down a job. Moreover, the degree of difference between male and female roles also changes. Children and adolescents adopt behaviors consistent

with their “boy” or “girl” roles, but the two sexes otherwise adopt similar roles in society—namely, those of children and students. Even as they enter adulthood, male and female roles differ little because members of both sexes are often single and in school or working.

However, the roles of men and women become more distinct when they marry or settle into a stable romantic relationship and especially when (and if) they become parents. Anthropologist David Gutmann (1987, 1997) has offered the intriguing hypothesis that gender roles and gender-related traits in adulthood are shaped by what he calls the **parental imperative**—the requirement that mothers and fathers adopt different roles to raise children successfully. Drawing on his own cross-cultural research and that of others, he suggests that in many cultures, young and middle-aged men must emphasize their “masculine” qualities to feed and protect their families, whereas young and middle-aged

women must express their “feminine” qualities to nurture the young and meet the emotional needs of their families.

The birth of a child tends to make even egalitarian couples divide their labors in more traditional ways than they did before the birth and migrate toward more traditional gender-role attitudes: Mothers become primarily responsible for child care and household tasks and fathers tend to emphasize their role as breadwinner for the family. Consistent with this, Andrea Abele (2014) found that women’s work hours dropped significantly after becoming mothers, but men’s work hours were virtually unchanged after becoming fathers. The American Time Use Survey shows that, for most heterosexual couples with children, the mother typically does about 18 hours of housework and 14 hours of childcare, whereas the father does about 10 hours of housework and 7 hours of childcare (Pew Research Center, 2013). In contrast, fathers spend more hours working outside the home (37 hours per week) compared to mothers (21 hours). Thus, there may be something to the concept of the parental imperative, although perhaps not to the extent suggested by Gutmann.

Women have less leisure time than men, perhaps as a result of their desire to “have it all.” Michelle Hoffnung (2004; Hoffnung and Williams, 2013) interviewed women in their senior year of college and found that these young women wanted marriage, career, and motherhood. Following graduation, the women planned to focus first on establishing their careers. When Hoffnung (2004) checked up on the women 7 years after graduation, she found that some of the women were now married, but marital status was not related to educational attainment or career status. In contrast, motherhood was related to both educational attainment and career status: Those women who had children had not gone as far with their education or career as those women without children. Thus, as they neared the age of 30, women seemed to be able to have marriage and a career, or marriage and a baby, but having all three led to some compromises, namely less progress in their careers.

Sixteen years after college graduation, when they were in their mid- to late-30s, Hoffnung and Williams (2013) again interviewed the women. At this point, about 90% had married and about 75% had children. Only 57% of those with children were employed full time. Most women indicated that they still “wanted to have it all,” but not necessarily all at the same time. Women with children who were not employed full time indicated that they looked forward to working full time sometime in the future. And some child-free working women indicated that they had not ruled out becoming mothers. Thus, women may have it all by juggling the various roles and adjusting their expectations to the realities of fitting all the pieces together.

What happens after the children are grown? Based on his cross-cultural studies, Gutmann suggests that, freed from the demands of the parental imperative, men become less active and more passive, take less interest in community affairs, and focus more on religious contemplation and family relationships. They also become more sensitive and emotionally expressive. Women, meanwhile, are changing in the opposite direction. After being relatively passive and nurturing in their younger years, they become more active, domineering, and assertive in later life. In many cultures, they take charge of the household after being the

What traits might we associate with this woman based on her agentic role in the workplace?

underlings of their mothers-in-law and become stronger forces in their communities. In short, then, the roles of men and women are fairly similar before marriage, maximally different during the child-rearing years, and similar again later (Gutmann, 1997).

Androgyny?

Do the shifts in the roles played by men and women during adulthood affect them psychologically? For years, psychologists assumed that “being masculine” or having agentic traits and “being feminine” or having communal traits were at opposite ends of a single continuum and mutually exclusive. If a person possessed agentic traits, then that person must be noncommunal, whereas being highly communal implied being nonagentic. This bipolar view was challenged with evidence that at least some individuals can be characterized by psychological **androgyny**—that is, by a balancing or blending of both agentic traits and communal traits (Spence, Helmreich, & Stapp, 1973). According to this perspective, then, agency and communion are two separate dimensions of

personality. A male or female who has many agentic traits and few communal ones is considered to have a stereotypic “masculine” gender type. A person who has many communal traits and few agentic traits is said to have a “feminine” gender type. The androgynous person possesses both agentic and communal traits, whereas the undifferentiated individual lacks both kinds of attributes.

Most college students—both males and females—believe that the ideal person is androgynous (Slavkin & Stright, 2000). However, being well-adjusted psychologically is generally associated with gender-congruent personality traits (that is, males displaying agentic traits and females expressing communal traits), agentic traits in general, and having flexible attitudes about gender (Didonato & Berenbaum, 2010). In addition, you may need to distinguish between the androgynous individual who possesses *positive* agentic and communal traits and the one who possesses *negative* agentic and communal traits (Woodhill & Samuels, 2003, 2004). People with positive androgyny score higher on measures of mental health and well-being than those with negative androgyny (Woodhill & Samuels, 2003). It may be premature, then, to conclude that it is better in all respects to be androgynous rather than either agentic or communal in orientation. Still, you can at least conclude that it is unlikely to be damaging for men to become a little more communal or for women to become a little more agentic than they have traditionally been.

Changes in Sexuality

Adults’ sexual lifestyles are as varied as their personalities and intellects. Some adults remain single—some of them actively seeking a range of partners, others having one partner at a time, and still others leading celibate lives. Almost 9 of 10 Americans marry, and most adults are married at any given time. Men have more sexual partners and report more sexual activity than women during their adult lives, but most members of both sexes have just one sexual partner at a time (Chandra, Mosher, Copen, & Sionean, 2011; Copen, Chandra, & Febo-Vazquez, 2016).

Among married couples, there is a small decline in the quality of sex over the course of marriage, as well as a drop in the quantity of sex (Liu, 2003). There are also some gender differences, with married women reporting somewhat less satisfaction with their sex lives than married men (Liu, 2003). Middle-aged women report more positive moods and lower stress levels on days following sexual behavior with a partner (Burluson, Trevathan, & Todd, 2007). This benefit may be due to sexual activity alone or in combination with the affection that many women report with the sexual activity. Tim Wadsworth (2013) analyzed survey results on frequency of sex and happiness levels of over 15,000 men and women. He found that as one went up, so did the other: Adults are happier when they are having more frequent sex. What’s more, adults who believe they are having sex more frequently than their peers are even happier (Wadsworth, 2013).

What becomes of people’s sex lives as they age? Just as parents may be uncomfortable thinking of their teens as sexual beings, many young people struggle to conceive of their parents or—heaven forbid—their grandparents as sexual beings. We tend to stereotype older adults as sexless or asexual. But we are wrong: People continue to be sexual beings throughout the life

span. For example, on surveys of adults ranging in age from 25 to 85, most adults reported being interested in sex and being sexually active (Lindau & Gavrilova, 2010; Thomas et al., 2014). As **Figure 12.6** shows, most sexual activity among adults consists of vaginal intercourse or oral sex with an opposite-sex partner.

Gender differences were small among younger adults but became larger with age, leading to relatively large differences among the oldest adults: 75- to 85-year-old men were twice as likely to be sexually active and four times as likely to express interest in sex as women the same age. Other research shows a decline in sexual desire with age, although as **Figure 12.7** illustrates, desire can remain moderate or high well into old age.

With longer and healthier life spans and greater recognition and acceptance of middle and older adults’ sexual activity, there have been some unexpected consequences. Perhaps most alarming has been the doubling of STIs among those 45 and older (Bodley-Tickell et al., 2008). Many postmenopausal women assume that there is no need to practice “safe sex” because the threat of an unintended pregnancy is no longer present. They may be uninformed about STIs and too embarrassed to ask for information. Even more disturbing, many older adults do not get tested for STIs, including HIV, and may not get the treatment to save their life or improve the quality of their life (Jacobs & Kane, 2010). Consider Jane Fowler’s story (Evans & Goldman, 2010): Divorced at age 47 after 23 years of marriage and monogamous sex, Jane dated a few men whom she knew from her larger circle of friends. She didn’t worry about using condoms because she knew pregnancy wouldn’t be an issue and, after all, she *knew* these men; they weren’t strangers. But a routine blood test for

an insurance company revealed that Jane was infected with HIV. In the aftermath of her shocking diagnosis, Jane withdrew from many activities and retired from her career as a journalist. Fortunately, she eventually overcame her embarrassment and fears over contracting an STI in midlife and founded an organization, *HIV Wisdom for Older Women*, to educate other women on the importance of safe-sex practices at all ages (Evans & Goldman, 2010). Such cases illustrate that we need to do much more to improve sex education across the entire life span.

For older adults who experience declines in sexual interest and activity, what might explain this change? Consider first the physiological changes in sexual capacity that occur with age, as revealed by the pioneering research of William Masters and Virginia Johnson (1966, 1970). Males are at their peak of sexual responsiveness in their late teens and early 20s and gradually become less responsive thereafter. A young man is easily and quickly aroused; his orgasm is intense; and he may have a refractory, or recovery, period of only minutes before he is capable of sexual activity again. The older man is likely to be slower—slower to arouse, slower to ejaculate after being aroused, and slower to recover afterward. In addition, levels of male sex hormones decline gradually with age in many men. This may contribute to diminished sexual functioning among older men (Schiavi et al., 1991), although most researchers do not believe that hormonal factors fully explain the changes in sexual behavior that most men experience (Kaye, 1993).

Physiological changes in women are less dramatic. Females reach their peak of sexual responsiveness later than men do, often not until their mid-30s. Women are capable of more orgasms in a given time span than men are because they have little or no refractory period after orgasm, and this capacity is retained into old age.

As noted in Chapter 5, menopause does not seem to reduce sexual activity or interest for most women. However, like older men, older women typically are slower to become sexually excited. Moreover, some experience discomfort associated with decreased lubrication that occurs as estrogen levels drop with menopause.

The physiological changes that men and women experience do not explain why many of them become less sexually active in

Most adults continue to be interested in sex and engage in sexual behaviors on a regular basis. For those older adults who experience a decline in sexual desire or behavior, what factors might be behind the change?

Rappholdt/Shutterstock.com

middle and old age. Masters and Johnson (1966) concluded that both men and women are physiologically capable of sexual behavior well into old age. Women retain this physiological capacity even longer than men, yet they are less sexually active in old age.

Apparently, we must turn to factors other than biological aging to explain changes in sexual behavior. In summarizing these factors, Pauline Robinson (1983) quotes Alex Comfort (1974): “In our experience, old folks stop having sex for the same reason they stop riding a bicycle—general infirmity, thinking it looks ridiculous, and no bicycle” (p. 440; and see DeLamater, 2012).

Under the category of infirmity, diseases and disabilities, as well as the drugs prescribed for them, can limit sexual functioning (DeLamater & Sill, 2005). Older adults in good or excellent health not only report engaging in more frequent sex than their peers in poor or fair health, they also report more interest in sex and greater satisfaction with their sexual activity (Lindau & Gavrilova, 2010). Poor health may be especially problematic for men, who may become impotent if they have high blood pressure, coronary disease, diabetes, or other health problems. Mental health problems are also important: Many cases of impotence among middle-aged and elderly men are attributable to psychological causes such as stress at work and depression rather than to physiological causes (Persson & Svanborg, 1992).

The second source of problems is social attitudes that view sexual activity in old age as ridiculous, or at least inappropriate. Old people are stereotyped as sexually unappealing and sexless (or as “dirty old men”) and are discouraged from expressing sexual interests. These negative attitudes may be internalized by elderly people, causing them to suppress their sexual desires (Kaye, 1993; Purifoy, Grodsky, & Giambra, 1992). Older females may be even further inhibited by the double standard of aging, which regards aging in women more negatively than aging in men (Arber & Ginn, 1991).

Third, there is the “no bicycle” part of Comfort’s analogy—the lack of a partner, or at least of a willing and desirable partner. Most older women are widowed, divorced, or single and face the reality

that there just are not enough older men to go around. Lack of a partner, then, is the major problem for elderly women, many of whom continue to be interested in sex, physiologically capable of sexual behavior, and desirous of love and affection (DeLamater & Sill, 2005; Karraker, DeLamater, & Schwartz, 2011).

Perhaps we should add one more element to Comfort’s bicycle analogy: lack of cycling experience. Masters and Johnson (1966, 1970) proposed a “use it or lose it” principle of sexual behavior to reflect two findings. First, an individual’s level of sexual activity early in adulthood predicts his level of sexual activity in later life. The relationship is not necessarily causal, by the way; it could simply be that some people are more sexually motivated than others throughout adulthood. A second aspect of the use it or lose it rule may be causal, however: Middle-aged and elderly adults who experience a long period of sexual abstinence often have difficulty regaining their sexual capacity.

● Checking Mastery

1. How do gender roles shift during adulthood?
2. What is androgyny? Is it beneficial to be androgynous?
3. How do sexual behaviors change across adulthood?

● Making Connections

1. The extent to which males and females differ changes from infancy to old age. When are gender differences in psychological characteristics and roles played in society most evident, and when are they least evident? How would you account for this pattern?
2. Fewer women than men become architects. Drawing on the material in this chapter, explain the extent to which nature and nurture may be responsible for this, citing evidence.

Chapter Summary

12.1 Sex and Gender

- Differences between males and females can be detected in the physical, psychological, and social realms; gender differences arise from an interaction of biological influences and socialization into gender roles (including the learning of gender-role norms and stereotypes).
- Research comparing males and females indicates that the two sexes are far more similar than different psychologically. The average male is more aggressive and better at spatial tasks and some mathematical problem-solving tasks, but less adept at verbal tasks, than the average female. Males also tend to be more active and assertive than females, who tend to be more nurturant and anxious. Children tend to play in highly gendered

ways and most men and women have gender identities that are quite distinct. Most gender differences are small, however, and some are becoming smaller.

12.2 The Infant

- During infancy, boys and girls are similar but adults treat them differently.
- Because their sex is important to those around them, and because they see that males and females differ, infants begin to form categories of “male” and “female.”
- By age 2, infants have often gained knowledge of their basic gender identity and display “gender-appropriate” play preferences.

12.3 The Child

- Gender-role development proceeds with remarkable speed. By the time they enter school, children have long been aware of their basic gender identities, have acquired many stereotypes about how the sexes differ, and have come to prefer gender-appropriate activities and same-sex playmates.
- During middle childhood, their knowledge continues to expand as they learn more about gender-stereotyped psychological traits, but they also become more flexible in their thinking about gender roles. Their behavior, especially if they are boys, becomes even more gender typed, and they segregate themselves even more from the other sex.
- Theories of gender-role development consider biological and socialization factors. These include prenatal biological developments (as illustrated by the biosocial theory), the differential reinforcement and observational learning highlighted by social learning theorists, and developing cognitive understanding of gender concepts and the formation of gender schemas.
- School-age children engage in sex play and appear to experience their first sexual attractions around age 10.
- Some children experience sexual abuse, which can have significant and long-lasting effects on their development.

12.4 The Adolescent

- Adolescents become intolerant in their thinking about gender-role deviations and, through gender intensification, show increased concern with conforming to gender norms.

- In adolescence, forming a positive sexual identity is an important task, one that can be difficult for those with a gay or lesbian sexual orientation.
- Some adolescents wrestle with the identity they were assigned at birth and may transition to transgender.
- During the past century, we have witnessed increased endorsement of the view that sex with affection is acceptable, a weakening of the double standard, and increased confusion about sexual norms.
- An increasing number of college women report being sexually assaulted on campus.

12.5 The Adult

- Gender roles become more distinct when adults marry and have children, as men and women fulfill their roles as husband/wife and father/mother. Once children are grown, however, older adults often display greater flexibility in their behavior.
- Some adults display androgyny, a combination of both masculine-stereotypic and feminine-stereotypic traits. Some evidence suggests that androgyny is beneficial, but not at all ages or in all situations.
- Many older adults continue having sexual intercourse, and many of those who cease having it or have it less frequently continue to be sexually motivated. Elderly people can continue to enjoy an active sex life if they retain their physical and mental health, do not allow negative attitudes surrounding sexuality in later life to stand in their way, have a willing and able partner, and continue to “use” their capacity for sex.

Certain campers one summer repeatedly pulled a prank on Edward. Edward was a small, uneven-legged, mildly retarded adult who was the basic maintenance staffer for the camp. He was kind, conscientious in his duties, and proud that he was earning his way in life. There was just one thing: At a point of frustration or moment of embarrassment, Ed would invariably unleash a torrent of profanities that was surprising and, to some campers, entertaining. Several campers had devised a way to set off this “entertainment.” Ed worked hard mowing and doing other chores on the camp grounds and would sometimes take a nap during the day. . . . Seeing Ed asleep, the plotters would move in. They would gently sink one of Ed’s hands into a pail of water. Ed would wet his pants in bed and awaken, swearing madly and running frantically after the hysterically laughing campers (Gibbs, 2010, p. 1).

John Gibbs, author of the book *Moral Development and Reality*, attended the camp just described, watched the torment of Edward play out again and again, and feels guilty to this day that he did nothing to stop it, fearful of his fellow campers' reactions if he did. Many of you, we wager, can recall episodes like this when you and/or your peers did something hurtful to a nerdy, overweight, or otherwise different individual who did not deserve it, when you failed to take the perspective of and empathize with an innocent victim. What might have stopped you from mistreating someone like Edward or prompted you to intervene to save him from abuse by others? What does it take to optimize the helpful and cooperative tendencies of human beings and reduce the antisocial ones?

In this chapter, we continue our examination of the development of the self by exploring how we come to understand the social world and make decisions about issues of right and wrong like those raised by the campers' treatment of Edward. We begin with a look at the development of thinking about people and their behavior, which includes learning to take the perspectives of other people, including victims like Edward. We then look closely at moral development and positive and negative social behavior. We ask how humans acquire moral standards, how they decide what to do when faced with moral dilemmas, how empathy, guilt, and other emotions influence what they do, and why some individuals behave more morally than others.

13.1

Social Cognition

LEARNING OBJECTIVES

- Define social cognition and explain the meaning and significance of having a theory of mind.
- Summarize key steps in the development of a theory of mind and the contributions of nature and nurture to this development.
- Describe developments in trait perception and perspective taking and explain whether or not social cognitive skills hold up well in later life.

Social cognition is thinking about the perceptions, thoughts, emotions, motives, and behaviors of self, other people, groups, and even whole social systems (Flavell, 1985). We have touched already on some important aspects of social cognitive development, seeing, for example, that older children think differently than younger children about what they are like as individuals and about how males and females differ. Here, we focus on developmental changes in the ability to understand human psychology, describe other people, and adopt other people's perspectives.

Developing a Theory of Mind

Imagine that you are a young child, are brought to the laboratory, and are led through the research scenario portrayed in **Figure 13.1**. A girl named Sally, you are told, puts her marble in her basket and leaves the room. While she is gone, Anne moves the marble to her box. Sally returns to the room. Where will Sally look for her marble?

This task, called a **false belief task**, assesses the understanding that people can hold incorrect beliefs and that these beliefs, even though incorrect, can influence their behavior. The task was used in a pioneering study by Simon Baron-Cohen, Alan Leslie, and Uta Frith (1985) to determine whether young children, children with Down syndrome, and children with autism have a theory of mind. A **theory of mind** is the understanding that (a) people have mental states such as desires, beliefs, and intentions and that (b) these mental states guide (and help explain) their behavior. We all rely on a theory of mind, also called mind-reading skills, to predict and explain human behavior. We refer to mental states every day, saying, for example, that people did what they did because they wanted to, intended to, or believed that doing so would have a desired effect.

Children who pass the false belief task in **Figure 13.1**, and therefore show evidence of having a theory of mind to explain human behavior, say that Sally will look for her marble in the basket (where she falsely believes it to be) rather than in the box (where it

was moved without her knowledge). Children who have a theory of mind believe that Sally's behavior will be guided by her false belief about the marble's location. They are able to set aside their own knowledge of where the marble ended up after Anne moved it.

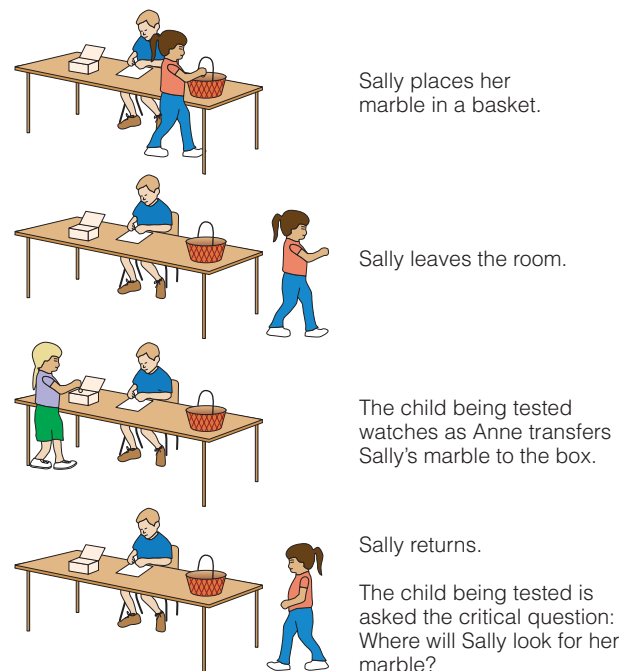

Figure 13.1 The false belief task involving Sally and Anne. The child who has developed a theory of mind should say that Sally will look in the basket based on her false belief that the marble is there. The child who has not yet developed a theory of mind fails this false belief task, saying that Sally will look in the box (where the child knows the marble has been moved).

Source: From Baron-Cohen, S., Leslie, A. M., & Frith, U. (1985). Does the autistic child have a "Theory of Mind"? *Cognition*, 21, 37–46 Copyright © 1985. Reprinted with permission from Elsevier.

In the study by Baron-Cohen and his colleagues, about 85% of 4-year-olds of average intelligence and older children with Down syndrome passed the false belief task about Sally and her marble. Yet despite mental ages greater than those of the children with Down syndrome, 80% of the children with autism failed.

This study aroused much excitement because it suggested that children with autism display the social deficits they display because they lack a theory of mind and suffer from a kind of “mindblindness” (Baron-Cohen, 1995; and see Chapter 16). Imagine trying to understand and interact with people if you were unable to appreciate such fundamentals of human psychology as that people look for objects where they believe the objects are located, choose things that they want and reject things that they dislike, and sometimes attempt to plant false beliefs in others (that is, lie).

Temple Grandin, a now-famous woman with autism who is intelligent enough to be a professor of animal sciences, describes what it is like to lack a theory of mind: She must create a memory bank of how people behave and what emotions they express in various situations and then “compute” how people might be expected to behave in similar situations (Sacks, 1993). Although she can grasp simple emotions like happiness, she confesses that she could never quite get what *Romeo and Juliet* was all about. She feels awkward trying to carry on everyday conversations with people but relates well to animals and has used that talent to develop more humane ways of handling livestock. Just as we cannot understand falling objects without employing the concept of gravity, we cannot understand humans without invoking the concept of mental states and our theory of mind.

First Steps in Infancy

Although children normally do not pass the false belief task in Figure 13.1 until about age 4, a theory of mind begins to form in infancy. Indeed, infants have far more sophisticated social cognitive skills than we ever suspected. Consider these early steps in developing a theory of mind; most of these skills are deficient in children with autism (see, for example, Charman, 2000; and Doherty, 2009):

- **Joint attention.** Starting around 9 months, infants and their caregivers engage in joint attention, both looking at the same object at the same time. At this age, infants sometimes point to toys and then look toward their companions, encouraging others to look at what they are looking at. By doing so, infants show awareness that other people have different perceptual experiences than they do—and that two people can share a perceptual experience.
- **Understanding intentions.** In their first months of life, infants seem to understand that other people have *intentions*, set goals, and act to achieve them (Woodward, 2009). For example, by 6 months of age, if not earlier, infants much prefer a “helper” puppet who helps an actor achieve a goal to a “hinderer” who blocks goal achievement, showing that they understand good and bad intentions when they see them (Hamlin & Wynn, 2011; Hamlin, Wynn, & Bloom, 2007).
- **Pretend play.** When infants engage in their first simple *pretend play*, between 1 and 2 years, they show that they distinguish between pretense (a kind of false belief) and reality (see Chapter 14). They show that they know the difference between a pretend tea party and a real one, for example, when they make exaggerated lip-smacking noises and laugh as they drink from a cup at a pretend tea party.

Temple Grandin, who has autism, is an animal sciences professor, author, and subject of films. Yet understanding people is a daily challenge for her because of limitations in her theory-of-mind skills.

Frank Trapper/Corbis Entertainment/Getty Images

- **Imitation.** Imitation of other people in the first year of life reveals an ability to mentally represent others’ actions—and very likely the goals or intentions behind them.
- **Emotional understanding.** In the second year of life, teasing a sibling or comforting a playmate who is crying reflects an understanding that other people have emotions and that these emotions can be influenced for bad or good (Flavell, 1999; and see Section 13.3).

Some researchers even claim that infants as young as 15 months understand that people can hold false beliefs. By simplifying the false belief task, Kristine Onishi and Renée Baillargeon (2005) found that infants this age are surprised (as indicated by looking longer) when an actor does not look for a toy where she should believe it was hidden (and see Scott & Baillargeon, 2009). This intuitive surprise is probably not the same as the more explicit, conscious understanding of how false beliefs can lead people astray that children normally achieve by age 4 (Hughes & Devine, 2015; Sodian, 2011). However, it certainly adds to our picture of an infant who is very ready to understand and participate in the social world.

Desire and Belief–Desire Psychologies

Henry Wellman (1990) has theorized that children’s theories of mind unfold in two main phases. Around age 2, children develop a **desire psychology**. Toddlers talk about what they want and explain their own behavior and that of others in terms of wants or desires. Thus Ross (at 2 years, 7 months), asked why he kept asking why, replied, “I want to say ‘why,’” explaining his behavior in terms of his desire (Wellman & Bartsch, 1994, p. 345). This early desire psychology was observed among 18-month-olds in a clever study by Betty Repacholi and Alison Gopnik (1997). An experimenter tried two foods—Goldfish crackers and broccoli florets—and

Even 1-year-olds show awareness that other people can have mental states (perceptions) different from their own when they point at objects so that they and their companions can jointly attend to the same object.

wonderlandstock/Alamy Stock Photo

expressed delight in response to one but disgust in response to the other. Because the toddlers almost universally preferred the crackers to the broccoli, the acid test was a scenario in which toddlers saw the experimenter express her liking for broccoli but her disgust at the crackers (“Eww! Crackers! I tasted crackers! Eww!”). When confronted with the two bowls of food and asked to give the experimenter some, would these toddlers give her broccoli or crackers? The 14-month-olds in the study either did not comply with the request or gave the experimenter crackers, despite her distaste for them. However, the 18-month-olds gave her broccoli (undoubtedly against their better judgment!), showing that they were able to infer and honor her desire based on her previous emotional reactions to the two foods.

By age 3 or 4, children normally progress to a **belief–desire psychology**. They appreciate that people do what they do because they *desire* certain things and because they *believe* that certain actions will help them fulfill their desires. They now pass false belief tasks like the one about Sally and her marble, understanding that beliefs, true or false, guide people’s behavior just as desires do (Wellman, Cross, & Watson, 2001; Wellman & Liu, 2004). So, Adam (at 3 years, 3 months), commenting on a bus, said “I thought it was a taxi,” showing awareness that he held a false belief about the bus (Wellman & Bartsch, 1994, p. 345).

Notice that the 4-year-olds described by theory-of-mind researchers are more sophisticated students of psychology than the egocentric preschoolers described by Jean Piaget (see Chapter 7). However, it is better to think of a theory of mind as a set of understandings that children begin to develop in infancy and continue to refine into adolescence than to view it as something children “have” at age 4 (Miller, 2012; Wellman & Liu, 2004). Even much older children can be challenged when they are asked to understand sarcasm, where the intended meaning of a statement is different from the literal meaning, as in the theory-of-mind task in **Engagement 13.1** (Peterson, Wellman, & Slaughter, 2012). In late elementary school, children are also still mastering

● ENGAGEMENT 13.1

Do You Have a Theory of Mind?

Try this example of a higher-level theory-of-mind problem suitable for elementary school-aged children (from Peterson et al., 2012, pp. 474 and 485; based on Happé, 1994):

The girl and boy [shown in a picture] are going on a picnic. It is the boy’s idea. He says it will be a lovely sunny day.

But when they get the food out, big storm clouds come. It rains and the food gets all wet. The girl says: “It’s a lovely day for a picnic.”

1. Is it true, what the girl said?
2. Why did the girl say “it’s a lovely day for a picnic”?
3. Was the girl happy about the rain?

In the Peterson et al. (2012) study, only 4% of children ages 3 to 5 passed the key item, question 2, compared to 41% of children 7½ to 11½. Thus even the older children tested found this theory-of-mind task challenging. How did you do? (See the scoring guide, upside down.)

(reflecting understanding that the girl’s intended meaning is different from the literal meaning of what she said):
 She’s being sarcastic/using sarcasm; she doesn’t mean it; because it’s an idiom; she tricked him; it’s her way of telling him she is upset; just to make up a little joke; she is saying politely that she is not happy; because she is a smart aleck; because she is meaning “Why tell me it was nice?”
Failing Answers:
 Because it is sunny [raining]; it’s lovely outside; she likes rain [picnics] we need rain; she wants to play in the puddles; because she [the cake] got wet; because he lied to her; she thought it was sunny/did not see clouds; she’s cross; to tell him off; because it’s not sunny; so he doesn’t feel bad; because he said it first; because her Dad likes the rain but she doesn’t.

This task assesses a child’s ability to recognize sarcasm. The critical test question is the second question, “Why did the girl say ‘it’s a lovely day for a picnic?’”
Passing Answers:

complex second-order belief statements such as, “Mary thinks that Jeff thinks that she hates him,” in which people have beliefs about other people’s beliefs (Miller, 2012). Indeed, theory-of-mind skills continue to improve from adolescence to adulthood (Dumontheil, Apperly, & Blakemore, 2010; Hughes & Devine, 2015).

Nature and Nurture

How do nature and nurture contribute to the development of theory-of-mind skills? We seem to need both the brain for it and the right kinds of social experience.

An Evolved Brain On the nature side of the nature–nurture issue, evolutionary theorists argue that having a theory of mind proved adaptive to our ancestors and became part of our biological endowment as a species through natural selection (Buss, 2012; Tomasello & Herrmann, 2010). Figuring out other people’s intentions would be useful in deciding whether to trust them or be wary of them. Social behaviors such as bargaining, conflict resolution, cooperation, and competition all depend on understanding other people and predicting their behavior accurately. Although chimpanzees, like humans, can be deceptive at times, human children have more advanced theory-of-mind skills than chimps and distinguish themselves by being more able to cooperate with others to achieve a goal (Tomasello & Herrmann, 2010).

In further support of the nature side of the nature–nurture issue, developing a theory of mind requires neurological and cognitive maturation. This may be why children everywhere develop a theory of mind and progress from a desire psychology to a belief–desire psychology in the same manner at about the same age (Wellman et al., 2001). Meanwhile, atypical brain development in children with autism seems to be behind their great difficulty passing theory-of-mind tasks (Hughes & Devine, 2015).

Neuropsychologists have identified areas in the prefrontal cortex and the temporoparietal junction of the brain that are highly active when we are thinking about people’s beliefs (Saxe, Carey, & Kanwisher, 2004; Spunt & Adolphs, 2015). Using *functional magnetic resonance imaging (fMRI)* to determine which areas of the brain are active while a person completes a task, for example, Rebecca Saxe and Nancy Kanwisher (2003) found that the areas of adults’ brains that respond strongly during false belief tasks do not respond as strongly to similar tasks that do not involve thinking about mental states. Moreover, 4- to 6-year-old children who pass false belief tasks rely on the same brain areas to think about others’ beliefs as adults do, whereas children who fail these tasks have not yet come to rely on these brain areas (Liu, Meltzoff, & Wellman, 2009; Gweon et al., 2012; and Saxe et al., 2009).

Neuropsychologists also believe social cognition involves **mirror neurons**, neurons that are activated both when we perform an action and when we observe someone else perform the same action (Iacoboni, 2009; Oberman & Ramachandran, 2007; Pineda, 2009; Rizzolatti & Sinigaglia, 2008). Thus, observing someone grasp a ball activates the same neurons that fire when we grasp a ball ourselves. Mirror neuron systems may therefore facilitate observational learning and imitation of what we see and hear. These neurons, found in many areas of the brain, may also be critical in allowing us to quickly infer another person’s mental state based on

our own experiences of the same actions and facial expressions and of corresponding internal states. For example, watching a person reach for a Coke on a hot day, we readily infer that she’s thirsty and wants a drink, and when she takes a sip, we readily infer from her facial expression that she’s happy. Thanks to mirror neurons, we are likely to unconsciously and subtly imitate her happy face (as we cringe a bit in response to the face of someone cringing in pain).

Mirror neuron systems appear to be involved in imitation, theory-of-mind understandings, language, and empathy, although their exact roles are still not certain (Iacoboni & Dapretto, 2006; Lamm & Majdandžic, 2015). Meanwhile, mirror neuron deficits may help explain the difficulties individuals with autism have in these areas of development (Gallese, Rochat, & Berchio, 2013; Glenberg, 2011). For example, the mirror neurons of individuals with autism are not as active as those of typically developing individuals when they are asked to observe others’ facial expressions or imitate their actions (Dapretto et al., 2006; McIntosh et al., 2006; Williams et al., 2006). In sum, our human genetic endowment makes for brains that are exquisitely designed for social cognition.

Talk of Mental States On the nurture side of the nature–nurture issue is evidence that acquiring a theory of mind and other social cognitive skills, much like acquiring language, requires not only a normal human brain but also experience interacting with other humans—participating in a “community of minds” (Nelson et al., 2003). Children do not construct their theories of mind on their own; instead, they construct them jointly with others during conversations about mental states.

The evidence? Here is a sampling (and see Hughes & Devine, 2015):

- **Language experience.** Deaf children of deaf parents, who can communicate with their companions using sign language, develop theory-of-mind skills right on schedule. However, deaf children of hearing parents, who usually do not have an opportunity to converse in sign language from an early age, achieve milestones in social cognitive development slowly, sometimes struggling with false belief tasks even at ages 8–10 (Peterson & Siegal, 1999; Peterson & Wellman, 2009; Peterson et al., 2012).
- **Mind-minded parents.** Parents who form secure attachments with their children and are sensitive to their needs and perspectives (Symons & Clark, 2000; Thompson, 2012), and parents who show **mind-mindedness** and talk with their children in elaborated ways about mental states (“You were probably sad because you thought Grandma would stay with us longer”) tend to have children with advanced theory-of-mind skills (Meins et al., 2002; Peterson & Slaughter, 2003).
- **Interactions with siblings and peers.** Conversations with siblings and peers also contribute to mind-reading skills (Hughes & Devine, 2015). Children with siblings seem to grasp the elements of a theory of mind earlier than children without siblings (McAlister & Peterson, 2006, 2007). And children have plenty of opportunities to think and talk about mental states in bouts of pretend play (“Pretend the robber stole your money”) and in conflicts with siblings and peers (“I thought you were done with your ice cream,” “I didn’t mean to step on your head”).

This mother signs “You” to her deaf son on his fifth birthday. Deaf children who can communicate with their companions through sign language develop theory-of-mind skills on schedule, but deaf children of hearing parents who have limited early language experience often develop such skills more slowly.

Huntstock/Getty Images

- **Cultural differences.** Although most children worldwide master theory-of-mind skills in much the same order and at much the same rate, children are slow to develop theory-of-mind skills in cultures where there is not much talk about mental states (Hughes & Devine, 2015). In Samoa, for example, others’ minds are considered unknowable so mental states are not discussed much. Perhaps as a result, it was not until age 8 that a majority of Samoan children in one study passed false belief tasks (Mayer & Trauble, 2013; and see Vinden & Astington, 2000).

In sum, acquiring a theory of mind—the foundation for all later social cognitive development—begins in infancy and toddlerhood with first steps such as joint attention, understanding of intentions, pretend play, imitation, and emotional understanding. It advances from a desire psychology to a belief–desire psychology and beyond universally (see • **Table 13.1** for a timetable). It is the product of both nature and nurture. It is an evolved and genetically influenced set of skills that relies on specialized areas of the brain and mirror neurons and that will not emerge without normal neurological and cognitive growth. But its development also requires social experiences that involve learning and using a language to communicate and frequently talking about mental states with parents, siblings, peers, and other companions.

Implications

It is essential to master theory-of-mind skills if we want to participate in the social world. Children who have mastered these skills well generally can think more maturely about moral issues and other social problems, and they tend to have more advanced social skills and better social adjustment than those who have not (Doherty, 2009; Miller, 2012; Repacholi et al., 2003). However, theory-of-mind skills can be used for good or bad ends. Bullies and liars often prove to be very adept at “mind reading” too (Repacholi et al., 2003; Talwar & Lee, 2008). And training 3-year-olds

• **Table 13.1** Milestones in the Development of Theory of Mind

Age	Achievements
Birth to 2	Joint attention, understanding of intentions, pretend play, imitation, emotional understanding
Age 2	Desire psychology
Age 4	Belief–desire psychology
Age 5 and beyond	Understanding of second-order beliefs, sarcasm, different views of reality

in theory-of-mind skills actually makes them more likely than untrained children to lie when they are given the opportunity to deceive someone (Ding et al., 2015). So, developing a theory of mind is an important ingredient of social competence, but there is no guarantee that good “mind readers” will be socially well-adjusted or will behave in moral ways.

Trait Perception

Although research on theory of mind shows that even infants and preschool children are budding psychologists, they still have a way to go to understand people in terms of their enduring personality traits and to predict how others will react and behave. Consider how children of different ages describe people they know—parents, friends, disliked classmates, and so on.

As you discovered in Chapter 11, children younger than 7 or 8 describe themselves primarily in physical rather than psychological terms. They describe other people that way, too (Livesley & Bromley, 1973; Yuill, 1993). Thus, 4-year-old Evan says of his father, “He has one nose, one Mom, two eyes, brown hair.” And 5-year-old Keisha says, “My daddy is big. He has hairy legs and eats mustard. Yuck! My daddy likes dogs—do you?” Not much of a personality profile there.

Young children perceive others primarily in terms of their physical appearance, possessions, and activities. When they use psychological terms, the terms are often global, evaluative ones such as “nice” or “mean,” “good” or “bad,” rather than specific personality-trait labels (Ruble & Dweck, 1995). Moreover, preschool children do not yet seem to understand traits as enduring qualities that predict how a person will behave in the future and explain why a person behaves as he does. The 5-year-old who describes a friend as “dumb” may be using this trait label only to describe that friend’s recent “dumb” behavior; she may expect “smart” behavior tomorrow and may not view “dumbness” as the cause of the recent dumb behavior. Preschool children have difficulty inferring a trait from past behavior *and* using it to predict future behavior (Liu, Gelman, & Wellman, 2007).

Around age 7 or 8, children’s descriptions of people show that they think about others in terms of their enduring psychological traits. Thus, 10-year-old Juanita describes her friend Tonya: “She’s funny and friendly to everyone, and she’s in the gifted program because she’s smart, but sometimes she’s very bossy.” As children reach age 11 or 12, they also make more use of psychological traits to explain why people behave as they do, saying, for instance, that Mike pulled the dog’s tail *because* he is cruel (Gnepp &

Chilamkurti, 1988). Clearly, then, children become more psychologically minded as their emerging social cognitive abilities permit them to make inferences about enduring inner qualities from people's behavior.

When asked to describe people they know, adolescents offer personality profiles that are even more psychological than those provided by children (Livesley & Bromley, 1973). They see people as unique individuals with distinctive personality traits, interests, values, and feelings. Moreover, they are able to create more integrated personality profiles, analyzing how an individual's often inconsistent traits fit together and make sense as a whole personality—for example, how a friend's insecurity could lead her to brag at times but seem very unsure of herself at other times. Some adolescents spend hours “psychoanalyzing” people, trying to figure out what makes them tick.

In sum, characterizations of other people progress from (1) physical descriptions and global evaluations during the preschool years to (2) more differentiated descriptions that refer to inner and enduring personality traits starting at age 7 or 8 and, finally, to (3) more integrated personality profiles during adolescence that show how even seemingly inconsistent traits fit together.

Perspective Taking

Another important aspect of social cognitive development involves outgrowing the egocentrism of early childhood and developing **perspective-taking skills**, also called role-taking skills: the ability to adopt another person's perspective and understand her thoughts and feelings. Perspective-taking skills are critical in thinking about moral issues from different points of view, predicting the consequences of a person's actions for others, and empathizing with others (Gibbs, 2010). If the campers at the start of the chapter had taken Edward's perspective, perhaps they would have laid off him.

Robert Selman (1976, 1980; Yeates & Selman, 1989) contributed greatly to our understanding of role-taking abilities by asking children questions about interpersonal dilemmas like this one (Selman, 1976, p. 302):

Holly is an 8-year-old girl who likes to climb trees. She is the best tree climber in the neighborhood. One day while climbing down from a tall tree, she falls . . . but does not hurt herself. Her father sees her fall. He is upset and asks her to promise not to climb trees anymore. Holly promises.

Later that day, Holly and her friends meet Shawn. Shawn's kitten is caught in a tree and can't get down. Something has to be done right away or the kitten may fall. Holly is the only one who climbs trees well enough to reach the kitten and get it down but she remembers her promise to her father.

Selman asked children questions to assess how well they understand the perspectives of Holly, her father, and Shawn. He concluded that perspective-taking abilities develop in a stagelike manner as children progress through Piaget's stages of cognitive development. Here are highlights of this progression:

- Children 3–6 years old tend to respond egocentrically, assuming that others share their point of view. If young children like

Adolescents who have limited role-taking, or social perspective-taking, skills are less able than those who have advanced skills to resolve conflicts with their parents (Selman et al., 1986). They may not adopt the perspectives of their parents (and parents in general) in order to identify mutually acceptable solutions.

Gpointstudio/Dreamstime.com

kittens, for example, they assume that Holly's father does, too, and therefore will be delighted if Holly saves the kitten.

- By age 8–10, children appreciate that two people can have different points of view even when they have access to the same information. Children are able to think about their own thoughts and about the thoughts of another person. Thus, they can appreciate that Holly may think about her father's concern for her safety but also believe that he will understand her reasons for climbing the tree.
- At around age 12, adolescents become capable of mentally juggling multiple perspectives—their own, that of another person, and even that of the “generalized other,” or a broader social group such as children or fathers. Thus, an adolescent might consider how fathers in general react when children disobey them and consider whether Holly's father is similar to or different from the typical father.

Children and adolescents with advanced perspective-taking skills are likely to be sociable and popular and enjoy good relationships with peers (Kurdek & Krile, 1982; LeMare & Rubin, 1987). They are also better able than children with less advanced skills to resolve conflicts with parents and peers (Selman et al., 1986).

Social Cognition in Adulthood

As you saw in earlier chapters, nonsocial cognitive abilities, such as those used in solving scientific problems, tend to improve during early and middle adulthood and decline in later life. Do social cognitive skills also increase to a peak in middle age and decline later?

Overall, social cognitive skills seem to hold up better during adulthood than nonsocial cognitive skills (Blanchard-Fields, 1996; Hess, 1999). For example, Fredda Blanchard-Fields (1986)

Close social relationships and frequent social interactions keep social cognitive skills sharp in later life.

CREATISTA/Shutterstock.com

presented adolescents, young adults, and middle-aged adults with dilemmas that required them to engage in perspective taking and to integrate discrepant perspectives—for example, between a teenage boy and his parents regarding whether he must visit his grandparents with the family. Adults, especially middle-aged ones, were better able than adolescents to see both sides of the issues and to integrate the perspectives of both parties into a workable solution. Here, then, is evidence that social cognitive skills continue to improve after adolescence.

Do older adults continue to display the sophisticated social cognitive skills that middle-aged adults display or do their skills decline? Igor Grossmann and his colleagues (2010) asked young, middle-aged, and older American adults from diverse socioeconomic backgrounds to reason about conflicts between individuals that appeared in letters to advice columns and conflicts between ethnic or national groups as described in newspaper articles. Social cognitive performance improved across the three age groups, as indicated by such criteria as taking multiple perspectives and seeing possibilities for compromise. This improvement in social cognition with age occurred despite a decline in fluid intelligence with age. Growth with age was not evident in a sample of Japanese adults (Grossmann et al., 2012), but that was because Japanese young and middle-aged adults outperformed their American counterparts and achieved about the same level of performance as both Japanese and American elders. Possibly in Japan's collectivist society, then, people learn earlier in adulthood sophisticated ways of resolving social conflicts.

Yet other studies sometimes find that older adults perform less well than middle-aged and young adults on social cognitive tasks. For example, they sometimes have a harder time understanding sarcasm and passing adult versions of theory-of-mind tasks (Henry et al., 2013; Phillips et al., 2015). This is especially likely if tasks overload their basic cognitive capacities by requiring fast

information processing or high levels of executive control (Charlton et al., 2009; Moran, 2013; Sullivan & Ruffman, 2004).

So, declines in basic cognitive capacities such as processing speed sometimes take a toll on social cognitive performance, but social cognitive skills hold up fairly well—better than nonsocial cognitive abilities—in later life. This may be because people use their social cognitive abilities every day and accumulate expertise about the world of people over the years (Charlton et al., 2009; Hess & Queen, 2014). Those seniors who have the sharpest social cognitive skills tend to be socially active and involved in meaningful social roles such as spouse, grandparent, church member, and worker (Dolen & Bearison, 1982; Hess et al., 2005). Moreover, a few hours of training can also help older adults brush up on their social cognitive skills (Rosi et al., 2016).

In sum, social cognition takes shape in infancy through precursors of a theory of mind such as joint attention and pretend play; a desire psychology at age 2; and then a belief–desire psychology at age 4, thanks to both nature and nurture. Children's descriptions of other people progress from a focus on physical appearance and activities to a focus on inner psychological traits to the integration of trait descriptions, and perspective-taking skills improve with age. Social cognitive skills then often improve during early and middle adulthood and hold up well in old age if tasks are not too cognitively demanding and adults remain socially engaged.

Having examined some important and dramatic changes in social cognition over the life span, we are well positioned to focus on an important area of development in which social cognitive skills play a crucial role: moral development. Along the way, we will see how theory-of-mind and perspective-taking skills help shape thinking about right and wrong.

● Checking Mastery

1. Sharon wonders if Baby Ben, age 18 months, is on his way to developing a theory of mind. What three developments in infancy can you point to as early signs of a developing theory of mind?
2. If you were trying to make sure a deaf child, Luis, develops a theory of mind, what kinds of experiences would you try to provide him?
3. What breakthrough in perspective-taking skills is achieved at about age 8–10 according to Robert Selman?

● Making Connections

1. Eavesdrop on a conversation in which your friends gossip or talk about other people, and write down any statements in which they refer to beliefs, desires, intentions, emotions, and the like in attempting to account for someone's behavior. What evidence do you see that your friends have and use a theory of mind?
2. For whatever reasons, Alice has very poor theory-of-mind, trait-perception, and perspective-taking skills. How would each of these limitations affect her social relationships?

13.2

Perspectives on Moral Development

LEARNING OBJECTIVES

- Define and illustrate the three main components of morality.
- Compare and contrast the main messages about moral development of psychoanalytic, cognitive-developmental, social learning, and evolutionary theorists.
- Distinguish between Kohlberg’s preconventional, conventional, and postconventional levels of moral reasoning.

Although we could debate endlessly what **morality** is, most of us might agree that it involves the ability to distinguish right from wrong, to act on this distinction, and to experience emotions such as pride when we do the right things and guilt or shame when we do not. Accordingly, three basic components of morality have been of interest to developmental scientists (see Gibbs, 2014; Vozzola, 2014):

1. The *emotional* component consists of the feelings (guilt, concern for others’ feelings, and so on) that surround right or wrong actions and that motivate moral thoughts and actions.
2. The *cognitive* component centers on how we think about right and wrong and make decisions about how to behave, drawing on social cognitive skills such as perspective taking.
3. The *behavioral* component is about how we behave when, for example, we experience the temptation to cheat or are called upon to help a person in need.

Major theoretical perspectives on moral development focus on different aspects of morality. So in this section we look at what psychoanalytic theory says about moral emotions, what cognitive-developmental theory says about moral cognition or reasoning, and what social learning (or social cognitive) theory reveals about moral behavior. Then we view all three components of morality from a broad, evolutionary perspective.

Moral Emotion: Psychoanalytic Theory and Beyond

What kind of moral emotions do you experience if you contemplate cheating or lying? Chances are you experience such negative feelings as shame, guilt, anxiety, and fear of being detected—feelings that keep you from doing what you know is wrong. You may also experience disgust or righteous anger when witnessing harmful acts and injustices (Tangney, Stuewig, & Mashek, 2007). Positive emotions, such as pride and self-satisfaction when you have done the right thing and admiration or gratitude when you witness moral acts, are also important moral emotions (Turiel, 2006). We are generally motivated to avoid negative moral emotions and to experience positive ones by acting in moral ways.

Sigmund Freud’s (1960) psychoanalytic theory called attention to the role of emotions in the development of morality (see Chapter 2). As you will recall, Freud believed that the *superego*, or conscience, has the important task of ensuring that any plans formed by the rational ego to gratify the id’s selfish urges are morally acceptable. The superego is formed during the phallic stage

of psychosexual development (ages 3–6). According to Freud, children experience an emotional conflict over their love for the other-sex parent and resolve it by identifying with the same-sex parent, taking on the parent’s moral standards as their own. Having a superego, then, is like having a parent inside your head—there, even when your parent is not, to tell you what is right or wrong and to arouse emotions such as shame and guilt if you so much as think about doing wrong.

Although the particulars of Freud’s theory of moral development lack support (Hoffman, 2000; Silverman, 2003), his main themes are taken very seriously today. Research has shown that: (1) moral emotions are an important part of morality, motivating moral behavior, (2) early relationships with parents contribute in important ways to moral development, and (3) children must internalize moral standards if they are to behave morally even when no authority figure is present to detect and punish their misbehavior (Kochanska & Aksan, 2006).

Empathy is the vicarious experiencing of another person’s feelings. Although it is not a specific emotion, it is an emotional process believed to be especially important in moral development by modern theorists such as Martin Hoffman (2000, 2008), whom we will encounter later. Empathizing with individuals who are suffering—not only taking their perspective but feeling their pain—can motivate **prosocial behavior**—positive social acts, such as helping or sharing, that reflect

Young children learn to experience moral emotions such as guilt and shame when they violate rules.

iStockphoto.com/Kali9

concern for the welfare of others. Empathy can also keep us from engaging in **antisocial behavior**—behavior that violates social norms, rules, or laws and often involves harming other people or society (for example, lying, stealing, behaving aggressively). If the campers in the chapter opener had really empathized with Edward’s distress, they might have refrained from picking on him. As we will see later, modern theorists such as Martin Hoffman (2000) and Grazyna Kochanska (1993, 2002), like Freud, place a great deal of emphasis on the motivating role of emotional processes such as empathy and guilt in moral development.

Moral Reasoning: Cognitive-Developmental Theory

Cognitive-developmental theorists focus on the development of **moral reasoning**—the thinking process involved in deciding whether an act is right or wrong. These theorists assume that moral development depends on social cognitive development, particularly perspective-taking skills that allow us to picture how our victims might react to our misdeeds or how people in distress must feel. Moral reasoning is said to progress through universal stages, each of which represents a consistent way of thinking about moral issues. To cognitive-developmental theorists, what is of interest is *how* we decide what to do, not what we decide or what we actually do. A young child and an adult may both decide not to steal a pen, but the reasons they give for their decision may be entirely different.

Jean Piaget paved the way for the influential cognitive-developmental theory of moral development put forth by Lawrence Kohlberg. Piaget (1965) studied children’s concepts of rules by asking Swiss children about their games of marbles and explored children’s concepts of right and wrong by presenting them with moral dilemmas to ponder. He concluded that preschool children do not truly understand rules and are best thought of as “pre-moral.” Children ages 6–10, he observed, emphasize consequences more than intentions in judging the wrongness of acts (for example, they judge a boy who accidentally broke 15 cups while obeying his mother naughtier than a boy who broke only one cup while trying to sneak jam from the kitchen). They also tend to believe that rules are handed down by parents and other authorities and are unalterable. At age 10 or 11, Piaget found, children weigh more heavily whether a person’s intentions were good or bad in judging his actions. They also begin to appreciate that rules are agreements among individuals—agreements that can be changed through a consensus of those individuals.

Inspired by Piaget’s pioneering work, Lawrence Kohlberg (1963, 1981, 1984; Colby & Kohlberg, 1987) formulated his own, highly influential cognitive-developmental theory of moral development by asking 10-, 13-, and 16-year-old boys questions about various moral dilemmas to assess how they thought about these issues. Kohlberg concluded that moral growth progresses through a universal and invariant sequence of three broad moral levels, each of which is composed of two distinct stages. Each stage represents a more complex way of thinking about moral issues.

Moral dilemma: Do you think a doctor should give a pain-ridden and terminal patient a drug that would hasten her death if she asks for it? Amelie Van Esbeen, pictured in her bed in a home for the elderly in Belgium, thought so. The 93-year-old went on a hunger strike when her request for mercy killing was denied. She had already tried to commit suicide.

AFP/Stringer/Getty Images

Kohlberg’s Stages of Moral Reasoning

Think about how you would respond to the following moral dilemma posed by Kohlberg and his colleagues (Colby et al., 1983, p. 79):

There was a woman who had very bad cancer, and there was no treatment known to medicine that would save her. Her doctor, Dr. Jefferson, knew that she had only about 6 months to live. She was in terrible pain, but she was so weak that a good dose of a pain killer like ether or morphine would make her die sooner. She was delirious and almost crazy with pain, and in her calm periods she would ask Dr. Jefferson to give her enough ether to kill her. She said she couldn’t stand the pain and she was going to die in a few months anyway. Although he knows that mercy killing is against the law, the doctor thinks about granting her request.

Should Dr. Jefferson give her the drug that would make her die? Why or why not? Should the woman have the right to make the final decision? Why or why not? These are among the questions that people are asked after hearing the dilemma. You may want to answer them for yourself before reading further so that you can then analyze your own moral thinking.

Remember, Kohlberg’s goal is to understand the complexity of a person’s reasoning, not whether he or she is for or against providing the woman with the drug. Individuals at each stage of moral reasoning might endorse either of the alternative courses of action, but for different reasons. Following are Kohlberg’s three levels of moral reasoning, and the two stages within each level.

Level 1: Preconventional Morality At the level of **preconventional morality**, rules are external to the self rather than internalized. The child conforms to rules imposed by authority figures to avoid punishment or to obtain personal rewards. The

perspective of the self dominates: What is right is what one can get away with or what is personally satisfying.

- **Stage 1: Punishment-and-Obedience Orientation.** The goodness or badness of an act depends on its consequences. The child will obey authorities to avoid punishment but may not consider an act wrong if it will not be punished. The greater the harm done or the more severe the punishment, the more “bad” the act is.
- **Stage 2: Instrumental Hedonism.** A person at the second stage of moral development conforms to rules to gain rewards or satisfy personal needs. There is some concern for the perspectives of others, but it is motivated by the hope of benefit in return. “You scratch my back and I’ll scratch yours” and “an eye for an eye” are the guiding philosophies.

Level 2: Conventional Morality At the level of **conventional morality**, the individual has internalized many moral values. He shows respect for the rules set by others (parents, peers, the government), at first to win their approval, later to maintain social order. The perspectives of other people are clearly recognized and given serious consideration.

- **Stage 3: “Good Boy” or “Good Girl” Morality.** What is right is now what pleases, helps, or is approved by others. People are often judged by their intentions; “meaning well” is valued, and being “nice” is important. Other people’s feelings, not just one’s own, should be considered. At its best, Stage 3 thinking involves **reciprocity**, or mutual give-and-take in relationships, leading to a simple Golden Rule morality of doing unto someone else what you would want done unto you.
- **Stage 4: Authority and Social Order–Maintaining Morality.** Now what is right is what conforms to the rules of legitimate authorities and is good for society as a whole. The reason for conforming is not so much a fear of punishment as a belief that rules and laws maintain a social order worth preserving. Doing one’s duty and respecting law and order are valued.

Level 3: Postconventional Morality At the final level of moral reasoning, **postconventional morality**, the individual defines what is right in terms of broad principles of justice that have validity apart from the views of particular authority figures. The individual may distinguish between what is morally right and what is legal, recognizing that some laws—for example, the racial segregation laws that Dr. Martin Luther King, Jr., challenged—violate basic moral principles or human rights. Thus, the person transcends the perspective of a particular social group or authority and begins to take the perspective of *all* individuals.

- **Stage 5: Morality of Contract, Individual Rights, and Democratically Accepted Law.** At this “social contract” stage, there is an understanding of the underlying purposes served by laws and a concern that rules should be arrived at through a democratic consensus so that they express the will of the majority and maximize social welfare. Whereas the person at Stage 4 is unlikely to challenge an established law, the moral reasoner at Stage 5 might call for democratic change in a law that compromises basic rights.

- **Stage 6: Morality of Individual Principles of Conscience.** At this “highest” stage of moral reasoning, the individual defines right and wrong on the basis of self-generated principles that are broad and universal in application. The Stage 6 thinker does not just make up whatever principles she chooses. She discovers, through reflection, abstract principles of respect for all individuals and their rights—principles that all religious and moral authorities would view as moral. Kohlberg (1981) described Stage 6 thinking as a kind of “moral musical chairs” in which the person facing a moral dilemma is able to take the “chair,” or perspective, of each person and group and social system, present or future, that could potentially be affected by a decision and to arrive at a solution that would be regarded as just from every chair. Stage 6 is Kohlberg’s vision of ideal moral reasoning, but it is so rarely observed that Kohlberg stopped attempting to measure its existence.

In **Table 13.2**, we present examples of how people at the preconventional, conventional, and postconventional levels might reason about the mercy-killing dilemma. As you can see, progress through Kohlberg’s stages of moral reasoning is linked to the development of perspective-taking abilities. Specifically, as individuals become more able to consider perspectives other than their own, moral reasoning progresses from an egocentric focus on personal welfare at the preconventional level, to a concern with the perspectives of other people (parents, friends, and other members of society) at the conventional level, and to an ability to coordinate multiple perspectives and determine what is right from the perspective of all people at the postconventional level (Carpendale, 2000).

Influences on Moral Thinking

Whereas Freud emphasized the role of parents in moral development, Kohlberg, like Piaget before him, believed that the two main influences on moral development are cognitive growth and social interactions with peers. Regarding cognitive growth, reaching the conventional level of moral reasoning and becoming concerned about living up to the moral standards of parents and society requires perspective-taking skills, and gaining the capacity for postconventional moral reasoning requires still more cognitive growth—namely, a solid command of formal-operational thinking (Tomlinson-Keasey & Keasey, 1974; Walker, 1980).

The social interactions that count involve taking the perspectives of others and experiencing growth-promoting cognitive disequilibrium when one’s own ideas conflict with those of other people. Piaget and Kohlberg both maintained that interactions with peers or equals, in which we must work out differences between our own and others’ perspectives through negotiation, contribute more to moral growth than one-sided interactions with adult authority figures in which we are expected to bow to the adult’s power. So, moral growth is facilitated by:

- discussions of moral issues with peers, especially when peers challenge our ideas;
- advanced schooling; going to college both contributes to cognitive growth and exposes students to diverse perspectives (Pratt et al., 1991); and
- participating in a complex, diverse, democratic society where people weigh various opinions and appreciate that laws reflect a consensus of the citizens.

● **Table 13.2** Sample Responses to the Mercy-Killing Dilemma at Kohlberg’s Three Levels of Moral Reasoning

Give the Drug	Do Not Give the Drug
Preconventional Morality	Preconventional Morality
Stage 1: The doctor should give the terminally ill woman a drug that will kill her because there is little chance that he will be found out and punished.	Stage 1: The doctor runs a big risk of losing his license and being thrown in prison if he gives her the drug.
Stage 2: He should give her the drug; he might benefit from the gratitude of her family if he does what she wants. He should think of it as the right thing to do if it serves his purposes to be for mercy killing.	Stage 2: He has little to gain by taking such a big chance. If the woman wants to kill herself, that is her business, but why should he help her if he stands to gain little in return?
Conventional Morality	Conventional Morality
Stage 3: Most people would understand that the doctor was motivated by concern for the woman’s welfare rather than by self-interest. They would be able to forgive him for what was essentially an act of kindness.	Stage 3: Most people are likely to disapprove of mercy killing. The doctor would clearly lose the respect of his colleagues if he administered the drug. A good person simply would not do this.
Stage 4: The doctor should give the woman the drug because of the Hippocratic oath, which spells out a doctor’s duty to relieve suffering. This oath is binding and should be taken seriously by all doctors.	Stage 4: Mercy killing with this drug is against the laws that doctors are obligated to uphold. The Bible is another compelling authority, and it says, “Thou shalt not kill.” The doctor simply cannot take the law into his own hands; rather, he has a duty to uphold the law.
Postconventional Morality	Postconventional Morality
Stage 5: Although most of our laws have a sound basis in moral principle, laws against mercy killing do not. The doctor’s act is morally justified because it relieves the suffering of an agonized human without harming other people. Yet if he breaks the law in the service of a greater good, he should still be willing to be held legally accountable; society would be damaged if everyone simply ignored laws they do not agree with.	Stage 5: The laws against mercy killing protect citizens from harm at the hands of unscrupulous doctors and selfish relatives and should be upheld because they serve a positive function for society. If the laws were to be changed through the democratic process, that might be another thing, but right now the doctor can do the most good for society by adhering to them.
