14.3.3 Disorders of Carbohydrate Metabolism

Robin H. Lachmann

Introduction

Sugar molecules play many roles in metabolism. Glucose is an essential source of energy in the body, but carbohydrates also have important structural and signalling functions as constituents of glycoproteins, glycolipids, and glycosaminoglycans. In this chapter, we will describe a number of monogenic diseases which involve the monosaccharides glucose, galactose, and fructose and their roles in intermediary metabolism. The many other inherited metabolic diseases which affect the formation of glycosylated macromolecules (the congenital disorders of glycosylation) or their breakdown (lysosomal storage disorders) [1] will not be discussed.

Disorders of carbohydrate metabolism, although caused be defects in individual enzymes, are best viewed as disorders of metabolic *pathways*. Their tissue pathology can be due to deficiency of a product of metabolism, but just as often it is due to accumulation of toxic molecules which cannot be metabolized. Thus hypoglycaemia, which occurs in a number of these disorders, may be due to disabling mutations in enzymes of the glycogenolytic or gluconeogenic pathways, or to the inhibition of these enzymes by other accumulating molecules. In addition, hypoglycaemia can be caused by disorders in metabolic pathways affecting use of other fuels, such as those producing fatty acids and ketone bodies, which are both important alternative sources of energy. The interrelation between these glucose generating pathways is shown in **Figure 14.3.3.1**.

Glycogen Storage Diseases

The first process which maintains blood glucose during fasting is glycogenolysis: that is, the release of glucose from carbohydrate stores. The body stores carbohydrate in the form of glycogen, a branched polymer of glucose. Glycogen stores in the liver are used to maintain normoglycaemia, but muscle also stores glycogen for its own use as an energy source during exercise. Glycogen storage disorders (GSDs) are the inherited metabolic diseases which affect the synthesis and breakdown of glycogen.

Glycogen

Glycogen allows for the compact storage of glucose in a form that has a minimal osmotic effect but which is readily accessible and metabolically active. The core of a glycogen molecule is a small protein, glycogenin. Branched chains of polymerized α-d-glucose units are covalently attached to this at their reducing termini (**Figure 14.3.3.2**).

The glucose molecules in glycogen chains are linked to each other by α-1,4 glycosidic bonds with α-1,6 bonds at the branch

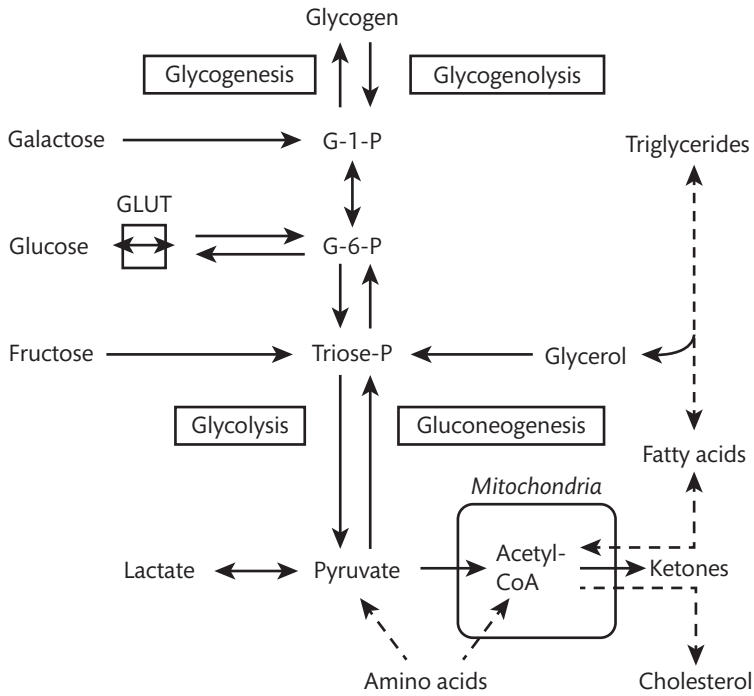

Figure 14.3.3.1 Main pathways of carbohydrate metabolism and relation with lipid metabolism. Acetyl-CoA, acetyl-coenzyme A; G-1-P, glucose-1-phosphate; G-6-P, glucose-6-phosphate; GLUT, glucose transporter; triose-P, triose phosphate.

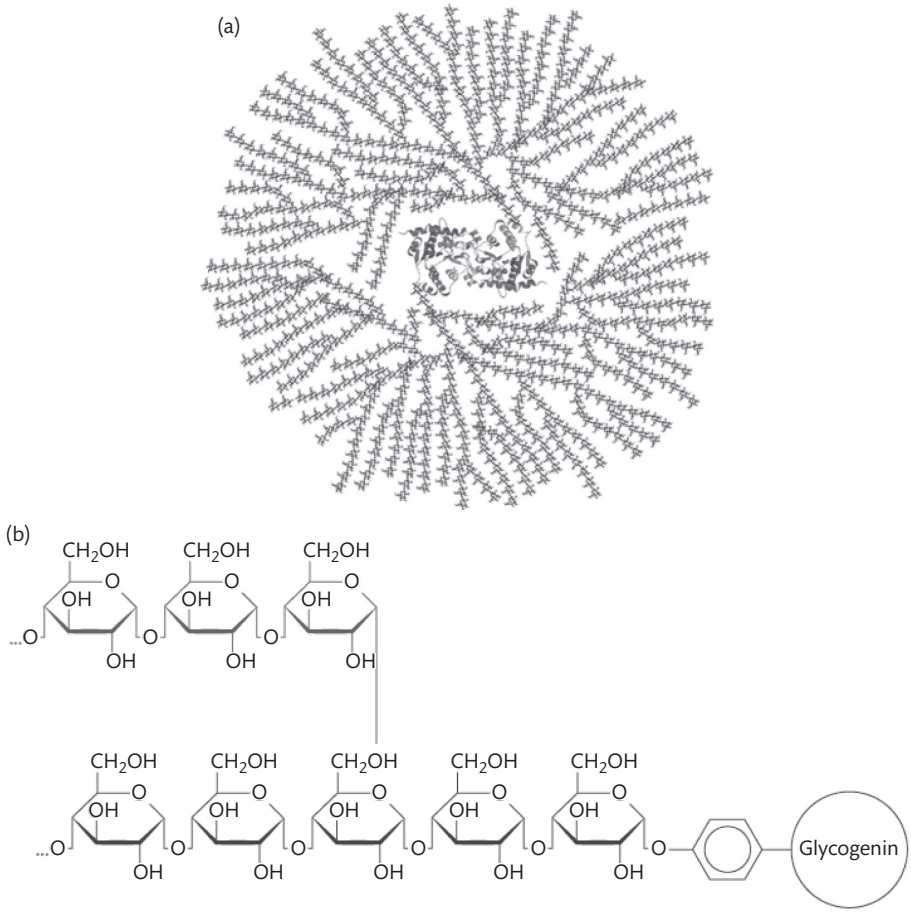

Figure 14.3.3.2 (a) A cross-sectional view of glycogen, showing the core glycogen protein surrounded by branches of glucose units, up to 60 000 of which can be contained within a glycogen granule. (b) Linear chains of glucose are formed by a-1,4 glycosidic bonds, with a-1,6 bonds at the branch points.

points. Glycogen molecules can contain up to 60,000 glucose molecules, have a molecular weight of several million daltons and are visible to the electron microscope. The liver and muscle contain between 200 and 300 g of glycogen. The 'arborization', or extensive branching, of the molecule, with large numbers of long outer chains that terminate in non-reducing glucose residues means that the enzymes of glycogen degradation can rapidly release large quantities of glucose.

Glycogen storage diseases can be caused by defects in glycogen synthesis or glycogen breakdown. The stored glycogen may have a normal or an aberrant structure. Depending on the enzymatic defect, glycogen metabolism in the liver, muscle, or both tissues may be affected. In this chapter we will focus on the diseases which affect glycogen breakdown in the liver and which can cause hypoglycaemia (Figure 14.3.3.3).

Glycogen Breakdown

Two enzymes are involved in the breakdown of glycogen in the cytoplasm: phosphorylase and debranching enzyme. Other enzymes are required subsequently to produce free glucose.

Phosphorylase sequentially removes glucose 1-phosphate units from the α-1,4-linked chains of glycogen. Debranching enzyme possesses transferase and α-1,6-glucosidase activities. When phosphorylase has degraded glycogen chains to within four α-1,4-glucosyl units of an α-1,6 linkage, three glucose residues are transferred to the end of another chain by the glycosyltransferase activity. Debranching enzyme then hydrolyses the remaining α-1,6 bond to release free glucose using its amylo-1,6-glucosidase activity. Debranching enzyme also cleaves the unique glucosyl–tyrosine linkage that anchors the terminal reducing glucose unit to glycogenin.

The main product of glycogen breakdown in muscle and liver is glucose 1-phosphate. Glucose 1-phosphate is a key intermediate of glycolysis, gluconeogenesis, glycogenolysis, and the pentose-phosphate pathway (Figure 14.3.3.1), but cannot be transferred outside the cell. However, after conversion to glucose 6-phosphate by phosphoglucomutase, free glucose is formed by the action of glucose 6-phosphatase. Glucose 6-phosphatase exists as a multicomponent complex in the endoplasmic reticulum of hepatocytes and, to a lesser extent, in renal tubular cells—it is not found in muscle. This complex contains glucose 6-phosphatase, several proteins that facilitate the transport of glucose, glucose 6-phosphate, and phosphate, as well as other stabilizing and regulatory units. Hepatic activity of glucose 6-phosphatase is the predominant metabolic source of blood glucose.

A summary of hepatic GSDs, their enzymology, and principal features is given in Table 14.3.3.1.

The commoner disorders are described next.

Glycogen Storage Disease Type I (Von Gierke's Disease)

Biochemistry

GSD I is due to Glucose-6-phosphatase deficiency. GSD Ia is caused by defects in subunits of the endoplasmic reticular enzyme complex that enable production of glucose from glucose 6-phosphate. In

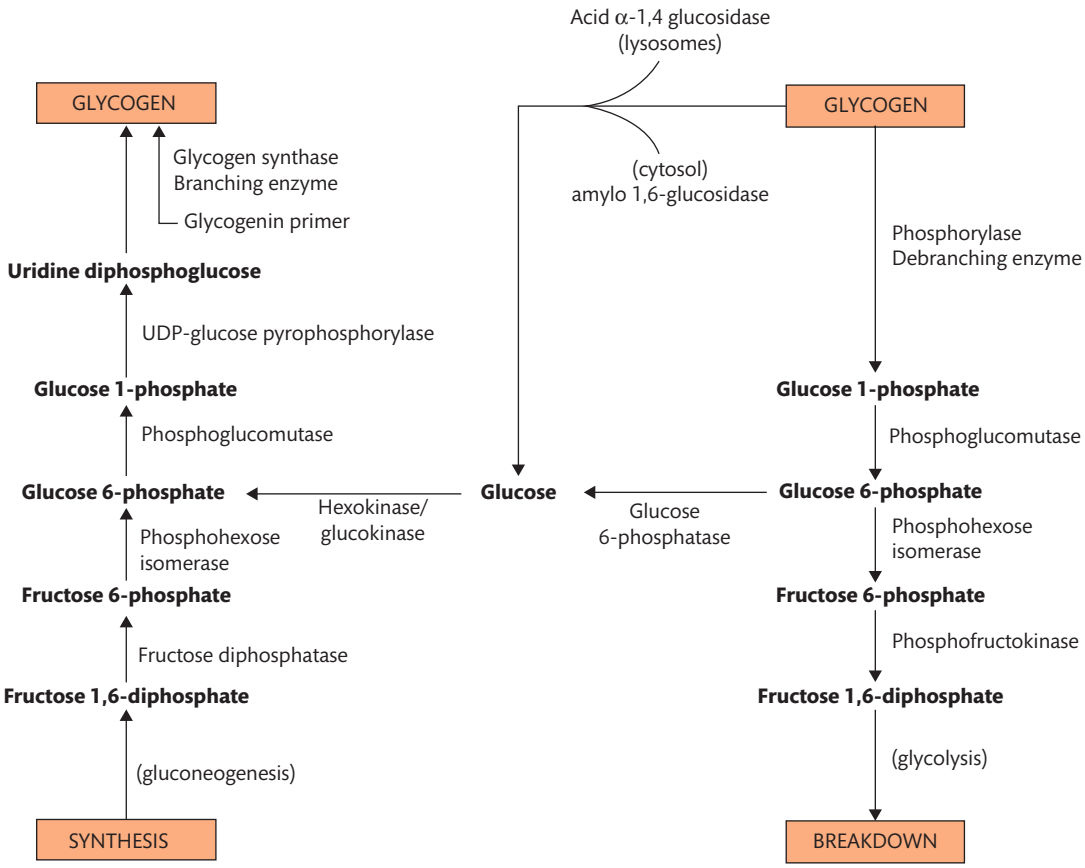

Figure 14.3.3.3 Glycogen breakdown.

Table 14.3.3.1 The glycogen storage disorders: genetic and enzymatic defects, and principal clinical features

GSD designation	Gene	Locus	Common term/Implicated protein	Supplementary	Clinical features
I (A) I (B)	*G6P6* *SLC37A4*	17q 21.31 11q 23.3	Von Gierke disease	Glucose 6-phosphatase G-6-P translocase	Hypoglycaemia, hyperlacticaemia, hyperuricaemia, hypertriglyceridaemia. Hepatomegaly, hepatic adenomata. Renal failure. As GSD Ia with neutropenia and colitis
III	*AGL*	1p21.2	Cori-Forbes disease (Limit dextrinosis)	Debranching enzyme	Hypoglycaemia, hepatomegaly, cardiomyopathy, myopathy
VI	*PYGL*	14q22.1	Hers disease	Glycogen phosphorylase Liver (very rare—Mennonite)	Hypoglycaemia, hepatomegaly
IX a2	*PHKA2*	Xp22.13	Phosphorylase kinase α2 subunit	Liver (regulatory)	Hypoglycaemia, hepatomegaly

GSD Ib the endoplasmic reticular transmembrane protein glucose-6-phosphate translocase is deficient. In both forms, the production of glucose from both glycogenolytic and gluconeogenic pathways is blocked, resulting in profound fasting hypoglycaemia (although this may be somewhat mitigated by the fact that small quantities of free glucose can be liberated by the α-1,6-glucosidase activity of the secondary action of debranching enzyme). Accompanying this, there is a build-up of glucose 6-phosphate. This is then metabolized by the pentose-phosphate shunt, or transferred back into glycogen which is stored in the liver and, to a lesser extent, the kidney, causing organomegaly. The products of glucose 6-phosphate metabolism have an important role to play in the other metabolic consequences of GSD I: hyperlacticaemia, hyperuricaemia, and hypertriglyceridaemia.

Lactic acidaemia results from stimulation of glycolysis at the level of phosphofructokinase by high concentrations of glucose 6-phosphate. Failure to dephosphorylate glucose 6-phosphate stimulates substrate cycling and increases the activity of the pentose-phosphate pathway, with enhanced production of purines. Degradation of purine nucleotides leads to overproduction of uric acid in the liver and hyperuricaemia. Enhanced flux through glycolysis and underutilization of gluconeogenic precursors leads to a cascade of metabolic changes that hypertriglyceridaemia.

Clinical Presentation

Patients typically present in infancy with symptomatic hypoglycaemia and failure to thrive, accompanied by a swollen abdomen due to hepatomegaly. Hypoglycaemic encephalopathy is often accompanied by seizures and can be fatal: recurrent episodes lead to permanent neurodisability. Children have impaired growth and increased subcutaneous fat deposition leading to a 'doll's face' appearance.

With aggressive dietary management (see next), the immediate life-threatening complications can be avoided. With improved survival, chronic, multisystem complications of GSD I have emerged (Figure 14.3.3.4).

There is persistent hepatomegaly, with glycogen storage accompanied by gross infiltration with fat. Cirrhosis and portal hypertension are, however, rare. Short stature, often combined with obesity, is common. The kidneys are enlarged by glycogen deposition. Progressive focal glomerulosclerosis and proximal tubular failure with a secondary Fanconi syndrome may also occur. Short periods of fasting, or other metabolic stressors such as infection provoke hypoglycaemia and lactic acidosis. In the longer term, poor metabolic control causes: growth arrest; hyperuricaemia and gout; marked hypertriglyceridaemia (which can lead to acute pancreatitis) and hypercholesterolaemia with raised very low-density lipoprotein (VLDL) and normal low-density lipoprotein (LDL) cholesterol concentrations in the plasma; and prolonged bleeding time related to an acquired von Willebrand-like defect affecting the platelet. Hepatic adenomata are seen in adults.

Patients with defects of the glucose 6-phosphate translocase system (type 1B) also have a neutropenia with impaired neutrophil migration and chemotaxis and are prone to recurrent bacterial infections. These patients are also at risk of developing granulomatous colitis with clinical features resembling ulcerative colitis.

Management

Historically, GSD I (and the other GSDs presenting with hypoglycaemia in infancy) were associated with a very poor outcome. This has been transformed by the introduction of aggressive dietary management aimed at maintaining a constant exogenous supply of glucose to meet basal requirements. Regular oral carbohydrate during the day and continuous overnight pump feeding with glucose, delivered either by nasogastric or gastrostomy tube, clearly improved clinical and biochemical parameters. Subsequently, fasting tolerance has been improved with the use of uncooked corn starch (obtained from the supermarket and suspended in water): this acts as a 'slow-release' form of glucose and, particularly in older patients, allows for more time between meals during the day and for some patients to discontinue overnight feeds. Modified corn starches have now been produced with the aim of increasing fasting tolerance further, although it is not yet clear that they offer a significant benefit over shop bought cornflour.

Maintaining normoglycaemia requires a diet with about 65% of dietary energy as carbohydrate (2). Continuous glucose monitoring can be useful in adjusting doses of uncooked corn starch and concentrations of overnight feeds. Regular dietetic review is important to minimize excessive weight gain, insulin resistance, and ensure the diet is nutritionally complete.

Intercurrent illness can rapidly provoke hypoglycaemia and patients with GSD I are given an 'emergency regime' to use in times of metabolic stress. This consists of frequent oral glucose polymer. If for any reason patients can't tolerate oral intake, glucose should be given intravenously at a rate of 0.2 g/kg/h.

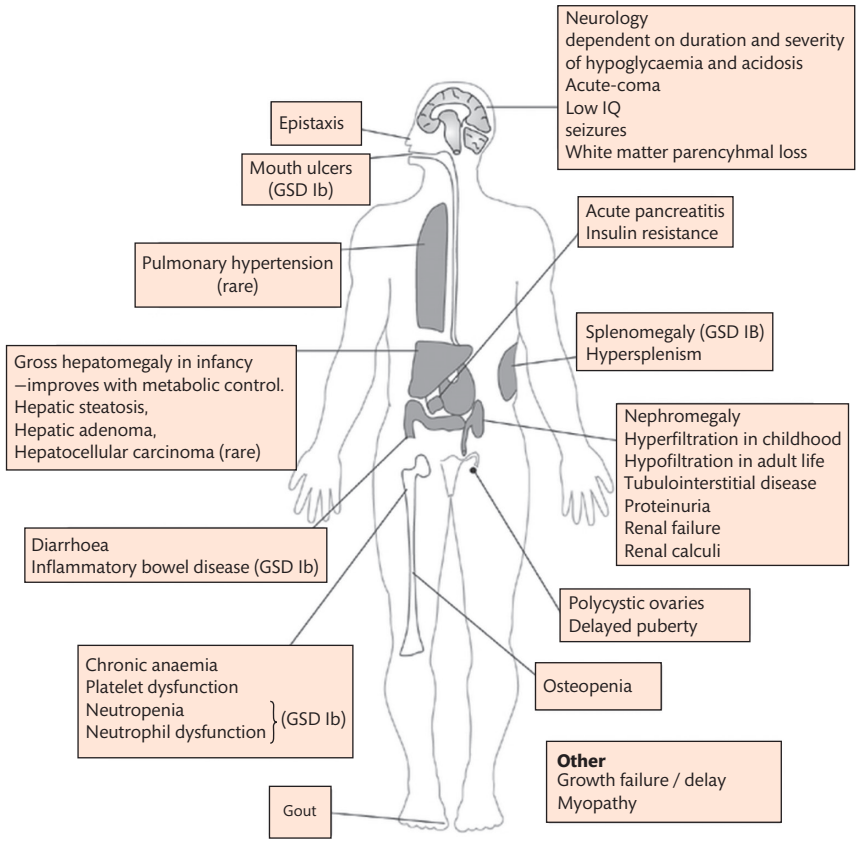

Figure 14.3.3.4 Complications of GSD I.

Hyperlipidaemia and hyperuricaemia need to be treated. Hyperfiltration or albuminuria indicate renal involvement and ACE inhibitors or ARBs should be introduced. Hypocitraturia may contribute to the increased incidence of nephrolithiasis and citrate supplementation may be useful. Iron supplementation is often needed. Osteopenia is common and calcium and vitamin D supplementation should be considered.

Surveillance for hepatic adenomata is important. MRI with the use of iv contrast is the preferred method. Around 70–80% of adult patients have been reported to have at least one lesion, and these progress in size or number in 50% of cases. The occurrence of adenomata seems to be related to metabolic control and in some cases improving biochemical parameters can lead to adenoma regression. Spontaneous regression is also seen.

The occurrence of hepatic adenomata is concerning because they can progress to hepatocellular carcinoma: predicting this progression is difficult [2]. Blood markers such as α-fetopotein have not proved useful. A rapid increase in size or number of adenomata, changes in vascularization and bleeding should lead to a multidisciplinary team (MDT) review to discuss surgical intervention, including liver transplantation.

Human granulocyte colony-stimulating factor is often required in patients with GSD Ib to increase the neutrophil count and control mouth ulcers, recurrent infections, and inflammatory bowel disease. Long-term use of granulocyte colony-stimulating factor is associated with a number of complications and should be supervised by a haematologist.

Due to the dangers of fasting and the bleeding tendency associated with GSD I, surgery must be managed carefully. Patients should be admitted the day before so that fasting can be covered with intravenous glucose. Platelets should be available in case of postoperative haemorrhage.

Pregnancy in women with GSD I is now relatively routine. With careful planning, close attention to glycaemic control and increased carbohydrate requirements, especially in the second half of pregnancy, and a well-managed labour, outcomes are good.

With optimal medical management patients with GSD I now lead relatively normal lives, but some patients remain in whom good metabolic control is never obtained. For these patients, liver transplantation offers a long-term 'cure' for many features of the disease [3]. Where there is also end stage renal failure, combined liver and renal transplantation can be performed.

Glycogen Storage Disease Type III (Forbes–Cori Disease)

Biochemistry

GSD III is due to deficiency of debranching enzyme. This results in the storage of structurally abnormal glycogen, with short outer chains, called limit dextrin, in both liver and muscle. Although glycogenolysis is blocked, gluconeogenesis is unaffected and fasting hypoglycaemia is milder than that seen in GSD I and accompanied

by ketosis rather than lactic acidosis. The secondary metabolic consequences are mostly confined to mild hyperlipidaemia.

Clinical Presentation

GSD III affects both liver and muscle. Hypoglycaemia and the hepatic consequences of storage dominate the clinical picture in children, with fasting hypoglycaemia and poor growth. The condition is less severe than GSD I and even in historic cohorts, most patients survived to adulthood.

In adults, fasting tolerance improves and on the whole hypoglycaemia can be prevented with dietary management. Hepatic adenomata have only rarely been reported, although patients can occasionally develop cirrhosis, and the kidneys are not affected.

Patients do, however, develop muscle symptoms and complain of exercise intolerance [4], although rhabdomyolysis is not a recognized feature. Some patients develop a progressive, disabling myopathy with pronounced distal weakness and myopathic facies. Cardiac muscle is also involved and hypertrophic cardiomyopathy can result in arrhythmias or heart failure [5].

Management

The management of hypoglycaemia in childhood is as in GSD I [6]. In adult patients it is important not to overtreat as this can lead to insulin resistance: with home glucose monitoring it is often possible to reduce the dietary content of complex carbohydrate.

Although left ventricular hypertrophy occurs in many patients, its clinical significance is not clear [7]. To date there are very few case reports of heart failure or significant arrhythmia in adults. This may change as patients age and periodic echocardiography and electrocardiographic (ECG) monitoring is probably prudent.

The incidence of clinically significant hepatic fibrosis and cirrhosis may also increase with age and liver imaging can be used to monitor this as well as the occurrence of hepatic adenomata.

GSD IX

Biochemistry

GSD IX is due to deficiency of phosphorylase kinase. Phosphorylase kinase consists of four subunits, two of which have tissue specific isoforms. The commonest form of GSD IX, and the commonest GSD, is X-linked, and due to mutations in *PHKA2*.

Clinical Presentation

GSD IXa is a hepatic GSD presenting early in life with hepatomegaly and fasting hypoglycaemia and ketosis. It is milder than GSD I and symptoms generally resolve in adulthood. Liver fibrosis has, however, been reported as a long-term complication.

Management

Management of hypoglycaemia is as for GSD I, but adult patients have normal fasting tolerance and do not need uncooked corn starch.

Diagnosis of GSD

Most patients with hepatic GSDs present with hypoglycaemia in early life. Historically, definitive diagnosis relied on demonstrating glycogen storage and assaying enzyme activity in the affected tissue: many adults with GSD I still bear the scars of liver biopsies performed in infancy. This approach to diagnosis was not only invasive but also technically difficult, and has to a large extent been superseded by new techniques.

In infants with suggestive symptoms, biochemical profiling, with measurements of glucose, lactate, and ketones, can suggest the correct diagnosis. In some cases (e.g. GSD III) this can be confirmed by enzymological study of blood-derived leucocytes, but in GSD I molecular genetic analysis is required as the enzymes are only expressed in liver.

Some patients present with hepatomegaly without biochemical features suggesting GSD. In these cases, histological examination reveals glycogen storage. If frozen tissue has been kept, enzymology may then confirm the diagnosis of a GSD. Electron microscopy can also be helpful if structurally abnormal glycogen is present. A diagnostic fast, with measurement of glucose, lactate, and ketones can also provide useful information. Hepatomegaly with glycogen storage is not, however, always due to a GSD: hepatic glycogenosis is a well-recognized complication of poorly controlled diabetes mellitus [8].

Increasingly, molecular genetics is becoming the diagnostic test of choice. Next generation sequencing allows large arrays of genes to be sequenced at the same time, and genetic panels to screen for all known GSDs, are now available [9].

Disorders of Galactose Metabolism

Galactosaemia

Biochemistry

The disaccharide lactose, which is the most important carbohydrate in both human and cow's milk, is formed from glucose and galactose. Galactose therefore forms a large part of the energy intake of infants. Galactose metabolism is shown in Figure 14.3.3.5.

Galactosemia is caused by deficiency of galactose-1-phosphate uridyltransferase (transferase, EC 2.7.7.10) (Figure 14.3.3.5, enzyme 2). Galactose-1-phosphate, which accumulates due to the metabolic block, is toxic to many organs and tissues, including the liver, kidney, and brain. It suppresses the activities of some enzymes of glycogenolysis and gluconeogenesis, which may lead to hypoglycaemia. Galactitol, produced from galactose excess, leads to cataract formation and is excreted in the urine. As well as being derived from exogenous sources of galactose, galactose-1-phosphate is also produced endogenously from glucose-1-phosphate, by a reversal of the pyrophosphorylase-epimerase pathway (Figure 14.3.3.5, enzymes 3 and 4). This 'self-intoxication' may contribute to late complications, such as ovarian failure and neurological disease, which can develop despite a strict lactose-free diet.

Clinical Presentation

Infants with classic galactosaemia (MIM 230400), caused by severe deficiency of galactose-1-phosphate uridyltransferase (GALT) (transferase, EC 2.7.7.10) (Figure 14.3.3.5, enzyme 2) appear normal at birth but rapidly become very unwell. Refusal to feed and vomiting are accompanied by signs of liver disease: jaundice, hepatomegaly, oedema, and ascites. Cataracts appear within a few days

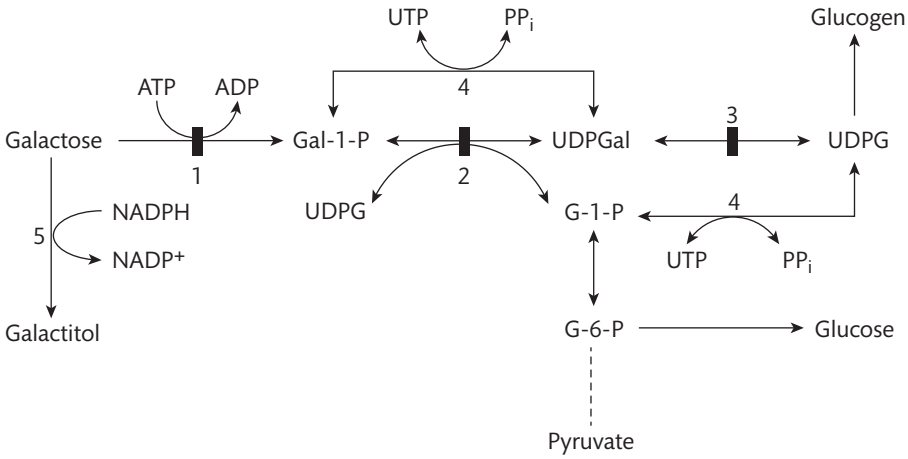

Figure 14.3.3.5 Galactose metabolism. 1, galactokinase; 2, galactose-1-phosphate uridyltransferase; 3, UDP galactose 4′-epimerase; 4, UDP glucose (UDP galactose) pyrophosphorylase; 5, aldose reductase. or weeks. Left untreated, liver and kidney failure develop and, along with sepsis are rapidly fatal [10].

Diagnosis

Many countries include galactosemia in their newborn screening programmes but, as classical galactosaemia presents very early in life, the newborn bloodspot needs to be taken early and processed quickly if the result is to be available before the neonate presents clinically: for this reason it is not included in newborn screening in the United Kingdom. Diagnosis otherwise rests on screening for total blood galactose, red blood cell (RBC) Gal-1-P, and/or urinary galactitol and confirmation by the measurement of GALT activity in RBC with or without genetic confirmation [11].

Treatment

Rapid introduction of a galactose-free diet rapidly reverses the acute presentation [11]. This involves withdrawal of breast milk or whey-based infant formula and the introduction of a soy-based or elemental formula. At weaning, the child should be started on a diet which is essentially dairy-free. Although there are small amounts of galactose in some fruits and vegetables, these are negligible when compared to endogenous galactose production, which is at least 8.4 mg/kg/day in adults, and so non-dairy sources of galactose are allowed. Many mature cheeses are also allowed as bacterial fermentation has removed all sugars and these provide a valuable source of calcium which is otherwise lacking in this diet. Low bone density is well recognized in adults with galactosemia and calcium and vitamin D intake should be carefully monitored throughout life and supplemented if required.

Long-Term Complications

Although acute intoxication with liver and kidney failure is only seen in infants, the long-term outcomes in galactosemia, even with early institution of dietary treatment, are not always good [12]. Average IQ is below the normal range and many patients have verbal dyspraxia. Adult patients often find it difficult to function in society and form relationships [13]. Neurological complications can also occur, and a few patients develop a progressive leukodystrophy [14]. The vast majority of women develop either primary or premature ovarian failure and require hormone replacement [11, 12]. This also contributes to the high risk of osteoporosis.

Currently it is recommended that a lactose-free diet is maintained for life, but there is little evidence to support this. There are reports of patients with galactosaemia who have relaxed their diets and not experienced any ill effects. Equally, there are patients who remain on a strict diet but go on to develop neurological disease.

Long-term problems might be due to continuous intoxication with galactose-1-phosphate, either produced endogenously or derived from complex sugars such as raffinose and stachyose by bacterial fermentation in the gut. In fact, it is possible that these effects are not related to the build-up of toxic metabolites at all, but actually reflect a generalized defect in glycosylation of proteins. Patients with congenital glycosylation defects demonstrate similar clinical features including hypogonadotropic premature ovarian failure, which is thought to relate to lack of glycosylation of follicle-stimulating hormone. Certainly, outcomes for patients with galactosemia on current treatment are not good and research is needed to find ways to improve them.

Disorders of Fructose Metabolism

Fructose is found in fruits, vegetables, and honey. With glucose, it forms the disaccharide sucrose, which is an important carbohydrate in many foods and beverages. Sucrose is hydrolysed into its two monosaccharides by the enzyme sucrase (EC 3.2.1.48) on the small intestinal mucosa. Another source of fructose is sorbitol, which is widely distributed in fruits and vegetables. It is converted in the liver into fructose by the enzyme sorbitol dehydrogenase (EC 1.1.1.14). The three inborn errors of fructose metabolism are shown in Figure 14.3.3.6.

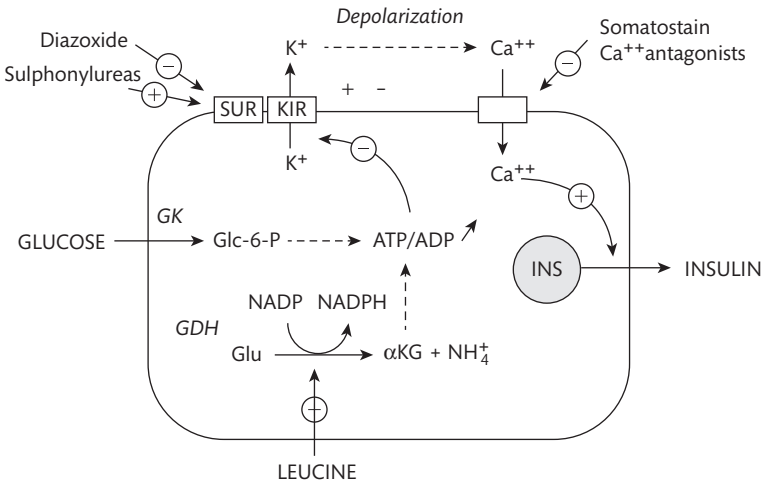

Figure 14.3.3.6 Fructose metabolism. 1, fructokinase; 2, aldolase-B; 3, fructose-1,6-bisphosphatase; 4, phosphofructokinase; 5, sorbitol dehydrogenase. The enzyme defects are depicted by solid bars across the arrows. ADP, adenosine diphosphate; ATP, adenosine triphosphate; DHA-P, dihydroxyacetone phosphate; F-1-P, fructose-1-phosphate; F-6-P, fructose-6-phosphate; F-1,6-P_2, fructose-1,6-bisphosphate; G-6-P, glucose-6-phosphate; Pi, inorganic phosphate; GAH-3-P, glycer-aldehyde-3-phosphate.

Essential Fructosuria

This is a rare 'non-disease', which does not show any clinical symptoms. It is caused by a deficiency of fructokinase (EC 2.7.1.4) (Figure 14.3.3.6, enzyme 1), which is normally found in liver, kidney, and small intestinal mucosa. Thus, fructose cannot be phosphorylated into fructose-1-phosphate. Instead, it is slowly phosphorylated into fructose-6-phosphate by the enzyme hexokinase in adipose tissue and muscle with the excess being excreted in the urine. The resultant fructosuria is the only finding. A discrepancy between a positive test for reducing sugars and a negative reaction with glucose oxidase should allow the identification of fructose as a non-glucose-reducing sugar. Dietary treatment is unnecessary.

Hereditary Fructose Intolerance

Clinical Presentation

Deficiency of aldolase-B (EC 4.1.2.13, MIM 229600), the second enzyme of the fructose pathway (Figure 14.3.3.6, enzyme 2) causes fructose-1-phosphate to accumulate after consumption of fructose containing foods. The mechanism of toxicity of fructose-1-phosphate is like that of galactose-1-phosphate in classical galactosaemia and there are some clinical similarities between the two disorders. When fructose/sucrose containing foods are introduced into the diet at weaning, the infant starts to vomit and refuse food, and develops failure to thrive with jaundice, hepatomegaly, oedema, ascites, and a bleeding tendency, reflecting liver dysfunction. Urinary findings are mellituria, proteinuria, and aminoaciduria, reflecting renal proximal tubular dysfunction. Diarrhoea and malabsorption reflect small intestinal involvement. Lethargy, tremor, and convulsions are due to hypoglycaemia (see next). The larger the fructose load and the younger the infant, the more acute the symptoms of intolerance. Older children may selectively refuse fructose containing products and never present in acute crisis. In these cases the diagnosis may be made by their dentist due to a complete freedom from dental caries.

Biochemistry

Fructose-1-phosphate, which accumulates due to the aldolase-B defect, is toxic. It causes hypoglycaemia by inhibiting enzymes of both glycogenolysis and gluconeogenesis: not only is the splitting of fructose-1-phosphate into three-carbon sugars impaired (Figure 14.3.3.6, enzyme 2), but also the condensation of the three—carbon sugars into fructose-1,6-bisphosphate (Figure 14.3.3.6, enzyme 3). The accumulation of fructose-1-phosphate also leads to the sequestration of inorganic phosphate, which is then not available for the regeneration of adenosine triphosphate (ATP) from ADP, causing a generalized energy defect in the cell. This provokes the catabolism of adenine nucleotides, which leads to the overproduction of uric acid.

Diagnosis

The clinical picture, combined with the finding of a combination of fructosuria and disturbed liver function tests, should lead to the suspicion of hereditary fructose intolerance Traditionally an intravenous fructose tolerance test was performed, but assay of aldolase-B activity in a biopsy of liver, jejunal mucosa or kidney cortex, or DNA analysis is simpler and safer.

Treatment and Prognosis

All sources of fructose, sucrose, and sorbitol (which can be present in many products such as medicines) should be excluded from the diet. They should be replaced by glucose, maltose, and starch. This elimination diet rapidly corrects all abnormalities except the hepatomegaly, which is slower to resolve. If small amounts of fructose remain in the diet growth may remain slow, but will catch up after further adjustment of the diet and overall, with treatment, the prognosis is excellent [15].

Fructose-1,6-Bisphosphatase Deficiency (MIM 229700)

Clinical Presentation

Fructose-1,6-bisphosphatase (EC 3.1.3.11) has a role both in the conversion of fructose to glucose (Figure 14.3.3.6, enzyme 3) and in gluconeogenesis, in which fructose-1,6-bisphosphatase is the third unidirectional enzyme (Figure 14.3.3.3, enzyme 3). Therefore, deficiency of the enzyme leads to abnormalities due to the impairment of both pathways, though those of failing gluconeogenesis are more serious than those of impaired fructose conversion. Hypoglycaemia, associated with lactic acidosis, occurs in the neonatal period and can recur in later childhood. It usually develops after prolonged fasting or with an intercurrent febrile illness. The clinical symptoms of hypoglycaemia (lethargy, irritability, apnoea, coma, and convulsions) are accompanied by hyperpnoea, somnolence, and vomiting due to the lactic acidosis. Attacks may also occur after ingestion of fructose or sucrose. The frequency of attacks decreases with increasing age. Mild hyperlactacidaemia may persist between episodes. Growth and psychomotor development are usually normal.

Biochemistry

As gluconeogenesis is blocked, glucose cannot be synthesized from lactate, pyruvate, alanine, glycerol, or fructose. The patient depends on exogenous glucose and galactose and endogenous glycogen for their glucose requirements. On fasting, hypoglycaemia and lactic acidosis develop, sometimes accompanied by hyperketonaemia. Lactate, pyruvate, alanine, glycerol, and glycerol-3-phosphate accumulate in blood and urine.

Diagnosis

Enzymatic assay of fructose-1,6-bisphosphatase in a biopsy of the liver, jejunal mucosa, or kidney cortex is the only reliable means for the diagnosis.

Treatment and Prognosis

The acute, life-threatening attack is treated with an intravenous glucose drip: an intravenous glucose bolus (200 mg glucose/kg bodyweight over 5 min) followed by a continuous infusion (*c.* 12 mg glucose/kg bodyweight per min). Sodium bicarbonate may be given to treat the lactic acidosis. In order to prevent further attacks, it is important to avoid prolonged fasting. An emergency regimen consisting of frequent carbohydrate is given during intercurrent infection. In small children restriction (not elimination) of fructose, sucrose, and sorbitol is recommended. The tolerance for fasting improves with age and the prognosis is good if adequate treatment is introduced in infancy.

14.3.4 Haemochromatosis and Other Inherited Diseases of Iron Metabolism

Yves Deugnier and Edouard Bardou-Jacquet

Introduction

Iron is a vital element for many biological processes, but can also be deleterious if present in excess. Because we lack a physiological pathway to remove iron absorption is tightly regulated to maintain a balanced iron store. Iron overload disease has been recognized centuries ago, but its understanding drastically improved in the recent decades. Identification of the main genes involved in iron metabolism, and association of mutations in some of these genes with different iron overload syndromes over the past 25 years, have streamlined precise diagnosis of these heterogeneous disorders, and have made it possible to construct a mechanism-based classification [1]. Genetic disorders are classified as haemochromatotic and non-haemochromatotic, and contrast with acquired iron excess, which is associated mainly with haematological conditions, cirrhosis, and metabolic syndrome. However even in these disorders clinical expression is often modulated by genetic as well as environmental factors

Hereditary Disorders

Genetic Haemochromatosis

Genetic haemochromatosis is heterogeneous, accounted for by several gene defects that share certain characteristics, namely (i) dysregulation of hepcidin synthesis or impairment of hepcidin action resulting in intestinal hyperabsorption and increased macrophage egress of iron; (ii) elevated serum iron with increased transferrin saturation; (iii) variable clinical phenotypes, ranging from early and severe disease in juvenile haemochromatosis related to the hemojuvelin (*HJV*) or the hepcidin (*HAMP*) genes to late and less severe disease in adult haemochromatosis related to the *HFE* or the transferrin 2 receptor (*TfR2*) gene (Figure 14.3.4.1); and (iv) recessive transmission, except in the exceptional case of ferroportin disease, caused by underlying gain-of-function mutations.

HFE Haemochromatosis

This condition alone accounts for almost all cases of haemochromatosis in populations of European descent [2].

Genetics and Pathophysiology

A major causal mutation, C282Y, and many minor mutations have been described on the *HFE* gene [3]. The C282Y mutation (Replacement of tyrosine by cysteine in position 282 of the protein) immobilizes the HFE protein intracellularly and impairs regulation of hepcidin synthesis. This leads to intestinal hyperabsorption of iron and to release of iron from macrophages with the following consequences: (i) hypersaturation of transferrin, the plasma iron transport protein; (ii) appearance of non-transferrin-bound iron (NTBI) [4] which, penetrating easily into parenchyma, is responsible for tissue iron loading (Figure 14.3.4.1). Among *HFE* genotypes, only C282Y homozygosity—whose prevalence ranges between 1 and 9% in Europe [5]—is associated with overt haemochromatosis. However, its clinical penetrance is rather low [6, 7], estimated at 1% in females and 27% in males [8]. Double heterozygosity for C282Y and a minor mutation, including the H63D and the S65C mutations, has no significant effect on intracellular migration of the HFE protein and its physiological role. However, compound C282Y—H63D heterozygosity may mildly increase body iron stores, but with no clinical expression in the absence of genetic or environmental cofactors [6, 9, 10].

Natural History

Initially, the disease is quiescent. An increase in serum iron and in transferrin saturation (the earliest and most sensitive marker) then occurs, followed by a gradual rise in serum ferritin concentration. Later, most often between 35 and 45 years of age in men and 45 and 55 years of age in women, clinical symptoms and then visceral complications may occur. This results in the division of disease progression into five stages (Figure 14.3.4.2), however passage from one stage to the next is never guaranteed given the low penetrance of the disease.

Clinical Expression

In daily practice, a-, mono—and pauci-symptomatic forms have become the rule due to (i) the highly variable expressiveness of the disease, particularly in women in whom asthenia and joint symptoms dominate; (ii) the frequent involvement of cofactors, which may determine selective visceral expression, such as hepatic forms in men; and (iii) the systematization of biochemical assessment and family screening in healthy people, leading to early diagnosis.

Endocrine Complications

Dominated by diabetes and pituitary disease, endocrine complications of HFE-related iron overload indicate an advanced form of the disease. Overt diabetes [11], which was part of the historical picture of hemochromatosis, is currently present in less than 10% of cases at the time of diagnosis. Moreover, systematic searches for haemochromatosis in newly developed diabetes reveal it in less than 2% of cases. Conversely, the incidence of insulin-requiring diabetes in haemochromatotic cirrhosis is significantly higher than in non-haemochromatotic cirrhosis, which supports a specific role of iron. The underlying mechanism is dual, involving insulin resistance in liver and, to a lesser degree, muscle, as well as insulinopenia secondary to destruction of pancreatic islet cells by iron accumulation. Haemochromatotic subjects exhibit insulin resistance/hyperinsulinemia while glucose tolerance is still normal, and function of both β cells (normal C peptide blood concentration) and α cells (normal glucagonemia and secretion of GIP—gastric inhibitory polypeptide) is intact. Subsequently there is parallel progression of hyperglycaemia towards diabetes due to iron-mediated loss of β cells, and of liver disease towards cirrhosis, while secretion of other pancreatic hormones remains normal. Involvement of additional factors, many genetic, has been advanced on the basis of early family studies, but has not been

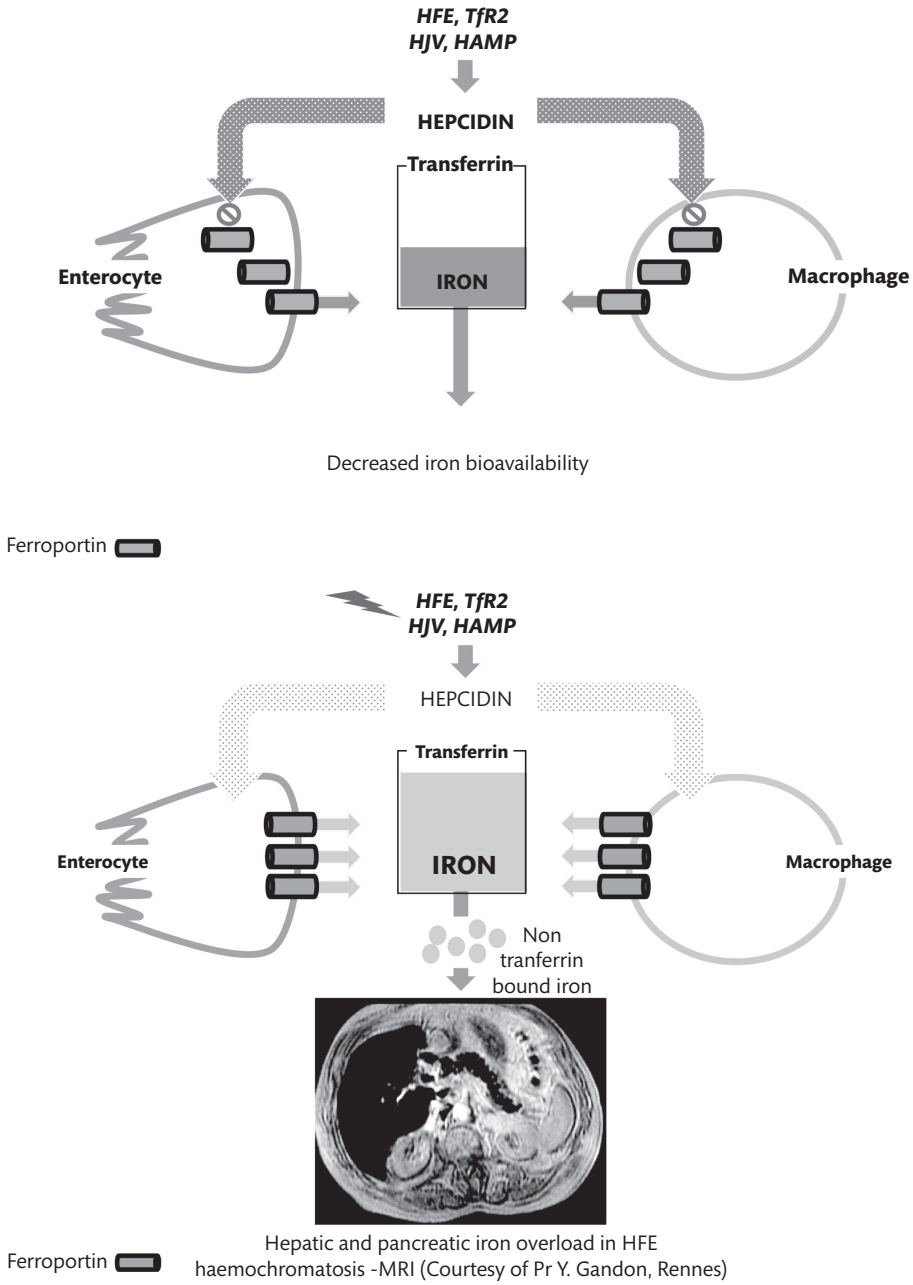

Figure 14.3.4.1 (a) Physiological role of hepcidin. The iron stock regulates hepcidin synthesis via a cascade including the HFE, hemojuvelin and transferrin 2 receptor (TfR 2) proteins. Hepcidin controls the release of iron by ferroportin, especially in enterocytes and macrophages. It acts by reducing the cellular egress of iron, which results in decreasing both serum iron and transferrin saturation and, then, the bioavailability of iron. (b) Pathophysiology of iron loading in haemochromatosis. Alteration of the HFE, hemojuvelin, transferrin 2 receptor, or hepcidin gene is responsible for the dysregulation of hepcidin production. This results in lifting of the inhibition of iron egress from enterocytes and macrophages which is responsible for increased serum iron and transferrin saturation. The subsequent production of non-transferrin-bound iron (NTBI) leads to iron loading, as NTBI is avidly taken up by parenchymas.

confirmed by the most recent studies that failed to find an increased frequency of hyperglycaemia in relatives of people with haemochromatotic diabetes. The role of C282Y heterozygosity in development of diabetes also remains debated but, if it exists, it is minimal.

Diabetes in haemochromatosis does not differ from other forms of diabetes with respect to the frequency of onset and presentation of ophthalmologic, cardiovascular, neurologic, and renal complications. However, it is a major independent prognostic factor: survival of haemochromatotic patients is reduced in those with diabetes (93% at 5 years, 77% at 10 years, 62% at 15 years and 55% at 20 years) while that of non-diabetic haemochromatotic patients is almost identical to that of the general population. Diabetes is rarely the direct cause of death, however. It rather intervenes indirectly by promoting the occurrence of coronary heart disease, infections, and even hepatocellular carcinoma.

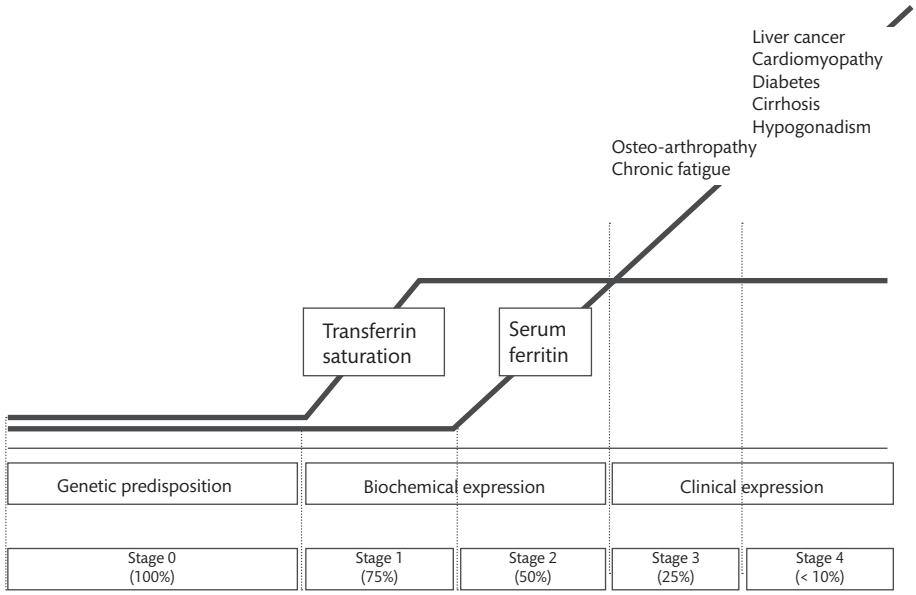

Figure 14.3.4.2 Phenotypic stages in HFE haemochromatosis (C282Y homozygosity). Not all patients progress to overt disease. According to the recommendations of the Haute Autorité de Santé, http://www.anaes.fr.

Pituitary damage in haemochromatosis [12, 13] has long been known from autopsy studies that showed major iron loading in pituitary cells, particularly gonadotrophs. Its main clinical consequence is hypogonadism [14], seen in 12% to 38% of men at the time of diagnosis and manifest as decreased libido, testicular atrophy, and hair loss and, biochemically, as decreased testosteronemia [14]. Lowering of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) concentrations, the lack of response to gonadotropin-releasing hormone (GnRH) that is general seen, and the improvement of hypogonadism on administration of hCG all support a predominantly pituitary origin of the disorder. Cirrhosis also contributes to the decline of testosteronemia through a poorly understood mechanism, and diabetes can also be involved through neurological and vascular damage. Panhypopituitarism, central hypothyroidism [15], GH hyposecretion and adrenal insufficiency [16] due to haemochromatosis are all exceptional and anecdotal.

Extra-Endocrine Disorders

Chronic fatigue is one of the first symptoms of the disease, and biochemical workup frequently has the initial aim of seeking iron deficiency. The classically described greyish-brown skin pigmentation, predominating in exposed areas, nipples, and external genitalia, is a late sign, sometimes associated with ichthyosis of the arms and legs, leukonychia, and koilonychia.

Joint symptoms are common initial presentations, especially in women [17, 18] and are not correlated with the extent of iron excess. Nevertheless, they can be seriously debilitating [19]. Small distal joints are worst affected, especially the metacarpophalangeal and proximal interphalangeal joints of the second and third fingers, resulting in pain on shaking hands. Other joints may also be affected including wrists, ankles and, more rarely, hips, knees, and shoulders. Symptoms are arthralgias with a rather inflammatory rhythm, with a relapsing and remitting pattern, and acute flares in 5–10% of cases. In advanced disease joints are deformed and functional impairment can become major. Radiologically, reduction of joint space, cystic subchondral osteopathy, sclerosis, and osteophytosis are seen in different combinations. Chondrocalcinosis is present in a quarter of cases. The pathophysiology of joint damage remains poorly understood.

Decreased bone mineral density [20] is detected in one-third of patients and is associated in 15% to 18% of cases with spinal fractures. It is somewhat correlated with iron excess, but is also driven by hypogonadism, cirrhosis and, possibly hyperparathormonaemia [21].

Hepatomegaly can be major in advanced disease and is characterized by (i) classical left lobe predominance; (ii) undisturbed or almost normal liver functions (the most frequent abnormality is moderately (<3 fold) increased serum alanine amino transaminase (ALT) concentration); and (iii) rarity of hepatocellular failure and portal hypertension, even when cirrhosis is present, in the absence of cofactors. A major risk, however, is the development of primary liver cancer—especially hepatocellular carcinoma—as soon as cirrhosis has developed [22, 23]. Although reduced, the risk persists even if the patients is appropriately treated and fibrosis has regressed [24].

When present, heart damage is usually limited to echocardiographic abnormalities including cardiac hyperechogenicity, increased left ventricular volume without parietal thickening, and decreased left ventricular ejection fraction. In advanced disease, rhythm disorders may be seen, including atrial fibrillation, paroxysmal supraventricular tachycardia, atrial flutter or atrioventricular block and/or congestive heart failure associated with cardiomegaly and systolic dysfunction on echocardiography and cardiac hyposignal on magnetic resonance imaging (MRI).

A causal relationship between iron overload (and/or chelator therapy) and certain infections, particularly those due to *Yersinia enterolitica*, *Vibrio vulnificus*, and *Mucor*, has been suggested. Asymptomatic deficiency in vitamins A and C is common.

Diagnosis

Haemochromatosis is diagnosed based on a combination of abnormal serum iron tests, and presence of the HFE C282Y mutation.

Serum iron concentration greater than 30 mmol/L and, more specifically, transferrin saturation exceeding 60%, are common, together with slight hypotransferrinaemia of around 1.9 g/L. It is essential, however, to consider and exclude (i) false negatives where there is associated systemic inflammation or metabolic syndrome; and (ii) false positives connected with haemolysis in the sampling tube, cell lysis (e.g. hepatic necrosis, haemolysis, rhabdomyolysis), metabolic syndrome, and/or hepatic disease (increased transferrin saturation due to deficient transferrin synthesis by the liver). Transferrin saturation remains the best index for both diagnosis of and disease monitoring in haemochromatosis, and indeed in the absence of systemic inflammation, metabolic syndrome, and outside the context of systematic screening, normal transferrin saturation rules out the disease.

Unlike serum iron concentration, serum ferritin concentration provides information on the degree of iron excess and therefore varies greatly from one subject to another. However, although a normal concentration allows exclusion of the diagnosis of iron overload, normal serum ferritin concentration does not exclude HFE C282Y homozygosity. Conversely, there are frequent false positive cases of hyperferritinaemia in the absence of excess body iron due to numerous conditions including excessive alcohol consumption, metabolic syndrome, cell lysis, inflammatory, and macrophage activation syndromes, tumours, Gaucher disease, and hyperferritinaemia-cataract syndrome.

HFE genotyping is indicated if, and only if, transferrin saturation is elevated and requires prior consent and subsequent genetic counselling. A diagnosis of HFE haemochromatosis is certain in people with HFE C282Y homozygosity. C282Y-H63D compound heterozygosity may be responsible for mild, clinically asymptomatic iron excess but not overt haemochromatosis. The diagnosis must be ruled out in the case of any other HFE genotypes **except** when the three following conditions are met: (1) authentication of significant iron overload by MRI or liver biopsy; (2) exclusion of all other causes of iron overload (see next); and (3) demonstration of two major mutations on the HFE gene, which generally corresponds to compound heterozygote states combining C282Y with a very rare or 'private' mutation [25].

Further Clinical Evaluation

No special evaluation is needed in patients with stage 0/1 haemochromatosis. In stages 2, 3, and four clinical examination should seek the various manifestations of the disease, and blood count, determination of serum transaminases and fasting glucose, and electrocardiography should be undertaken. Additional assessments may be helpful depending on the context. Liver biopsy may be necessary to assess hepatic fibrosis as cirrhosis confers an increased risk of liver cancer and thus modifies subsequent management. It is not indicated in C282Y homozygotes whose the liver is not enlarged AND serum ferritin levels are lower than 1000 ng/ml AND serum alanine aminotransaminase (ALAT) levels are normal, since these patients have been shown never to have bridging fibrosis or cirrhosis [26]. It remains indicated in those who do not meet these three criteria. Elastometry may, in the near future, further restrict use of biopsy [27]. Hepatic MRI replaces biopsy in quantification of iron excess [28] when it is likely to be overestimated by serum ferritin alone. It also detects (pre)neoplastic lesions [29] which exhibit relative hyperintensity of signal (by absence of iron at their level) [30]. Joint radiography may be indicated in case of painful joints as well as bone densitometry if risk factors for low bone mineral density are present (e.g. peri or postmenopause, cirrhosis, and/or hypogonadism). Determination of serum testosterone may be useful in men with sexual disturbances, while echocardiography is indicated in case of heart-related symptoms or systematically when serum ferritin levels exceed 1000 ng/ml.

Treatment

Phlebotomy remains the main approach to depletion of excess iron. This involves removal of 5–7 ml blood/kg per session, which are weekly until serum ferritin concentration falls below 50 µg/L. This first phase can last from a few weeks to more than two years, depending on the extent of the initial iron excess. It is followed by a lifelong maintenance phase consisting of regular phlebotomy whose rate and volume are adjusted to maintain serum ferritin concentration below 50–100 µg/L and, if possible, transferrin saturation below 50% [31]. One phlebotomy every 1–4 months is then sufficient, except for (i) during pregnancy, when iron removal is suspended; (ii) the time of menopause, when the rhythm and/or volume of phlebotomy must be adapted to the new physiological conditions; and (iii) in the elderly, when it is customary to reduce the unit volume of phlebotomy to 150–250ml or to stop, according to the patient's general condition and tolerance of the procedure.

Tolerance of phlebotomy is excellent as long as puncture points are varied and fluid is replenished before and after each session. Blood pressure measured before and after each blood removal, and blood count monthly initially or at each bleeding during the maintenance phase are used to monitor for side effects of therapy. Its effectiveness is monitored by serum ferritin concentration monthly at the beginning of treatment then every two bleeds once serum ferritin has dropped below 300 ng/ml (200 ng/ml in women).

Survival outcomes are excellent. Indeed, when initial serum ferritin concentration lies between the upper limit of normal and 1000 µg/L, survival is longer than that of the general population due to lower mortality from cardiovascular disease and extrahepatic cancer [32]. Only people with initial serum ferritin greater than 2000 µg/L have reduced life expectancy, mainly due to liver cancer and diabetes [32]. Phlebotomy normalizes prevalence of asthenia, melanoderma, heart damage, hepatomegaly, and increased serum transaminase levels, but does not lead to full resolution of joint manifestations, diabetes, and hypogonadism. Glucose intolerance can be improved, but not insulin-requiring diabetes, although insulin requirement is reduced in 40% of cases [11]. A few cases of regression of hypogonadism on depletive treatment have been reported [14, 33, 34], but hypogonadism generally requires additional specific management. The risk of liver cancer is reduced but remains above background in 'de-ironed' cirrhotic patients, mandating continued biannual ultrasound surveillance.

Although phlebotomy is convenient, cheap, and efficient, some patients are reluctant to undergo this treatment or are unable to tolerate it because of associated disorders (e.g. anaemia, heart failure). In this setting iron chelators may be used to deplete the excess iron burden. Deferoxamine has been used for decades in iron-overloading anaemias, and some reports showed good results in haemochromatosis. However continuous subcutaneous infusion is required, hampering adherence to treatment. The oral iron chelator deferasirox showed good efficacy but poor tolerability in a phase 1/2 clinical trial [35] and cannot be used to maintain low body iron

stores. In the near future, hepcidin agonists currently under development and clinical evaluation could prove valuable options, as they would fully address the pathological hepcidin deficiency that causes haemochromatosis [36].

There is no evidence that a low iron diet is beneficial in the long term. Reduction of intestinal absorption of iron by tea consumption [37] or by proton pump inhibitor has been advocated in small controlled studies [38, 39]. Alcohol consumption should be discouraged during the initial depletion period and should then be limited, except in cirrhosis where it should be prohibited. Vitamin C supplementation should be avoided at the beginning of depletive treatment as it may precipitate cardiac decompensation. The finding of macrocytosis may motivate the use of folic acid. Visceral complications do not require specific measures. Treatment of hypogonadism may include use of androgens administered transcutaneously at physiological doses, other forms of androgen therapy being suspected of increasing risk of liver cancer.

Screening and Prevention

European [5] and American [40] recommendations do not advocate systematic screening for the disease but strongly recommend family screening of first-degree relatives of any C282Y homozygote. Collection of both phenotypic and genotypic data is recommended in siblings, but screening of parents may be phenotypic only. For children it is suggested either to wait until the age of 18 or to offer genotyping to the other parent to clarify their risk. In C282Y homozygotes detected at stage 0 or 1, simple biological monitoring is required every 3 years (stage 0) or annually (stage 1). For those who are screened at stages 2 to 4, depletive therapy should be implemented after appropriate pretherapeutic assessment. C282Y heterozygotes can be reassured and released from any surveillance, except in the event of an abnormality of their iron balance, which requires the search for compound heterozygosity or any other cause of disturbance of iron metabolism. Genotyping of their partner is suitable in order to assess any possible risk of homozygosity in any offspring.

Non-HFE Haemochromatosis

These are extremely rare conditions. Type 2 haemochromatosis or juvenile haemochromatosis is linked to mutation of the hemojuvelin gene (*HJV*) [41] or, even more exceptionally, in the hepcidin gene (*HAMP*) [42]. It is expressed in adolescents or young adults by hypogonadotropic hypogonadism, heart failure, and cirrhosis which, as a rule, respond well to vigorous treatment with phlebotomy. Type 3 haemochromatosis has been described in some Mediterranean and other European families [43]. It is linked to mutation of the transferrin receptor 2 gene (*TFR2*) and produces a picture superimposable upon that of HFE hemochromatosis.

Non-Haemochromatotic Iron Overload Syndromes

These are genetic conditions that also affect iron metabolism, but that have a disease phenotype distinct from that of genetic haemochromatosis.

Ferroportin Disease

Ferroportin is a protein that, under the control of hepcidin, ensures egress of iron from enterocytes and macrophages to plasma [44]. Mutations of the ferroportin gene are rare and lead to type 4 haemochromatosis, also known as 'ferroportin disease'. The most frequent form (Type 4A) is clearly distinguished from HFE haemochromatosis by (i) its dominant autosomal mode of transmission; (i) its very low clinical expressiveness; (iii) its biochemical phenotype, which is characterized by elevated serum ferritin concentration but normal or only slightly increased transferrin saturation; and (iv) a predominantly mesenchymal pattern of iron deposition [45]. The disease is usually diagnosed in adulthood because of its long clinical latency in the absence of environmental cofactors. Rare mutations rendering ferroportin insensitive to hepcidin lead to phenotype similar to that of HFE haemochromatosis (Type 4B).

Aceruloplasminemia

This is an autosomal recessive disease of adulthood featuring parenchymal iron overload affecting the liver, pancreas (diabetes) and central nervous system (retinitis pigmentosa, extrapyramidal syndrome and disorders of cognitive functions up to dementia) [46]. Biochemically, it is characterized by hyperferritinaemia with low transferrin saturation, but its hallmark is the extremely low rate of serum ceruloplasmin. Phlebotomy rapidly induces anaemia. Iron chelation is then the treatment of choice.

Acquired Disorders

Excessive iron therapy of anaemias, excessive iron intake, and liver cirrhosis all usually induce significant iron overload. The metabolic syndrome is responsible for only mild iron excess, in contrast.

Haematologic Disorders

Dyserythropoiesis, whatever its cause (e.g. thalassemia, hereditary or acquired sideroblastic anaemias, congenital dyserythropoietic anaemia) can induce iron overload secondary to iron hyperabsorption even before blood transfusion. The resulting clinical picture is similar to that of haemochromatosis. Most often, the haematological disorder is known and the patient is already treated by regular blood transfusions when the problem of iron overload is unmasked, however. In thalassemia major [47], which remains the most frequent cause of secondary iron overload, iron hyperabsorption and high transfusion requirements (on average 200–300 ml/kg/day, or 0.25–0.40 mg/kg/day of iron) contribute to early iron overload. In the first decade, this manifest as hepatomegaly with fibrosis and growth retardation. It is later responsible for delayed sexual maturation and cardiomyopathy, the latter being the main cause of death in young patients. All serum iron load markers are increased. Treatment is based on dietary measures to limit intake and absorption of iron (e.g. tea consumption) and use of iron chelators. Deferasirox, an orally active chelator that is generally well tolerated by young patients has revolutionized the management of this type of overload.

Excessive Iron Intake

Whatever its route of administration, regular and prolonged iron intake can lead to iron overload, as seen sometimes in high performance athletes unduly supplemented with iron [48], for example.

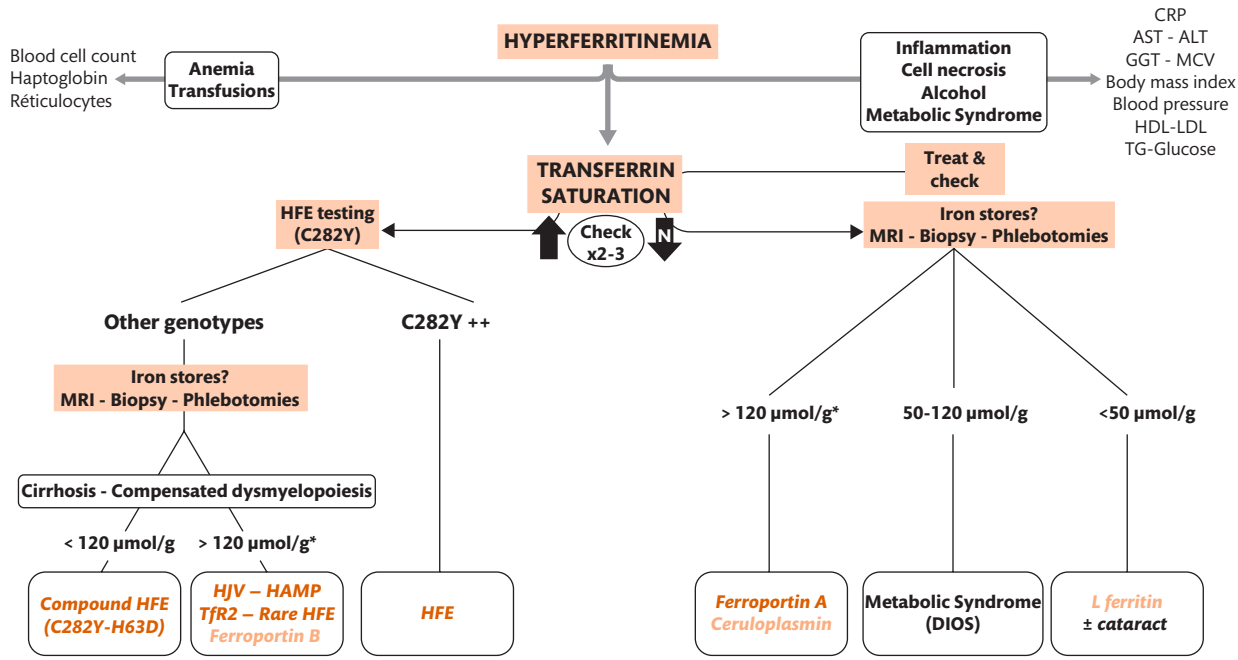

Figure 14.3.4.3 Diagnostic algorithm for hyperferritinaemia. DIOS, dysmetabolic iron overload syndrome; HAMP, hepcidin; HJV, hemojuvelin; TfR2, transferrin receptor 2. *Italics: genetic disorders (recessive/dominant).* * Or amount of iron removed by weekly/bimonthly phlebotomies: 3 g in males and 2 g in females (1 L of blood = 0.5 g of iron).

Cirrhosis of the Liver

In any cirrhosis, a pseudo-haemochromatotic picture including melanoderma, hypogonadism, diabetes, hyperferritinaemia, increased transferrin saturation (by hypotransferrinaemia and hypohepcidinaemia secondary to hepatocellular insufficiency [49–51]) and hepatic iron overload (by hepatocytic uptake of NTBI). In these cases, it is often necessary to look for the underlying mutation to distinguish confidently between genetic haemochromatosis and iron overload secondary to cirrhosis.

Metabolic Syndrome

Hyperferritinaemia is present in almost half of patients with metabolic syndrome [52, 53]. It is related to subclinical inflammation and steatohepatitis associated with insulin resistance, but may indicate true excess of body iron, as part of what has been coined as the dysmetabolic iron overload syndrome (DIOS) [54]. DIOS denotes a combination of unexplained hepatic iron overload and one or more elements of the metabolic syndrome. Its diagnosis is based on (i) this association; (ii) the absence of any other identifiable cause of hepatic iron overload; and (iii) certain biochemical patterns of abnormality, including absence of increased transferrin saturation despite hyperferritinaemia up to 1500 ng/ml [55], a mixed pattern of hepatic iron deposits (i.e. in hepatocytes and macrophages) and a moderate increase of hepatic iron concentration, rarely exceeding 120 µmol/g (N <35). In half of such patients, steatosis, or steatohepatitis coexists, with severe fibrosis or cirrhosis in 15% of cases. This explains the fairly broad indications for liver biopsy in these individuals. Alteration of iron metabolism in DIOS likely results from a multifactorial and dynamic process driven by chronic positive energy balance, and featuring cross-talk between the liver and overloaded adipose tissue. Successful treatment of metabolic abnormalities to current targets is mandatory but is insufficient to normalize serum ferritin. Two recent controlled studies [56, 57], however, have failed to support phlebotomy as a useful option in DIOS patients. Sustained modification of diet and lifestyle thus remains the first therapeutic intervention, together with pharmacological control of blood pressure, blood glucose, and dyslipidaemia when necessary.

As shown in Figure 14.3.4.3, diagnosis of disorders of iron metabolism has benefited greatly from advances in molecular genetics and MRI. Nevertheless, it remains firmly rooted upon a strict clinical approach recognizing that acquired conditions are the rule and genetic causes the exception. Targeting hepcidin with drugs represents the most promising prospect for novel therapeutics in future.

14.3.5 The Porphyrias

Michael N. Badminton and Danja Schulenburg-Brand

Introduction

The porphyrias are metabolic diseases resulting from deficiency, or in one disease increased activity, of specific enzymes of haem biosynthesis [1]. Each of the eight types of porphyria is defined by association of characteristic clinical features with a specific pattern of overproduction of pathway intermediates which identifies the underlying enzymatic abnormality (Figure 14.3.5.1).

The porphyrias are subdivided clinically into those that are acute, characterized by acute neurovisceral attacks associated with the overproduction of the porphyrin precursor, 5-aminolaevulinic acid (ALA) and porphobilinogen (PBG), and those that are non-acute, in which attacks are absent and photocutaneous symptoms due to excess porphyrins are the main clinical manifestation. An

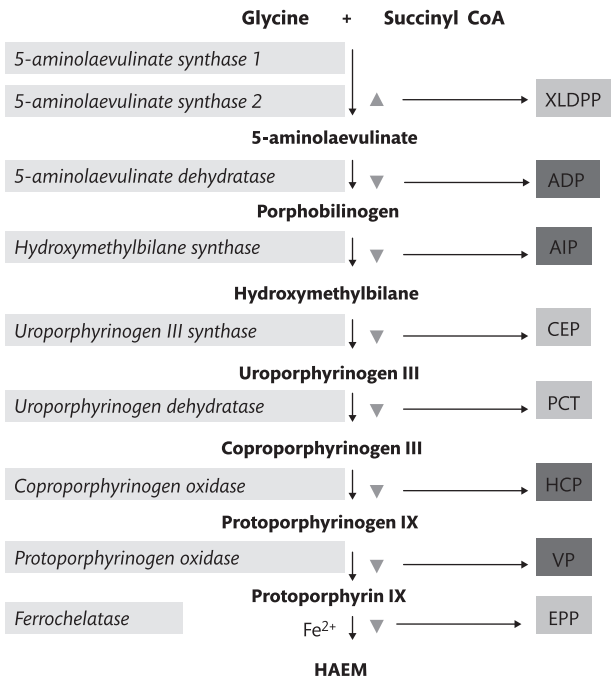

Figure 14.3.5.1 Haem biosynthesis pathway and enzyme abnormalities in the porphyrias. Enzymes (and genes) denoted in italics; ▲, increased enzyme activity; ▼, decreased enzyme activity. 5-Aminolaevulinate synthase 2 is expressed only in erythroid cells; inherited abnormal function of ubiquitous 5-aminolevulinate synthase 1, has not yet been identified in any disease. Dark box denotes acute porphyria. XLDPP, X-linked erythropoietic protoporphyria; AIP, acute intermittent porphyria; ADP, 5—aminolaevulinate dehydratase deficiency porphyria; CEP, congenital erythropoietic porphyria; PCT, porphyria cutanea tarda; HCP, hereditary coproporphyria; VP, variegate porphyria; EPP, erythropoietic protoporphyria.

alternative classification of erythropoietic or hepatic porphyria is based on the principal site of metabolite overproduction.

Acute Porphyrias–Autosomal Dominant

Clinically identical acute neurovisceral attacks occur in three AD porphyrias: acute intermittent porphyria (AIP; OMIM176000), hereditary coproporphyria (HCP; OMIM 121300), and variegate porphyria (VP; OMIM600923) [2]. Acute attacks can be life threatening if not recognized and appropriately treated. In most countries, AIP affects about 1 in 170 000 of the population, VP about 1 in 300 000, and HCP about 1 in 10^6. Acute neurovisceral attacks are the main clinical feature of AIP; photocutaneous symptoms do not occur. In VP, 40% of patients present with acute attacks, of whom half also have skin lesions, but 60% present with skin lesions alone. HCP presents with acute attacks that are accompanied by skin lesions in about 30% of patients; photocutaneous symptoms alone are rare and usually provoked by intercurrent liver disease. The skin lesions of VP and HCP are identical to those of bullous non-acute porphyrias.

Biochemical and Genetic Basis

The underlying defect in each of the AD acute porphyrias is a mutation leading to inactivation of one copy of the gene encoding the enzyme, and enzyme activities are thus half–normal in all tissues. Haem supply is maintained in the liver and other non-erythroid tissues by up-regulation of the rate controlling enzyme 5-aminolaevulinate synthase (ALAS1), with increases in substrate concentration of the affected enzyme. Compensatory change varies between tissues and between individuals with some showing no evidence of heme precursor overproduction while others have biochemically manifest disease with or without clinical symptoms.

Low clinical penetrance is a feature of AIP, HCP, and VP and many affected individuals remain asymptomatic throughout life. About 25% of patients with overt acute porphyria therefore have no family history. *De novo* mutations are uncommon. All three diseases show extensive allelic heterogeneity except in countries where founder effects occur. No clear genotype-phenotype correlation has been identified.

Pathogenesis of Acute Attacks

The symptomatology of acute attacks relates to dysfunction of autonomic, motor, and central nervous system neurons. The exact pathogenesis is not fully understood although ALA toxicity is currently the leading hypothesis [2].

Precipitating Factors

Factors implicated either individually or in combination include: hormonal fluctuations (particularly menstrual), certain prescribed and illicit drugs, excessive alcohol intake, calorie restriction, systemic illness, and stress. Attacks are more common in women, rare before puberty, and unusual after menopause. Attacks complicate less than 10% of pregnancies. A clear precipitant is not always identified [3].

Clinical Features

Pain is virtually always the initial symptom of an acute attack (95–100%). It is usually abdominal, but can affect the lower back, buttocks, and thighs [3]. It is frequently associated with nausea, vomiting, and constipation. Abdominal pain can mimic an acute abdomen, and may lead to inappropriate surgery. Diminishing pain in the absence of treatment can indicate worsening neuropathy. Hypertension and tachycardia due to autonomic dysfunction are common.

Hyponatraemia is common and can be severe, leading to seizures. Seizures may also be secondary to porphyric encephalopathy. Despite inappropriate urine sodium excretion patients are usually dehydrated and fluid restriction is not usually effective, implying renal sodium wasting rather than inappropriate antidiuretic hormone (ADH) secretion.

Symmetrical, distal motor neuropathy can occur, particularly where the attack is severe or treatment delayed. This can progress rapidly to complete motor paralysis mimicking Guillain–Barré syndrome. Other neurological signs include cranial nerve deficits and sensory changes in the same distribution as the motor neuropathy.

CNS involvement may cause confusion, anxiety, hallucinations, and paranoia. Chronic psychiatric illness is not a feature of acute porphyria.

Urine may appear 'port-wine red' due to the high content of porphyrin metabolites.

A small minority of patients, usually female, have repeated acute attacks. These may be premenstrual, occur as frequently as every month and are more likely in AIP and HCP than VP. Chronic complications include hypertension, impaired renal function, and hepatocellular carcinoma. Patients with active porphyria appear most at risk.

Laboratory Diagnosis

Measurement of urinary PBG excretion is the essential diagnostic investigation for an acute attack. Excretion of PBG and, to a lesser extent ALA is always increased during an attack, with PBG concentrations at least ten times the upper reference limit. PBG excretion decreases during remission, however, falling to normal over a period of years in AIP and a few weeks in HCP or VP. PBG excretion may be increased in adults with AIP who have never had symptoms. Although increased urinary PBG excretion makes it likely that symptoms are due to porphyria, the final diagnosis should be made on clinical grounds. Once the diagnosis of an attack of acute porphyria has been established, further investigation by analysis of plasma and faecal porphyrin identifies the type of porphyria (Table 14.3.5.1) [4]. If urine, plasma, and faecal porphyrins are normal, an acute attack is excluded as the cause of current or recent symptoms. Neither enzyme measurement nor mutational analysis are helpful for diagnosis of active porphyria in patients with suggestive symptoms [4].

Managing Acute Attacks

Unsafe drugs should immediately be withdrawn, and prompt treatment of possible precipitants with medication known to be safe begun [5]. Opiate analgesia is invariably needed and very large doses are usually required. Nausea and vomiting may be treated with an antiemetic (ondansetron, prochlorperazine) and convulsions with clonazepam, lorazepam, or magnesium sulphate. Hypertension and tachycardia should be treated with β-blockers. Intravenous fluids should include saline plus dextrose to provide calories without

Table 14.3.5.1 Inheritance and main clinical and diagnostic features of the porphyrias

Porphyria	Gene	Inheritance	Symptoms	Diagnosis
Acute intermittent porphyria	*HMBS*	autosomal dominant	acute attacks	urine PBG, ALA increased; normal faecal copro III[b]
Hereditary coproporphyria	*CPOX*	autosomal dominant	acute attacks and/or skin fragility, bullae	urine PBG, ALA increased[c]; faecal copro III increased[b]
Variegate porphyria	*PPOX*	autosomal dominant	skin fragility, bullae, and/or acute attacks	urine PBG, ALA increased[c]; plasma porphyrin peak at 624–628 nm; faecal proto increased
ALA dehydratase deficiency porphyria	*ALAD*	autosomal recessive	acute attacks	urine ALA and copro III increased; erythrocyte Zn-proto increased
Porphyria cutanea tarda	*UROD*	complex[a]	skin fragility, bullae	urine PBG, ALA normal with increased uro and hepta; faecal hepta, isocopro increased[b]
Congenital erythropoietic porphyria	*UROS*	autosomal recessive	skin fragility, bullae; haemolytic anaemia	urine PBG, ALA normal with increased uro I and copro I; faecal copro I increased; erythrocyte porphyrin increased[b]
Erythropoietic protoporphyria	*FECH*	autosomal recessive	acute painful photosensitivity	urine PBG, ALA, porphyrins normal; erythrocyte protoporphyrin increased; plasma porphyrin peak at 626–634 nm
X-linked erythropoietic protoporphyria	*ALAS2*	X-linked	acute painful photosensitivity	urine PBG, ALA, porphyrins normal; erythrocyte proto and Zn-proto increased; plasma porphyrin peak at 626–634 nm

[a] Acquired or, in about 20%, autosomal dominant; [b] plasma porphyrin peak at 615–622 nm may be present in AIP and HCP and is always present in PCT and CEP; [c] urine PBG may be normal in patients with skin lesions alone.

Copro, hepta, isocopro, proto, uro indicate coproporphyrin, heptacarboxylate porphyrin, isocoproporphyrin, protoporphyrin, uroporphyrin.

HMBS, hydroxymethylbilane synthase; CPOX, coproporphyrinogen oxidase; PPOX, protoporphyrinogen oxidase; ALAD, ALA dehydratase; UROD, uroporphyrinogen decarboxylase; UROS, uroporphyrinogen synthase; FECH, ferrochelatase; ALAS, ALA synthase

inducing hyponatraemia. Intravenous haematin is the recommended first line treatment [2, 4, 5], and is available as haem arginate (Normosang, Orphan Europe) in Europe. It is administered as a 30-minute infusion of 3 mg/kg daily on four consecutive days.

Recurrent acute attacks should prompt the seeking of advice from an expert porphyria centre [2, 5]. Options for treatment include suppression of ovulation using gonadorelin analogues [6] or regular administration of haematin. For the most severely affected patients where acute attacks become life threatening, venous access for ongoing treatment with haematin is inadequate and/or quality of life is severely reduced, liver transplantation may be considered [7]. Givosiran, a gene silencing therapy which targets hepatic ALAS1, was licensed for treating recurrent acute attacks by the US Food and Drug Administration Drugs (FDA) in November 2019 [8].

Preventing Acute Attacks

Patients should be advised about known precipitating factors and strategies to reduce the risk of acute attacks through patient information leaflets (e.g. available in 10 languages from the European Porphyria Network website, http://porphyria.eu/). Safe drug lists are available from several sources (e.g. the Welsh Medicines Information Centre; http://www.wmic.wales.nhs.uk). Patient support groups include the British Porphyria Association (http://www.porphyria.org.uk), and warning jewellery in case of emergencies should also be considered (e.g. MedicAlert). Finally, family members should be offered genetic testing so that presymptomatic relatives can also be advised on reducing the risk of acute attacks.

Acute Porphyrias—5-Aminolaevulinate Dehydratase Porphyria (ADP)

ADP (OMIM125270) is an exceedingly rare autosomal recessive porphyria that results from almost complete deficiency of 5-aminolaevulinate dehydratase (ALAD) activity with consequent overproduction of ALA. Only six cases have been reported [9]. Clinically it is indistinguishable from AIP and requires the same treatment. Diagnosis depends on demonstration of markedly increased urinary ALA excretion without an increase in PBG, increased erythrocyte zinc-protoporphyrin concentration, and very low erythrocyte ALAD activity.

Non-Acute Porphyrias

In the non-acute porphyrias, symptoms result from photosensitization of the skin by porphyrins activated by sunlight (UVA-visible range ~410 nm). The skin reacts to photo-damage in two different ways. First, accumulation of protoporphyrin in erythropoietic protoporphyria (EPP) and X-linked erythropoietic protoporphyria (XLEPP) causes acute painful photosensitivity. Second, accumulation of less hydrophobic porphyrins in porphyria cutanea tarda (PCT), congenital erythropoietic porphyria (CEP) VP and HCP, causes fragility of sun-exposed skin with erosions and subepidermal bullae. Painful photosensitivity is usually absent.

Porphyria Cutanea Tarda (PCT)

PCT is the most common type of porphyria with an annual incidence in the United Kingdom of between 2 and 5 per million.

Biochemical and Genetic Basis

The primary enzyme defect in PCT is decreased activity of liver uroporphyrinogen decarboxylase (UROD) leading to overproduction of uroporphyrin and other intermediate porphyrins. About 75% of patients have an acquired PCT (OMIM176090) usually associated with liver disease. The *UROD* gene is normal

and there is usually no family history of PCT. The remainder have familial PCT (OMIM176100) in which half–normal UROD activity is caused by mutations in the *UROD* gene, inherited in an autosomal dominant pattern with low penetrance. Further inactivation of UROD by the same process involved in sporadic PCT is required. Hepatic UROD is inactivated by an inhibitor produced by iron-dependent oxidation of uroporphyrinogen, the substrate of the UROD reaction [10].

Clinical Features

PCT occurs at all ages in both sexes with onset usually during the 5th–6th decades. Familial PCT tends to occur at younger ages. Patients have fragile sun-exposed skin. Minor trauma results in erosions as well as vesicle and bullae formation, particularly on backs of the hands, forearms, and face. Lesions are slow to heal, leaving atrophic scars, milia, and patchy depigmentation. Hyperpigmentation and melanosis may also develop and facial hypertrichosis is common. Alopecia may develop at sites of repeated trauma or bullae.

Skin lesions are often the first sign of underlying hepatocyte damage. Overt liver disease is uncommon, but minor alterations in biochemical liver function tests are common. The majority have hepatic iron overload with increased transferrin saturation and ferritin. Cirrhosis is present in <15% of patients, but confers high risk of hepatocellular carcinoma.

Associated Conditions

This combination of skin lesions and liver damage is strongly associated with excessive alcohol intake, oestrogen use, hepatitis C, or HIV infection, or mutations in the hemochromatosis (*HFE*) gene [11]. PCT may also occur in association with other disorders, notably chronic renal failure, systemic lupus erythematosus, and haematological malignancies.

Treatment

Avoidable risk factors such as alcohol or oestrogens should be identified, and underlying associated disorders sought and treated [12]. Exposure to light should be reduced by use of suitable clothing and reflectant sunscreens protecting against UVA/visible light. Either of two specific treatments produce clinical and biochemical remission in most patients in 6 to 12 months, and can be monitored by urinary total porphyrin measurement. The first is reduction of iron stores by phlebotomy (450 ml, 1 to 2 weekly) until borderline iron deficient is achieved (assessed by haemoglobin, plasma transferrin saturation, and ferritin measurement). This is preferred in patient with genetic haemochromatosis. The second option is low dose intermittent oral chloroquine (125 mg) or hydroxychloroquine (100 mg) taken twice weekly. Antimalarial doses can provoke a severe hepatotoxic reaction.

Congenital Erythropoietic Porphyria (CEP)

CEP or Gunther disease (OMIM236700) is an autosomal recessive severe bullous porphyria that normally presents in infancy [13, 14]. It affects <1:1 000 000 of the UK population.

Biochemical and Genetic Basis

Mutations in the uroporphyrinogen synthase (*UROS)* gene, or, rarely, the *GATA1* gene, decreases UROS activity resulting in massive overproduction of predominantly bone marrow uroporphyrin-I. Porphyrin-laden erythroid cells have a shortened life span leading to haemolytic anaemia, porphyrin release into plasma, and ineffective erythropoiesis. There is some correlation between genotype and severity of disease.

Clinical Features

Clinical severity varies from non-immune hydrops fetalis to a mild PCT-like syndrome in young adults, but the majority of patients present in infancy with red urine, skin lesions, and haemolytic anaemia. Skin lesions are similar to those of PCT but more persistent and severe. Progression to severe scarring with photo-mutilation is common. Haemolytic anaemia may worsen porphyrin overproduction and photosensitivity; splenomegaly is common. Porphyrin accumulates in the bones and is visible in the teeth as erythrodontia (brown pigmentation which fluoresces under ultraviolet light). Expansion of hyperactive bone marrow may result in pathological fractures, vertebral compression, or collapse, shortness of stature, and rarely osteolytic and sclerotic lesions in the skeleton.

Treatment

Protection against sunlight and prevention of skin infections are essential. In addition to reflectant sunscreen ointments, rigorous physical avoidance of sunlight is usually necessary. Haemolytic anaemia may require repeated transfusion and iron chelation to prevent iron overload, but splenectomy is rarely effective. Bone involvement may require bisphosphonate treatment and vitamin D supplementation. Allogeneic haematopoietic stem cell transplantation is curative, while gene therapy for those without donors or otherwise unsuitable for transplantation is under development.

Erythropoietic Protoporphyria (EPP)

EPP (OMIM 177000) is the more common of two porphyrias characterized by acute painful photosensitivity resulting from accumulation of protoporphyrin IX in the skin. The prevalence of EPP in Western Europe is one per 75 000 to 130 000.

Biochemical and Genetic Basis

Deficiency of ferrochelatase (FECH) activity leads to accumulation of protoporphyrin IX in skin, liver, and erythroid cells. In >90% of families, patients are compound heterozygotes for a *FECH* mutation that markedly decreases activity on one allele and a hypomorphic variant (*FECH* IVS3-48C) [15]. These reduce FECH activity below the threshold at which protoporphyrin accumulates. The population prevalence of EPP relates directly to the frequency of the hypomorphic allele which ranges from 45% in Japan to less than 1% in West Africa. The frequency in Europe is 7–11%, sufficiently high for some families to show pseudodominant inheritance. About 4% of EPP families have deleterious FECH mutations on both alleles.

Clinical Features

Symptoms normally start between birth and 6 years in both sexes, with median age of onset 1 year [16]. Exclusively photocutaneous symptoms occur in light-exposed areas such as the face and hands. Within 1 hour of sun exposure, stinging or painful burning sensations occur in skin, usually followed several hours later by erythema and oedema although in some there may be no objective signs of phototoxicity. Petechiae, purpura, vesicles, and crusting

may develop, and persist for several days. Recurrent episodes lead to chronic changes; typically, shallow linear scars over the nose and face with thickened waxy skin, especially over the knuckles. Symptoms tend to be more severe during spring and summer and may improve during pregnancy.

Protoporphyrin is hepatotoxic. About 20% of patients have abnormal biochemical liver function tests and 2% to 5% develop liver failure [17]. EPP may also increase the risk of cholelithiasis. Erythropoiesis is impaired in all patients with a lower haemoglobin concentration resulting in a mild microcytic anaemia. Fifty per cent (50%) of patients are vitamin D deficient and at risk of osteoporosis [18].

Treatment

Acute photosensitivity can be controlled by avoidance of sunlight, suitable clothing, and reflectant sunscreens. A subcutaneous implant, afamelanotide (α-melanocyte-stimulating hormone analogue) has recently been licensed. It increases the time during which patients are pain free in direct sunlight with improvement in quality of life reported [19]. Other options include production of a photoprotectant tan by narrowband ultraviolet B (UVB) phototherapy or oral β-carotene, which acts as a singlet oxygen quencher. Liver function and vitamin D status should be monitoring at least annually, and orthotopic liver transplantation is the only treatment for acute liver failure. Patients and families may request genetic counselling to assess the risk that offspring will be affected. Testing the unaffected partner for the presence of the hypomorphic *FECH* IVS3-48C allele is helpful.

X-Linked Erythropoietic Protoporphyria (XLEPP)

About 2% of protoporphyria families have XLEPP (OMIM 300752) [20]. Protoporphyrin accumulation is secondary to increased erythroid 5-aminolaevulinate synthase (ALAS2) activity caused by gain-of-function mutations in the *ALAS2* gene. This X-linked condition is expressed in males and most females and may carry a higher risk of severe liver disease than EPP.

Laboratory Diagnosis of Non-Acute Porphyrias

Skin biopsy is not required to diagnose cutaneous porphyria (Table 14.3.5.1). Active skin lesions are always accompanied by increased circulating plasma porphyrins. The first line test is therefore a plasma porphyrin screen, which if negative, excludes active cutaneous porphyria. Specialist porphyrin biochemistry can readily distinguish between the different non-acute porphyrias provided appropriate samples are analysed (Table 14.3.5.1). Mutational analysis of the *UROD* gene to distinguish familial from sporadic PCT is not necessary for clinical management. Identification of *UROS* mutations may help to assess prognosis in CEP.

Diabetes Mellitus

15.1

Introduction to Diabetes Mellitus

15.1.1 Physiology of Glucose Homeostasis

Shanta J. Persaud and Peter M. Jones

Islets of Langerhans

The pancreas possesses both exocrine and endocrine functions. The acinar cells of the exocrine pancreas produce digestive enzymes and account for over 97% of the pancreatic mass. The endocrine function is performed by the islets of Langerhans, which are spherical clusters of 1000–3000 cells scattered throughout the pancreas. A human pancreas contains up to 1 million individual islets, each approximately 0.2 mm in diameter and composed of three main cell types: insulin-producing beta-cells, glucagon-secreting alpha-cells, and somatostatin-producing delta-cells, which constitute ~60%, 35%, and 5%, respectively, of a typical human islet. The islets are penetrated by blood capillaries into which the hormones are secreted.

Insulin Biosynthesis and Storage

Human insulin consists of 51 amino acids that are arranged into two polypeptide chains. The A chain contains 21 amino acids and is linked to the 30 amino acid B chain by two disulphide bonds. The biosynthesis of insulin takes place in the beta-cell rough endoplasmic reticulum and occurs via two intermediate single chain polypeptides: preproinsulin, which is cleaved to generate proinsulin. Proinsulin contains the A and B chains of insulin linked by a connecting peptide (C-peptide) that ensures that the A and B chains are correctly orientated within the proinsulin molecule and that the disulphide bonds are aligned. Proinsulin is transported from the endoplasmic reticulum to the Golgi apparatus and packaged into secretory granules, where C-peptide is removed by enzymatic cleavage at specific amino acid residues. It is in these granules that the newly synthesized insulin forms insoluble crystalline hexamers by binding of insulin B-chain histidine residues to granule zinc ions (see **Figure 15.1.1.1**). C-peptide is also stored in the secretory granules, and it is released in equimolar amounts with insulin when the appropriate signal from the extracellular environment causes fusion of the granules with the beta-cell plasma membrane. C-peptide has been traditionally regarded as an inert molecule, useful only as an indicator of residual β-cell function in patients receiving insulin injections. However, it has been suggested that C-peptide exerts significant physiological effects such as increased glucose disposal, improved metabolic control and amelioration of diabetic nephropathy [1], which are thought to be mediated by activation of the G-protein-coupled receptor GPR146 [2].

The amino acid sequence of insulin is very similar among a range of mammalian species. Thus, porcine and human insulin differ by only one amino acid, and bovine insulin by three, which meant that insulin extracted from pig and cow pancreases was used to treat

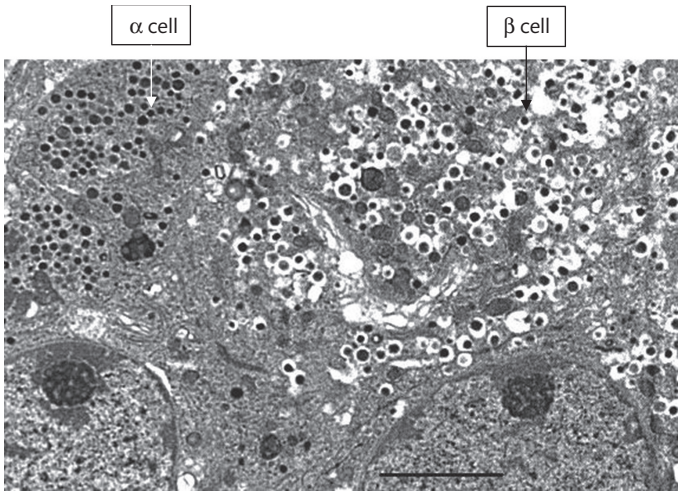

Figure 15.1.1.1 Islet ultrastructure. Transmission electron micrograph showing an islet beta-cell with typical dense core secretory granules and electrotranslucent halos. The secretory granules in the neighbouring alpha-cell have very dense cores and no halos. The scale bar is 2 μm.

diabetes until production of human insulin by recombinant DNA technology in the 1980s.

Nutrient-Induced Insulin Secretion

Glucose

Glucose is the major physiological regulator of insulin secretion in mammals. In humans beta-cells are adapted to secrete insulin only when circulating glucose concentrations are elevated above 4 mM so that glucose is tightly regulated in the range of ~4–7 mM [3]. The beta-cell responses are both very sensitive and rapid, usually within 30 seconds of the arrival of a glucose stimulus. Insulin is secreted by a process known as exocytosis, whereby the insulin-containing secretory granules fuse with the beta-cell plasma membrane, thus releasing the granule contents into the circulation. It occurs in a biphasic manner in response to glucose, with an initial spike of insulin release within 1–2 min, followed by a plateau phase that persists for as long as the stimulus is maintained. Islet beta-cells are well-equipped for immediate and sustained insulin release. Insulin is approximately 10% of the total beta-cell protein and there are in excess of 10 000 secretory granules in each beta-cell, sufficient for a 24-hour supply of insulin in the absence of any additional synthesis.

Glucose is taken up into beta-cells by glucose transporters (GLUTs), and the first stage in its metabolism is phosphorylation by a high specificity glucokinase. Subsequent metabolic events result in an increase in the cellular ATP/ADP ratio, which leads to closure of ATP-sensitive K^+-channels (K_{ATP}-channels) in the beta-cell plasma membrane (see Figure 15.1.1.2). The ensuing inhibition of K^+ efflux from the beta-cells results in changes in cellular electrical activity (depolarization) that leads to opening of specialized voltage-gated Ca^{2+} channels (VGCCs) that allow Ca^{2+} entry down a steep concentration gradient. The increase in beta-cell Ca^{2+} levels in response to glucose leads to activation of Ca^{2+}-sensitive proteins that are involved in the exocytotic fusion of insulin secretory granules. In addition, Ca^{2+}-dependent enzymes, such as the Ca^{2+}/calmodulin-dependent protein kinases (CaMKs), are activated when elevations in intracellular Ca^{2+} ($[Ca^{2+}]_i$) are detected by the Ca^{2+}-sensing protein calmodulin (CaM). This leads to the formation of Ca^{2+}/CaM complexes and activation of CaMKs to regulate Ca^{2+}-initiated cellular responses. CaMK II, in particular, is expressed by beta-cells and its activation has been implicated in glucose-induced insulin secretion [4].

The Ca^{2+}-sensitive enzyme phospholipase C (PLC) is also activated by glucose, resulting in hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP_2) to generate two second messenger molecules, diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP_3). DAG activates protein kinase C to phosphorylate proteins, including a subunit of the K_{ATP}-channel and VGCCs, both of which are important in beta-cell secretory responses to glucose. However, glucose-stimulated insulin release is not dependent on PKC activation, but DAG-sensitive PKC isoforms are required for potentiation of glucose-stimulated insulin secretion by some agonists such as the cholinergic neurotransmitter acetylcholine (ACh). The other second messenger produced by PLC-stimulated PIP_2 hydrolysis, IP_3, binds to specific receptors on the endoplasmic reticulum to stimulate release of stored Ca^{2+}.

Glucose also activates adenylate cyclase in beta-cells, most likely as a consequence of elevations in Ca^{2+}, to increase cyclic AMP generation from ATP. Cyclic AMP potentiates both phases of glucose-induced

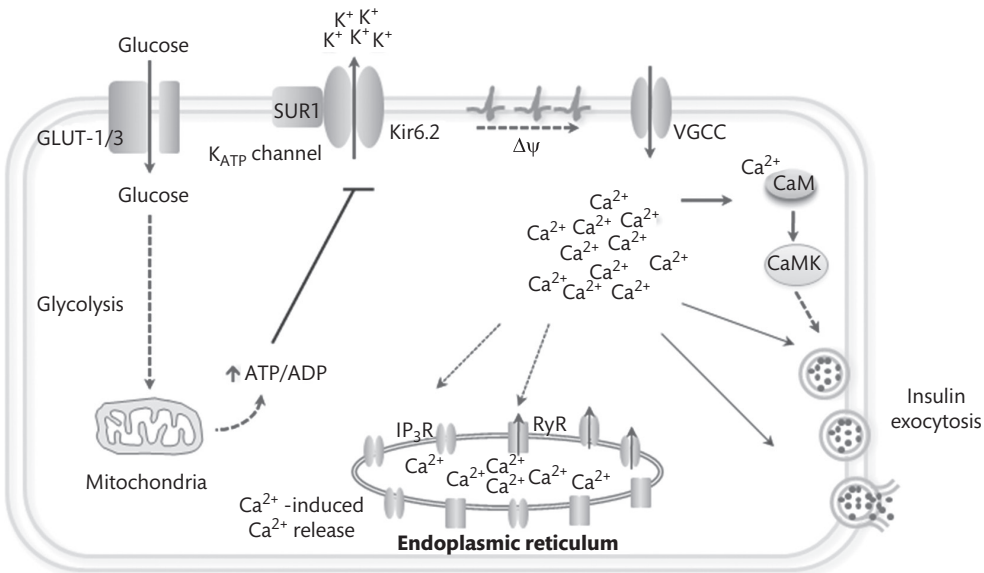

Figure 15.1.1.2 Islet beta-cell stimulus-secretion coupling pathways. Glucose is taken up by human beta-cells via GLUT-1 and GLUT-3 transporters and it is phosphorylated to glucose-6-phosphate by glucokinase. The end product of glycolysis, pyruvate, is transported to the mitochondria where ATP is produced upon pyruvate oxidation through the TCA cycle. The increase in ATP generation inhibits activity of K_{ATP}-channels, which consist of an ATP-sensitive sulphonylurea receptor (SUR1) and an inward rectifier K^+ channel (Kir6.2). ATP-induced closure of K_{ATP}-channels results in decreased K^+ efflux, beta-cell depolarization, and the opening of voltage-gated Ca^{2+} channels (VGCCs). Influx of Ca^{2+} through the VGCCs leads to a rapid increase in $[Ca^{2+}]_i$ which is further enhanced by Ca^{2+}-induced Ca^{2+} release through the opening of inositol 1,4,5-trisphosphate receptors (IP_3Rs) and ryanodine receptors (RyRs) on the endoplasmic reticulum. Cytosolic Ca^{2+} activates Ca^{2+}-sensing kinases (such as CaMKs) and Ca^{2+}-sensitive proteins of the exocytotic machinery, which facilitate release of insulin from secretory granules.

insulin secretion, exerting its effects via protein kinase (PKA) and cyclic AMP-activated GTP-exchange factors (Epacs). Once activated by cyclic AMP, PKA phosphorylates beta-cell proteins, including VGCCs and IP_3 receptors, on serine and threonine residues, which causes sustained increases in $[Ca^{2+}]_i$ during glucose-induced insulin secretion. Cyclic AMP activation of Epacs can inhibit beta-cell K_{ATP}-channels, resulting in decreased K^+ efflux, increased $[Ca^{2+}]_i$ and insulin secretion. One of the Epac proteins (Epac2) associates with two other proteins, Rim and Piccolo, which allow the docking and fusion steps of insulin exocytosis. Agonists that selectively activate Epac2 have been developed, and they are able to potentiate glucose-induced insulin secretion from human islets [5], confirming the importance of this cyclic AMP-activated signalling cascade in physiological human beta-cell function.

The precise mechanisms responsible for the first and second phases of glucose-stimulated insulin secretion have not been fully identified. However, it is thought that the first phase involves fusion of 'primed' insulin secretory granules that are present in a readily releasable pool close to the plasma membrane site of Ca^{2+} influx [6]. In contrast, the second phase of insulin release is a more sustained process that occurs from the reserve granule pool and depends on granule maturation and translocation along directed pathways involving microtubule and actin filaments.

Amino Acids

Most amino acids only stimulate insulin secretion in the presence of stimulatory concentrations of glucose, but leucine, lysine, and arginine act as insulin secretagogues in the absence of glucose. Leucine is transported into beta-cells by a sodium-independent transporter and stimulates biphasic insulin release, similar to that induced by glucose. Its metabolism leads to closure of K_{ATP}-channels with the consequent series of events that triggers insulin secretion in response to glucose, as described for glucose. Lysine and arginine are charged amino acids that enter β-cells via a cationic amino acid transporter and stimulate Ca^{2+} influx via VGCCs following membrane depolarization. Alanine, a neutral amino acid, has weak stimulatory effects on insulin secretion. It enters β-cells mainly through a sodium-dependent transport system, to elicit a small depolarization of the β-cell plasma membrane and elevation in $[Ca^{2+}]_i$.

Fatty Acids

Dietary free fatty acids (FFAs) stimulate insulin secretion in the absence of glucose and also potentiate the stimulatory effect of glucose on insulin release. A family of cell surface G-protein coupled FFAR receptors are known to be important in mediating FFA effects in β-cells. In particular, FFAR2 has been implicated in the secretagogue effects of the short chain fatty acid propionate in humans [7] while agonists that target the long chain fatty acid receptor FFAR1 are candidates for novel therapies for type 2 diabetes [8].

Regulation of Insulin Secretion by Non-Nutrient Secretagogues

Parasympathetic and Sympathetic Innervation

Parasympathetic stimulation leads to the release of acetylcholine (ACh) from cholinergic nerve terminals found close to all islet cell types, both at the periphery and deep within the islet. ACh binds to and activates cholinergic muscarinic receptors on β-cells, leading to potentiation of glucose-stimulated insulin release. This occurs via activation of PLC, which generates IP_3 and DAG, and PKC activation by DAG is important in a sustained potentiation of insulin release by cholinergic agonists. The main function of islet cholinergic innervations is potentiation of insulin secretion in response to the cephalic phase of food intake, which is triggered by the sight, smell, or taste of food.

Sympathetic neural activity has a direct effect through the release of the neurotransmitter noradrenaline (NA) from nerve terminals within islets. NA inhibits glucose-induced insulin secretion by activating α_2-adrenergic receptors, which are coupled to inhibition of adenylate cyclase activity resulting in reductions in cyclic AMP levels. NA also promotes activation of beta-cell K_{ATP}-channels and inhibition of VGCCs, resulting in decreased $[Ca^{2+}]_i$ that contributes to the reduction in insulin secretion. The related catecholamine, adrenaline, which is secreted from the adrenal medulla under conditions of stress, also inhibits insulin secretion and this contributes to the increased availability of glucose as an energy source for 'fight or flight' activities.

Islet Hormones

Hormones released from neighbouring alpha- or delta-cells, or from the beta-cells themselves, can bind to specific receptors on beta-cells to modify beta-cell function in a paracrine or autocrine fashion.

Glucagon is synthesized in islet alpha-cells as a precursor peptide, proglucagon, which is enzymatically cleaved to functional glucagon. Like insulin, glucagon is packaged into secretory granules within alpha-cells, and its secretion is regulated by changes in circulating glucose concentrations. However, while increased blood glucose stimulates exocytotic release of insulin, it inhibits glucagon secretion. The most important stimuli for glucagon release are hypoglycaemia and sympathetic nervous input, and when it is released from alpha-cells glucagon stimulates glycogenolysis and gluconeogenesis, thus restoring blood glucose levels. It also acts locally at neighbouring β-cells to stimulate insulin secretion via Gs-coupled receptors, which activate adenylate cyclase to increase cyclic AMP and PKA activation.

Somatostatin (SST) is synthesized and secreted by islet delta-cells in response to elevations in blood glucose levels. It binds to G-protein-coupled SST receptors on β-cells to act as a local inhibitor of insulin release via Gi-coupled inhibition of adenylate cyclase. SST also hyperpolarizes beta-cells through the opening of K_{ATP}-channels, which decreases $[Ca^{2+}]_i$ and contributes to its inhibitory effects. As well as being released from islets, SST is also secreted from gastrointestinal cells after food intake, but the circulating levels are insufficient to significantly affect insulin secretion. Thus, SST appears to inhibit insulin release mainly by a paracrine rather than a circulatory route.

Insulin receptors and downstream signalling elements are expressed by human islet beta-cells, suggesting that when insulin is released it may interact with these receptors to modify beta-cell function in an autocrine or paracrine manner [9]. There have been reports of insulin exerting positive or negative feedback on further insulin output from beta-cells, but the general consensus is that insulin does not regulate its own secretion. The most likely role for

insulin on β-cells is the regulation of gene expression and maintenance of beta-cell mass through stimulation of proliferation and/or inhibition of apoptosis.

Incretins

It has been known for over 50 years that islets are more responsive to oral rather than intravenous administration of glucose [10]—the incretin effect. This is due to the release of the gastrointestinal peptides GLP-1 and glucose-dependent insulinotropic peptide (GIP), which enhance the insulin secretory response to glucose by up to 60%. In the fasting state plasma levels of GIP and GLP-1 are low and they are released from specialized gut endocrine cells into the bloodstream after food intake.

GLP-1 is a 30 amino acid peptide that is synthesized by alternative splicing of proglucagon in L-cells of the ileum and colon and released in response to nutrient absorption in the gastrointestinal tract [11]. The major biologically active form of GLP-1 is GLP-1 (7–36) amide, which is the predominant form in plasma. GLP-1 binds to its Gs-coupled receptors on islet beta-cells to stimulate insulin release through elevations in intracellular cyclic AMP. In addition, GLP-1 also regulates glucose homeostasis through effects at α-cells to inhibit glucagon secretion and it reduces food intake by direct anorexigenic central effects. In addition, it is reported to stimulate beta-cell mass in rodents, but similar beneficial effects have not yet been identified in humans.

These properties have made GLP-1 an attractive therapy for type 2 diabetes, but its actions *in vivo* are rapidly curtailed through its degradation by dipeptidyl protease 4 (DPP-4), resulting in a half-life in plasma of only approximately two minutes. Pharmaceutical agents that improve the longevity of GLP-1 action through modification of its sequence have therefore been developed and are now in clinical use, as are therapies that inhibit DPP4-mediated GLP-1 degradation.

GIP, originally known as gastric inhibitory polypeptide due to its inhibitory effects on gastric acid secretion, is a 42-amino acid peptide that is synthesized from a precursor peptide (proGIP) in K-cells of the duodenum and jejunum. Circulating levels of GIP increase in response to nutrient absorption and it is carried in the circulation to islets where it potentiates glucose-induced insulin secretion through action at beta-cell GIP receptors to elevate cyclic AMP. As for GLP-1, the activity of GIP is terminated by DPP-4-mediated degradation. In contrast to GLP-1, however, GIP is unlikely to be developed as an antidiabetes agent because in type 2 diabetes GIP levels are normal, but it has a reduced effect to stimulate insulin secretion. In addition, GIP does not have the additional beneficial effects of GLP-1 such as inhibition of glucagon secretion. Nonetheless, DPP-4 inhibitor therapies that have been developed to increase the half-life of GLP-1 will also maintain plasma GIP levels.

Regulation of Plasma Glucose Levels

Insulin stimulates storage of fuels in adipose tissue, liver, and skeletal muscle, thus providing readily available depots of glycogen and fat for energy requirements during periods where there is no food intake. Thus, in healthy individuals blood glucose levels are maintained in the range of 3–4 mM under fasting conditions and 6–7 mM postprandially. Following food intake the elevation in blood glucose levels leads to increased glucose transport into beta-cells with a resulting increase in insulin output, as indicated in Figure 15.1.1.2. Insulin is transported in the blood to target tissues where it binds to cell surface insulin receptors. Skeletal muscle, one of the major sites for glucose storage in the form of glycogen, is responsible for up to 75% of glucose uptake, and insulin stimulates this by promoting translocation of GLUT4 glucose transporters to the myocyte cell surface. In addition, insulin also stimulates glucose uptake via GLUT4 in adipocytes, while glucose transport into hepatocytes is mediated by insulin-independent GLUT2 transporters. Insulin exerts its effects by binding to a heterotetrameric receptor complex that consists of two extracellular α subunits and two transmembrane beta-subunits. When insulin binds to the alpha-subunits it causes a conformational change that results in activation of the beta-subunit tyrosine kinase domain and receptor autophosphorylation. This fully activates the insulin receptor tyrosine kinase, which then phosphorylates intracellular substrates on multiple tyrosine residues [12].

The main proteins responsible for signalling downstream of insulin binding to its receptors are the insulin receptor substrate (IRS) family members, IRS-1 and IRS-2, which act as adapter proteins following insulin-induced tyrosine phosphorylation. Global deletion of IRS-1 in mice indicated its importance in intrauterine and postnatal growth, but insulin metabolic signalling was only impaired rather than abolished, and this led to the discovery of IRS-2. IRS-2 deletion in mice results in type 2 diabetes because it plays important roles in maintenance of β-cell mass as well transducing insulin action in peripheral tissues [13].

The pathways downstream of IRS phosphorylation are now reasonably well understood [12]. Thus, effectors containing src homology (SH2) domains bind to phosphotyrosine residues on IRS and are recruited into insulin receptor/IRS signalling complexes. Following its interaction with phosphorylated IRS the 85 kDa regulatory subunit of class I phosphatidylinositol 3 kinases (PI3K) binds to and activates the 110kDa PI3K catalytic subunit leading to phosphorylation of phosphatidylinositols on position 3 of the inositol ring. The resulting generation of phosphatidylinositol-3,4,5-trisphosphate (PI-3,4,5-P_3) recruits phosphoinositide-dependent kinases (PDKs) and protein kinase B (PKB, also known as Akt) to the plasma membrane site of PI-3,4,5-P_3 synthesis via their Pleckstrin homology domains. PDKs phosphorylate and activate PKB, which then phosphorylates substrates on serine and/or threonine residues to bring about the metabolic effects of insulin. In this way, GLUT4 transporters are translocated to the plasma membrane of adipocytes and myocytes, glycogen and fatty acid synthesis are stimulated, and gluconeogenesis and fatty acid oxidation are inhibited. The growth-promoting effects of insulin are largely mediated by mitogen-activated protein kinases (MAPKs), which, like PI3K, are downstream of IRS tyrosine phosphorylation. In this pathway phosphorylated IRS proteins bind to the SH2 domain of growth factor receptor binding protein 2 (Grb2), which forms a complex with son-of-sevenless to promote GTP binding to Ras and activation of the MAPK cascade. When MAPK is phosphorylated on tyrosine and threonine residues it translocates into the nucleus and phosphorylates transcription factors that stimulate cell proliferation.

The anabolic actions of insulin are counteracted by glucagon, which is released from islet alpha-cells when blood glucose levels fall. Glucagon acts at specific G-protein-coupled receptors on

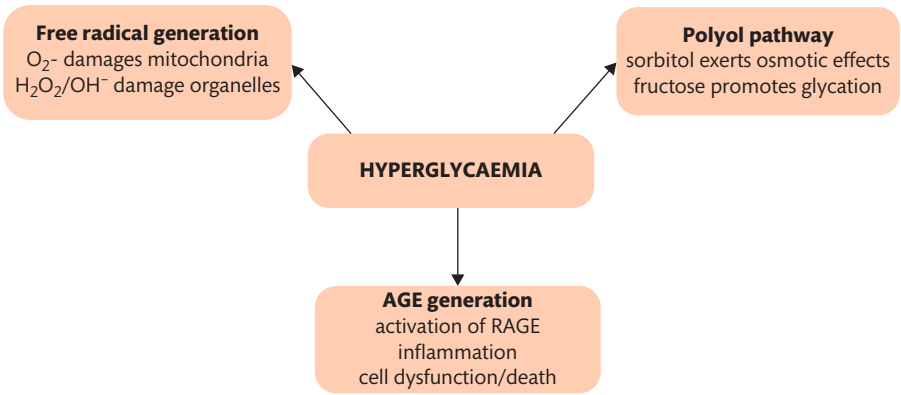

Figure 15.1.1.3 Consequences of chronic hyperglycaemia. In untreated or poorly controlled diabetes glucose levels are high in tissues that do not require insulin for glucose uptake. Deleterious effects arise in these tissues through enhanced free radical generation, overactivation of the polyol pathway, and increased production of advanced glycation end-products, all of which contribute to cell dysfunction and death.

hepatocytes to stimulate gluconeogenesis and glycogenolysis, to restore glycaemia. The glucagon receptors are coupled to adenylate cyclase via Gs, resulting in increased cyclic AMP generation, PKA activation, and phosphorylation of effectors such as phosphorylase kinase, which promotes glycogen breakdown. Thus, under normal conditions the relative contributions of insulin in the absorptive state (after food intake) and glucagon in the post-absorptive state (when the gastrointestinal tract is empty) ensure that blood glucose levels are tightly regulated.

Consequences of Chronic Hyperglycaemia in Diabetes

The importance of maintaining good blood glucose regulation to prevent or slow the onset of diabetic complications was defined in two landmark studies: the Diabetes Control and Complications Trial for type 1 diabetes [14], and the UK Prospective Diabetes Study for type 2 diabetes [15]. It is clear that prolonged exposure to elevated glucose concentrations damages tissues through metabolic changes that are mostly related to increased reactive oxygen species (ROS) generation, enhanced polyol pathway activity, and protein glycation, as summarized in Figure 15.1.1.3.

Hyperglycaemia in untreated or poorly controlled diabetes raises intracellular glucose levels in tissues such as neurons, renal glomerulus, lens, and retina that do not require insulin for glucose uptake. It increases cellular mitochondrial oxidative phosphorylation, resulting in enhanced production of superoxide ($O_2^{\cdot-}$) radicals through incomplete reduction of molecular oxygen. These charged $O_2^{\cdot-}$ radicals are the major ROS generated in mitochondria. Mitochondrial superoxide dismutase converts $O_2^{\cdot-}$ to hydrogen peroxide, another ROS, which is normally removed by catalase. However, when glucose levels are high radical production exceeds detoxification by cellular antioxidants. Hydrogen peroxide generates highly reactive hydroxyl radicals that damage organelles and the intramitochondrial accumulation of $O_2^{\cdot-}$ is associated with damage to mitochondrial membranes and DNA.

Elevated blood glucose levels are also associated with increased reduction of glucose to sorbitol by aldose reductase, the rate-limiting enzyme of the polyol pathway. Sorbitol does not readily cross cell membranes so it accumulates intracellularly, and elevated sorbitol levels correlate with the onset of diabetic complications. It causes damage through its osmotic effects, by depleting levels of intracellular myoinositol, a precursor of the membrane phospholipid phosphatidylinositol and by altering the redox state of pyridine nucleotides. Epalrestat, an aldose reductase inhibitor, has been shown to delay progression of diabetic neuropathy [16], most likely as a consequence of reductions in production of both sorbitol and fructose, the product of sorbitol oxidation, which exerts deleterious effects by promoting glycation.

Glycation is the non-enzymatic attachment of monosaccharides (glucose or fructose) to intracellular proteins, lipids, and nucleic acids and chronic hyperglycaemia causes gradual, cumulative, and irreversible changes in these long-lived molecules. Early glycation products combine to form complex cross-linked structures termed advanced glycation end-products (AGE) and impaired renal function in diabetes leads to their accumulation. They bind to a cell surface receptor known as RAGE, whose activation leads to signal transduction cascades that generate more ROS, increase pro-inflammatory cytokines, and culminate in cell dysfunction and apoptosis. RAGE activation induces permanent changes, which may explain why restoration of normoglycaemia does not always reverse tissue damage inflicted by previous exposure to hyperglycaemia. However, reduction in glycation with the use of AGE cross-link breakers such as alagebrium may be clinically useful to prevent hyperglycaemia-induced progression to microvascular complications [17].

15.1.2 Classification and Diagnosis of Diabetes Mellitus

Stephen Colagiuri and Crystal Man Ying Lee

Introduction

Diabetes is a major contributor to the global disease burden. The first International Diabetes Federation (IDF) global estimate in 2000 reported that 151 million people aged 20–79 years had diabetes [1]. Since then the numbers have increased substantially with the latest estimate that 425 million people had diabetes in 2017 [2]. Independently, the NCD Risk Factor Collaboration (NCD-RisC) estimated that 422 million people aged ≥18 years had diabetes in 2014 [3]. Accurate estimations of diabetes prevalence rely on sources and quality of data, modelling assumptions, and methods and criteria used to diagnose diabetes. The IDF selects data based on method of diagnosis, sample size, representation of the sample, age of data source, and type of publication [4]. NCD-RisC included data that measured at least one glycaemic biomarker and adjusted for differences in diabetes prevalence between these biomarkers [3, 5]. Despite different methodologies, the two groups generated similar estimations.

There have been several modifications to diagnostic criteria and classification of diabetes since the first World Health Organization (WHO) report was published over half a century ago [6]. These changes impact comparability of epidemiological data over time, medical care, and non-health related issues associated with labelling of a person as having diabetes.

Diagnostic Criteria for Diabetes

A diagnosis of diabetes can be made when an individual has classic symptoms of diabetes and a clearly elevated plasma glucose. However, many people with diabetes are asymptomatic for many years and blood tests are required for diagnosis. The WHO and American Diabetes Association (ADA) use the same diagnostic criteria for diabetes based on fasting plasma glucose (FPG) ≥7.0 mmol/L (126 mg/dl), 2-hour post-load plasma glucose during an oral glucose tolerance test (2hPG) ≥11.1 mmol/L (200 mg/dl), and glycated haemoglobin (HbA1c) ≥6.5% (48 mmol/mol) [7–9] (Table 15.1.2.1). Repeat testing in asymptomatic individuals is recommended to confirm the diagnosis.

Diagnostic Criteria for Intermediate Hyperglycaemia

Intermediate hyperglycaemia (IH) denotes an elevated blood glucose but lower than levels considered diagnostic of diabetes and is associated with increased risk of developing diabetes and cardiovascular disease. Criteria for IH differ between the WHO and ADA. WHO separates IH into impaired glucose tolerance (IGT) and impaired fasting glucose (IFG) based on FPG and 2hPG levels [7–8] (Table 15.1.2.1). The ADA refers to IH as 'prediabetes', a debated term as the progression to diabetes is variable with a recent report suggesting that two out of three individuals with IFG never develop diabetes [10]. The ADA FPG cut-point is lower than that recommended by WHO and the ADA uses HbA1c as a criterion for prediabetes [9] (Table 15.1.2.1). The ADA criterion of 5.7–6.4% (39–47 mmol/mol) has been questioned as identifying too many people with prediabetes with one large study reporting 35% with

Table 15.1.2.1 Current World Health Organization and American Diabetes Association diagnostic criteria for diabetes and intermediate hyperglycaemia

	Diabetes (WHO)	Intermediate hyperglycaemia (WHO)		Diabetes (ADA)	Prediabetes (ADA)
		Impaired glucose tolerance	Impaired fasting glucose		
Fasting plasma glucose	≥7.0 mmol/L (126 mg/dl)	<7.0 mmol/L (126 mg/dl)	6.1–6.9 mmol/L (110–125 mg/dl)	≥7.0 mmol/L (126 mg/dl)	5.6–6.9 mmol/L (100–125 mg/dl)
	AND/OR	AND	AND	OR	OR
2 hour plasma glucose during a 75 g OGTT	≥11.1 mmol/L (200 mg/dl)	7.8–11.0 mmol/L (140–199 mg/dl)	<7.8 mmol/L (140 mg/dl) (if measured)	≥11.1 mmol/L (200 mg/dl)	7.8–11.0 mmol/L (140–199 mg/dl)
	AND/OR			OR	OR
Glycated haemoglobin	≥6.5% (48 mmol/mol)			≥6.5% (48 mmol/mol)	5.7–6.4% (39–47 mmol/mol)
Random plasma glucose	≥11.1 mmol/L (200 mg/dl) in the presence of diabetes symptoms			≥11.1 mmol/L (200 mg/dl) in the presence of diabetes symptoms	

OGTT, oral glucose tolerance test.

prediabetes based on HbA1c compared with 8% based on 2h PG [11]. WHO is currently considering the use of HbA1c to identify IH but has yet to issue a statement about its use or level.

Major Changes in Diagnostic Criteria Over Time

The WHO initially recommended a single diagnostic criterion for diabetes (2hPG ≥7.2 mmol/L [130 mg/dl]) and referred to 2hPG 6.1–7.1 mmol/L (110–128 mg/dl) as a borderline state [6]. The current 2hPG cut-offs of ≥11.1 mmol/L (200 mg/dl) for diabetes and 7.8–11.0 mmol/L (140–199 mg/dl) for IGT were introduced in 1985 [12]. Glucose doses of 50 g and 100 g were used in the oral glucose tolerance test in the early years but was standardized to 75 g in 1980 [13]. FPG was included in the WHO diagnostic criteria in 1980 [13]. The FPG diagnostic level for diabetes was initially ≥8.0 mmol/L (145 mg/dl) but was revised to ≥7.8 mmol/L (140 mg/dl) in 1985 and further revised down to ≥7.0 mmol/L (126 mg/dl) by the ADA in 1997 and WHO in 1999 [11–14]. IFG was introduced to define FPG levels equivalent to IGT in 1997 by the ADA [14] and in 1999 by WHO [15]. In 2003, the ADA lowered the FPG cut-point for IFG from 6.1 mmol/L (110 mg/dl) to 5.6 mmol/L (100 mg/dl). However, the WHO decided in 2006 to continue with a FPG of 6.1 mmol/L (110 mg/dl) [7]; hence the difference in FPG criterion for IH between these two groups.

HbA1c measurement has a number of potential advantages compared with FPG and 2hPG testing. Although HbA1c had been used to monitor diabetes control for decades, there was concern about considering it as a diagnostic criterion for diabetes until international standardization of the HbA1c assay improved. In 2009, an international expert committee recommended the use of HbA1c for the diagnosis of diabetes [16]. The ADA adopted HbA1c for the diagnosis of diabetes in 2010 [17] and WHO in 2011 [8].

Methods for Determining Diagnostic Cut-Points

A 1971 Pima Indian study reported that the distribution of 2hPG was represented by two overlapping curves [18]. Later studies in populations with high prevalence of diabetes reported a similar bimodal glucose distribution [19, 20]. This bimodal distribution was assumed to comprise two distinct but overlapping groups (normal glucose versus abnormal glucose) and the point where the two curves intersect was used to define the 2hPG cut-point to diagnose diabetes. However, the DETECT-2 Collaboration showed that cut-points derived from bimodal distribution varied considerably between countries and that not all populations demonstrated a bimodal distribution [21]. Moreover, cut-points obtained from this method may not align with those derived from increased risk of diabetes complications.

The 1997 decision of the ADA to lower the diabetes diagnostic cut-point for FPG to the current level was based largely on three studies on the relationship between diabetic retinopathy and FPG, 2hPG, and HbA1c [14]. The prevalence of retinopathy was examined by deciles (ten equally sized groups) of the distribution for each glycaemic measure. The distribution graphs showed that the prevalence of retinopathy was initially low and then increased substantially from the eighth decile (FPG 7.2 mmol/L [130 mg/dl]; 2hPG 12.1 mmol/L [218 mg/dl]; HbA1c 6.9% [52 mmol/mol]) in the Egyptian population, ninth decile (FPG 7.5 mmol/L [135 mg/dl]; 2hPG 13.5 mmol/L [243 mg/dl]; HbA1c 6.7% [50 mmol/mol]) in the Pima Indian population, and tenth decile (FPG 6.7 mmol/L [121 mg/dl]; 2hPG 10.8 mmol/L [195 mg/dl]; HbA1c 6.2% [44 mmol/mol]) in the US population. By consensus, the new FPG cut-point was established and the 2hPG cut-point was not changed. Using data from 45 000 participants, the DETECT-2 Collaboration studied the relationship by vigintiles (20 equally sized groups) and by 0.5 unit intervals of glycaemic measures and was able to focus on moderate to severe retinopathy cases which are specific to diabetes [22]. The various analyses performed in this study indicated that an HbA1c of 6.5% (48 mmol/mol) was a suitable alternative diagnostic criterion for diabetes and has now been universally adopted [8, 16, 17].

Effect of the Different Diagnostic Criteria on Prevalence

The diagnostic cut-points of the three glycaemic measures are individually derived and relate to their association with diabetic retinopathy rather than attempting to identify the same individuals with

hyperglycaemia by each of these measures. Therefore, the diagnostic result of one test may not correspond to that of another test. Data from the 16 000 participants without known diabetes in the DETECT-2 Collaboration who had all three glycaemic measures showed that the proportion with newly diagnosed diabetes varied between the three measures (7.7% for FPG, 13.9% for 2hPG, and 5.7% for HbA1c) [22]. More recently, the NCD-RisC reported 2–6% higher diabetes prevalence based on FPG or 2hPG than that based solely on FPG [5]. More importantly, the results suggested 47% of participants with newly diagnosed diabetes based on the FPG would not have had diabetes based on the HbA1c measurement. This incongruence remains a concern both for population estimates of diabetes but more importantly for the diagnosis of diabetes in an individual and will need to be addressed in future deliberations on diagnostic criteria for diabetes.

Classification of Diabetes

Diabetes is a heterogenous group of diseases which share the common feature of hyperglycaemia. Different types of diabetes are recognized based on natural history, aetiology, pathophysiology, risk of developing complications, and treatment. Classification systems serve several purposes including informing clinical care decisions and individualizing treatment, describing aetiopathology, and for epidemiological studies. While types of diabetes should be defined by categorical features specific and exclusive to that type of diabetes [3 New WHO report], our current state of knowledge does not allow a single classification system to address all these objectives for the majority of people with diabetes.

The first WHO report in 1965 recommended classification of diabetes by age of diabetes onset but also recognized other clinical types, including juvenile-onset diabetes, brittle diabetes, insulin resistant diabetes, gestational diabetes, pancreatic diabetes, endocrine diabetes, and iatrogenic diabetes [6]. The 1979 National Diabetes Data Group [23] and the 1980 WHO [13] classification described four classes of diabetes namely insulin dependent diabetes mellitus, non-insulin dependent diabetes mellitus, gestational diabetes, and another type of diabetes with six subtypes (pancreatic, hormonal, drug or chemical-induced, insulin-receptor abnormalities, genetic syndromes, and others). Malnutrition-related diabetes mellitus was added as a fifth class in the 1985 WHO report [12].

The most recent WHO classification was published in 1999 and returned to four basic types—type 1 diabetes, type 2 diabetes, other specific types, and gestational diabetes [15] (**Box 15.1.2.1**). The subtypes for other specific types included genetic defects of β-cell function which included maturity onset diabetes of the young (MODY), genetic defects in insulin action, diseases of the exocrine pancreas, endocrinopathies, drug- or chemical-induced diabetes, infections, uncommon forms of immune-mediated diabetes, and other genetic syndromes sometimes associated with diabetes [15]. In addition, the classification acknowledged different stages in the natural history of diabetes—normoglycaemia, intermediate hyperglycaemia, diabetes not requiring insulin, diabetes requiring insulin for control, and diabetes requiring insulin for survival [15].

Few studies have reported population prevalence by diabetes types. The 2016 US National Health Interview Survey classified diabetes types based on self-report and insulin use and estimated that of all diagnosed cases, 5.8% were type 1 diabetes, 90.9% were type 2 diabetes and the remaining 3.3% were other types of diabetes [24]. A Swedish study of 13 720 adults reported 1.5% with type 1 diabetes, 88.3% with type 2 diabetes, 5.3% with latent autoimmune diabetes of adults (LADA), 1.2% with diabetes secondary to pancreatic disease, and 3.8% as unclassifiable [25]. A Norwegian study in antibody-negative children with diabetes aged under 15 years showed up to 6.5% had MODY, one in three of whom had not been previously recognized [26].

Type 1 and type 2 diabetes are becoming increasingly difficult to distinguish due to obesity in the young and the occurrence of type 2 diabetes in young people [27]. This and the increasing recognition of intermediate forms of diabetes such as LADA and ketosis-prone type 2 diabetes, a syndrome of episodic diabetic ketoacidosis without immunologic markers characterized by variable insulin dependence [28], have led to calls to review the classification system for diabetes to better assist clinicians and reflect advances in knowledge of pathophysiological pathways [29, 30]. One proposal suggested classification centred on the abnormal β-cell function common to all forms of diabetes and 11 distinct pathways contributing to β-cell stress, dysfunction, or loss [31].

A recent study reported five distinct subtypes of type 2 diabetes based on a cluster analysis of six variables (glutamate decarboxylase antibodies, age at diagnosis, BMI, HbA1c, and homoeostatic model assessment of β-cell function and insulin resistance) which compared time to medication, time to reach treatment goal, risk of diabetic complications and genetic associations [25]. Whether this clustering is applicable to other populations and ethnicities remains to be demonstrated. In addition, adopting such a system in most parts of the world would be challenging due to lack of the necessary laboratory tests. Therefore, it seems that for the immediate future, classification systems will rely on phenotypic characteristics, clinical judgement, and careful monitoring of clinical course and responses to treatment. This is especially important in those individuals in whom diabetes type is difficult to assign at presentation.

Box 15.1.2.1 Aetiological classification of diabetes

Type 1—β-cell destruction, usually leading to absolute insulin deficiency
- Autoimmune
- Idiopathic

Type 2—may range from predominantly insulin resistance with relative insulin deficiency to a predominantly secretory defect with or without insulin resistance

Other specific types
- Genetic defects of β-cell function
- Genetic defects of insulin action
- Diseases of the endocrine pancreas
- Endocrinopathies
- Drug- or chemical-induced
- Infections
- Uncommon forms of immune-related diabetes
- Other genetic syndromes sometimes associated with diabetes

Gestational diabetes

15.2

Type 1 Diabetes

15.2.1 Epidemiology and Public Health

Elizabeth J. Mayer-Davis and Daria Igudesman

Introduction

Diabetes is broadly classified into type 1 diabetes mellitus (T1D), type 2 diabetes mellitus (T2D), gestational diabetes mellitus (GDM), and specific types due to other causes [1]. In T1D, a combination of genetic and environmental factors results in autoimmune destruction of pancreatic β-cells and insufficient insulin production. Meanwhile, insulin resistance is the hallmark of T2D—the most common diabetes type—alongside insufficient insulin production, resulting in hyperglycaemia. GDM usually occurs in the second or third trimesters of pregnancy and resolves post-delivery. Specific diabetes types due to other causes include those resulting from a genetic mutation, diseases of the exocrine pancreas, and drug- or chemical-induced diabetes.

While T1D develops most commonly in childhood and adolescence, T2D is more frequent (albeit not exclusively) among adults and is associated with obesity. Genetic risk scores for T1D have been established through genome-wide association studies (GWAS) that have identified several alleles involved in immunity [2]. GWAS have also linked T2D and obesity-related genetic loci, including body mass index (BMI) and waist-to-hip ratio [3]. Strong evidence exists for lifestyle prevention of T2D, which in long-term studies has been more effective than metformin [4]. Because acute complications are typically less severe than in T1D, T2D can go undetected for long periods, and is often diagnosed due to complications of prolonged hyperglycaemia.

Diagnosis of Diabetes

According to the American Diabetes Association (ADA), a fasting plasma glucose (FPG) of >126 mg/dl indicates diabetes, while impaired fasting glucose (IFG) is between 100 and 125 mg/dl. The World Health Organization (WHO) recommends performing an oral glucose tolerance test (OGTT), by which diabetes is defined as 2-hour plasma glucose (PG) ≥ 200 mg/dl. Haemoglobin A1c (HbA1c) may also be used for diagnosis (prediabetes between 5.7% and 6.4%; diabetes >6.5%), although the assay is not universally standardized, can be affected by other diseases such as malaria, and is not feasible in some low-resource settings (see Chapter 15.1.2).

Diabetes Prevalence

Globally, an estimated 8.8% (95% CI 7.2–11.3) of adults, or 425 million people, have diagnosed diabetes. Of these, 79% live in low- and middle-income countries. This is expected to increase to 629 million adults by 2045, owing largely to countries whose economic status will shift from low to middle income with increasing exposure to risk factors for development of (primarily) T2D. Prevalence is lower among women compared to men (8.4% compared to 9.1%), and greater in urban compared to rural environments (10.2% vs. 6.9%). Meanwhile, undiagnosed diabetes accounts for half of all diabetes cases worldwide, with 84.5% occurring in low- and middle-income countries. The proportion of undiagnosed diabetes is as high as 69.2% in Africa, likely due to low screening priority and resource availability [1].

US age-standardized estimates of total (diagnosed and undiagnosed) diabetes prevalence increased from 10.8% (9.5–12.0) in 2001–2002 to 12.4% (10.8–14.2) in 2011–2012 (P <0.001) [5]. This was attributable to increases in diagnosed diabetes, as undiagnosed prevalence only changed among Mexican Americans (5.6% and 5.9% in 1988–1994 and 2011–2012, respectively). Estimates

have increased significantly in every stratum of age, sex, race/ethnicity, education level, and poverty income ratio tertiles, although the only increase among BMI strata occurred in the 30+ stratum (18% (15.9–20.0) in 1988–1994 vs. 20.1% (17.8–22.4) in 2011–2012, $P = 0.003$). 2011–2012 prevalence was lower among non-Hispanic whites (NHW) (11.3% (9.0–14.1)) than non-Hispanic blacks (21.8% (17.7–26.7)), non-Hispanic Asians (20.6% (15.0–27.6)), and Hispanics (22.6% (18.4–27.5)). Meanwhile, prevalence of diagnosed diabetes among adults was 9.1% (7.8–10.6), and 5.2% (4.0–6.9) for undiagnosed diabetes; prediabetes prevalence was 38% (34.7–41.3), of which 36.4% (30.5–42.7) cases were undiagnosed.

T1D Prevalence and Incidence

In high income countries, between 7% and 12% of all individuals with diabetes have T1D [1, 6]. In the United States, three-quarters of all T1D diagnoses are made to individuals under the age of 18 [7]. Global annual incidence has ranged from 0.5 to over 60 cases per 100 000 children under the age of 15 [8].

Incidence rates of T1D appear to be increasing in the United States, where age, sex, and race/ethnicity adjusted estimates among youths aged 0 to 19 have increased by 1.8% annually between 2002–2003 and 2011–2012 [9]. This equates to 15 900 cases diagnosed in 2002–2003, compared to 17 900 new cases in 2011–2012. The estimated annual increase in incidence was highest among Hispanic youth. Trends in international incidence rates have varied, however; while in Australia, annual incidence among children has followed a sinusoidal trend [10], it seems to have stabilized in Scandinavian nations [11], and increased in other European paediatric populations [12].

T2D Prevalence and Incidence

US estimates of diagnosed T2D prevalence increased from 4.96% to 7.78% between 1999 and 2010 among adults over age 30, while undiagnosed T2D prevalence increased from 3.45% to 4.36%. Adjusted incidence rates among US youths with T2D increased by 4.8% annually from the 2002–2003 to the 2011–2012 period ($P < 0.001$). Incidence rates increased in all age, sex, and race/ethnicity categories, except among NHW; greater relative increases were observed in non-Hispanic blacks, Asians, and Native Americans combined compared to NHW (8.9% vs. 3.1%, $P < 0.01$).

Between 2001 and 2009, prevalence of diagnosed T2D increased among youths aged 10–19 from 0.34 per 1000 (0.31–0.37) to 0.46 per 1000 (0.43–0.49) [13]. Reliable international estimates for T2D among youths are lacking, as diagnostic procedures vary by region. However, a systematic review suggests that both incidence and prevalence rates are increasing worldwide [14].

GDM Prevalence and Complications

GDM occurs in 8.3% of pregnancies worldwide [15], and is thought to be increasing due to increased prevalence of overweight and obesity [16]. Fetal complications include high and low birth weight, congenital defects, and perinatal death. Maternal complications include eclampsia, preeclampsia, and Caesarean section [17]. Both women with GDM and children born to mothers with GDM are at increased risk for developing T2D [18, 19].

Complications of Diabetes

Acute Complications

Although severe hypoglycaemia has been associated with intensive diabetes therapy, long-term studies suggest that rates are becoming more similar among intensively treated versus conventionally treated T1D patients [20]. Incidence of hospitalization for severe hypoglycaemia among adults with T1D has increased by 3.74% (1.70–5.83) annually between 1998 and 2013, and by 8.59% (5.76–11.50) among elderly adults with T2D between 1998 and 2009. Although incidence decreased by 8.05% (–14.48–1.13) annually among this population between 2009 and 2013, 2013 incidence remained higher than in 1998. This reduction may be attributed to reduced use of sulfonylurea medications, which can induce hypoglycaemia [21].

Diabetic ketoacidosis (DKA) can be life-threatening, and often results in hospitalization. Annual incidence of hospitalizations for DKA in T1D remained stable in an English population between 1998 and 2004, but increased by 14.10% annually between 2004 and 2007, after which it plateaued. Incidence among adults with T2D increased annually by 4.24% between 1998 and 2013 [22].

Chronic Complications

Macrovascular complications lead to cardiovascular disease (CVD), and can be prevented through management of blood glucose (BG), hypertension, and dyslipidaemia. Individuals with diabetes are two to four times more likely to have CVD than non-diabetic individuals [23]; this estimate increases with age, and in low- and middle-income compared to high-income countries [1]. While intensive glucose-lowering therapy was shown to reduce the hazard of myocardial infarction among individuals with T1D and T2D compared to standard therapy [24, 25], intensive insulin treatment of T1D can also result in weight gain, which itself may increase risk for CVD [25]. US estimates approximate a 6.3% 10-year CVD risk among participants aged 30–39 [26]. Approximately 14–45% of children with T1D have two or more CVD risk factors, with girls at higher risk than boys.

Increased diabetes duration and poor glycaemic control have been associated with microvascular complications. Of these, diabetic kidney disease (DKD) is a major cause of end-stage renal disease, morbidity, and mortality among young adults with T1D. Because DKD is associated with CVD [27], controlling blood pressure and BG through lifestyle and pharmacology is key for prevention of progression to dialysis or need for kidney transplant [28].

Diabetic retinopathy (DR) is a microvascular complication that is the primary cause of vision loss among 20–65 year olds, and occurs to some degree in 1 of every 3 individuals with diabetes (see Chapter 15.12.2). It is more prevalent in T2D than T1D, and adolescents are at greater risk of progression to vision loss than adults. Prevalence is as high as 41% in South-East Asia, while the lowest documented prevalence of 12% is in Africa [1]. Risk of DR progression may be reduced by managing lipids [29], and severity may

be reduced through intensive BG control [30]. Prevention requires regular retinal screening, as DR is often asymptomatic in early stages, although screening is often unavailable in low- and middle-income countries.

Uncontrolled BG can also lead to neuropathy—microvascular-mediated damage of nerve cells—particularly in peripheral tissues such as the feet (see Chapter 15.4.1). The resulting loss of sensation can lead to unattended injuries and wounds. Thus, ulceration, infection, and amputation occur at higher rates among individuals with diabetes compared with non-diabetic controls [31]. Global diabetic foot ulceration was estimated to be 6.4% (4.6–8.1) among individuals with T2D—higher than those with T1D (5.5%, 3.2–7.7).

Cerebrovascular risk, or damage to the microvasculature of the brain through poorly managed BG, has been associated with cognitive impairment among individuals with diabetes [32]. Complex tasks of executive function have been subtly reduced among young adults with T1D compared with controls, although no differences in IQ or memory were observed between groups [33]. Likewise, academic performance among children with T1D has been negatively associated with severe hypoglycaemia [34]. Reduced performance in verbal memory, attention tasks, and processing speed were detected in a meta-analysis of individuals with T2D compared with controls [35].

A recent WHO report attributes 1.6 million annual deaths to diabetes globally. This number is greater among women (2.1 million, 1.7–2.7) than men (1.0 million, 1.5–2.3) in all global regions, except in the North American and Caribbean region. Among individuals with T1D, standardized mortality ratios (SMR) for total mortality and CVD are elevated among women compared to men [36]. Among middle-aged individuals with T2D in high- and middle-income countries, 27 out of every 1000 are estimated to experience CVD-related deaths annually, primarily due to stroke and coronary artery disease [1]. Other diabetes-related complications result in 4.0 (3.2–5.0) million deaths worldwide among adults.

Additional complications of diabetes include depression, dementia, tuberculosis, and non-alcoholic fatty liver disease (NAFLD). Quality of life is also impacted heavily. For instance, DR has been associated with deteriorating physical state among individuals with diabetes, with 58% of those surveyed globally reporting limitations in daily activities of life, compared with 37% without DR [1].

Economic Impact

Diabetes care expenditures were recently estimated to be 727 billion USD annually, or one-eighth of all global income spent on healthcare (see Chapter 15.15.2). This is expected to increase by 104 billion USD by 2045 [1]. Another study estimated global diabetes cost to be 1.3 trillion USD in 2015 [37], while diabetes-related CVD resulted in a loss of 84 billion USD globally between 2005 and 2015. Direct healthcare costs to those living with diagnosed diabetes tend to be twice as high as those of non-diabetic individuals, while work absenteeism in the United States results in annual loss of 5 billion USD to individuals; reduced productivity while working and inability to work lead to annual losses of 20.8 and 21.6 billion USD, respectively.

Summary

The epidemiology of diabetes mellitus is a critical element in developing public health policy and advancing healthcare systems. Subgroup analyses of incidence and prevalence estimates can help identify high-risk subpopulations that would benefit from tailored interventions. However, data are limited in some settings, which complicates efforts to obtain valid estimates and to differentiate between T1D and T2D. Nonetheless, updates in epidemiologic data are necessary for improving diabetes prevention and treatment both globally and regionally.

15.2.2 Presentation and Natural History of Type 1 Diabetes

Augustin Brooks

Historical Perspective and Type 1 Diabetes Subtypes

Physician Aretaeus of Cappadocia first used the term 'diabetes' to summarize the presentation and natural history of sufferers in the second century AD:

> Diabetes is a dreadful affliction, not very frequent among men, being a melting down of the flesh and limbs into urine. The patients never stop making water and the flow is incessant, like the opening of aqueducts. Life is short, unpleasant and painful, thirst

> unquenchable, drinking excessive, and disproportionate to the large quantity of urine … the viscera seem scorched up, the patients are affected by nausea, restlessness and a burning thirst, and within a short time, they expire.

The term 'diabetes' means siphon, and it is likely Aretaeus' patients had type 1A diabetes, the classical hallmark of which is autoimmune destruction of pancreatic β-cells (seen in 70–90% of type 1 diabetes), producing an insulin deficient state which results in spontaneous hyperglycaemia and subsequent ketone formation. Rate of β-cell loss is highly variable, and onset in prepubertal childhood may reflect a more aggressive destructive process, while presentation later in life may be associated with high residual β-cell mass (see Chapter 15.2.3, 'Pathogenesis'). Latent autoimmune diabetes of adulthood (LADA) is slowly progressive but ultimately requires insulin therapy; autoimmune antibodies are detectable at presentation and genetic studies suggest that it is not a distinct entity from type 1A diabetes.

A minority of those presenting with ketoacidosis due to insulin insufficiency show no evidence of autoimmune activation, and can later achieve good glycaemic control for many years with adjustment of lifestyle, with or without insulin therapy. This form of type 1B idiopathic diabetes is described in individuals of African and Caribbean origin, termed 'J type' or 'Flatbush' diabetes and best summarized as periodic insulin insufficiency, although diabetic ketoacidosis can recur many years after initial presentation [1].

Incidence

Classically described as a disease of childhood, onset of type 1 diabetes can occur at any age beyond the first 6 months of life, with two peak incidences at 5–7 years old and around commencement of puberty, with a slight male preponderance.

Incidence varies markedly between countries and is positively related to distance away from the equator: the Chinese province of Guizhou has a low incidence of 0.1/100 000/year, while highest rates are found in European countries peaking in Finland at 60/100 000/year. Temporal trends suggest that incidence is increasing at 3–4% per calendar year, most notably in younger age groups. A seasonal winter peak supports a theoretical role for an environmental agent driving pathogenesis.

Natural History Preceding Clinical Onset

Genetic Predisposition

Aetiology of type 1 diabetes remains unclear but a genetic predisposition is apparent: 4–6% of siblings of type 1 diabetes probands develop the condition. Risk is 5–8% in offspring from diabetic fathers, and 2–5% from diabetic mothers, although cumulative incidence in a monozygotic twin is less than 50%.

Over 40 genetic loci contributing to type 1 diabetes risk have been identified [2]. The Human Leukocyte Antigen (HLA) complex on chromosome 6p21 provides the greatest contribution to the overall genetic susceptibility (~60%). HLA genes encode molecules that participate in antigen presentation to CD4 cells, and the HLA-DQ locus has a greater association with type 1 diabetes than any other HLA subtype. HLA class II proteins associated with diabetes might promote antigen presentations that generate T-helper cells responsible for an immune response to specific islet cell autoantigens, activating cytotoxic CD8 T cells that destroy insulin-producing β cells in the islets of Langerhans.

Environmental Trigger

Twin studies demonstrate that not all individuals with genetic susceptibility to type 1 diabetes develop the condition and rapidly changing incidence of diabetes within a genetically stable population implies non-genetic factors must have a causative role.

Leading hypotheses have proposed early rubella and enterovirus infections as environmental triggers; destruction of infected β cells by virus-induced cytolysis could release antigens that trigger a pathogenic autoreactive T cell response. However, no direct evidence for a causative viral strain has been identified. Nutritional influences have been considered, with shortened period of breastfeeding, early exposure to cow's milk or wheat gluten and low vitamin D levels all proposed as potential causative factors (see Chapter 15.2.3, 'Pathogenesis').

Prodrome and Autoantibody Formation

The β-cell decline hypothesis remains a widely referenced benchmark model for type 1 diabetes [3]. This model proposes that genetically susceptible individuals encounter an environmental trigger that initiates an autoimmune process, which subsequently leads to autoantibody formation, activation of autoreactive T cells capable of destroying β-cells and a linear decay in β-cell mass. In this model, type 1 diabetes presents when 80–90% of β-cells have been destroyed, although β-cell mass between individuals varies 3–5-fold and timeline to clinical onset might be determined by initial β-cell mass rather than aggressiveness of the autoimmune attack.

Antibodies formed against prominent antigens are important markers of β-cell autoimmunity, detectable in 85% of patients at time of disease presentation. More than two dozen autoantibodies have been identified, the most significant being autoantibodies to insulin (micro IAA), glutamic acid decarboxylase (GAD65), insulinoma-associated antigen-2 (IA-2A), and zinc transporter 8 (ZnT8). Current generation assays demonstrate high diagnostic sensitivity and specificity for type 1 diabetes.

Autoantibodies are surrogate measures for β-cell autoimmunity and type 1 diabetes risk, with 5-year incidence 20–25% for subjects with one autoantibody, 50–60% with two autoantibodies, 70% with three antibodies, and 80% with four autoantibodies [4]. IAA autoantibodies are usually the earliest detectable, and a higher titre is consistent with a more aggressive disease course, associated with presentation before the age of 5 years. Autoantibody titres typically drop to low levels in the years after diagnosis. Loss of endogenous insulin production is more rapid in the first year following diagnosis than the second year, with a greater loss in children and adolescents than adults. Some residual β cell function may persist for many years, with detectable C-peptide production reported decades after diagnosis in small cohorts [5].

Box 15.2.2.1 Physiological effects of insulin insufficiency

Consequences of insulin insufficiency

Hepatic
- Glycogenolysis
- Reduced glycogen stores
- Reduced glucose oxidation
- Ketone body formation

Muscle
- Reduced glucose uptake
- Reduced glucose oxidation
- Reduced glycogen synthesis
- Increased proteolysis
- Loss of muscle mass

Fat tissue
- Increased lipolysis
- Reduced triglyceride synthesis
- Reduced adipocyte maturation
- Fat tissue breakdown

Other consequences
- Reduced cell and tissue growth
- Impaired immune modulation

Clinical Presentation

There is a wide gap between subclinical initiation of autoimmune damage and symptom onset; loss of first phase insulin response is usually followed by a period of glucose intolerance and patients do not present with pancreatic inflammation. Eventually, reduction in endogenous insulin production is so severe that a catabolic state of unrestrained glycogenolysis and hepatic gluconeogenesis develops, alongside failure of glucose uptake into peripheral tissues (see Box 15.2.2.1). Chronic hyperglycaemia ensues with clinical onset of symptoms.

Classic Symptom Triad

Osmotic symptoms of polyuria and polydipsia occur in 96% of individuals presenting with type 1 diabetes, with weight loss reported in 85% [6]. Symptom prevalence is increased in autoantibody positive individuals, while increasing age has been independently associated with weight loss and fatigue. Median symptom duration prior to presentation is typically 4 weeks in females and 3 weeks in males. Symptoms and signs of type 1 diabetes are listed in Table 15.2.2.1; their presence in combination with venous plasma glucose ≥11.1 mmol/L is diagnostic of diabetes.

Diabetic Ketoacidosis

Diabetic ketoacidosis (DKA) was identified in 42% of individuals presenting with newly diagnosed type 1 diabetes in a recent large cohort study [6]. Higher rates can occur in the very young, with an associated mortality risk as a result of cerebral oedema.

Insulin insufficiency causes unrestrained lipolysis, increasing non-esterified fatty acids that the liver converts to ketones providing an alternative energy source to glucose. Ketonaemia leads to metabolic acidosis, however, associated with nausea and eventually vomiting, with ketone excretion into the urine increasing osmotic diuresis. A vicious cycle of increasing ketones, vomiting, and acute renal impairment contribute to a worsening metabolic acidosis. Bicarbonate falls as carbon dioxide excretion is increased from respiratory compensation, while acid accumulation from ketones produces an increased anion gap.

The inability of insulin-deprived cells to take up glucose and potassium intracellularly leads to worsening hyperglycaemia and hyperkalaemia, with loss in urine and gastric secretions. Although hyperkalaemia occurs at DKA presentation, it must be remembered that total body potassium is depleted and a rapid reduction in serum potassium levels can occur if fluid and insulin are administered without potassium replacement.

Prolonged solute loss prior to DKA presentation may deplete total body sodium, and hyperglycaemia causes a further artefactual fall in measured plasma sodium exacerbated by hypertriglyceridaemia: each 3 mmol/L elevation in glucose accounts for approximately a 1 mmol/L drop in measured plasma sodium. Increased serum sodium at DKA presentation therefore reflects profound dehydration.

Natural History Following Diagnosis

In 1913, Harvard Medical School described the near uniform fatality of childhood onset diabetes, with anticipated survival 18–24 months if diagnosed under the age of 7 years [7]. The discovery of exogenous insulin therapy in 1921 was a monumental achievement, transforming type 1 diabetes from a terminal disease to a manageable medical condition. A contemporary picture of mortality between 1970 and 2007 in Finland reported an overall cumulative mortality of 17.9% after 35 years' duration of type 1 diabetes [8]. Standardized mortality ratio (SMR) 20 years post-diagnosis decreased with time from 3.5 for patients diagnosed in 1970–1974 to 1.9 for those diagnosed in 1985–1989. Mortality due to chronic complications reduced from 10.0 to 2.2 per 10 000 person-years for patients diagnosed between the ages of 0–15 years.

Loss in life expectancy from type 1 diabetes has been estimated at 11.1 years in men and 12.9 years in women, with greatest loss in expectancy from ischaemic heart disease [9]. Diabetic coma and ketoacidosis remain the greatest contributors to mortality before the age of 50 years, and even today childhood diabetes remains a rapidly progressive and ultimately fatal condition in parts of sub-Saharan Africa. Addressing global disparity in access to healthcare is a priority for present day management.

The Diabetes Control and Complications Trial (DCCT) confirmed that tight blood glucose control can reduce the incidence of complications but regulation of blood glucose levels within the normal physiological range remains challenging despite recent advances in medical therapy. Exogenous insulins are unable to mimic the natural regulatory ability of pancreatic β cells and nearly all individuals with type 1 diabetes remain prone to microvascular and macrovascular complications.

Macrovascular Complications Influence Mortality

Improvements in life expectancy have unmasked higher incidence of macrovascular disease in type 1 diabetes populations. Atheroma develops faster and more extensively in individuals with diabetes, with coronary lesions more prone to plaque ulceration and rupture. The risk of a cardiac event is ten times that of age-matched non-diabetic populations [10], although intensive diabetes treatment

Table 15.2.2.1 Symptoms and signs of type 1 diabetes

Symptoms	Signs	Causation
Urinary symptoms Polyuria Nocturia Polydipsia Dysuria	Dehydration	Hyperglycaemia exceeds the capacity of the renal tubule to reabsorb glucose in the distal convoluted tubule and increased urinary glucose creates an osmotic diuresis, producing increased urine production. Urine volume and frequency are increased, and affected individuals can report nocturia. Increase in urine volume differentiates new onset diabetes from infection or causes of bladder outflow obstruction, although high glucose levels do predispose to increased risk of infection.
Polydipsia Thirst Dizziness on standing	Dehydration Resting tachycardia Postural hypotension	Increased plasma osmolality and fluid losses from recurrent osmotic diuresis cause thirst and increased fluid intake. Intracellular dehydration occurs as water moves out of cells into the hyperosmolar interstitial fluid and circulation. In the later stages of undiagnosed diabetes preceding diabetic ketoacidosis (see below), the patient's intake may be insufficient to replace fluid losses, causing dehydration.
Weight loss	Reduced body mass index Muscle loss Loss of subcutaneous and visceral fat	Common in weeks preceding diagnosis, due to dehydration and worsening catabolic state. Lipolysis and proteolysis occur with insulin deficiency. Although weight loss is common, average body weight at presentation is usually within the normal range.
Fatigue	Excessive somnolence	Increased urinary frequency, nocturia, fluid and muscle loss lead to increased lassitude.
Visual disturbance Blurred vision	Altered visual acuity (Retinal and macular changes should be excluded by examination)	Hyperglycaemia causes osmotic changes in the lens and chambers of the eye that alter refraction; reduction in ambient glucose that occurs with treatment restores fluid levels in the dehydrated eye chamber, correcting the refraction capacity of the lens.
Musculoskeletal Leg pains, cramps	Muscle cramps, especially lower extremities	Excessive electrolyte loss with diuresis, altered carbohydrate, fat and protein metabolism, and subsequent ketosis formation can lead to cramping.
Infection Skin infections Dysuria Genital soreness	Cellulitis Abscesses Otitis externa Conjunctivitis Vaginal thrush Vulvovaginitis Balanitis Urinary tract/Genital infection	Increased glucose levels in body secretions encourage culture of bacteria, fungi, and viruses. Glucose levels should be tested in any individual presenting with significant skin or urogenital infection. Insulin deficiency may also have adverse effects on neutrophil function, and it is not uncommon for type 1 diabetes to present at times of infection as the stress response increases sympathetic activation, cortisol, and growth hormone release, all of which produce further hyperglycaemia.
Gastrointestinal symptoms Nausea Constipation (paediatric cases)	Oral and oesophageal candidiasis may complicate newly presenting type 1 diabetes.	Nausea and bloating result in physiological delay of gastric emptying with concurrent hyperglycaemia. Constipation noted in paediatric presentations, arising as a consequence of constipation from dehydration. Diarrhoea is rare, unless associated with coeliac disease at presentation.
Diabetic ketoacidosis		
Extreme thirst Excessive polyuria Vomiting Hyperventilation Reduced consciousness	Dehydration Increased skin turgor Resting tachycardia Postural hypotension Sunken fontanelle (infants) Kussmaul breathing Coma	Fluid losses excessive due to osmotic effects of profound hyperglycaemia. Acute renal failure may be present, and hyperkalaemia occurs as potassium cannot be moved into cells with insulin insufficiency. Unrestrained lipolysis and ketone formation cause nausea and subsequently vomiting. Ketones are acidic, reducing plasma pH. Metabolic acidosis drives respiratory compensation and hyperventilation can ensue, producing a deep sighing respiration. The breath smells of ketones, likened to pear drops. Rising osmolality and reduction in plasma pH reduce consciousness; often a late sign of established ketoacidosis necessitating intensive care admission.

might reduce the risk of cardiovascular events by more than 40%. Hazard ratio for ischaemic stroke is three times that of control subjects, increasing incrementally with worsening glycaemic control [11]. Amputation risk is 30 times that of the general population [12], with 20% of peripheral vascular disease patients dying within 2 years of symptom onset. Incidence of hypertension is increased in patients with type 1 diabetes, and attenuation of cardiovascular risk factors (blood pressure and cholesterol) remains paramount to reduce the risk of fatal coronary heart disease, although guidance is often based on outcomes from type 2 diabetes intervention studies [13].

Microvascular Complications Influence Morbidity

Prolonged exposure to hyperglycaemia particularly affects tissues that cannot downregulate glucose uptake, leading to raised intracellular concentrations and mitochondrial overproduction of superoxides that cause vascular damage.

Retinopathy

Each 5-year increase in the duration of diabetes at baseline is associated with a 10% increase in the risk of diabetic retinopathy and a 26% increase in the risk of sight-threatening severe retinopathy. Childhood diabetes exposure, puberty, and pregnancy contribute to added risk. Complication rates are improving; incidence of severe diabetic retinopathy in the United Kingdom decreased non-significantly from 48 events per 10 000 person-years in 2004 to 25.4 events per 10 000 years in 2014 [14]. Treatment options such as pan-retinal laser photocoagulation can control neovascularization and prevent blindness, although 25-year cumulative incidence of severe visual impairment (defined as visual acuity poorer than 6/60

in the better eye) has been reported at 3% [15]. In addition, lifetime risk of developing cataracts is increased threefold and glaucoma risk by nearly 50% in individuals with type 1 diabetes.

Nephropathy

Incidence of diabetic nephropathy increases linearly with duration of diabetes, with genetic propensity peaking at 10–14 years. Microalbuminuria develops in 30–40% of individuals with type 1 diabetes, although a significant proportion of patients can revert to normoalbuminuria with improvements in glycaemic control and blood pressure management. A third of microalbuminuria patients progress to macroalbuminuria over a decade [16], of which two-thirds later develop end-stage renal disease. Kidney disease accounts for a fifth of deaths in type 1 diabetes and all stages of nephropathy are associated with increased risk of death from cardiovascular disease (2–3-fold with microalbuminuria, 10-fold with overt proteinuria).

Neuropathy

Chronic distal symmetrical neuropathy with reduced sensation in the lower limbs and feet occurs in approximately a third of patients with 20–25 years' type 1 diabetes, although encouragingly incidence has decreased with improvements in glycaemic control. Distal neuropathy increases the likelihood of ulceration and amputation in diabetes, and in Westernized countries 7% of patients with diabetes are managed for foot ulcers. Abnormalities of the autonomic nervous system can manifest as gustatory sweating, altered bowel habit, postural hypotension, impotence, and blunting of physiological heart-rate variations; overt gastroparesis with vomiting and bladder dysfunction are rare.

Hypoglycaemia

Insulin therapy is life-sustaining and enables glycaemic control. However, hypoglycaemia is a potentially lethal side effect, and repeated exposure can result in impaired awareness of low blood glucose levels. Impaired awareness affects an estimated 20–30% of individuals with type 1 diabetes, and is associated with increased risk of severe hypoglycaemia requiring third party assistance. One episode has potential implications regarding lifestyle choices and driving but ultimately it can be truly life-threatening: not waking from sleep during nocturnal hypoglycaemia increases the risk of 'dead-in-bed' syndrome and sudden death [17]. The frequency of impaired awareness of hypoglycaemia has not declined in the past two decades, and despite major advances in conventional insulin therapy, there remains a group of patients in whom recurrent severe hypoglycaemia is associated with increased mortality (see Chapter 15.5.5 'Hypoglycaemia in the Treatment of Diabetes Mellitus').

Autoimmune Associations

Clustering of autoimmune disorders due to shared genetic susceptibility increases the lifetime risk of other autoimmune conditions developing in individuals with type 1 diabetes. A prevalence of 6% was recently reported [6], and the most common autoimmune conditions associated with type 1 diabetes are listed in Table 15.2.2.2.

Table 15.2.2.2 Autoimmune associations of type 1 diabetes

Condition	Autoantibody prevalence in type 1 diabetes	Screening test
Thyroid disease (Hyper and hypothyroidism)	15–30% express thyroid autoantibodies	Thyroid function tests (British Thyroid Association and American Diabetes Association suggest annual screening)
Addison's disease	1–2% express adrenal antibodies	9 am cortisol Short synacthen test
Coeliac disease	5–10% express coeliac antibodies	Tissue transglutaminase antibodies Duodenal biopsy if positive
Gastritis and pernicious anaemia	Antiparietal cell antibodies in 5–15%	Full blood count Vitamin B_{12} levels Antiparietal cell antibodies Iron studies
Vitiligo Alopecia areata	Rarely measured Reported frequency 2–10%	Clinical diagnosis Skin biopsy rarely used to confirm diagnosis

Future Management Strategies Might Influence Natural History

Redefining type 1 diabetes as having a silent or asymptomatic phase defined by autoantibody status and genetic risk could allow therapeutic interventions to be given earlier in the natural history of the disease, with the goal of maintaining β-cell mass and endogenous insulin production. Organized trial networks now facilitate testing of immunotherapy agents which might be capable of preventing disease onset. However, the current risk-benefit ratio is such that interventions have not yet provided sufficient evidence for routine clinical use to be indicated. Given that exogenous insulin therapy has considerably increased life expectancy for type 1 diabetes, a high safety bar has been set for immune-based interventions, and they must achieve long-lasting outcomes with minimal side effects before they can replace insulin therapy.

15.2.3 Pathogenesis

Ayat Bashir, Richard A. Oram, and F. Susan Wong

Introduction

The autoimmune basis for human type 1 diabetes is well established. It is recognized that there may be considerable heterogeneity in the features of disease, and that type 1 diabetes is not a disease only of children, but also presents in adulthood. There are several lines of evidence supporting the autoimmune nature of type 1 diabetes, and these are summarized in Figure 15.2.3.1; each of these will be discussed in turn in the sections next.

Adding to the heterogeneity of disease, the period of time from initiation of the disease process to clinical presentation may range from weeks (in those presenting before the age of 5 years) to years in those presenting at an older age. A current model setting out the early stages of disease pathogenesis is shown in Figure 15.2.3.2. There are genetic and environmental risk factors, which may or may not lead to the development of autoimmunity. In stage 1, following initiation of the immune process, there is autoimmunity against beta-cells but normal blood glucose. As more beta-cells are destroyed there is asymptomatic dysglycaemia, finally leading to presentation of symptomatic diabetes.

Genetics—Association with Immune System Genes

Type 1 diabetes is a polygenic disease with a significant heritable component stemming from multiple risk genes [1, 2]. Monozygotic twin concordance for type 1 diabetes is 30–70%, compared to dizygotic twin concordance of 6–10%. Risk for people who have a first degree relative affected varies from 3% with an affected mother, to 5% with an affected father, and 8% with an affected sibling. Type 1 diabetes is most common in white Caucasian populations, but can occur in all races and ethnicities. Genetic associations of type 1 diabetes highlight the critical role of the immune system in type 1 diabetes, with the human leucocyte antigen (HLA) class II genes having the strongest association. Large differences in incidence of type 1 diabetes in genetically similar populations [3], and the increasing incidence of type 1 diabetes in low genetic risk individuals, highlight the importance of the interaction between genetic and environmental risk factors in type 1 diabetes development.

The Main Susceptibility Locus: Human Histocompatibility Complex (HLA)

The association of T1D with the HLA region on chromosome 6p21 was determined over 40 years ago [4, 5]. This region is now known to contribute around 50% of genetic susceptibility to type 1 diabetes [6]. The strongest association is with highly polymorphic HLA DR and DQ genes, which are commonly inherited together, due to tight genetic linkage between DR and DQ alleles. These genes encode proteins that display self and non-self-peptides on the surface of antigen-presenting immune cells. The highest risk haplotypes include DR4-DQ8 (DRB1*0401 DQA1*0301-DQB1*0302) and DR3-DQ2 (DRB1*0301-DQA1*0501-DQB1*0201) and at least one of these alleles is found in 85% of white Caucasians with T1D. The primary genetic drivers of risk seem to be amino acid and protein structural changes in the antigen binding pockets of HLA class II molecules at 3 key amino acid positions in the DRB1 and DQB1

Figure 15.2.3.1 Indicators of the autoimmune pathogenesis of type 1 diabetes.

genes [7]. This presumably impacts the binding affinity, the repertoire of peptides that can be presented and their impact on the T cells they bind. Certain DR-DQ alleles (such as DRB1*1501-DQA1*0102-DQB1*0602) confer strong dominant protection from type 1 diabetes [8]. The mechanisms for this are not fully understood but may offer valuable insights into how to reduce or prevent islet-specific autoimmunity.

Additional associations with the HLA region include the class II DPB1 locus, and HLA class I A, B, and C loci. Alleles with particularly strong associations include the protective B*57:01 allele, and B*39:06 and A24 risk alleles [9]. HLA class I/peptide antigen complexes are involved in in the development of the $CD8^+$ T-cell repertoire in the thymus and antigen-specific T-cell-mediated cytotoxicity.

Non-HLA Loci are Important Contributors to Genetic Risk of Type 1 Diabetes and Reveal Further Immune Insights

Linkage and genome wide association studies have demonstrated over 50 additional non-HLA genetic associations with type 1 diabetes risk [2]. The majority of these associations are with genes in key immune pathways and further highlight the importance of the immune system function and regulation in the pathogenesis of type 1 diabetes [10] (Figure 15.2.3.3).

The strongest non-HLA genetic association, initially described as the IDDM2 locus, was discovered in the early 1980s, and is a variable number of tandem repeats (VNTR) polymorphism next to the insulin gene (INS) on chromosome 11p15 [11]. The class III protective VNTR is associated with increased insulin expression in the thymus and may increase negative selection of insulin-specific autoreactive T cells.

The PTPN22 gene on chromosome 1p13 encodes the lymphoid-specific phosphatase LYP, which normally suppresses T-cell activation [12]. A gain of function variant in PTPN22 may lead to a failure of deletion of autoreactive T cells during thymic selection, and altered function of effector and regulatory T (Treg) lymphocytes, and B lymphocytes in the periphery. Cytotoxic T-lymphocyte–associated protein 4 (CTLA4), encoded on chromosome 2q33, plays a role in T-cell development and it is a negative regulator of T-cell activation. Its expression in both regulatory and effector T cells is essential for suppression of autoreactive T-cell-mediated cytotoxicity. The IL-2 receptor alpha (IL-2RA) gene encodes the IL-2 receptor alpha chain, CD25. The T1D-susceptibility *IL2RA* association is associated with decreased signalling via the IL-2 pathway in both memory T cells and Tregs and this is linked to diminished Treg function. These and other genetic immune associations (reviewed in [2, 13]) have led to better understanding of mechanisms of islet-specific autoimmunity, and identified pathways that are being targeted for therapeutic intervention.

Not all genetic associations of type 1 diabetes point to adaptive immunity. Both common and rare deleterious variants in IFIH1 are associated with type 1 diabetes [14]. IFH 1 encodes melanoma differentiated associated protein 5 (MDA5) which binds to double-stranded RNA viruses and thus mediates the innate immune system's interferon response to certain viruses. A recent study demonstrated evidence for a causal relationship between the common IFIH variant (rs1990760) and both autoimmunity and viral resistance [15]. Additionally there is emerging evidence that several type 1 diabetes genes are expressed in insulin-producing beta-cells and abnormalities within the beta-cell may contribute to type 1 diabetes pathogenesis [10].

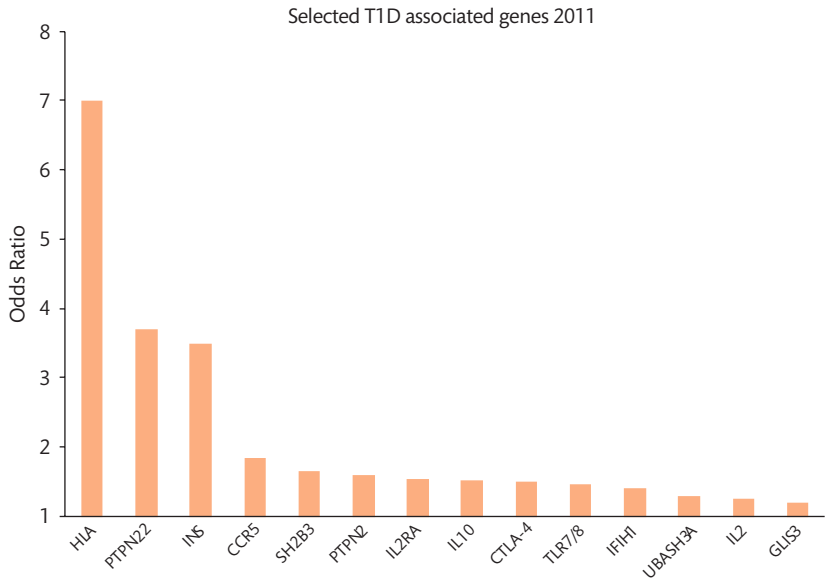

Figure 15.2.3.3 Genetic associations with type 1 diabetes. Genome-wide association studies have identified a number of genes associated with type 1 diabetes. Colour-coding designates year of discovery of these candidate genes. The *y*-axis indicates the best estimate of the odds ratio (OR) for risk alleles at each of the indicated loci. For each genomic region where convincing association with type 1 diabetes has been reported, the gene of interest, or containing the most associated SNP is indicated on the x-axis. The majority of these genes are implicated in the immune response, but several of the non-HLA genes are expressed in human pancreatic islets (marked with *).

Reproduced with permission from Pociot F, Akolkar B, Concannon P, Erlich HA, Julier C, Morahan G, *et al.* Genetics of type 1 diabetes: what's next? *Diabetes.* 2010;59(7):1561–71.

The majority of genetic linkage and association studies have been in groups of type 1 diabetes cases compared to control individuals. However, there is increasing awareness of heterogeneity of aetiopathology, immune phenotype, age of presentation, and beta-cell loss in type 1 diabetes. To elucidate the genetic contribution to this heterogeneity will require large association studies of these features within cohorts of people who progress to type 1 diabetes and well-phenotyped individuals with type 1 diabetes. It is possible, as is the case with some other autoimmune diseases, that genetic associations and predictors of disease progression may be independent of risk loci. Initial analyses have highlighted independent genetic associations with age of diagnosis [16], beta-cell loss [17], and incidence of islet autoantibody development [18].

Thus, there have been considerable advances in determining genetic factors that lead to increased susceptibility to type 1 diabetes. However, it is clear that genetic susceptibility alone is not sufficient for diabetes to develop, and environmental factors have been implicated in triggering or perpetuating the immune responses that lead to islet beta-cell damage, discussed in the next section.

What is the Role of the Environment in the Loss of Immune Tolerance?

Several studies have been designed to characterize the progression over time to islet autoimmunity and clinical disease in children at risk of type 1 diabetes, including The Environmental Determinants of Diabetes in the Young (TEDDY) [19], and the Diabetes Autoimmunity Study in the Young (DAISY) [20]. Evidence emerging from these and other studies is consistent with diverse genetic and environmental factors driving initiation of islet autoimmunity and progression to type 1 diabetes.

Infections, particularly viral, have long been implicated as a potential cause of type 1 diabetes. Evidence of persistent enteroviral infection has come from detection of enteroviral VP1 protein, and RNA in the beta-cells of individuals with type 1 diabetes [21, 22]. However, whether this is a causative factor or an additional factor causing stress to beta-cells is unknown. Recently, considerable interest has been focused on the intestinal microbiome. The gut bacteria are acquired at the time of birth, and the microbiota increase in diversity, particularly over the first 3 years of life [23]. Children who develop type 1 diabetes have reduced diversity [24] of the gut microbiota. These commensal bacterial influence host metabolism, and have an important role in maturation of the immune system and development of immune tolerance. In animal models, gut microbes could activate autoreactive T cells and contribute to development of diabetes by molecular mimicry [25], but this has yet to be proven in humans. Other influences in early life, such as dietary factors including early introduction of cows' milk, cereals, polyunsaturated fatty acids, and vitamin D have all been considered as possible determinants, but as yet, no firm conclusions can be drawn [26, 27]. Vaccines and antibiotic use have not been shown to be a factor in diabetes development. Large prospective studies will be important to help throw light on this, although heterogeneity of type 1 diabetes may continue to make this a very difficult task.

Thus, either one or more of these environmental factors may be important in both triggering and perpetuating the immune responses that damage the islet beta-cells. A proposed scheme for the components involved in the immune damage is shown in Figure 15.2.3.4, and these will be discussed further in the sections that follow.

Insulitis—Beta-Cell Antigen-Specific T Cells Found in Human Islets

The earliest evidence for immune cell involvement was infiltration of mononuclear cells in the pancreatic islets [28, 29]. Autopsies of young patients who died shortly after diagnosis of diabetes showed variable degrees of lymphocytic infiltration, resembling that seen in autoimmune thyroiditis. In a large series of post-mortem examinations, infiltration was found in insulin-containing islets, with few cells found in insulin-deficient islets [30]. More recently, the insulitis has been further characterized in post-mortem samples where $CD8^+$ T cells and B cells are found more commonly than $CD4^+$ cells, with other cell types including $CD68^+$ macrophages [31]. In addition, biopsies of pancreas in newly diagnosed individuals confirmed $CD8^+$ T cells to be the most abundant cells present [32]. Furthermore, infiltrating $CD8^+$ T cells have been shown to be islet autoantigen-reactive to proinsulin, glutamic acid decarboxylase, and islet-specific glucose-6-phosphatase catalytic subunit-related protein (IGRP) [33, 34]. Nevertheless, it is perhaps somewhat surprising that relatively few cells are found in the islets of the pancreatic samples that have been studied post-mortem, and this may reflect the fact that the immune processes may have commenced a considerable time before diagnosis.

Humoral Immunity—The Presence of Anti-Islet Autoantibodies in the Circulation

The identification of islet cell antibodies (ICA) by immunofluorescence in 1974 was a key step in the recognition of type 1 diabetes as an immune-mediated disease. ICA have now been characterized at the molecular level and are summarized in Table 15.2.3.1. Circulating islet autoantibodies are present in sera from ~95% of children with new-onset diabetes, and provide evidence of an active and disease-specific B lymphocytic response. Furthermore, the observation that ICA preceded the development of diabetes in high-risk relatives led to the understanding that onset of autoimmunity commonly occurs years before clinical presentation with diabetes. Although individuals with single autoantibody positivity do not necessarily progress to a decline in beta-cell function, the presence of two or more high-titre autoantibodies predicts development of type 1 diabetes over the following 10–15 years [35]. The risk of developing autoantibodies in these relatives is high in the youngest children and reduces with age. Models have been developed to estimate the risk of developing type 1 diabetes at different ages from birth through childhood, and was greatest in younger islet autoantibody positive children [88].

While anti-islet autoantibodies may appear many years before clinical onset of diabetes and allow prediction and classification of type 1 diabetes, the autoantibodies are not thought to be effectors of the immune attack; rather they are a sign of autoreactive B cell

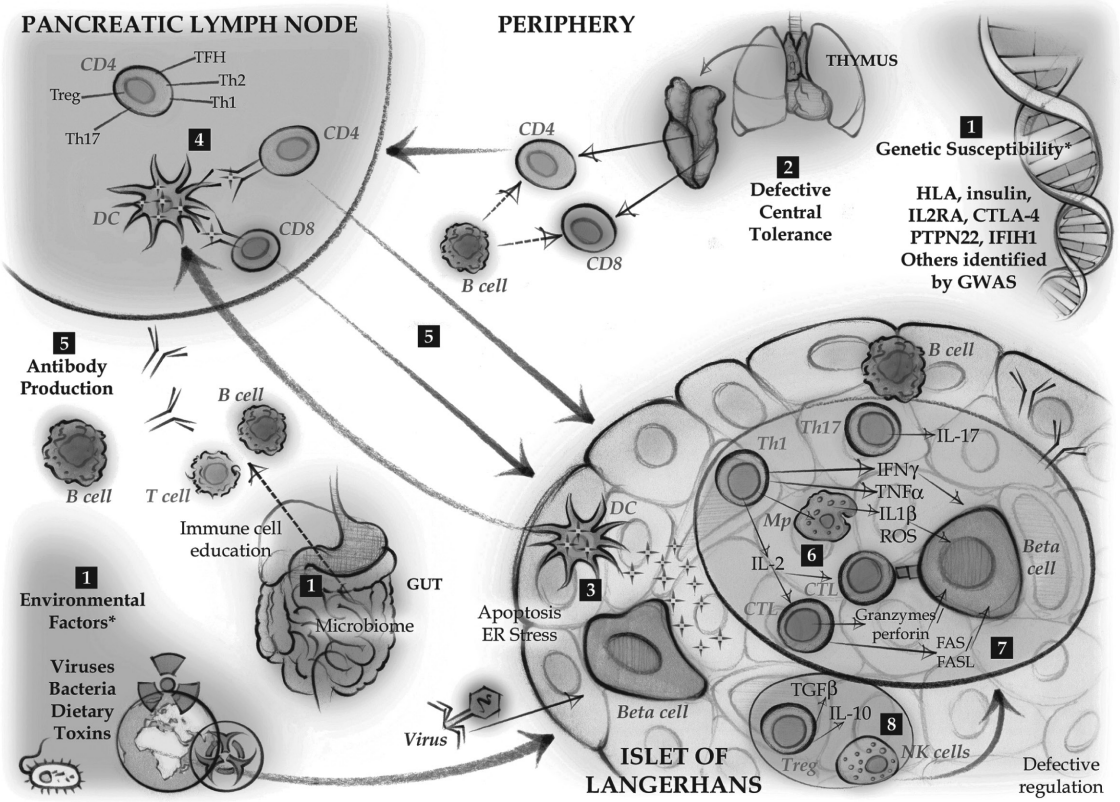

Figure 15.2.3.4 Proposed scheme for pathogenesis of type 1 diabetes. (1) Genetic and environmental factors, such as viral infections, are likely to impact on loss of peripheral tolerance, a major contributing factor in the pathogenesis of type 1 diabetes. The intestinal microbiome has also been implicated as an environmental factor in pathogenesis. (2) Defective central tolerance allows naïve islet-reactive $CD4^+$ and $CD8^+$ T cells to escape the thymus and migrate to the pancreatic lymph node. (3) Several possible mechanisms, including remodelling by apoptosis, viral infection, endoplasmic reticulum (ER) stress could promote beta-cell death and release of beta-cell antigens. Antigens can be taken up by dendritic cells (DC), which migrate to the pancreatic lymph node. (4) Dendritic cells present beta-cell antigens to naïve CD4 T cells, leading to activation of several possible subsets including: Th1, Th2, TFH, Th17, Treg. Dendritic cells also cross-present antigens to $CD8^+$ T cells. (5) $CD4^+$ cells can help B lymphocytes to produce autoantibodies that target beta-cell proteins. They may also assist in activation and migration of $CD8^+$ T cells. Activated T cells traffic to the islets. (6) $CD4^+$ Th1 secrete pro-inflammatory cytokines IFNγ and TNFα, which could induce beta-cell death and stimulate macrophages to produce reactive oxygen species (ROS), TNFα and IL1β. This may augment beta-cell death. (7) Furthermore CTL infiltration can induce direct killing of beta-cell by lysing beta-cells presenting self-antigen, via secretion of granzymes/perforin and through the Fas–FasL pathway. (8) Treg cells function to reduce autoimmune responses through interaction with dendritic cells and secretion of TGFβ and IL-10. In diabetes, regulatory T-cell function is impaired.

activation. As many of these autoantibodies are IgG, suggesting that they are T-cell-dependent antibodies, they are also likely to indicate autoreactive T-cell activity. It is interesting to note that many of the islet autoantibodies are directed towards components of the islet secretory granule, and some of these are also targets of T lymphocytes (see next).

Cellular Immunity–Pancreas Transplantation, Adoptive Transfer of Diabetes and Islet Beta-Cell Antigen-Responsive T Cells

Understanding of immune cell subsets has increased considerably over the last few years, and many of these subsets, shown in Figure 15.2.3.4, participate in autoimmune reactivity. As illustrated, the interactions are complex and the diversity of cells involved is likely to make immune intervention potentially difficult. Much information relating to cellular immunity has initially been derived from rodent models that develop spontaneous autoimmune diabetes. The most studied of these models is the non-obese diabetic (NOD) mouse, which has given us early insights and signposted cellular immune processes. Like humans, the most important genetic susceptibility factor is in the MHC class II region, and the structure of the MHC class II molecule most closely associated with diabetes, is very similar in both humans and NOD mice. As in humans, environmental factors also play a role, which contributes to the variation in incidence of diabetes in different mouse colonies across the world, as well as over time within the same colony [49]. Some of the target T-cell antigens in NOD mice, which are also targeted in humans, are very similar to the autoantibody targets (Table 15.2.3.2). Early studies in the NOD mouse indicated that both $CD8^+$ and $CD4^+$ T cells as well as B cells themselves (rather than antibodies) are likely to be important in the developing cellular responses against islet beta-cells (reviewed in [50]). This has been

Table 15.2.3.1 Autoantibodies in type 1 diabetes

Target antigen	Key information	References
Insulin (IAA)	• Presence demonstrated using sensitive radiobinding assay. • Appear very early in the natural history of type 1 prodrome. • Overall prevalence in childhood diabetes (<15 years) has been reported as 70%, with higher prevalence in younger children. • High affinity IAA strongly associated with *HLA DRB1*04*, subsequent progression to multiple autoantibody positivity, binding to human insulin A chain residues 8–13, and binding to proinsulin.	[36–38]
Glutamate decarboxylase 65 kD molecular weight isoform (GAD65)	• Originally discovered by immunoprecipitation of a 64kDa protein from 35S methionine-labelled rat islets by sera from patients with type 1 diabetes. • Found in >70% of people with type 1 diabetes at all ages. GAD is not confined to beta-cells, and is also found in other cell types. • GAD antibodies show a positive correlation with age and can persist longer than other islet cell autoantibodies. • The affinity and epitope specificity of the antibody response predicts progression of the disease process.	[37, 39, 40]
Insulinoma-associated antigen-2 (IA2)	• Identified by screening patient sera with an islet cDNA expression library. • Found in 65–75% patients at diagnosis. • Almost always detected with other islet autoantibodies and are very specific for type 1 diabetes. • More likely to appear closer to clinical onset. • Critical epitope regions/residues for IA-2A and IA-2β antibodies have been defined, with a hierarchy of risk for future development of type 1 diabetes. • Subreactivity to IA-2β is strongly associated with progression to diabetes within 5 years.	[41–44]
Zinc-transporter isoform 8 (ZnT8)	• Discovered by screening highly-expressed islet beta-cell specific molecules. • Found in 60–80% patients at diagnosis. • Typically disappear very early after disease onset. • Autoimmunity against the COOH-terminal region of ZnT8 is of particular prognostic significance. • Greatest risk of disease progression occurs in ZnT8A-positive children who are homozygous for either arginine or tryptophan at position 325.	[45, 46]
Tetraspanin-7	• Identified by mass spectrometry. • Found in approximately 19–38% of patients. • Significantly higher prevalence in children. • In addition to other antibodies, Tetraspanin-7 provides only minor further value in identifying beta-cell autoimmunity. • Not known to influence disease progression.	[47, 48]

facilitated by the ability to clone islet-reactive T cells, and to study their targets and mechanism of action. Furthermore, of note in considering the immune role in destruction of islet beta-cells, T cells, both polyclonal populations from diabetic NOD mice as well as individual cloned T cells, are able to transfer diabetes to non-diabetic immunocompromised mice.

The strongest MHC susceptibility factor associated with the immune response in type 1 diabetes is in the MHC class II region, as noted in Section 1, coding for antigen-presenting molecules that are required for $CD4^+$ T cells to recognize their antigen. The autoantibodies indicate that the B cells that produce them are likely to have interacted with CD4+ T cells. However, the presence of hyperexpression of HLA class I in insulitis, genetic HLA class I associations, and $CD8^+$ T-cell transfer experiments in mice highlight that $CD8^+$ T cells are also critical to the autoimmune process. A major barrier to progress in understanding type 1 diabetes has been the difficulty in identifying and studying islet-specific autoreactive lymphocytes from insulitis lesions in humans, with a reliance on studying the very small proportion of islet autoreactive lymphocytes circulating in peripheral blood [51].

The importance of $CD8^+$ T cells in the final effector phases of type 1 diabetes was emphasized in early identical twin-to-twin pancreas transplants. Unaffected monozygotic twins in long-term discordant pairs who were thought not to require immunosuppression because they were HLA-identical, donated the tail of their pancreas to their affected co-twin. However, the graft was rapidly destroyed by recrudescence of the type 1 diabetes disease process, with a preponderance of $CD8^+$ T cells in the insulitis that developed in the transplanted organ within weeks of transplantation and unfortunately, rapid recurrence of diabetes occurred [52].

Evidence for transfer of diabetes by T cells in humans comes from bone marrow transplantation, from donors with type 1 diabetes to non-diabetic recipients. In nine cases in which the donor had type 1 diabetes, 2 of 3 long-term survivors developed type 1 diabetes [53]. This transfer of disease can be prevented by depletion of mature T cells prior to transplantation, which is now routine practice.

What do the T cells recognize? Many, but not all, of the autoantigenic targets are those that are also targets of the humoral response, shown in Table 15.2.3.2. $CD8^+$ T cells recognizing islet autoantigens can be found within the islets, as highlighted earlier, as well as in the peripheral blood [54, 55] and some of these also demonstrate the ability to damage islets *in vitro* [56]. Under normal circumstances, autoreactive T cells are removed in the thymus, by the process of central tolerance. T cells that have sufficient affinity for peptides of self-antigens, presented on medullary thymic epithelial cells within the thymus, will be deleted. It is recognized that a number of the islet autoantigens recognized, are either not presented in the thymus or the peptide recognized by the islet antigen-specific T cells are of very low affinity and do not trigger thymic deletion. Furthermore, some of the genetic susceptibility factors associated with type 1 diabetes encode alleles that reduce thymic negative selection, as discussed in the earlier genetics section, and reviewed in [57]. In addition, recent studies have indicated that some autoantigenic targets recognized by

$CD4^+$ T cells may be hybrid peptides of two autoantigens, generating unique antigens within the beta-cells or local environment (58, 59). This may further explain why some autoreactive T cells are not eliminated by central tolerance mechanisms in the thymus during development.

The role of pathogenic $CD4^+$ T cells is less clear, as fewer of these are found within the islet infiltrate, but it is likely that they may help activation of both $CD8^+$ T cells as well as B cells to produce autoantibodies, although this has not been shown directly in man. In recent years, newer subsets of $CD4^+$ T cells including T follicular helper (T_{FH}) cells were shown to be increased in the circulation [73]. These T_{FH}, which are found in germinal centres and aid B cells in class-switching of antibodies, are important in autoantibody production. Furthermore, among the many subsets of $CD4^+$ T cells, the Treg cells, involved in terminating immune responses, are important in preventing autoimmunity under normal circumstances. While, overall, these cells are not altered in number, there is evidence that their function is defective in type 1 diabetes, being less able to control cytokine production and proliferation of effector $CD4^+$ T cells [74]. This may be related to a variety of mechanisms that are genetically encoded and include reduced sensitivity to IL-2, increased apoptosis, alteration in Treg function and instability of the expression of forkhead box P3 (FOXP3), a central transcription factor for a major subset of Tregs, and alteration of other genes involved in T reg function reviewed in [75]. In addition, not only have defects in these cells been shown in peripheral blood, but also in pancreatic lymph nodes, the draining nodes of the pancreas [76].

How are the Beta-Cells Damaged or Destroyed?

Type 1 diabetes is a disease of progressive, severe insulin deficiency caused by autoimmune beta-cell destruction. Despite historical dogma, it is increasingly clear that progression of beta-cell destruction is variable and does not always lead to complete beta-cell loss. Post-mortem histological studies of individuals who have had diabetes for more than 50 years, have indicated that some pancreatic beta-cells remain insulin-positive [77]. Almost all people with type 1 diabetes have measurable beta-cell function at diagnosis, and recently, highly sensitive C-peptide assays have shown that even years after diagnosis, many people with type 1 diabetes, particularly those diagnosed as adults, have low levels of detectable beta-cell function [77]. The source of remaining beta-cells is unclear and could relate to a "burning out" of autoimmunity, some beta-cells being more resistant to immune attack, or regeneration of beta-cells.

The islet beta-cells are likely to be damaged by a combination of both necrosis and apoptosis. Cytotoxic CD8+ T cells play a role in immune damage, and release of perforin and granzymes from the cytotoxic granules damage the cell membrane. Islet beta-cells are also particularly susceptible to damage by cytokines [78] and reactive oxygen species (ROS) [79]. The cytokines and ROS cause mitochondrial damage, and lead to increased permeability, disrupting oxygen phosphorylation and production of ATP. However, apoptosis may also play a role, and this may also be initiated by cytokine damage by TNF, as well as activation through the Fas/Fas ligand pathway.

Recent advances in imaging of beta-cells will enhance understanding of the rate of loss, and will allow the loss of beta-cell mass to be quantified. The insulin-containing beta-cell granules express vesicular monoamine transporter2 (VMAT2) and the density of this can be visualized and quantified by PET imaging [80]. Further advances in this and other MRI imaging techniques, may considerably aid the understanding of the processes of islet cell damage. In addition to the imaging techniques, turnover of islet beta-cells in the context of beta-cell death has also been studied by measurement of unmethylated insulin gene (*INS*) DNA that originates in beta-cells where the insulin gene is transcribed, compared with other tissues where no transcription takes place. Thus, these epigenetic changes can be estimated, by unmethylated to methylated *INS* gene measurements in serum by polymerase chain reaction (PCR), to provide an indication of beta-cell death. While there are limitations to this method, reviewed in [81], refinements may allow functional measurements of beta-cell mass and indicate ongoing beta-cell destruction.

Immune Intervention

As evidence points to autoimmunity as a major contributor to the pathogenesis of type 1 diabetes, this should be amenable to therapy targeting the immune system. Early trials of cyclosporin A showed that there was an apparent delay in loss of beta-cells using a non-specific immunosuppressive approach [82, 83]. However, despite much optimism that type 1 diabetes can be halted or reversed by immune intervention, in the human studies to date, this goal has not yet been achieved [84]. This may, in part, be because of the complexity and heterogeneity of the immune process in type 1 diabetes, or the fact that too many beta-cells are lost by the time of presentation. A few recent studies have shown some slowing of loss of beta-cells, as detected by preservation of C-peptide, within the first year with anti-CD3 (teplizumab, otelixizumab) [85, 86] as well as anti-CD20 targeting B cells [87]. Further promise has also been shown with agents targeting costimulatory molecules. Of importance would be the ability to more specifically target either pathogenic cells with antigen-specific tolerance strategies or boosting regulatory T cells, and clearly there is much scope for further research. These will be discussed in more detail in Chapter 15.6.3, 'Immunotherapy in Type 1 Diabetes'.

Summary

There have been considerable advances in our understanding of the genetic susceptibility and the immune pathogenesis of type 1 diabetes. However, there are still unanswered questions about the pathogenesis of type 1 diabetes, particularly in relation to the environmental factors that may trigger the immune attack, and disease heterogeneity. The refinements in modern technology that will allow more sophisticated imaging, as well as advances in our ability to interrogate the immune processes at a single cell level, and understand the interaction with islet biology should allow further progress to be made in this area.

15.3

Type 2 Diabetes

15.3.1 Epidemiology and Public Health

Sarah Wild and Jackie Price

Definition of Type 2 Diabetes

The 2006 World Health Organization (WHO) definition of diabetes is based on a fasting plasma glucose concentration of 7 mmol/L or above and/or a 2 hour venous plasma glucose value of 11.1 mmol/L or above after a 75 g glucose load during an oral glucose tolerance test (OGTT) [1]. The American Diabetes Association (ADA) definition uses a fasting glucose of 7 mmol/L or above alone to identify diabetes. Both WHO and ADA now recognize the use of non-fasting glycosylated haemoglobin (HbA1c) levels >6.5% (48 mmol/mol) to diagnose diabetes. WHO has concluded that 'HbA1c can be used as a diagnostic test for diabetes, provided that stringent quality assurance tests are in place and assays are standardized to criteria aligned to the international reference values, and there are no conditions present which preclude its accurate measurement' [2]. Diabetes may still be diagnosed using glucose criteria even if HbA1c is less than 6.5% (48 mmol/mol). In people who are asymptomatic two abnormal tests are required to diagnose diabetes. Recent research has identified clinically important subtypes of type 2 diabetes that can be distinguished by measurement of six variables: glutamate decarboxylase antibodies, age at diagnosis, body mass index (BMI), HbA1c, and homoeostatic model assessment two estimates of β-cell function and insulin resistance although several of these are not measured in routine clinical practice [3].

Estimates of diabetes prevalence (that is the proportion of people within a population with diabetes) may be based on self-reported diabetes from population surveys, medical records/diabetes registers or on models of diabetes prevalence which extrapolate data from other populations. Such estimates, based on known diabetes, have been shown to underestimate the prevalence of diabetes identified by biochemical testing by anywhere between 30% and 70% depending on the population and the year of data collection. Undiagnosed diabetes can be identified by screening.

Prevalence of Type 2 Diabetes

The prevalence of diabetes recorded in any given population is affected by the definition and data sources used. The risk of type 2 diabetes increases with age and therefore the crude prevalence of diabetes will tend to be higher in older than younger populations. As a consequence, comparisons of prevalence are usually age-standardized to enable fair comparisons. Ageing of populations and improving survival of people with diabetes contributes to increasing prevalence of diabetes over time [4] even if incidence (that is the number of people developing new diabetes each year) remains stable or declines.

Many epidemiological studies of diabetes prevalence do not distinguish between type 1 and type 2 diabetes. However, the proportion of all diabetes accounted for by type 2 diabetes is likely to be a minimum of 85% (e.g. in Scandinavian countries in which type 1 diabetes is relatively common) and may be higher than 95% in countries in which type 1 diabetes is less common. The International Diabetes Federation (IDF) produces an atlas of diabetes prevalence (https://www.diabetesatlas.org/en/). In the estimates for 2019, the world age-standardized prevalence of combined known and undiagnosed diabetes among 20–79-year-olds was estimated to be 8.3% overall and varied from 4.7% in Africa to 12.2% in the Middle East and North Africa (https://www.diabetesatlas.org/en/).

The IDF also produces projections of estimated number of adults with diabetes and have estimated that numbers of people with diabetes of 20-79 years of age in the world will increase from 463 million 2019 to 700 million in 2045. These projections of future numbers of people with diabetes take into account changes in population distribution by age and urban/rural residence for less developed countries. Increasing trends in prevalence of obesity other than those associated with urbanization in less developed countries and improvements in survival of people with diabetes

mean that these figures are likely to underestimate future diabetes prevalence.

Risk Factors for Type 2 Diabetes

Non-modifiable risk factors for type 2 diabetes include age, sex, genetic background, and ancestry. Incidence and prevalence in most countries increase with increasing age up to late middle age and fall in the oldest age groups. The incidence of type 2 diabetes among northern European populations increases with age up to 70–79 years of age. The sex ratio differs between populations with, for example, higher prevalence in European men than women but higher prevalence among Middle Eastern women than men. This probably reflects sex differences in the prevalence of obesity. A family history of type 2 diabetes increases the risk of type 2 diabetes, arising from a combination of shared genetic and environmental factors. Multiple genetic polymorphisms have been found to be associated with increased risk of diabetes, but at present these only explain a fraction of the heritability of diabetes. However, it is likely that interaction between genetic and lifestyle factors contribute to the risk of diabetes. Considerably higher prevalence of type 2 diabetes has been found among people of South Asian, African, Middle Eastern, and Hispanic descent and among indigenous populations of America, Australasia, and Pacific Islands than among European populations. The important ethnic differences in the prevalence of diabetes are discussed in detail in Chapter 15.7.3. Ethnic differences in the prevalence of diabetes may be at least partly explained by genetic adaptation to famine during evolution, resulting in a differential maladaptation to the energy imbalance that has developed in modern life, a situation termed the 'thrifty genotype'. There is evidence that fetal adaptation to the maternal environment, or programming, results in the thrifty phenotype—babies who are relatively malnourished at birth are at higher risk of developing diabetes in later life than normal birth weight babies, suggesting an important developmental component to diabetes risk.

Modifiable Risk Factors for Diabetes

Lifestyle factors associated with urbanization, particularly increases in energy intake and decreases in physical activity, lead to an increase in the prevalence of obesity and an associated increase in the risk of type 2 diabetes. Increasing prevalence of obesity is likely to explain much of the increasing prevalence and incidence of type 2 diabetes observed in recent years. The prevalence of type 2 diabetes tends to be higher in lower socioeconomic groups in developed countries and in higher socioeconomic groups in developing countries, reflecting similar patterns in the prevalence of obesity. The importance of obesity as a risk factor for diabetes is demonstrated by associations observed in numerous cross-sectional and prospective studies and in the prevention of diabetes observed with interventions resulting in weight loss in several populations [5–7]. Differences in fat distribution between populations may explain some of the ethnic differences in diabetes risk—people with central fat distribution are at higher risk of diabetes than those with peripheral fat distribution and ethnic specific cut points of BMI should be used to define obesity. Regular physical activity is associated with reduced risk of developing diabetes even after adjusting for BMI (for review see [8]). The effect of cigarette smoking is complicated by its association with BMI and fat distribution but a meta-analysis suggests that current smoking is associated with increased risk of developing diabetes [9].

Epidemiological studies investigating the role of diet have found that increased consumption of fibre and coffee is associated with a decreased risk of diabetes. High trans fatty acid intake and both absent and excess alcohol consumption have been associated with a higher risk of type 2 diabetes. However, diet is difficult to measure accurately and it is not clear how dietary components influence the risk of diabetes independent of BMI and physical activity levels. A striking inverse dose-response association has been shown between plasma vitamin C (as a marker of fruit/vegetable intake) and risk of incident diabetes, independent of lifestyle and anthropometric factors suggesting that biomarkers of dietary intake may be more reliable than self-reported dietary intake [10]. In contrast positive associations have been reported between consumption of sugar-sweetened beverages and incidence of diabetes [11].

The incidence of diabetes appears to be unchanged or increased by use of thiazide diuretics and β-blockers and unchanged or decreased by ACE inhibitors, calcium channel blockers, and angiotensin receptor blockers [12]. Treatment with antiretroviral agents is associated with an approximate doubling of the risk of type 2 diabetes [13]. Treatment with corticosteroids also increases the risk of diabetes. Diabetes is more common among people with schizophrenia, bipolar disorder, and schizoaffective disorder than among the general population and this may be related to side effects of antipsychotic drugs and increased prevalence of obesity.

Prevention of Type 2 Diabetes

Risk Scores for Diabetes

Several risk scores for diabetes have been developed either to identify people at high risk of developing future diabetes who would be eligible for primary prevention or to help identify people with undiagnosed diabetes who could be screened in order to start appropriate secondary prevention. The variables included in risk scores differ and include readily available factors from self-report on age, BMI, and family history, through those available routinely in medical records to those requiring biochemical testing of glucose and lipids. Risk scores tend to perform reasonably well in the populations in which they are developed but perform less well in other populations, particularly those of different ethnicity. Examples of risk scores include FINDRISC [14], a modified UK version of FINDRISC [15], the Cambridge Risk Score [16], the simplified Indian Diabetes Risk Score [17], and QDScore [18].

Primary Prevention

Several trials have now shown that diabetes can be prevented in a variety of populations with lifestyle intervention with long-term benefits [5, 6, 19, 20]. Metformin has also been used in some diabetes prevention studies but in general this does not appear to confer additional benefit over lifestyle intervention [21]. It remains

challenging to introduce effective diabetes prevention programmes outside the context of trials but the National Health Service in England is attempting to do this (see https://www.england.nhs.uk/diabetes/diabetes-prevention/ for more details).

Secondary Prevention and Screening

The role of screening for diabetes remains controversial with no evidence available at present to show cost-effectiveness of screening for diabetes alone. However screening for both type 2 diabetes and impaired glucose tolerance in relatively high risk populations if an intervention is offered to people with impaired glucose tolerance appears to be cost effective [22]. The Anglo-Danish-Dutch Study of Intensive Treatment In People with Screen Detected Diabetes in Primary Care (ADDITION) trial found that intensive management of patients with screen-detected type 2 diabetes was associated with a small, non-significant reduction in the incidence of cardiovascular events and death [23].

Complications of Diabetes and Tertiary Prevention

Complications of diabetes make the major contribution to healthcare costs of treating people with diabetes. Many people will have macrovascular (coronary, cerebrovascular, or peripheral arterial disease) and microvascular (retinopathy, nephropathy, and neuropathy) complications of diabetes present at diagnosis of diabetes. Increasing duration of diabetes and poor glycaemic control are important risk factors for microvascular disease and hypertension and dyslipidaemia, which are common among people with type 2 diabetes, are important risk factors for macrovascular disease. Diabetes is a common cause of blindness and end-stage renal disease and is the leading cause of non-traumatic leg amputation. It is important that evidence-based approaches such as those used in national guidelines are used to screen for and manage complications of diabetes and their risk factors.

Depression is approximately twice as common among people with diabetes compared with the general population. Type 2 diabetes is also associated with an increased risk of cognitive impairment and dementia. Collated results from a large number of epidemiological studies indicate that overall, people with diabetes have a 1.2–1.7 times greater decline in cognitive performance than those without diabetes and are 1.6 times more likely to develop dementia. Perhaps predictably, given the association between diabetes and cardiovascular disease, diabetes is associated with a 2.2–3.4 times greater risk of vascular dementia.

Non-alcoholic fatty liver disease (NAFLD, which covers a spectrum ranging from fat accumulation alone (steatosis), through steatohepatitis (NASH) and advanced fibrosis to end-stage liver disease with cirrhosis and hepatocellular carcinoma), occurs more commonly in people with type 2 diabetes than those without diabetes. Prevalence of NAFLD among people with diabetes ranges from 34% to 74% in studies of participants unselected by BMI but has been reported to be up to 100% in those with coexistent obesity. The severity of NAFLD is also increased in type 2 diabetes and several studies have shown that type 2 diabetes is a risk factor for progression of NAFLD from steatosis to fibrosis and cirrhosis. The presence of NAFLD among people with diabetes confers increased risk of cardiovascular disease and mortality from all causes [24].

Mortality

Estimating the effect of diabetes on mortality is difficult from routine data because diabetes is poorly recorded on death certificates. Life expectancy for people with diabetes in Scotland is between 0 and 6 years shorter on average compared to people without diabetes, depending on age, sex, and socioeconomic status [25]. The global mortality attributable to diabetes and its complications for 20-79- year-olds in the year 2019 was estimated to be 4.2 million deaths, equivalent to 11.3% of all death. Older studies suggest that relative risks of mortality for people with diabetes are approximately double those compared to those without diabetes but relative risks of mortality associated with type 2 diabetes have declined in developed countries in recent years. Relative risks of mortality associated with diabetes are generally higher for younger than older people, for women than for men, for type 1 diabetes than type 2 diabetes and for cardiovascular disease than for all-cause mortality. Cardiovascular disease accounts for a large proportion of deaths among people with diabetes in developed countries with larger proportions of deaths due to infectious diseases and renal disease reported in less developed than more developed countries.

15.3.2 Presentation and Natural History of Type 2 Diabetes

Roy Taylor

Clinical Presentations of Type 2 Diabetes

Screening

Presence of risk factors for type 2 diabetes such as a family history of the disease or obesity allow targeted screening. Given the typically long phase of prediabetes, this is of benefit. In an era when screening was much less common, tissue damage was present in around 50% of people newly diagnosed [1].

Thirst, Polydipsia, and Polyuria

These symptoms result from an osmotic diuresis as a consequence of hyperglycaemia. For glucose to escape into the urine, plasma concentration must exceed the renal threshold for tubular reabsorption of glucose. The renal threshold averages 11 mmol/L but displays a wide individual variation of around 6–14 mmol/L [2]. The maximum absorptive capacity rises with age such that older people exhibit glycosuria at higher plasma glucose levels [3]. They also have a higher threshold for thirst [4].

Hyperosmolar Hyperglycaemic Syndrome

The principal clinical features of this syndrome are profound dehydration with confusion, and associated focal neurological symptoms such as hemi-paresis or hemi-sensory abnormalities may easily be confused with stroke. Mild ketosis may be present at diagnosis simply because of antecedent decrease in food intake, and calculation of plasma osmolarity ((sodium + potassium) × 2 + urea + glucose) is important to distinguish this from ketoacidosis.

Infections

Leucocytes exhibit paralysis of phagocytic and other functions above glucose concentration of 11 mmol/L [5]. This explains the impaired ability to fight off bacterial and fungal infections. Recurrent or refractory yeast infections, vaginal candidiasis in women, or balanitis in men, may draw attention to previously undiagnosed diabetes.

Very rare but serious infective presentations of diabetes must be considered. Necrotizing fasciitis is commoner in people with diagnosed or undiagnosed diabetes [6]. Fournier's gangrene (gangrene of the perineum and genitalia) is associated with diabetes in almost 50% of instances [7]. The rare and facial/maxillary sinus fungal infection mucormycosis is most often associated with diabetes [8].

Complications of Diabetes

Type 2 diabetes frequently presents for the first time with acute myocardial infarction or stroke. Symptomatic loss of vision due to macula oedema, vitreous haemorrhage or central/ branch retinal vein occlusion may occasionally be the presenting feature. Very early ophthalmological treatment is essential as the initial treatment of the diabetes will decrease blood glucose levels, cause retinal blood flow to return acutely to normal levels, and may result in marked worsening of the retinopathy. As loss of pain sensation in the feet, affecting up to 60% in people with newly presenting diabetes [9, 10], is usually unnoticed, foot ulcer or black toe are common presentations.

Acute diabetic mononeuropathy and diabetic amyotrophy are much less common presenting features.

Pregnancy

Presentation of type 2 diabetes during pregnancy is not uncommon due to the physiological insulin resistance which increases through the second and early third trimester. Usually, true type 2 diabetes can be distinguished from gestational diabetes if HbA1c is raised (indicating pronged hyperglycaemia) or if it is detected before 24 weeks. Screening is wise for all women at higher risk of type 2 diabetes as early in pregnancy as healthcare resources allow.

Natural History of Prediabetes

The earliest predictor of development of type 2 diabetes is low insulin sensitivity in skeletal muscle [11–14]. This is associated with raised plasma insulin levels, and lack of ability to store meal-derived glucose as glycogen [15–17]. Meal-derived glucose must either be stored as glycogen, oxidized, or converted to triglyceride for storage. Especially as the process of *de novo* lipogenesis is stimulated by higher insulin levels [17, 18], hepatic fat accumulation is enhanced. Excess fat deposition in the liver is a strong predictor of development of diabetes [19–24]. In individuals with normal glucose tolerance, there is a very low 8-year incidence of type 2 diabetes if fatty liver is excluded, whereas if present the risk of developing diabetes rises fivefold [19]. In support of this, a temporal progression from weight gain to raised liver enzymes, onwards to hypertriglyceridemia and then glucose intolerance has been demonstrated [23, 25].

In the Nurses' Health study, women who put on weight during adult life and achieved body mass index (BMI) of between 23 and 25 exhibited a fourfold increase risk of diabetes compared with those whose BMI remained below 22 kg/m^2 [26]. This is a striking level of risk associated with very modest accumulation of excess total body weight, although usually overshadowed by the 39-fold increase in prevalence if BMI increases to over 35 kg/m^2 [26].

The 2008 Twin Cycle Hypothesis postulated that type 2 diabetes only occurred after a prolonged period of positive calorie balance [27]. Liver fat would gradually accumulate, cause increased export of triglyceride from the liver to all tissues, and result in increased fat exposure of the pancreatic islets. Consequently, a slow decline in beta-cell ability to respond to meals was postulated to pass a threshold after which a relatively rapid rise in plasma glucose levels would occur. The postulated time course was subsequently found to be consistent with the data from the Whitehall II study [28]. The Whitehall II study demonstrated that in an initially normoglycaemic population followed prospectively, those people developing diabetes exhibited a slight and gradual rise in fasting glucose over at least 12 years [28]. This was followed by a marked rise over an average of 18 months immediately prior to diagnosis. This insight has replaced the previous assumption that there would be a slow linear rise in fasting plasma glucose and gradual beta-cell decompensation [29].

The rate of decrease in glucose tolerance in first-degree relatives of type 2 diabetic individuals is determined by decline in beta-cell function, while the degree of muscle insulin sensitivity changes little [30, 31]. This mirrors observations on populations showing that the transition from hyperinsulinaemic normal glucose tolerance to overt diabetes involves a rapid rise in glucose levels as a result of a relatively small further loss of acute β-cell competence [32, 33]. The potential to halt or at least slow the progression to type 2 diabetes has been demonstrated by several population-based intervention studies. The Finnish Diabetes Prevention Programme demonstrated a 48% decrease in conversion from impaired glucose tolerance to type 2 diabetes after 4 years [34]. In that study, the central role of weight loss is demonstrated by the observation that change in weight of 5kg or more was associated with similar decrease in diabetes incidence in both intervention and control groups. After 15 years of follow-up in the Diabetes Prevention Programme, the initial weight loss of 5 kg (falling to 2 kg) was associated with a 9% decrease in risk of onset of type 2 diabetes [35]. The Da Qing study reported the longest follow-up, with a 19% decrease in diabetes incidence after 23 years [36].

Natural History of Diabetes

The Belfast diet study provided the first clear information on the apparently progressive nature of type 2 diabetes [37]. Fasting plasma glucose levels rose steadily over 6 years with increasing requirement for oral hypoglycaemic agents. In the UK Prospective Diabetes Study individuals were managed according to randomized group, with tighter glycaemic control in the intervention group [29, 38]. There was a striking deterioration in blood glucose control over years, and the rise in average blood glucose levels flattened out only when a majority had been transferred to insulin therapy. There was no difference in the rate of deterioration between intervention and control groups. 50% of people required insulin therapy 10 years after diagnosis. More detailed analysis showed that the deterioration was due to steady decline in beta-cell competence rather than any change in insulin resistance [39].

These data appeared to confirm the clinical impression that type 2 diabetes was inevitably progressive, requiring more and more oral agents and inexorably moving towards insulin requirement. However, these observations were made in the context of year-on-year weight gain. The observations relate only to a population of people with type 2 diabetes who follow the common trajectory of steady weight gain after diagnosis. Under these circumstances, the supranormal liver fat present at the time of diagnosis would continue to drive the underlying pathogenic processes [40–42]. However, current clinical guidelines reinforce the inevitably progressive view of natural history of the disease, emphasizing the expectation that hypoglycaemic agents must be added sequentially [43].

The possibility that the natural history could be influenced by weight loss was first raised over 40 years ago [44]. In 2005, Petersen and colleagues defined the detailed effects of moderate weight loss in type 2 diabetes [45]. They demonstrated that 8 kg weight loss over 2 months brought about normalization of liver fat content and normalization of hepatic insulin sensitivity. This allowed a clinically useful decrease in fasting plasma glucose levels. The rapidity of return to normal fasting plasma glucose levels in type 2 diabetes was observed following bariatric surgery [46], and subsequently in the Counterpoint study of calorie restriction [27]. The latter study was conducted to test the Twin Cycle Hypothesis of the aetiology of type 2 diabetes. It observed complete normalization of liver insulin sensitivity within 7 days of commencing a diet of 600 kcal/day and recovery of normal beta-cell function within 8 weeks. Subsequent studies found that this normalization of liver and pancreas function is durable over 6–12 months of weight stability during avoidance of weight regain while eating normally [41, 42]. The natural history of type 2 diabetes can now be seen to depend upon body weight. If the personal level of weight which allowed type 2 diabetes to develop is maintained or even allowed to increase, then the disease is steadily progressive. If weight loss sufficient to normalize intraorgan fat is achieved and maintained, non-diabetic glucose control can be re-established.

Insulin resistance in muscle has long been regarded as being responsible for the continued hyperglycaemia. Certainly, the muscle insulin resistance determines poor glycogen storage after meals [15] and drives on hepatic *de novo* lipogenesis [17] as the natural history of type 2 diabetes unfolds. However, reversing the processes in liver and pancreas which directly cause the syndrome of type 2 diabetes has minimal effect upon muscle insulin resistance [40, 41]. Insulin resistance in muscle appears to be permissive, leading to increase in liver fat levels in the circumstance of excess calorie intake, but not determinant for the natural history of type 2 diabetes.

Natural History of Post-Diabetes

Following demonstration of durable remission of type 2 diabetes after both dietary and surgically induced weight loss, it is important to describe the clinical state of post-diabetes. This is characterized by relatively low risk of both micro- and macro-vascular complications. It is defined as having achieved a non-diabetic level of HbA1c or fasting plasma glucose, after weight loss and off all hypoglycaemic agents. Confirmation by a second test at least two months later is required [47]. Even though HbA1c may be in the range associated with prediabetes, the clinical implications are very different. Prediabetes is a state of high risk for cardiovascular events whereas post-diabetes is not. This is illustrated in Figure 15.3.2.1, showing the change in major components of cardiovascular risk before and after weight loss plus 6 months of weight stability [41]. During the transition from diabetes to post-diabetes, the QRISK score falls on average from 23% to 7%. In the study group, with an average chronological age of 55 years, calculated heart age fell from 71 to 56 years.

The first hint that type 2 diabetes was a fully reversible syndrome came from bariatric surgery [48]. The phenomenon was examined in a randomized prospective study comparing gastric banding with intensive medical therapy for type 2 diabetes [49]. Mean fasting plasma glucose normalized in many, and this was related to the degree of weight loss rather than allocation to either surgical or medical group [49]. The rapidity of the fall in fasting plasma glucose after bariatric surgery led to the widespread belief that surgery itself brought about specific changes mediated via incretin hormone secretion [46, 50, 51]. This assumption overlooked the major change which follows bariatric surgery: an acute, profound decrease in calorie intake with sudden increase in carbon flow from stored triglyceride depots. Several more recent studies have confirmed the dramatic effect of calorie restriction *per se* with no role of incretins in achieving rapid glucose control [52, 53].

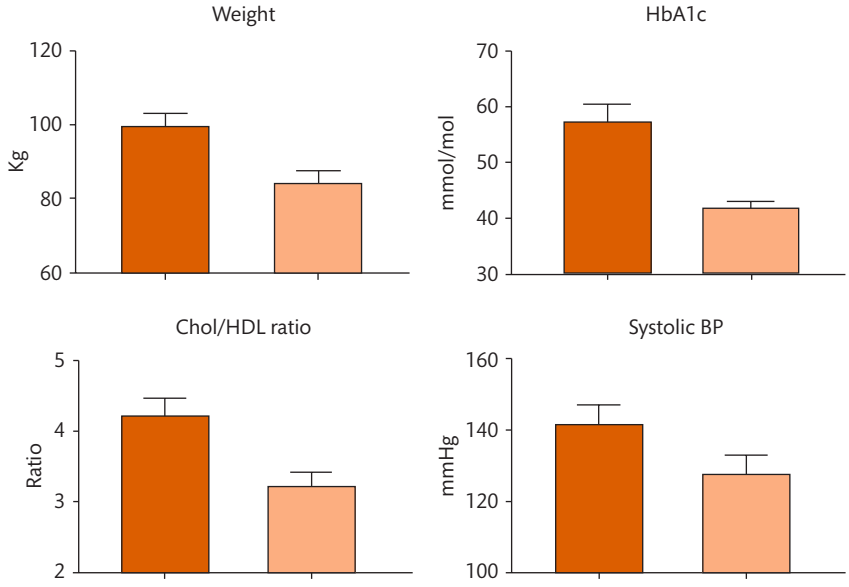

Figure 15.3.2.1 Effect of weight loss in type 2 diabetes on components of cardiovascular risk before (darker bars) and after 6 months of weight maintenance (lighter bars). The average QRISK 10-year cardiovascular risk score fell from 23.2% to 6.9%.
Data are plotted from Steven *et al.* with permission from American Diabetes Association.

The Counterpoint study demonstrated that in short duration type 2 diabetes, decreasing calorie intake sharply allowed return to normal fasting plasma glucose within 7 days [40]. The rapid return to normal was associated with a 30% decrease in liver fat content and normalization of insulin sensitivity in regulating hepatic glucose production. It also demonstrated that over the 8-week study period, the level of fat in the pancreas gradually decreased and in step with this, first phase insulin response returned to within the normal range [40].

The durability of post-diabetes was first tested in the Counterbalance study. Weight loss of around 15 kg followed by 6 months of weight stability achieved stable intrahepatic and intrapancreatic fat levels with both liver and pancreas function remaining normal [41].

Whether these changes could be reproduced by existing nursing or dietetic staff in Primary Care was examined in the Diabetes REmission Controlled Trial (DiRECT) [54]. This demonstrated that weight loss of 15 kg or more could be achieved in 25% with remission of type 2 diabetes maintained over 12 months in 46%, respectively (intention to treat analysis). To bring about this change in natural history of type 2 diabetes, the intervention consisted of 8

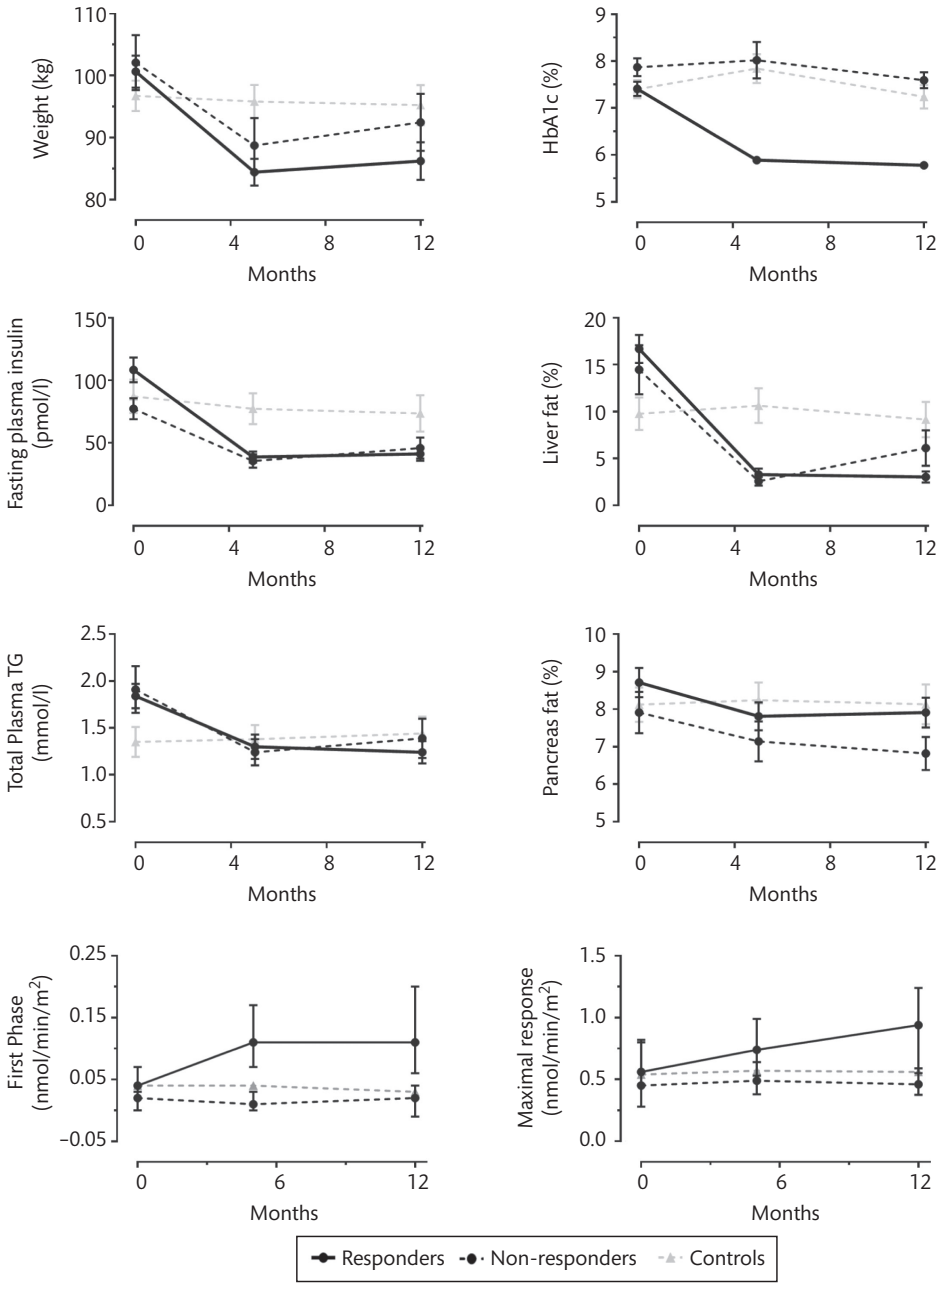

Figure 15.3.2.2 Change in metabolic parameters from baseline after weight loss on an isocaloric diet (5 months) and after the weight maintenance phase of DiRECT (12 months). Participants randomized to the control group continued best management according to guidelines. Those randomized to intervention group stopped all antihyperglycaemic therapy on day 1 of the weight loss diet, and data are shown separately for those who achieved non-diabetic levels of HbA1c (<48 mmol/mol) and fasting plasma glucose (<7.0 mmol/L).

hours of structured training for a primary care nurse or dietitian. Currently, data on durability of remission are sparse, but case histories suggest that if weight regain is avoided, the natural history of type 2 diabetes can be changed to long-term non-diabetic blood glucose control [55–57].

It is important to recognize the lack of relevance of the absolute level of BMI in maintaining the post-diabetic state. After weight loss in both Counterbalance and DiRECT, half of those who returned to non-diabetic glucose control still had a BMI greater than 30, but this had no impact upon their ability to avoid subsequent intraorgan fat re-accumulation during weight stability. This illustrates the important concept of the Personal Fat Threshold [58]. Each individual had dropped below a personal threshold permitting safe storage of fat in the subcutaneous compartment, and this was equally so whether BMI dropped from 40 to 36 or 28 to 24 kg/m². The ability to store fat safely in adipose tissue varies considerably between otherwise normal individuals [59, 60], and once that capacity has been exceeded the body has to use other storage sites including liver and pancreas. If pancreas fat exposure is too high there is clearly variable susceptibility to beta-cell dysfunction. Individuals can exceed their personal fat threshold at BMI's well within the 'normal' range. In the United Kingdom Prospective Diabetes Study [1], at the time of diagnosis of diabetes, 36% had a BMI less than 25 kg/m². The BMI distribution of participants was right-shifted compared with that of the UK population of that time, when 64% had a BMI less than 25 kg/m² [61].

The natural history of type 2 diabetes appears to depend upon more fat supply than could be tolerated by the beta-cells. Excess saturated fat produces endoplasmic reticulum stress, and that this is associated with dedifferentiation of the beta-cell [62–65]. In this survival mode its specialized functions are shut down. Removal of the fat allows re-expression of the insulin gene and resumption of acute glucose mediated insulin secretion [66]. When an individual achieves remission of type 2 diabetes after weight loss, that post-diabetic state is durable providing that weight regain is avoided [42, 67]. The changes in HbA1c and important physiological parameters during the natural history of post-diabetes is shown in **Figure 15.3.2.2**. The first phase insulin response is stable from the end of the weight loss phase to 12 months, and the maximal capacity of the beta-cells increases over the whole 12-month period.

Given that muscle insulin resistance remains essentially unchanged during reversal to the non-diabetic state [40, 67], individuals can be advised that weight regain of sufficient degree will inevitably precipitate return to the diabetic state.

Subsequent studies have found that the normalization of liver and pancreas function is durable over 6–12 months of weight stability during avoidance of weight regain while eating normally [41, 42]. Case reports indicate durability of the post-diabetic state for up to 5 years [55–57]. However, regular follow-up remains essential to monitor and minimize risk of weight regain.

15.3.3 Pathogenesis

Mark Walker, Xuefei Yu, and Amalia Gastaldelli

Introduction

Hyperglycaemia is the hallmark of type 2 diabetes. It results from a combination of decreased insulin secretion and insulin resistance (also referred to as decreased insulin sensitivity) as stated in the WHO definition of type 2 diabetes. These two characteristics are physiologically linked as demonstrated by previous studies of subjects with different glycaemic states. As shown in **Figure 15.3.3.1**, there exists an inverse hyperbolic relationship between insulin secretory response and insulin sensitivity for subjects with normal glucose tolerance. The relationship persists in patients with diabetes, but the curve is shifted downwards such that less insulin is secreted for a given level of whole body insulin sensitivity [1]. Progression from normal glucose tolerance to diabetes results from the failure of insulin secretion to compensate for the level of insulin resistance. Even within the range of normal glucose tolerance, there is evidence of progressive decrease in the insulin secretory response once adjustment has been made for the degree of insulin resistance [2] (**Figure 15.3.3.2**).

Over the last few decades, a large number of detailed physiological studies have been conducted to understand glucose metabolism in healthy, non-diabetic subjects and how it is perturbed in type 2 diabetes [3]. In the fasting state in non-diabetic subjects, circulating insulin acts primarily at the liver to regulate hepatic glucose release. In type 2 diabetes, fasting hepatic glucose release is increased and closely correlated with the fasting glucose concentration. The increased hepatic glucose release reflects the interaction of a number of factors including decreased hepatic insulin sensitivity and raised fasting glucagon levels. In the postprandial state in non-diabetic subjects, the increased circulating insulin levels serve to suppress hepatic glucose release and promote glucose uptake and metabolism in the peripheral insulin sensitive tissues, in particular skeletal muscle [3]. These processes are altered in type 2 diabetes and contribute to the postprandial hyperglycaemia. Specifically, the combination of impaired insulin secretion and decreased insulin sensitivity at the liver and peripheral tissues result, respectively, in impaired suppression of hepatic glucose release and impaired peripheral glucose uptake and metabolism [3]. The purpose of this chapter is to review the mechanisms underlying these physiological abnormalities that contribute to the hyperglycaemic state in type 2 diabetes.

Genetic Architecture

Type 2 diabetes is a complex trait with genetic and non-genetic factors contributing to the pathogenesis. The non-genetic factors are well documented as described in Chapter 15.3.1, 'Epidemiology and Public Health', with increased adiposity and physical activity being key factors. Our understanding of the genetic basis of type 2 diabetes has evolved over the last 12–15 years, driven by mapping of the human genome and technological advances in genotyping and sequencing.

Genome-wide association studies (GWAS) in populations of North European extraction have found that the genetic structure is primarily based upon common variants (minor allele frequency >5%) across many susceptibility loci [4]. At the present time, around 200 susceptibility loci have been identified. While rare variants in

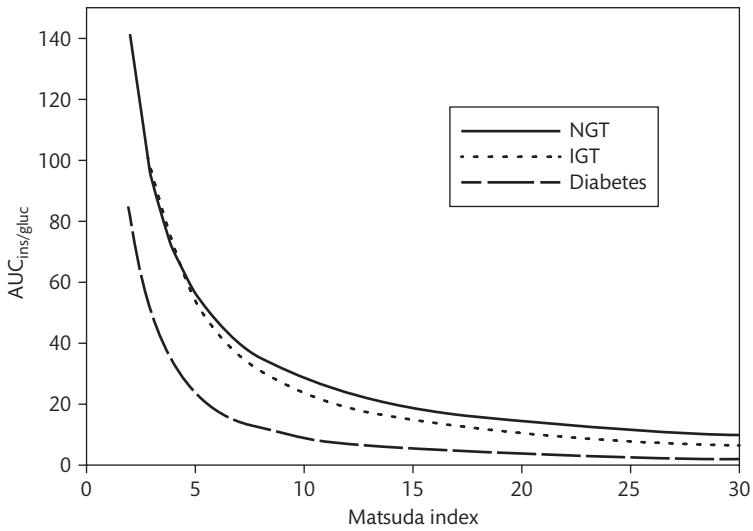

Figure 15.3.3.1 Inverse hyperbolic relationship between insulin secretory response (AUC ins/gluc) and whole body insulin sensitivity (Matsuda index) measures derived during an oral glucose tolerance test. For any given level of insulin sensitivity, the insulin secretory response is less in the diabetic versus normal glucose tolerant subjects.

known monogenic genes can contribute to diabetes segregation within certain families, there is little evidence for the role of rare variants in other loci [5]. This may not apply to genetically isolated populations such as the Greenland Inuits, in which a variant in the *TBC1D4* gene specific to this population was found to predispose to diabetes [6].

The common risk variants identified by GWAS are functionally weak, so an individual's genetic type 2 diabetes risk is a function of the accumulated number of common risk variants that they carry [7]. The level of risk is predicted to be modulated further by potential interactions between specific variants, and other genetic variants and non-genetic factors.

The majority of the susceptibility loci have been linked to impaired pancreatic beta-cell function [8]. This is not surprising as decreased insulin secretion is a prerequisite for hyperglycaemia, the defining feature of all type 2 diabetes. Variation at the *TCF7L2* locus provides the strongest signal for type 2 diabetes risk. It is involved in the WNT signalling pathway, and early physiological studies pointed to a role in modulating the incretin-insulin secretory axis. However, the exact mechanisms by which variation in other susceptibility gene loci such as *CDKAL1* and *CNKN2A/2B* remain to be defined. An important lesson arose from the study of *FTO*. Variation in this gene was linked to increased BMI. However, subsequent analysis demonstrated that the key risk variant did not alter *FTO*

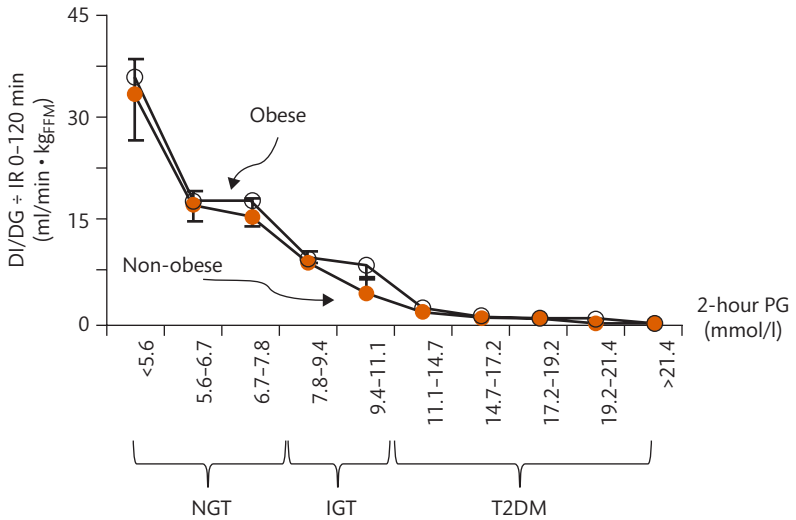

Figure 15.3.3.2 Disposition index (insulin secretion/insulin resistance); calculated as ΔAUC-Insulin/ΔAUC-Glucose ÷ clamp derived IR) plotted against 2-hour plasma glucose from an oral glucose tolerance test. Even in the normal glucose tolerance range, the disposition index markedly falls as the 2 hour plasma glucose increases in both obese and non-obese subject groups.

Gastaldelli A, Ferrannini E, Miyazaki Y, Matsuda M, DeFronzo RA. Beta- cell dysfunction and glucose intolerance; results from the San Antonio Metabolism (SAM) study. *Diabetologia*, 2004; **47**: 31–9. (Ref 2)

expression, but influenced expression of two distant genes, *IRX3* and *IRX5*, and these were involved in the process of thermogenesis [9]. In other words, while the diabetes risk variant was located at the *FTO* locus, the increased risk was mediated via regulation of genes located some physical distance away. This could complicate the delineation of the underlying mechanisms of diabetes susceptibility if it applies to other risk loci.

Adipose Tissue

Increased adiposity is a key risk factor for the development of type 2 diabetes. The rapid rise in the worldwide prevalence of type 2 diabetes is primarily driven by a concordant increase in the prevalence of obesity as described in Chapter 14.1.2. Our understanding of how and why obesity is linked to the pathogenesis of type 2 diabetes has evolved dramatically over the last few decades leading to the concept of lipotoxicity. A key question is what factors contribute to adipose tissue dysfunction that in turn impact on pancreatic beta-cell function and target tissue insulin sensitivity.

Adipose Tissue Dysfunction and Inflammation

Adipocyte number and distribution are key determinants of their function in man. Adipocyte size has been found to be negatively correlated with whole body insulin sensitivity in man [10]. An elegant study found that the number of adipocytes increases during childhood, but then remains stable throughout adulthood [11]. This implies that increased lipid storage in adulthood is achieved by adipocyte hypertrophy of the existing complement of cells. This is important as hypertrophy is linked to adipocyte stress, possibly through cellular hypoxia that is the trigger for a number of adverse processes including adipose tissue inflammation [12]. This involves the expression of pro-inflammatory cytokines by adipocytes and the attraction and infiltration of immune cells such as macrophages that serve to amplify the inflammatory process within the adipose tissue stores. A positive correlation was found between macrophage abundance and both BMI and adipocyte size in human adipose tissue [13]. The release of pro-inflammatory cytokines, for example TNF-alpha, is predicted to interfere with insulin action within the adipocytes and other local tissues such as muscle. Expansion of the adipose tissue stores leads to increased circulating fatty acid levels [14] and a relative decrease in circulating adiponectin [15]. Adiponectin is exclusively secreted by adipose tissue and exerts major effects on glucose metabolism in liver and muscle.

Adipose Tissue Insulin Resistance

Adipose tissue lipogenesis is regulated by insulin that promotes free fatty acid (FFA) re-esterification and triglyceride synthesis. Since adipose tissue lacks the enzyme glycerol kinase, it relies upon glucose and pyruvate to make glycerol-3-phosphate that is used to synthesize triglyceride. Insulin not only promotes fatty acid re-esterification but also glucose uptake in the adipose tissue. Moreover, insulin is the most potent antilipolytic hormone, since it inhibits triglyceride hydrolysis and fatty acid release. In type 2 diabetic patients, the antilipolytic effect of insulin is compromised leading to increased fasting and postprandial fatty acid concentrations, despite normal or raised circulating insulin levels [16]. This is recognized as adipose tissue insulin resistance that promotes the overflow of FFAs that are then taken up by other tissues and contribute to ectopic fat accumulation (see next).

Adipose Tissue Distribution

It is well recognized that adipose tissue distribution affects type 2 diabetes risk. Familial partial lipodystrophy is a monogenic condition characterized by decreased peripheral subcutaneous fat stores and compensatory increase in central fat deposition with increased visceral adiposity. This extreme form of fat redistribution is associated with decreased insulin sensitivity and increased risk of type 2 diabetes, fatty infiltration of the liver and cardiovascular disease. Genetic cluster analysis has been applied in two recent studies to identify overlapping clusters comprising 11 [17] and 53 [18] common genetic variants associated with decreased insulin sensitivity. Both studies found that the clusters were associated with increased central and decreased peripheral adiposity, but an increased risk of type 2 diabetes and coronary artery disease. This highlights the importance of altered adipose tissue distribution and diabetes risk.

Ectopic fat deposition describes the situation where lipid is stored in tissues other than adipose tissue, such as the liver, muscle, and pancreas. It arises when an individual's adipose storage capacity is overwhelmed, and is a particular problem in subjects with limited peripheral subcutaneous adipose tissue stores. Ectopic fat deposition *per se* is not a problem so long as the recipient tissues have the capability to fully metabolize the stored lipid. This capability appears to be impaired in type 2 diabetes and contributes to the situation of incomplete lipid metabolism and lipotoxicity.

Pancreatic Beta-Cell

Insulin secretion in non-diabetic subjects in response to either an oral or intravenous glucose load is characterized by an initial rapid response over 10 to 15 minutes (first phase) followed by slower more prolonged rise called the second phase [19]. It is well established that this insulin response is altered in type 2 diabetes, with a blunted first phase response and a delayed and lower second phase. These changes contribute to the hyperglycaemia of type 2 diabetes. It has been demonstrated that the first phase response plays a crucial role in regulating hepatic glucose output in non-diabetic subjects [20] and that the impaired first phase response leads to impaired suppression of hepatic glucose output and postprandial hyperglycaemia in type 2 diabetes [19].

By administering a progressive stepped glucose infusion, a dose response curve can be generated for insulin secretion rates against plasma glucose levels [21]. The slope of this curve decreases as glucose intolerance progresses to frank type 2 diabetes (**Figure 15.3.3.3**). In other words, there is a progressive decrease in the insulin secretion rate for a given plasma glucose concentration. Type 2 diabetes is characterized by abnormalities of pancreatic beta-cell function in the fasting state. Basal insulin secretion shows regular periodic oscillations in non-diabetic individuals which is lost in patients with type 2 diabetes [22]. Furthermore, the fasting proinsulin to insulin ratio is increased in type 2 diabetic patients compared to non-diabetic controls which is thought to reflect incomplete proinsulin processing in the diabetic state.

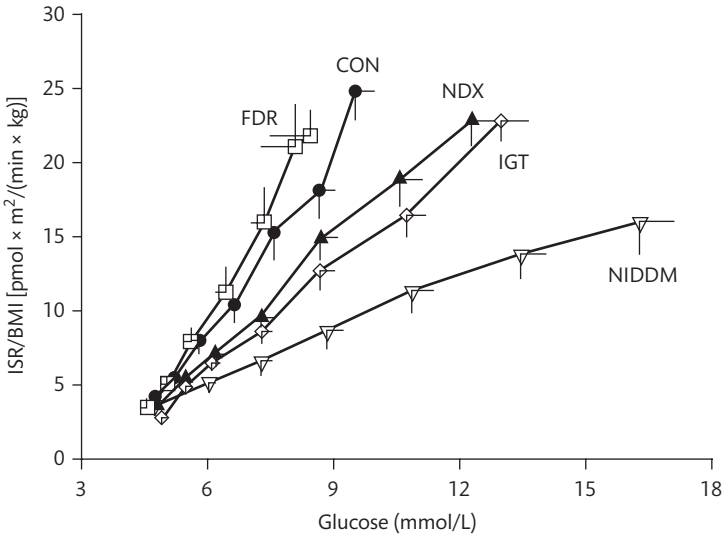

Figure 15.3.3.3 Dose response curves for insulin secretory rates versus plasma glucose concentration curves derived using a stepped glucose infusion. Curves are shown for subjects with different degrees of glucose tolerance, including those with normal glucose tolerance with (FDR) and without (CON) a family history of diabetes, and those with established type 2 diabetes (NIDDM).

While the pancreatic beta-cell phenotype is well characterized in type 2 diabetes, the underlying mechanisms remain to be determined. There is evidence that the impaired insulin secretion results from both decreased beta-cell function and mass.

Beta-Cell Genetic Susceptibility

As specified, the majority of genetic susceptibility loci identified to date are associated with impaired pancreatic beta-cell function. Some of the risk variants are within genes already associated with monogenic diabetes such as Wolfram Syndrome (*WFS1*) and different forms of Maturity Onset Diabetes of the Young (*GCK* and *HNF1A*). Others were within genes known to be involved in the insulin secretory process such *SLC30A8*, and *KCNJ11* that encodes part of the potassium channel. Physiological studies have tried to dissect the relationships between gene variants and the beta-cell phenotype. Such an approach showed that *TCF7L2, SLC30A8*, and a variant in the gastric inhibitory peptide receptor gene (*GIPR*) were all associated with raised circulating proinsulin levels and a decreased early insulin response, a pattern thought to reflect decreased insulin secretion on a background of decreased beta-cell mass/processing [8]. A further study examined the relationship between known risk variants and the insulin response to an intravenous glucose challenge to try to identify genes that affect the intrinsic beta-cell response [23]. Variants in *MTNR1B* and *CDKAL1* showed the strongest association, while variation in *TCF7L2* was comparatively weak supporting the concept that variation at this gene locus affects insulin secretion by mechanisms beyond the beta cell.

Beta-Cell Dysfunction

A series of mechanisms have been implicated in the development of pancreatic beta-cell dysfunction and type 2 diabetes. However, these have invariably been investigated using pancreatic islets or beta-cell lines derived from rodent models of diabetes. It well known that there are differences between rodent and human islets, for example, in terms of cellular composition and hyperplastic capacity. While the molecular mechanisms are expected to be the same across species, their relative importance may differ between rodents and man. With this in mind, emphasis has been given to those mechanisms where there is evidence for a role in type 2 diabetes in man.

The endoplasmic reticulum (ER) is a membranous tubular system involved in protein synthesis, and the removal of protein products. A number of conditions can lead to ER stress, including excess pro-inflammatory cytokines, and raised glucose and lipid levels that are known to impair beta-cell function [24]. ER stress elicits an adaptive reaction called the unfolded protein response (UPR) that temporarily decreases the ER synthetic output and increases the removal of protein products. In this way the stress is relieved and ER homeostasis is restored. A facet of the UPR in beta-cells is a decrease in insulin secretion that under chronic conditions will predispose to diabetes. Furthermore, failure of the UPR to restore ER homeostasis can with time lead to activation of the pro-apoptotic pathway and a loss of beta-cells [24]. There is evidence that ER dysfunction contributes to type 2 diabetes in man. First, mutations of the *WFS1* gene lead to altered ER function, and common low penetrant *WFS1* variants increase the susceptibility to type 2 diabetes [25]. ER distension is a marker of ER stress and has been identified in isolated pancreatic islets from type 2 diabetic patients [26].

There is strong evidence that sustained metabolic stress can impair pancreatic beta-cell function. Chronic elevated glucose levels decrease the expression of PDX-1, a key regulator of insulin gene transcription [27]. This appears to be mediated in part by the increased generation of reactive oxygen species (ROS) and underlies the concept of glucotoxicity. Similarly, a sustained increase in saturated fatty acid levels, such as palmitate, has been shown to impair beta-cell function and insulin secretion [28]. The mechanism appears to involve increased ROS production by the mitochondria and peroxisomes [29] and the induction of ER stress. The combination

of raised glucose and saturated fatty acid levels (glucolipotoxicity) is thought to be particularly harmful to beta-cell function.

Insulin secretion is highly energy dependent. This is reflected in the high mitochondrial content of pancreatic beta-cells that generates the required ATP through oxidative phosphorylation. Mutations of the mitochondrial DNA that impair mitochondrial function and ATP generation can lead to diabetes in man [30]. The role of mitochondrial dysfunction in type 2 diabetes remains to be fully defined. However, it is recognized that decreased mitochondrial DNA content can decrease insulin secretion, and that mitochondrial DNA content has been shown to decline with age in isolated human islets [31]. Uncoupling protein 2 (UCP2) is expressed by pancreatic beta-cells [32]. Increased UCP2 expression increases proton leak by the respiratory chain, leading to decreased ATP synthesis and decreased insulin secretion. Hyperglycaemia has been shown to increase UCP2 expression which could contribute to the mechanism of beta-cell glucotoxicity [32].

Immune cell infiltration and amyloid deposition have been identified in pancreatic islets in a proportion of patients with type 2 diabetes [33]. The macrophage is the predominant immune cell, with evidence for a pro-inflammatory subtype that predominates in type 2 diabetes islets and mediates the inflammatory process through cytokine release, in particular IL-1B. As a consequence, anti-IL-1B immune therapies have been developed and have been found to improve pancreatic beta-cell function and blood glucose levels in patients with type 2 diabetes [34]. There is extensive evidence from animal studies that elevated saturated fatty acids, including palmitate, trigger the pro-inflammatory process in pancreatic islets. The accumulation of islet amyloid is another activator [33]. Pancreatic islet amyloid deposition has been long been recognized as a feature of type 2 diabetes [35]. Islet amyloid polypeptide (IAPP) is cosecreted with insulin and is non-toxic in its monomeric form. However, there is recent evidence that oligomerization of human IAPP to form aggregates within islets can activate the pro-inflammatory response and impair insulin secretion in type 2 diabetes [33].

The mechanisms and their interactions contributing to pancreatic beta-cell dysfunction are summarized in Figure 15.3.3.4.

Beta-Cell Mass

There is consistent evidence for decreased beta-cell mass in type 2 diabetes, with estimates of 40–60% decrease in the number of beta cells [36]. A number of mechanisms may contribute to the decreased beta-cell mass in type 2 diabetes. Histological analyses of human islets have found an increase frequency of apoptotic markers in samples from type 2 diabetic compared with non-diabetic control subjects [37]. The increased beta-cell apoptosis could be driven by a number of factors through the common pathway of ER stress. Another process that has gained traction is beta-cell dedifferentiation. In a mouse model of diabetes, knockout of the transcription factor Fox01 resulted in a decrease in beta-cell mass and the development of diabetes [38]. Lineage tracing showed evidence of beta-cell dedifferentiation with a loss of expression of beta-cell markers, such as PDX1, and the expression of markers of other endocrine cell type including glucagon and somatostatin. Analysis of human pancreas samples reported an increase in the number of cells expressing markers of dedifferentiation and of other endocrine cell types, including glucagon [39], implying that dedifferentiation may be relevant to the pathogenesis of type 2 diabetes in man.

Glucagon and Incretins

Glucagon and glucagon-like peptide-1 (GLP-1) are hormones that are important for glucose metabolism and insulin release. Both are derived by the enzymatic cleavage of proglucagon, by tissue specific prohormone convertase (PC) enzymes. In the pancreatic α cells proglucagon is converted to glucagon, while in the intestinal L cells it is converted to GLP-1 [40].

Glucagon and insulin have opposite effects and counterregulate each other. Glucagon stimulates hepatic glucose production mainly by stimulating glycogenolysis [41]. Glucagon release is modulated by glucose (high glucose inhibits glucagon release while hypoglycaemia stimulates glucagon release) and by GLP-1 that suppresses glucagon secretion [42]. Glucagon concentrations are higher in

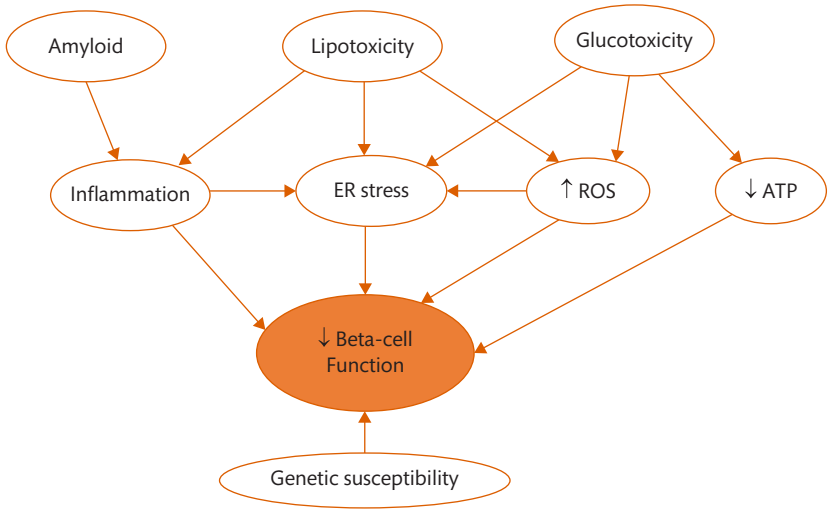

Figure 15.3.3.4 Schematic diagram summarizing the key mechanisms, and how they interact, that impair pancreatic beta-cell function in type 2 diabetes. ER = endoplasmic reticulum and ROS = reactive oxygen species.

T2D patients compared with non-diabetic subjects [41] and reduction of the plasma glucagon concentration is a potential target for treatment of patients with type 2 diabetes [43].

GLP-1 is an incretin hormone whose main action is the potentiation of the glucose stimulated insulin secretion [44]. GLP-1 is released by the intestinal L cells in response to nutrients (carbohydrates and lipids and its effects are mediated by activation of G-protein-coupled receptors) [45].

GLP-1 has a very short half-life (1–2 minutes) since it is rapidly degraded by dipeptidyl peptidase 4 (DPP-4). GLP-1 receptor agonists (GLP-1RA) and DPP-4 inhibitors are currently used as approved treatment for diabetic hyperglycaemia. The treatment with GLP-1RA has other beneficial effects that include the regulation of appetite and food intake [46].

Enzymatic cleavage of proglucagon also produces oxyntomodulin (OXM) that is a glucagon/GLP-1 receptor agonist [40]. OXM has a profound effect on appetite (reduced) and energy expenditure (increased) that improves glucose tolerance and insulin sensitivity [47].

Skeletal Muscle

Using a combination of hyperinsulinaemic clamp and limb catheterization techniques, it has been shown that skeletal muscle insulin stimulated glucose uptake is decreased in patients with type 2 diabetes [3]. Subsequent studies using magnetic resonance spectroscopy showed that the decreased insulin stimulated glucose uptake primarily resulted in decreased glycogen storage [48]. This combination of decreased insulin stimulated glucose and glycogen synthesis was also seen in the non-diabetic first-degree relatives of type 2 diabetes patients [49]. These subjects are at increased risk of progressing to diabetes, suggesting that impaired insulin action at skeletal muscle is an early defect in the pathogenesis of type 2 diabetes.

Insulin-Mediated Glucose Uptake

The insulin signalling pathway in relation to glucose metabolism is well defined [50]. The initial step involves insulin receptor binding and tyrosine kinase activation that leads to phosphorylation of insulin receptor substrate-1 (IRS1) that initiates a complex signalling cascade. For glucose uptake, the end point of the cascade is the activation of AS160 (previously known as TBC1D4) that stimulates translocation of GLUT4 to the cell membrane and glucose uptake. For glycogen synthesis, the principle end point is activation of glycogen synthase through the inhibition of the regulator, GSK-3.

A small proportion of the type 2 diabetes susceptibility variants identified by GWAS are associated with decreased insulin sensitivity [51]. These include *IGF1* and *IRS1* variants that are involved in signal transduction. No common variants that specifically and exclusively affect insulin sensitivity in skeletal muscle have been identified to date by GWAS. However, the retention of defects on insulin action in cultured skeletal muscle cells from type 2 diabetic patients [52] and their non-diabetic first-degree relatives [53] provides support for the role of genetic/epigenetic factors in the development of the peripheral insulin resistance in type 2 diabetes. Gene expression studies of skeletal muscle biopsy samples from type 2 diabetic patients found decreased expression of PGC1alpha, a transcriptional regulator of mitochondrial gene expression [54, 55]. It would seem, however, that these changes may not contribute directly to the peripheral insulin resistance in type 2 diabetes, as targeted *PGC1A* knockdown did not alter insulin action in skeletal muscle [56].

Metabolic and Inflammatory Mechanisms

Patients with type 2 diabetes have raised circulating FFA levels compared with weight matched non-diabetic control subjects [14]. In addition, patients with type 2 diabetes are prone to ectopic fat deposition in skeletal muscle. Interestingly, it has been shown that the intramuscular lipid content is increased to a comparable degree in type 2 diabetic patients and normal glucose tolerant athletes [57]. However, it would seem that the athletes but not the type 2 diabetic patients have the capacity for the efficient metabolism of the intramuscular lipid to generate energy.

The elevation of circulating FFA levels has been shown to decrease insulin signalling and impaired glucose uptake into skeletal muscle. Through a series of animal and human studies [58], it has been shown that elevated fatty acid levels increase intracellular lipid intermediaries that include diacylglycerol (DAG). DAG activates protein kinase C theta which serine phosphorylates IRS1 and inhibits downstream insulin signalling. As a consequence, there is decreased insulin stimulated glucose uptake and glycogen synthesis in the skeletal muscle. The same DAG-mediated mechanism is thought be involved in the decreased insulin action that is associated with ectopic lipid accumulation in skeletal muscle in type 2 diabetes.

Adipose tissue related inflammation is predicted to exacerbate skeletal muscle insulin sensitivity through the effect of locally released cytokines, in particular TNF-alpha, on skeletal muscle metabolism. TNF-alpha has been shown to inhibit insulin signalling through serine phosphorylation of IRS1 [59]. However, it is recognized that skeletal muscle *per se* can release a number of molecules, so called myokines, and includes IL-6. IL-6 release from contracting muscle increases as part of the normal physiological response to exercise in healthy man [60]. But there is emerging evidence that inflammation is a feature of skeletal muscle in type 2 diabetes, and that it mirrors the inflammatory process seen in other tissues in type 2 diabetes. Skeletal muscle cells from type 2 diabetic patients express a pro-inflammatory profile that persists in culture [61, 62], and there is evidence for skeletal muscle macrophage infiltration in type 2 diabetic patients [63].

Non-Insulin-Mediated Glucose Disposal

Insulin independent pathways also promote glucose uptake into skeletal muscle and clearance from the circulation. A major pathway involves AMPK activation, GLUT4 translocation, and increased glucose uptake. AMPK is the principle energy sensor of the cell and is activated by processes that diminish the intracellular ATP/AMP ratio [64]. A key activator of AMPK is muscle contraction, and underlines the potential role of exercise in controlling glycaemia in type 2 diabetes.

Adiponectin is another activator of AMPK and can exist as multiple complexes, with the high molecular form being the most active [65]. Adiponectin mediates its actions by binding to two receptors types, AdipoR1 and Adipo2. AdipoR1 is the predominant form in skeletal muscle, and receptor binding leads to activation of AMPK as well as other regulators of cellular energy provision such as

PGC1A. Through these mechanisms adiponectin increases GLUT4 translocation and glucose uptake into skeletal muscle [66]. There is evidence that the beneficial effects of adiponectin may be limited in type 2 diabetes. First, increased adiposity is associated with decreased circulating adiponectin levels and, second, adiponectin receptor expression has been reported to be decreased in skeletal muscle from type 2 diabetic patients [65].

Liver

The liver is the main organ that produces glucose during the fasting state. Glucose is produced either from the hydrolysis of the glycogen stored during the fed state or from gluconeogenesis (GNG). This involves the synthesis of glucose from gluconeogenic precursors such as lactate/pyruvate, gluconeogenic amino acids, and glycerol. While GNG can also occur in the kidney and small intestine, their contribution to the generation of glucose is minor relative to the liver.

In non-diabetic subjects, endogenous glucose production (EGP) by the liver is relatively similar among subjects when whole body fluxes are normalized by lean body mass [67]. However, in patients with type 2 diabetes the EGP is increased and closely linked to the fasting hyperglycaemia [68].

The application of stable isotope-based techniques has allowed the investigation of GNG in humans. After an overnight fast, GNG comprises approximately 50% of EGP in non-diabetic subjects and after 42h of fasting the great majority of glucose is produced as GNG as the hepatic glycogen stores are depleted [69]. The contribution of lactate/pyruvate, glycerol, or amino acids to GNG can vary. It has been shown that the liver utilizes these gluconeogenic precursors in proportion to their availability, a mechanism called 'hepatic autoregulation', although the overall rate of GNG remains steady [70]. However, in patients with type 2 diabetes, hepatic autoregulation is lost. As a consequence, an increase in gluconeogenic precursor supply leads to a direct increase GNG that in turn drives the increase in EGP [68].

Hepatic Insulin Resistance and Abnormal Hormonal Control

Hepatic glucose metabolism is tightly regulated by several hormones, in particular insulin and glucagon [71]. During the fasting state the most important hormone that regulates EGP is insulin by decreasing of hepatic glucose production. After a meal this is achieved through the inhibition of glycogenolysis and the stimulation of glycogen synthesis. The effect of insulin on gluconeogenesis is mainly indirect, since insulin also decreases peripheral lipolysis and protein catabolism thus diminishing the supply of gluconeogenic precursors to the liver.

In patients with type 2 diabetes, the ability of physiological insulin levels to suppress EGP is impaired indicating hepatic insulin resistance [3]. Using tracer techniques, it has been shown that EGP is raised under basal and elevated insulin levels in patients with type 2 diabetes due to the impaired ability of insulin to regulate hepatic gluconeogenesis [72]. Conversely, the effect of insulin to suppress hepatic glycogenolysis in type 2 diabetes is normal. Thus in type 2 diabetes hepatic insulin resistance is mediated by increased rates of gluconeogenesis under both fasting and insulinized states, thereby contributing to glucose overproduction under both conditions. The hepatic insulin resistance in type 2 diabetes is closely associated with fatty infiltration of the liver and decreased hepatic insulin clearance suggesting a potential mechanistic link [73].

The other important hormone that regulates hepatic metabolism is glucagon whose action is to stimulate gluconeogenesis, glycogenolysis, and net hepatic glucose output [71]. In type 2 diabetes, fasting plasma glucagon levels are increased and promote ongoing EGP.

Non-Alcoholic Fatty Liver Disease

Non-alcoholic fatty liver disease (NAFLD) affects almost 25% of the world population and the prevalence is much higher in patients with type 2 diabetes [74]. NAFLD is diagnosed when fat accumulation in the liver exceeds 5% in absence of excess alcohol intake [75].

Simple fat accumulation is considered a benign effect of excess fat overload to the liver. However, approximately 15–20% of subjects with NAFLD can progress to non-alcoholic steatohepatitis (NASH), defined by liver biopsy when together with steatosis hepatocytes show inflammation and ballooning with or without fibrosis [75]. These patients are at high risk of cirrhosis and hepatic cancer. International guidelines emphasize the importance of diagnosing NAFLD at its early stages in order to avoid or delay comorbidities, not only severe liver disease, but also cardiovascular disease and cancer [75, 76].

The pathophysiology of NAFLD is incompletely understood, although it is established that increased adiposity and diabetes are major risk factors. Several genotypes have been found to increase the risk of NAFLD and its progression to NASH, that include variants in *PNPLA3, TM6SF2, DGAT*, and *MBOAT7* [77]. Intriguingly, these genotypes are associated only with NAFLD and not insulin resistance [78].

Hepatic insulin resistance is increased in patients with type 2 diabetes and NAFLD, possibly related to an increased GNG [79]. It has been proposed that increased hepatic fat decreases insulin signalling by the same lipotoxicity mechanisms that operate in muscle [58]. Subjects with NAFLD have also increased peripheral insulin resistance in muscle and adipose tissue [79]. This peripheral insulin resistance results in unrestrained lipolysis and increased glycerol and FFA release that fuel hepatic lipogenesis and gluconeogenesis as summarized in Figure 15.3.3.5.

Conclusions

The principal pathophysiological changes of decreased pancreatic beta-cell function and impaired insulin action that characterize type 2 diabetes are well defined. Headway is now being made in defining the mechanisms that lead to these pathophysiological changes. As described in this chapter, a number of mechanisms are emerging that are common across the different tissues involved in the development of type 2 diabetes. In particular, ectopic fat deposition, tissue lipotoxicity, and the activation of pro-inflammatory pathways are emerging as common mechanisms. This presents the possibility that interventions targeted to these mechanisms could act across multiple tissues leading to an amplified therapeutic impact.

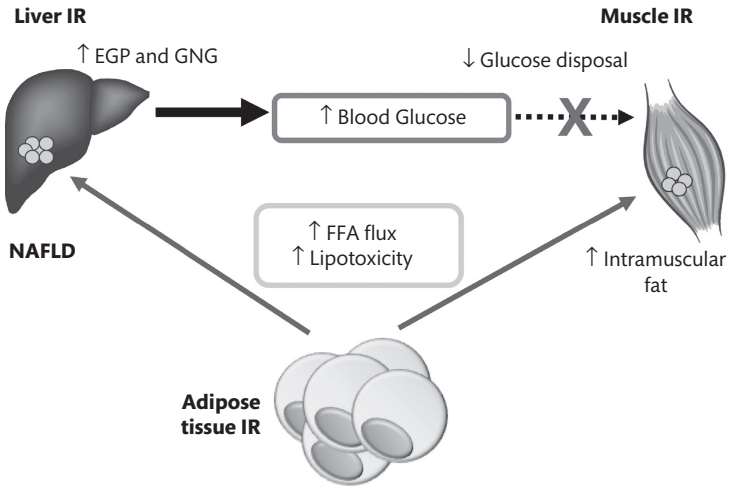

Figure 15.3.3.5 Insulin resistance (IR) at the liver leads to increased gluconeogenesis (GNG) and endogenous glucose production (EGP), and at the muscle it leads to decreased glucose clearance. Adipose tissue IR results in impaired suppression of lipolysis and increased FFA flux to increase hepatic lipogenesis and gluconeogenesis, and to impair insulin action in muscle.

15.4

Non Type 1, Non Type 2 Diabetes

15.4.1 Diagnosis of Non Type 1, Non Type 2 Forms of Diabetes

Katharine R. Owen

Introduction

Diabetes is an umbrella term for a raised blood glucose caused by a wide variety of different aetiologies. It is defined by exceeding a blood glucose threshold, and for many years was divided by treatment modality—insulin or not. The latter delineation has tended to rather stubbornly persist, with the labels 'NIDDM' (non-insulin dependent diabetes mellitus) and 'IDDM' (insulin dependent diabetes mellitus) still creeping into notes and referral letters. All too often the difference in aetiology and management between even type 1 and type 2 diabetes is not well appreciated, and the lack of a specialist input to assess aetiology around the time of diagnosis means that many individuals are miscoded [1]. This may lead to the use of inappropriate patient pathways, suboptimal treatment, and missed educational opportunities.

Although type 1 and type 2 diabetes together account for about 95% of people with diabetes, the remaining few percent reflect a large number of individuals with an eclectic group of aetiologies. In this chapter we will discuss how the correct use of clinical assessment along with a few basic investigations can differentiate aetiology at diagnosis (and beyond) and guide when more specialized investigations are required.

The wide range of differential diagnosis is particularly striking in diabetes arising in the young adult age range, up to around 40 years of age. Most monogenic causes of diabetes arise in this age range, as well as both classic and more slow-onset autoimmune diabetes, and an increasing prevalence of young-onset type 2 diabetes. There is often considerable clinical overlap between the subtypes so a careful assessment is required.

It is important to correctly diagnose the aetiology for a number of reasons. This will influence the first line treatment e.g. insulin for type 1 diabetes, low dose sulphonylureas for HNF1A- or HNF4A-MODY or metformin for unambiguous type 2 diabetes. Similarly, early interventions aimed at altering progression of diabetes, such as immunotherapy or closed loop glucose-regulated insulin delivery in type 1 diabetes; or weight reduction programmes to induce remission in type 2 diabetes rely on accurate assignment of aetiology. Finally, for the single gene causes of diabetes, family members require screening for diabetes and/or the gene variant.

Causes of Diabetes

Box 15.4.1.2 shows a classification incorporating some examples of the wide range of 'Non-type 1, non-type 2' causes of diabetes [2]. These include monogenic causes of beta-cell function and insulin resistance, primary pancreas pathologies (Chapter 15.10.3), endocrinopathies affecting glucose metabolism (Chapter 15.10.3), other rare syndromes, and drug-induced diabetes. Diabetes may be the only feature, or may present before or after other features of an associated condition. It is important to consider whether other clinical findings are coincident, or part of a unifying diagnosis. Thus the full clinical picture should be taken into account when assessing aetiology of diabetes, and the diagnosis revisited if additional features develop or information emerges (e.g. see Box 15.4.1.2). The finding of a monogenic or syndromic cause for diabetes should also trigger screening for other associated features of the syndrome—for example, investigation of the renal tract in those with diabetes and an *HNF1B* mutation, or cardiomyopathy screening in mitochondrial diabetes.

Table 15.4.1.1 contrasts the clinical features of type 1 and type 2 diabetes with the commoner forms of monogenic diabetes.

Monogenic Beta-Cell Dysfunction

Monogenic beta-cell dysfunction comprises neonatal diabetes (diagnosed before 6 months of age); Maturity Onset Diabetes of the Young (MODY); and mitochondrial diabetes. Some monogenic syndromes (e.g. Wolfram syndrome) also cause diabetes largely through beta-cell dysfunction. It is increasingly appreciated that there is an overlap between the genes causing neonatal diabetes and those causing MODY and it is important to specify the gene involved when describing cases. In general, MODY arises in adolescents and young adults, and the majority of children diagnosed

Box 15.4.1.1 Aetiology of diabetes

Autoimmune diabetes
- Classic type 1 diabetes
- Latent autoimmune diabetes of adulthood
- Monogenic autoimmunity

Type 2 diabetes

An insulin secretory defect with varying levels of insulin resistance; other specific diagnoses excluded

Genetic defects of β-cell function
- MODY
- Neonatal diabetes
- Mitochondrial diabetes

Genetic defects of insulin action
- Lipodystrophy
- Insulin receptor mutations
- Post-receptor insulin signalling defects
- Genetic severe obesity

Diseases of the exocrine pancreas
- Pancreatitis
- Haemochromatosis
- Cystic fibrosis-related diabetes
- Neoplasia

Endocrinopathies
- Cushing's syndrome
- Acromegaly
- Phaeochromocytoma

Syndromes associated with diabetes
- Chromosome abnormalities: Down's syndrome, Turner syndrome
- Myotonic dystrophy
- Friedreich ataxia
- Werner and other progeria syndromes
- Alström syndrome

Drug-induced diabetes
- Corticosteroids
- Diazoxide
- Thiazides
- Atypical antipsychotics
- Checkpoint inhibitors

between 6 months and 10 years have type 1 diabetes. One exception is glucokinase-MODY which can be diagnosed at any age.

MODY is the commonest form of monogenic diabetes seen in clinical practice. This is usually characterized by (Table 15.4.1.1):

- Diabetes onset in the 2nd–4th decade
- Absence of beta-cell antibodies/high risk HLA associated with type 1 diabetes
- Absence of obesity/insulin resistance associated with type 2 diabetes
- Non-acute presentation/DKA rare
- Frequent parental and other family history of diabetes

The most frequent subtypes seen in the clinic are due to mutations in transcription factors (Hepatocyte Nuclear Factor (HNF) 1A, HNF4A, HNF1B) and the glycolytic enzyme, glucokinase (GCK). See Chapter 15.10.1 for a more detailed description of the MODY subtypes and details of management. MODY is found in 1–6% of those with childhood or young-adult onset diabetes [3, 4] and has important treatment implications for those diagnosed with the commoner subtypes. Diagnostic genetic testing is now widely available, although uptake of this tends to be variable, dictated more by clinician experience and interest rather than formal guidelines.

It is very important to take a careful history of age of onset in individuals who were diagnosed in young childhood. A monogenic cause can be identified in more than 80% of those with a clinical diagnosis of neonatal diabetes (diabetes arising in the first 6 months of life) [5], often with an associated syndrome (see Chapter 15.10.1). Genetic testing is mandated in all those diagnosed under the age of 1 year, and (similarly to MODY), making a molecular diagnosis may have a substantial impact on treatment. Increasingly the early molecular diagnosis of syndromes presenting with diabetes in neonatal life means that timely counselling and screening for other features of the condition is possible.

Mitochondrial diabetes is due to mutations in the small mitochondrial genome [6]. Classically these individuals have diabetes and sensorineural deafness (see Box 15.4.1.2), but other neurological features are common and patients often complain of fatigue due to myopathy. Management of individuals with mitochondrial diabetes requires a multidisciplinary approach, including audiology, cardiology, and neurology review.

Genetic Defects of Insulin Action

Monogenic severe insulin resistance consists of disorders of body fat distribution (lipodystrophy), insulin signalling defects including insulin receptor mutations and syndromes associated with severe obesity [7]. More detailed descriptions of the subtypes can be found in Chapter 15.10.2. Severe insulin resistance is less common than MODY, but may still be encountered in a general diabetes clinic. Cases may also present to the endocrine clinic as polycystic ovarian syndrome in young women.

One clue to a rare monogenic form of severe insulin resistance is that features of metabolic syndrome may occur without significant obesity, or with evidence of central obesity only. Reactive hypoglycaemia may be a prominent early feature.

Diagnostic genetic testing is available for the commoner forms of severe insulin resistance including the lipodystrophy genes Lamin A/C (*LMNA*) and Peroxisome proliferator-activated gamma (*PPARG*) and for the insulin receptor.

Box 15.4.1.2 Case study—reassessing diagnosis

A 23-year-old woman presented to her GP with tinnitus. She also mentioned thirst and a blood glucose was requested. A fasting glucose of 7.2 mmol/L confirmed the diagnosis of diabetes and she was referred to the hospital clinic. There were no acute symptoms, weight loss, or ketonaemia. She was lean with no features of insulin resistance and 2 beta-cell antibodies were negative, so MODY was suspected. Genetic sequencing of the MODY genes *HNF1A*, *HNF4A*, and *GCK* was performed without any abnormal findings. She was commenced on metformin and reviewed after 3 months.

At review it was noted that she was wearing bilateral hearing aids. In the meantime, the original presentation of tinnitus had been investigated and she had been shown to have sensorineural hearing loss. This led to a suspicion of mitochondrial disease and the common A3243G mitochondrial mutation was confirmed on further genetic testing. Metformin was discontinued and she was managed on gliclazide, progressing to require insulin after a further 2 years.

Table 15.4.1.1 Clinical features associated with common forms of monogenic diabetes in comparison to type 1 and type 2 diabetes

	Age of onset	Features of insulin resistance	Family history of diabetes	Beta-cell antibodies	C-peptide	Neurological features	Exocrine pancreas dysfunction	Other features
Type 1 Diabetes	Peak incidence 1st–2nd decades, diagnosis often missed in older adults	No	10% of cases	80–90%	Classically C-peptide negative, but usually low detectable level at diagnosis with maintained low level in up to 10%	No	No	
Type 2 diabetes	Peak incidence after 4th decade, still relatively rare in paediatric age range	Typically found	50% of cases	No, by definition	C-peptide typically high at diagnosis, declines over time	No	No	
HNF1A/HNF4A MODY	2nd–4th decade	No	60–90% report parental diabetes	Not usually, some mixed MODY/T1 reported	Generally low normal range	No	No	HNF1A: Low renal glucose threshold, Low CRP HNF4A: fetal hyperinsulinaemia and macrosomia
GCK-MODY	Fasting hyperglycaemia present throughout life, may be diagnosed at any age	No	Less common that in other forms of MODY as often asymptomatic	Not usually, some mixed MODY/T1 reported	Normal range	No	No	Treatment not usually required Low risk of microvascular complications
HNF1B-MODY	Diabetes presents in 2nd–4th decade, other features may present earlier	Not typical	Less common than in other forms of MODY as spontaneous whole gene deletions are a frequent cause	No	Low normal range Usually progress to insulin quickly	No	Yes, common	Structural abnormalities of renal and genitourinary (GU) system, renal failure
Mitochondrial diabetes	Typically 3rd–4th decade	Not typical	Typically maternally transmitted, but clinical phenotype very variable due to heteroplasmy	No	Low normal range Usually progress to insulin quickly	Yes, typical	No	Myopathy, cardiomyopathy, pigmented retinopathy
Partial lipodystrophy	2nd-4th decade	Yes, often disproportionately to BMI	Autosomal dominant inheritance, but parents may be asymptomatic	No	High reflecting insulin resistance	Not typically	No	Abnormal body fat distribution from puberty with central adiposity and decreased fat on limbs. Muscular hypertrophy
Insulin receptor (IR) defects	Frequently presents in females with PCOS during puberty, rare severe cases in childhood. Males may be relatively asymptomatic	Partial features of metabolic syndrome: acanthosis nigricans and PCOS but not dyslipidaemia or hepatic steatosis	Parental diabetes may be seen in autosomal dominantly inherited cases, parents may be asymptomatic	No	High reflecting insulin resistance	Not typical	No	Postprandial hypoglycaemia Failure to thrive in childhood forms

Tools for Diagnosis

Clinical Assessment: Features from History, Examination, and Routine Biochemistry

Table 15.4.1.1 compares the features of the commoner types of monogenic diabetes in young adults. The most obvious clinical discriminator favouring type 2 diabetes, as opposed to type 1 diabetes or MODY, is obesity with associated features of metabolic syndrome such as dyslipidaemia, hypertension, hepatic steatosis, and PCOS. Clinical examination at diagnosis is important to detect acanthosis nigricans and lipodystrophy. Features of insulin resistance in the absence of obesity are strongly suggestive of genetically determined severe insulin resistance (see Chapter 15.10.2) warranting further evaluation.

As just discussed, coexistence of other clinical features with diabetes may give clues to the aetiology.

Beta-Cell Antibodies

At diagnosis 80–90% of those with type 1 diabetes will have at least one positive beta-cell antibody. In general younger individuals (under 45 years old) with positive antibodies are considered to have autoimmune diabetes. They may have a classic onset of type 1 diabetes, or a slower progression without initial insulin requirement consistent with a diagnosis of latent autoimmune diabetes of adulthood (seen in 10–20% of apparent young-onset type 2 diabetes [8]). Beta-cell antibodies are a good test for helping to confirm a diagnosis of type 1 diabetes in children and young adults, while absence of antibodies may indicate that an alternative diagnosis should be considered. However, there are some limitations to the tests which it is important to understand [9].

Firstly older tests such as Islet cell antibodies (ICA) are still commonly measured, but are difficult to standardize due to the qualitative immunofluorescence method used and have a low sensitivity. Glutamic acid decarboxylase (GAD), tyrosine phosphatase islet antigen 2 (IA2) and Zinc transporter (ZnT8) antibodies are measured using immunoassay which is standardized in an international laboratory programme. An appropriate reference range from the population being tested should be used. GAD is most often offered in diagnostic labs. Where only one or two antibodies are offered, there is a risk of missing a positive result, so that a negative antibody test does not exclude a diagnosis of type 1 diabetes.

Interpreting a positive test may also be difficult. A small percentage of people with non-autoimmune diabetes (as well as non-diabetic individuals) will have false-positive beta-cell antibodies depending on the threshold of the test. In older individuals where the proportion of people with type 2 diabetes is higher, the finding of a single positive antibody has a higher probability of being a false-positive test. This presents a conundrum—we know that type 1 diabetes in older adults is often missed, but the main diagnostic test we have at our disposal becomes less useful.

C-peptide

C-peptide is a marker for endogenous insulin secretion and is thus a useful indicator of the severe insulin deficiency seen in type 1 diabetes. C-peptide tends to be preserved in the low normal range in MODY and long-duration type 2 diabetes and is generally high as a marker of insulin resistance in more recent onset type 2, severe insulin resistance, or prediabetes. C-peptide testing can thus be used in those with insulin treated diabetes to confirm absent or very low insulin secretion (usually means type 1 diabetes), and where it is present to suggest an alternative diagnosis. C-peptide should ideally also be measured if discontinuation of insulin treatment is planned, particularly if insulin has been used since diagnosis. This gives confidence to both patients and healthcare professionals that this is a safe thing to do.

Interpreting C-peptide levels is not always straightforward, as both ambient glucose level and insulin sensitivity affect the insulin response. Measuring a paired glucose with any measure of insulin or C-peptide gives context for interpretation of the value, as a higher glucose provides greater beta-cell stimulation. C-peptide test should be repeated if the paired glucose is below 4 mmol/L.

In most studies of type 1 diabetes a stimulated C-peptide or C-peptide increment on stimulation of ≥200 pmol/L is considered to represent residual endogenous pancreatic insulin secretion [10]. A fasting C-peptide in an insulin-sensitive person could be lower than this and still represent useful insulin secretion. However in the context of a high glucose, a C-peptide of 200 pmol/L would be a poor response. There are no definitive thresholds for making treatment decisions, so the clinical scenario should be taken into account and gaining experience in using C-peptide values is important. For that reason C-peptide is probably best used in clinical settings where expertise exists to interpret results.

Research settings use standardized tests of beta-cell function such as the Homeostatic model assessment (HOMA) for the fasting state and glucagon, oral glucose tolerance test, or mixed meal tests for stimulated C-peptide, however formal testing is not usually needed to make clinical decisions.

Duration of diabetes is clearly one of the main factors when assessing residual insulin secretion. Most people with type 1 diabetes have measurable insulin secretion at diagnosis and this declines at a variable rate, tending to be a slower decline in those diagnosed as adults and in those with a higher C-peptide at diagnosis. One suggestion is that those with T1D should have a C-peptide measured after the 'honeymoon' period, when a negative C-peptide will confirm T1D. However if it is desirable to avoid a type 1 pathway (intensive insulin treatment, carb counting, etc.) for those who do not need it, then waiting months or years to make that assessment feels too long and other factors such as antibody status and clinical scenario will be the main determinants of such decisions.

Use of Novel Biomarkers and Other Tools for Diagnosing Monogenic Diabetes

Extrapancreatic effects of monogenic diabetes genes may result in measurable alterations in serum or urine constituents, which could then form the basis for a screening test for a specific subtype of diabetes. This has been explored most for *HNF1A*, which regulates many hepatic genes. One of the best potential candidates for clinical use is C-reactive protein (CRP), which was found to be low in individuals with HNF1A-MODY compared to other forms of diabetes [11]. The best discrimination, with a ROC curve C-statistic of >0.8, is from those with young-onset type 2 diabetes, partly because a higher CRP is seen in type 2 diabetes. Because HNF1A-MODY is uncommon compared to type 2 diabetes, using a low CRP of <0.5 mg/L as a screening test to select individuals for genetic testing for *HNF1A* would lead to sequencing of about 20 individuals with type 2 diabetes in order to diagnose one person with HNF1A-MODY.

To attempt to overcome the shortcomings of interpreting a number of clinical features and biomarkers, a MODY prediction model has been devised [12] which compares the clinical features of

the patient being considered to well-defined groups of MODY, type 1, and type 2 diabetes. This produces a probability that the patient has MODY, and the clinician can set their own acceptable probability threshold for requesting genetic testing (e.g. 20–30% likelihood of MODY). The probability calculator has some limitations in that it compares cases to a narrow test group and it is only currently recommended for use in those aged <35 years at diagnosis and in the white European population. Clinically useful biomarkers including antibodies, C-peptide, and CRP are not currently included in the model.

Genetic Testing in Diabetes

Diagnostic genetic testing for monogenic diabetes has been available in some countries since the early 2000s, allowing a definitive diagnosis of monogenic diabetes to be made. This is important to inform treatment decisions and to allow a proper evaluation of risk of diabetes in family members. The individual benefits of making a molecular diagnosis are easy to see and there is potential for cost saving if insulin can be discontinued in the common forms of MODY. To date the health economics of introducing widespread genetic testing in diabetes has not been proven although some modelling has been performed [13]. Availability and uptake of genetic testing remains rather variable in different parts of the world and even within the same country [14]. Educational initiatives such as the Genetic Diabetes Nurse network in the United Kingdom can help raise awareness of genetic testing and increase uptake [15].

Genetic testing for diabetes is now usually performed using targeted next generation sequencing for a panel of genes. The genes incorporated in the panel vary from lab to lab, but include at a minimum the common MODY genes. The panel may also include the common mitochondrial variant and lipodystrophy genes. All genes in the panel are sequenced simultaneously, rather than the older method of making a clinical diagnosis first and requesting the gene most likely to be responsible. Potentially a number of gene variants will be identified for each individual, and the challenge is to assess whether any of these variants may be responsible for the diabetes. Monogenic causes represent only a small proportion of diabetes diagnosed in adults and children after the neonatal period, so a careful assessment is required so that the correct advice can be given to patients. The American College of Medical Genetics and Genomics has produced guidelines to assist diagnostic laboratories and clinicians in the interpretation and reporting of sequence variants in suspected Mendelian disease [16] and it is important that any diagnostic service follows these recommendations. Even with genes such as *HNF1A*, where thousands of people have been sequenced and there is much clinical experience, it can be difficult to be confident that a variant is disease-causing. Exome and whole genome sequencing in populations have demonstrated that what may appear to be loss of function variants in genes can be associated with complete absence of clinical phenotype [17].

A polygenic genetic risk score for type 1 diabetes can also be calculated using combinations of known risk variants for type 1 [18]. The score captures the effect of the risk and protective HLA alleles which have traditionally been complex and expensive to measure using classic HLA typing. This can assist in determining likelihood of a type 1 diagnosis in cases where clinical features are ambiguous and antibodies are negative.

Who Should Be Seen in Secondary Care?

There is a body of evidence for misclassification of diabetes subtype in adults [19]. This could be due to assumptions based on age of onset, or because rarer subtypes of diabetes are not considered. Younger adults are more likely to be labelled as having type 1

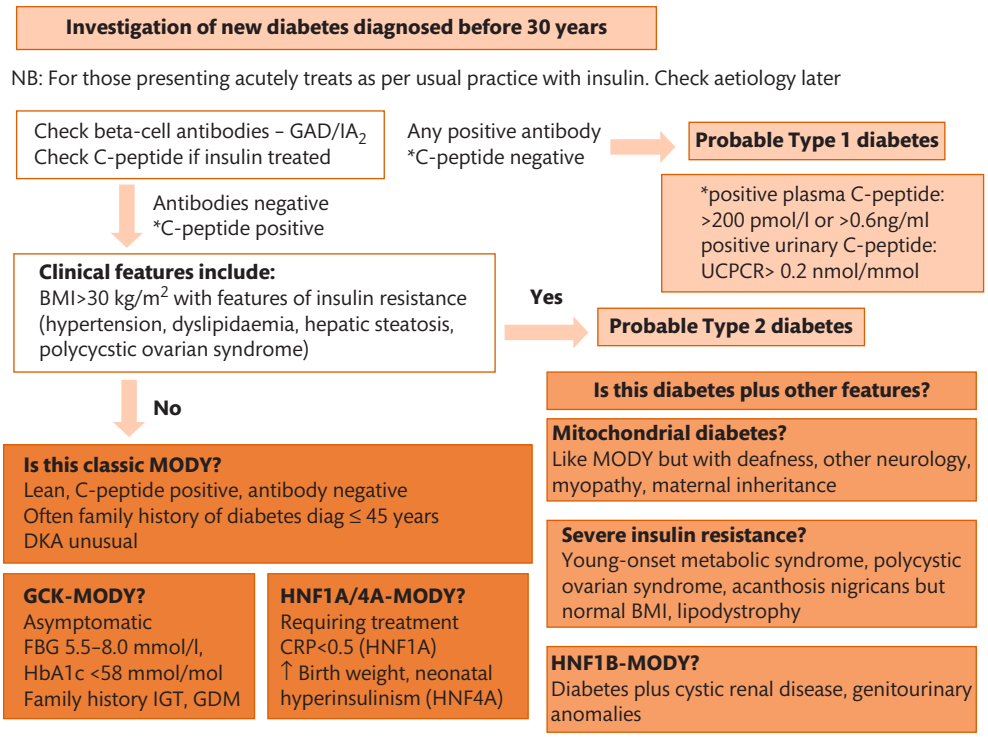

Figure 15.4.1.1 How to assess a newly diagnosed young adult.

diabetes and treated with insulin—this may be the safest option at diagnosis when uncertain, but should be revisited if there is any suggestion of an ambiguous clinical presentation or if beta-cell antibodies are negative. Conversely older adults may be routinely treated as type 2 diabetes and not have appropriate treatment escalation even if they respond poorly to oral hypoglycaemic agents. Therefore, there is much to be gained by developing pathways for assessing aetiology that can direct suitable individuals to specialist clinics—an example of such a pathway for newly diagnosed young adults is given in **Figure 15.4.1.1**.

Most UK care pathways direct type 1 diabetes into secondary care, and this is appropriate for the rare monogenic forms of diabetes too, with the exception of GCK-MODY where individuals can be discharged following genetic diagnosis. As young type 2 diabetes represents an equally high risk for poor outcomes as type 1 diagnosed at a similar age [20], one could argue that they would also benefit from intensive input.

Conclusions

Accurate assessment of aetiology is important for management of diabetes, both for choice of immediate pharmacological agent and for ensuring individuals with diabetes follow the most appropriate care pathway. Diagnosing non-type 1, non-type 2 diabetes can be challenging due to clinical overlap with the common forms of diabetes and relies on a variety of clinical skills and specialist investigation. It is important to understand the limitations of investigations as well as the most appropriate use. Monogenic diabetes may present with diabetes alone, or as part of a syndrome and family members will need to be counselled and investigated.

While at the moment stratified medicine approaches can be applied mainly to monogenic subtypes, there is much research aimed at understanding the clinical molecular features which define treatment response and complication development in polygenic type 2 diabetes. Assessment of aetiology will become both more complex and more commonplace in the future.

Principles of Management of Diabetes

15.5.1 Structured Education

Simon Heller and Jackie Elliott

Introduction

Diabetes mellitus is almost unique, even among chronic diseases, in that long-term outcomes are determined not by the knowledge and skill of the healthcare professional but by how successfully a patient can contribute to his/her own management. A crucial responsibility of their professional carers is to ensure that those with the condition are provided with knowledge and help to self-manage their condition effectively. There is now considerable evidence that acquisition of complex self-management skills requires high quality educational support and that this is best provided by attending structured educational courses. Thus, education provision is a fundamental component of the management of both type 1 and type 2 diabetes. In this chapter we describe the essential features of structured education and review the evidence for its effectiveness.

Background

The aim of treatment in both type 1 and type 2 diabetes is maintaining blood glucose levels close to normal both to prevent acute complications and in the long-term reduce micro- and macrovascular disease. In type 2 diabetes there is additional focus on controlling both blood pressure and lipids to reduce macrovascular events. Management frequently requires medication but there is strong evidence that major changes in lifestyle can achieve many of these aims without the need for medication. Significant weight loss achieved by a very low calorie diet or bariatric surgery can lead to complete and prolonged remission of diabetes while regular physical activity reduces macrovascular disease over the medium to long-term.

Despite the evidence for the effectiveness of lifestyle change, interventions specifically aimed at altering dietary habits or increasing physical activity often have only modest effects. The challenges faced by those affected are considerable. They include changing habits of a lifetime among individuals who have often been socialized into adopting an unhealthy lifestyle. Since these choices are one of the main reasons why individuals develop diabetes it is unsurprising that people find it so difficult people to alter their behaviour. It is increasingly realized that traditional approaches to diabetes management in which patients are encouraged to achieve healthcare outcomes framed from the healthcare professional prospective are less likely to be effective [1]. The recognition that regular 1:1 consultations with healthcare professionals who make the major decisions on management, particularly medication, are not conducive to successful treatment has prompted a move to a more patient-centred model of care. Diabetes associations in the United States, United Kingdom, and elsewhere now propose that newly diagnosed patients receive structured education from diagnosis and beyond. This has been reinforced in the United Kingdom by recent guidance from the National Institute for Health and Clinical Excellence (NICE) regarding structured education in both type 1 and type 2 diabetes as a fundamental component of treatment [2, 3].

How is Structured Education Defined?

A recent position statement from the United States has defined structured education as the process of facilitating the knowledge, skill, and ability necessary for diabetes self-care [4]. In 2003, the National Institute for Health and Clinical Excellence (NICE) proposed that structured education was 'a planned and graded programme that is comprehensive in scope, flexible in content, responsive to an individual's clinical and psychological needs, and adaptable to his or her educational and cultural background'[5].

The essential components of a structured education package have been expanded in recent NICE guidance [3].

These state that any structured education programme for adults with diabetes should include the following components:

- Outcomes are audited regularly.
- It is evidence-based, and suits the needs of the person.
- It has specific aims and learning objectives, supporting the person and their family members and carers in developing attitudes, beliefs, knowledge, and skills to self-manage diabetes.
- It has a structured curriculum that is theory-driven, evidence-based, and resource-effective, has supporting materials, and is written down.
- It is delivered by trained educators who have an understanding of educational theory appropriate to the age and needs of the person, and who are trained and competent to deliver the principles and content of the programme.
- It is quality assured, and reviewed by trained, competent, independent assessors who measure it against criteria that ensure consistency.

Structured Education Programmes Which Have Changed Practice

Type 1 Diabetes

The development of structured education in type 1 diabetes owes much to the vision of Berger and colleagues working in Düsseldorf. The basic principles of their insulin treatment and training programme (ITTP) included separation of basal and soluble insulin, given as pre-meal boluses based on pre-meal, blood glucose testing. Doses were calculated according to the carbohydrate content of the meal and the resulting dietary freedom allowed those participating to eat freely and flexibly, comparable to that of people without diabetes.

Their education course, provided as an in-patient, 5-day programme to groups of 6–8 adults, was evaluated in a series of clinical trials in the 1980s. In a large controlled trial involving 300 adults with type 1 diabetes, the course resulted in a 1.5% fall in HbA1c at 1 year (compared with control participants taught basic information alone) and was accompanied by a marked reduction in ketoacidosis [6].

A large observational study from the same group subsequently presented findings from a 6-year follow-up in a cohort of individuals with type 1 diabetes who had undergone the course [7]. They reported a reduction in HbA1c of 0.7%, while the incidence of severe hypoglycaemia had fallen from 0.28 episodes per person per year in the year at baseline to 0.17 episodes per person per year at follow-up (P <0.05). Observational studies provide a weaker level of evidence compared with clinical trials, but the large numbers and the relatively long follow-up indicate that structured education not only improves HbA1c but also reduces rates of severe hypoglycaemia by approximately 50%.

The success of these programmes has led to their adoption in other countries. In the United Kingdom, a multicentre randomized controlled trial (RCT), utilizing a waiting list design in three centres measured the impact of a structured education course (Dose Adjustment for Normal Eating [DAFNE]), based on the ITTP [8]. HbA1c improved by between 0.7 to 1% at 6 months, while no change was observed in the control group. Of equal importance was the marked improvement in quality of life, not included in previous evaluations. Flexible intensive insulin therapy demands more blood tests and injections but increased dietary freedom and the ability to adopt a more flexible lifestyle was highly valued by the participants. The approach has also been the subject of a health economics analysis, which concluded that even if HbA1c improvements were maintained only partially, the course would be highly cost-effective, due to the reduced incidence of microvascular complications [9].

Longer-term observational studies involving larger numbers of participants have demonstrated reductions in the incidence of severe hypoglycaemia that are comparable with those seen in the original ITTP studies from Germany, albeit at higher HbA1c levels. One reported reductions in HbA1c (mean difference pre- and post-DAFNE: 0.27%; P <0.001) and around a 50% reduction in rates of severe hypoglycaemia (mean ± SD: pre-DAFNE 1.7 ± 8.5 vs. post-DAFNE 0.6 ± 3.7 episodes per person per year; P <0.05), together with improved awareness of hypoglycaemia in up to 43% of participants at 1 year follow-up [10]. The overall rate of impaired awareness fell from 39.9% to 33%, with reductions in psychological distress and improved well-being up to 1 year following programme attendance [10]. A more recent study has also reported that DAFNE reduces the risk of diabetic ketoacidosis by 61% and combined emergency costs for DKA and severe hypoglycaemia are decreased by 64% [11].

DAFNE courses are now provided in more than 70 centres across the United Kingdom and Ireland (having been delivered to over 40 000 participants) and have been rolled out to other countries, including Australia, New Zealand, and Kuwait. In the United Kingdom, structured education is now recognized as a standard of care. Many centres who don't offer DAFNE training provide structured education in some form but, although some are based on the Düsseldorf course, the standard is inconsistent. Some centres provide shorter courses of a few days, despite evidence that these are less effective [12]. Few include formal training for educators, peer review, quality assurance, or regular audits as recommended by the Department of Health. This has been recognized by NHS England who have provided funding to try and ensure access to high quality structured education across the country.

Type 2 Diabetes

Structured education courses in type 1 diabetes primarily teach participants the skills of flexible intensive insulin therapy, focus on insulin delivery and maintaining glucose targets. In contrast, structured education in type 2 diabetes has a broader remit. Programmes need to address lifestyle issues of healthy eating, weight control, and the role of physical activity, particularly in those newly diagnosed. Individuals with more advanced type 2 diabetes require sufficient information to understand more advanced therapy, including the different medications used to lower glucose as well as those required to lower cholesterol, blood pressure, and reduce the risk of cardiovascular disease. A successful programme will also engage people in the management of their condition and help them understand how important their own contribution is to the success of treatment. This also explains why programmes often incorporate psychological approaches such as motivational interviewing or cognitive behavioural

therapy techniques. Indeed, the term 'psycho-educational' is often used to acknowledge the combined nature of these interventions.

In many respects this makes structured education programmes in type 2 diabetes more challenging to evaluate. In type 1 diabetes, appropriate outcomes include HbA1c, rates of severe hypoglycaemia, and DKA as well as psychosocial measures. While these are relevant in type 2 diabetes, it is necessary to include weight, lipids, blood pressure, and smoking. It is also important to understand the clinical context when interpreting the results. For example, a course designed for newly diagnosed individuals is unlikely to demonstrate major differences in HbA1c or glucose lowering medication whereas weight loss or levels of physical activity are more useful.

Other factors which add to the demands of comparing different interventions include different methods of delivery, varied contact time, group size, inclusion of technology, and healthcare setting. However, some generalizations can be made. A systematic review of trials in type 2 diabetes showed that on average, reductions in HbA1c of >0.4% compared to control groups were achieved, and improvements in glycaemic control were correlated with courses with delivery time of 11 hours or more [13]. Importantly in terms of resource there was no advantage in individual as opposed to group interventions. Other useful predictors of success appeared to relate to the demographics of the cohort. Younger participants under 65 years of age, and those of non-white ethnic backgrounds often appeared to gain greater benefit. Unsurprisingly those with higher baseline HbA1c exhibited greater improvement in glycaemic control. Measures of quality of life generally improved, but this was not universal.

The Diabetes Education and Self-Management for Ongoing and Newly Diagnosed (DESMOND) study was a randomized controlled trial of a group structured education intervention designed for adults with newly diagnosed diabetes [14]. The intervention consisted of 6 hours of education delivered in either one day, or two half-day sessions by two professional educators. Participants in both the intervention and the control arms of the study received routine care, with the intervention additionally receiving the DESMOND programme.

HbA1c fell in both intervention and control groups by around 1.5% with no significant difference in fall in HbA1c between the groups. Differences were observed in some secondary outcomes. Those in the intervention group lost more weight (3 kg vs. 1.8 kg), had lower levels of reported smoking, reduced depression scores, and reduced cardiovascular risk scores, at 12 months. The intervention group also demonstrated significant positive changes in their health beliefs about their diabetes, sustained at 12 months.

The lack of difference in HbA1c between the groups has been interpreted by some as indicating no additional benefit from DESMOND training. However, it is important that at diagnosis, HbA1c levels will fall in most individuals with type 2 diabetes. Somewhat disappointingly, a follow-up of the original cohort at 3 years, showed no difference in any biomedical outcome (including weight and HbA1c). The DESMOND intervention has been widely implemented in primary care in the United Kingdom, supported by an infrastructure which has provided training, quality assurance, and professional development.

The X-PERT study was conducted in a single centre primary care trust in the North West of England [15]. The 314 participants from a multiethnic population had a mean of duration of type 2 diabetes of 6.7 years. The intervention was delivered by single dietitian and consisted of six 2-hourly group sessions held once a week. The control group received routine care and additional individual education.

Significant reductions in HbA1c, total cholesterol, weight, and waist measurements were seen in the intervention group at 14 months compared to controls. In addition, the intervention group had significantly improved diabetes knowledge, treatment satisfaction, and feelings of empowerment. Intervention participants reported improved dietary habits and greater levels of physical activity. There were no differences in other clinical measures, nor in quality of life. A limitation of this study is that it was undertaken at a single centre. Nevertheless, the programme has been taken up in a number of UK centres.

The ROMEO trial also studied people with established type 2 diabetes and reported 4-year results in 2010 [16]. The intervention was partly structured education but an essential component was that the education was delivered within regular consultations to a group of patients. The trial was multicentre, delivered across Italy in 13 specialist clinics in which 815 participants received group education in sessions 40–50 minutes long, delivered every 3–4 months. The control group received standard routine care. At 4 years, the intervention group showed significantly improved HbA1c and other clinical outcomes, including blood pressure, lipids, weight, and body mass index (BMI) compared to controls. Quality of life and diabetes knowledge also improved. Despite the overall success, of the original 815 participants, only 592 completed the trial at 4 years and two of the participating centres were unsuccessful in implementing the education programme. This demonstrates the challenges inherent in integrating a successful intervention into routine care.

Technology in Structured Education

Technological innovations are making an increasingly important contribution to many aspects of care in diabetes and offer considerable potential to contribute to patient education. These range from continuous glucose monitoring to delivering education online. Innovations such as telehealth may provide education more effectively but there is a danger that the technology might merely be used to reduce costs. It is therefore important that technological development is accompanied by rigorous evaluation to measure its effectiveness.

Web-based strategies are potentially attractive in that they allow the user to access educational material at a time that suits them. They also increase flexibility by enabling users to learn at their own pace and decide how much to cover at each sitting. On the other hand, participants may lose the benefits of contextualized social learning, when participating individually rather than in a group. One systematic review examining online behaviour change interventions highlighted some benefits in type 2 diabetes [17] including improvements in both clinical and psychological outcomes. Relatively few behaviour change techniques were used and these were not always related to the theories underlying their intervention. A recent Cochrane review [18] assessed the effects on health status and health-related quality of life of computer-based diabetes self-management interventions for adults with type 2 diabetes mellitus in a large number of clinical trials. Effects on HbA1c

were modest (falls of around 0.2% compared to controls) although mobile phone applications appeared to have a greater effect. This review found no other biomedical improvements or psychological or behavioural benefits.

The Need to Improve the Uptake of Structured Education

Despite increasing evidence confirming the benefit of structured education, uptake is still generally poor. In the United Kingdom, many people with diabetes are now offered structured education at some point (~50% in type 1 and ~90% in type 2 diabetes) but rates of uptake for adults with both types of diabetes remain below 10% [19]. Low uptake is also seen in many other countries, where self-reported rates of receiving any formal educational input were between 23% and 84% in one study [20].

A recent systematic review examined reasons cited by patients for not attending structured education across several countries and cultures [21]. It found that the barriers to uptake are sometimes patient-orientated, for example, location, timing, duration, loss of income if in working hours, an unawareness that education can improve outcomes, and an unwillingness to return to a classroom type experience. However, healthcare professionals are frequently responsible; a perceived lack of effectiveness preventing them from encouraging patients to attend. This factor was also highlighted in a recent study examining the reason for poor take-up of structured education in a population of young people with type 1 diabetes in South London [22].

Conclusion

Structured education is increasingly considered to be a crucial component of diabetes care with an essential role to play in enabling people with diabetes to initiate and sustain successful management of their own condition. This requires stakeholders to commission high quality programmes which meet national and international standards. Such a policy need not be expensive. Spending on diabetes is largely directed at trying to contain devastating, but largely preventable long-term complications. If a small fraction of this spending were directed at trying to prevent complications occurring by encouraging better self-management this would be highly cost-effective.

Nevertheless, more work still needs to be done. Healthcare professionals should explain to their patients and their families that structured education is a fundamental part of diabetes management and insist that they participate from diagnosis. We need to understand the factors which underlie an individual's decision to engage with their diabetes and the perceived barriers to putting knowledge into practice. We must work closely with experts in the area of behaviour change if we are to develop more effective interventions.

Developing and implementing structured education programmes is complex and challenging. Recent achievements and the positive feedback from participants, demonstrate the potential of these programmes in enabling people with diabetes to exercise control over their experience of living with diabetes, rather than being controlled by it.

15.5.2 Glucose Monitoring and Sensing

John Pickup and Nick Oliver

Introduction

Blood glucose concentrations are measured to identify hyper- and hypoglycaemia. Healthcare teams use glucose data to diagnose diabetes, or impaired glucose regulation, adjust therapies, and to inform hypo- and hyperglycaemia correction. People with diabetes self-monitor blood glucose concentrations to inform decision making; enabling food, insulin, and activity to be titrated according to glucose levels, empowering people to achieve optimal glucose concentrations. Self-monitoring of blood glucose (SMBG) also supports activities such as driving and can provide reassurance to the person with diabetes, and their family and carers, especially for children and frail people.

Glucose monitoring has traditionally been performed by intermittent sampling of capillary blood glucose concentrations using finger-prick samples applied to reagent strips inserted into portable glucose meters. Since around 2000, continuous glucose monitoring (CGM) has entered clinical practice as a supplement to SMBG, and more recently flash glucose monitoring (FGM) has been available. CGM and FGM are based on the implantation of needle-type sensors into the subcutaneous tissue for measurement of interstitial glucose concentrations which are then calibrated to an estimate of blood glucose, either by SMBG or factory calibration.

Self-Monitoring of Blood Glucose

The History and Technology of SMBG

The first point of care blood glucose testing system was introduced in 1965; requiring application of blood to a strip containing immobilized glucose oxidase, peroxidase, and a dye. A colour change in the dye was compared semi-quantitatively with a colour chart to estimate the glucose concentration [1]. Automated and more quantitative reading of the strips using a portable reflectance meter was introduced in the early 1970s. SMBG was introduced into clinical practice in 1978 [2, 3], and has become an integral part of the self-management of type 1 diabetes.

Most SMBG technologies are now based on the electrochemical detection of glucose and a current response, which is converted into a digital read-out of the glucose concentration [4]. A small molecular weight mediator (e.g. ferrocene, hexacyanoferrate, or a quinone) is used to shuttle electrons from glucose to an electrode, thereby producing a current, catalysed by an enzyme such as glucose oxidase or glucose dehydrogenase. Very small volumes of blood are now required, typically less than 1 μl, with the blood taken up into the strip by capillary forces. A reading can usually be obtained in around 5 seconds.

Modern meters are equipped with a solid-state memory and are able to store test results for later display, and reporting simple statistics, such as mean glucose over preceding periods and at defined times of day. Data can be downloaded to a personal computer or in some cases meters can connect to a smartphone for display of data and more complete statistical analysis, including blood glucose mean, modal day display, standard deviation, and percentage of values within, over, or under target.

The Evidence Base for SMBG

The popularity of SMBG accelerated following the Diabetes Control and Complications Trial (DCCT) [5], where SMBG was used as a component of intensified therapy by both the multiple dose injection (MDI) and continuous subcutaneous insulin infusion (CSII) arms. The study evidence for the effectiveness of SMBG, however, is far from conclusive, and its best use is not always agreed by healthcare professionals [6].

In type 2 diabetes, the majority of trials indicate either marginal or no effectiveness of SMBG [7, 8] over no monitoring, although trials are difficult to interpret. Studies have failed to differentiate between types of oral agent; many have low statistical power; many did not assess hypoglycaemia, a major reason for

testing; and many did not give instructions on SMBG frequency or interpretation.

The reasons for, and likely benefits of, SMBG in type 1 diabetes seem more obvious than in type 2 diabetes: hypoglycaemia is more common and glucose more variable so frequent monitoring will allow adjustments in insulin dosage, avoidance of hypoglycaemia, and greater time in target. Surprisingly, the evidence for its effectiveness from formal randomized studies is weak, mostly because of poor trial design and reporting. Cross-sectional studies generally favour lower HbA_{1c} levels in those testing frequently in type 1 diabetes [9, 10] with a high negative correlation in type 1 diabetes between strip prescription and HbA_{1c}.

A Rational Approach to SMBG in Type 1 and 2 Diabetes

With conflicting evidence for effectiveness, how should SMBG be supported for people with diabetes? The major determinants of blood glucose testing frequency are the lability of the blood glucose concentration; the impact of the data on decision making, and personal preference [11]. With greater within-, and between-day glucose variability, as seen with absolute insulin deficiency, more glucose values are required to reveal glucose changes [12]. In type 2 diabetes, glucose is more stable and, although concentrations are elevated, may be more predictable. A single blood glucose measurement in type 2 diabetes, therefore, relates more closely to overall control and correlates well with HbA_{1c} [13].

The treatment of people with diabetes also determines the frequency of SMBG. Those with type 2 diabetes managed with diet alone, metformin, glitazones, or dipeptidyl peptidase-IV inhibitors have little or no hypoglycaemia; while those with insulin or sulphonylurea-treated diabetes are more exposed to hypoglycaemia.

In type 1 diabetes, SMBG is usually advised before and after meals, and at bedtime, with extra tests at certain times. National Institute for Health and Care Excellence (NICE) guidelines for self-management of type 1 diabetes support SMBG at least four times a day, and up to ten times a day if the desired target for blood glucose control is not achieved; if the frequency of hypoglycaemic episodes increases; if there is a legal requirement to do so (such as before driving); during periods of illness; before, during, and after sport and when planning pregnancy, during pregnancy and while breastfeeding [14].

The NICE guidance for self-management of type 2 diabetes recommends SMBG for adults with type 2 diabetes if the person is on insulin; there is evidence of hypoglycaemic episodes; the person is on oral medication that may increase their risk of hypoglycaemia while driving or operating machinery; or the person is pregnant, or is planning to become pregnant [15].

There is increasing interest in not only the mean blood glucose levels, but also in glycaemic variability and its clinical importance. While there is continued debate and conflicting evidence on whether glycaemic variability is a risk factor for complications in diabetes [16], the clearest consequence of excessive variability is that it restricts the HbA_{1c} level which can be achieved. The advent of continuous data from CGM has added further measures of glycaemic control such as 'time-in-range' (per cent glucose readings or hours per day between 3.9 and 10 mmol/L [70–180 mg/dl]) but the best indices have not been agreed [17].

CGM

The Technology and Performance of CGM

Most CGM used in clinical practice is based on needle-type electrodes [18] that are inserted subcutaneously. It is therefore minimally invasive. These amperometric (current-measuring) enzyme electrodes consist of glucose oxidase immobilized at a charged base electrode; oxidation of glucose to gluconic acid and hydrogen peroxide is monitored by the electrochemical detection of the hydrogen peroxide (Medtronic, Dexcom). One glucose sensor on the market (FreeStyle Navigator [CGM] and FreeStyle Libre [FGM], Abbott) uses a modification of this system, whereby an osmium mediator covalently bound to a polymer matrix 'wires' the enzyme to the electrode.

Glucose sensors are implanted in the subcutaneous tissue and record interstitial fluid glucose concentrations every 1–5 min over an operating period of 7–10 days. A transmitter attached to the sensor relays the data wirelessly to a storage and display device, either a portable meter, a modified insulin pump, or a smartphone. Most sensors require calibration using capillary blood glucose samples but calibration-free CGM is now available. CGM data can be either downloaded to a computer and reviewed by the multidisciplinary team and user retrospectively in order to identify patterns and aid treatment changes ('professional CGM'), or can be viewed in real-time with alerts and alarms for impending and established high and low blood glucose ('personal CGM'). Trend arrows give an indication of the direction and rate of change of blood glucose levels.

Recently a novel type of CGM technology has entered clinical practice based on a fully subcutaneously implanted capsule containing a non-enzymatic glucose-indicating fluorescence hydrogel polymer with a transmitter worn over the sensor site and transmission to a hand-held display device (Eversense, Senseonics). This technology has been successfully tested for up to 180 days' implantation, but has not yet received extensive clinical evaluation [19].

The Evidence Base for the Effectiveness of Real-Time CGM

CGM has the potential to improve overall glycaemic control (e.g. measured by HbA_{1c} and time-in-range), reduce exposure to hypoglycaemia, and positively impact on fear of hypoglycaemia. A landmark Juvenile Diabetes Research Foundation International (JDRF) study in 2008 demonstrated that CGM, when used for 6 days out of 7, reduces HbA_{1c} in children, young people and adults with type 1 diabetes compared with SMBG [20]. A subsequent meta-analysis of this and other randomized controlled trials of CGM vs. SMBG in people with type 1 diabetes treated by CSII or MDI reinforced this finding and showed that the HbA_{1c} reduction is dependent on both the frequency of sensor use and the baseline HbA_{1c} [21]. A reduction in median exposure to hypoglycaemia of 23% (CGM vs. SMBG) was also shown.

More recently studies have assessed the impact of CGM in populations most likely to use CGM in clinical practice: those with high baseline HbA_{1c} values or disabling hypoglycaemia during SMBG, as well as those using MDI regimens rather than CSII. These studies have reproducibly shown a mean reduction in HbA_{1c} of around 0.6% (6 mmol/mol) and clinically, and statistically, significant reductions in exposure to hypoglycaemia at all thresholds compared with SMBG [22, 23]. High risk populations have also been studied

with reductions in mild-to-moderate and severe hypoglycaemia (requiring the assistance of a third party) demonstrated compared to SMBG in people with type 1 diabetes and impaired awareness of hypoglycaemia or a recent history of severe hypoglycaemia [24]. Similar findings have been reported for CGM compared with FGM, suggesting that CGM is the preferred monitoring modality for people at high risk of hypoglycaemia [25]. In studies of people at highest risk of hypoglycaemia, hypoglycaemia fear is also reduced with CGM compared to SMBG and flash monitoring. Real-world data collected in a reimbursed health system suggest that CGM in people with type 1 diabetes managed in specialist centres improves HbA_{1c}, lessens fear of hypoglycaemia, and improves quality of life, while work absenteeism and admissions for acute diabetes complications, including severe hypoglycaemia, decreased [26].

Though the use of CGM in type 2 diabetes has been little investigated there is emerging RCT evidence that those using MDI and CGM have lowered HbA_{1c} compared to MDI and SMBG [27]

Clinical Recommendations for CGM

The NICE guidance for adults with type 1 diabetes supports the use of CGM devices where people have severe hypoglycaemia, unawareness of hypoglycaemia, frequent asymptomatic hypoglycaemia, extreme fear of hypoglycaemia, or where SMBG has failed, despite an intensified insulin regimen. CGM is supported by NICE for children with type 1 diabetes who are very young, unable to communicate the symptoms of hypoglycaemia, or who are at high risk of hypoglycaemia due to physical activity [14].

Flash Glucose Monitoring (FGM)

FGM or intermittently scanned CGM (isCGM) (FreeStyle Libre, Abbott) involves a subcutaneously implanted, factory-calibrated glucose sensor with up to 14 days lifetime. It provides a contemporaneous estimation of blood glucose, a trend arrow, and a graph of the preceding 8 hours' glycaemic data when a reader or smartphone is swiped ('flashed') over the sensor. There are no alarms on the original version but the recently introduced Libre 2 has customisable alarms for low and high blood glucose and is being selectively launched in several countries. It is less expensive than CGM and potentially enables users to reduce or avoid capillary SMBG. There is a limited evidence base for FGM, with few randomized controlled trials in type 1 and type 2 diabetes. First results have shown a reduction in time spent below 3.9 mmol/L (70 mg/dl) compared with SMBG, but no impact on HbA_{1c} [28, 29]. isCGM may therefore be best implemented as a replacement for SMBG where driving regulations allow, and where the budget impact is neutral or better.

Conclusion

Blood glucose monitoring in diabetes is in an exciting phase, undergoing a transition from SMBG to CGM and flash (isCGM). CGM provides information about the direction of change in glycaemic control and allows alarms when hypo- and hyperglycaemic thresholds are exceeded. Coupling sensor information to an insulin pump via suitable algorithms allows closed-loop insulin delivery—an artificial pancreas. Initially this was achieved via automatic threshold or predictive low glucose suspension of the basal insulin infusion rate of an insulin pump, and such devices are effective at reducing hypoglycaemia and are in routine clinical use [30]. Moment-to-moment, fully closed-loop systems remain a challenge but hybrid closed-loop devices (feedback control in the basal state but patient-activated meal insulin) are entering clinical practice.

15.5.3 Insulins and Insulin Delivery Devices

Pratik Choudhary and Peter Jacob

Introduction

Insulin is the life-saving treatment in type 1 diabetes, and increasingly used to treat advanced type 2 diabetes. Over the years there have been improvements and alterations in insulin treatment, moving from animal-derived insulin, through recombinant human insulin to genetically modified analogue insulins to help support people with diabetes to achieve better glucose control. Improved insulin delivery through insulin pens and more complex devices such as insulin pumps have helped improve quality of life and biomedical outcomes such as lower HbA1c and reduced hypoglycaemia. In this chapter we will describe currently available insulins with a focus on clinical trials that demonstrate differences relevant to individual users. We go on to discuss the wide variety of devices used to administer these insulins together with a discussion of their relative advantages and disadvantages.

Insulin

The insulin molecule is produced from post-translational modification of pre-proinsulin and then proinsulin. The final active hormone is a peptide comprising two amino acid chains linked by bi-sulphide bonds (Figure 15.5.3.1). In solution, insulin aggregates into hexamers around a zinc core. When injected subcutaneously, these hexamers dissociate to form monomers which can then be taken up into capillaries and enter the blood stream to exert their physiological action.

In health, insulin is secreted in a glucose-dependent manner into the portal circulation. After first pass metabolism, where more than 50% of insulin is metabolized by the liver, it acts on other organs, predominantly adipose tissue, and skeletal muscle. Ultimately, remaining insulin is cleared via kidneys [1]. Approximately 50% of insulin secretion is in response to meals (prandial insulin) and 50% is 'basal' insulin secreted at a background level even when the person is not eating [2].

Development of Insulin

The first insulins were prepared from animal pancreases and were typically either bovine or porcine. However, these only lasted a few hours and often patients needed frequent injections every day. The first modification was development of protamine or zinc-treated insulins [3]. This stabilized the insulin hexamers and prolonged the action of insulin. Human insulin was the first protein to be fully synthesized using recombinant DNA technology and this led to the development of recombinant human insulin generated within genetically modified *E. coli* [4]. These insulins were introduced in the 1980s. More recently, alterations to the amino acid sequence or addition of other molecules have

been used to create rapid-acting or long-acting insulin analogues which allow the individual more flexibility with the treatment regimen (Figure 15.5.3.2).

Today, we consider insulins in two main groups. The soluble or rapid-acting insulins are designed to cover the rapid rise in insulin requirements after ingestion of carbohydrates, or to correct acutely raised blood glucose levels, and are called meal-time or bolus insulins. Other longer acting insulins provide background or 'basal' insulin replacement to balance endogenous glucose production towards maintenance of stable blood glucose levels stable in the fasted or basal state.

Key goals of insulin development have been to increase the speed of onset of 'rapid-acting insulin' to better cover meal-time requirements; and to slow down and attain a longer and flatter profile for 'basal' insulins (Figure 15.5.3.3). Further development has been towards delivering the insulin via the inhaled or oral routes. On the horizon are numerous other insulins which have faster onset of action or the ability to reduce or switch off action in response

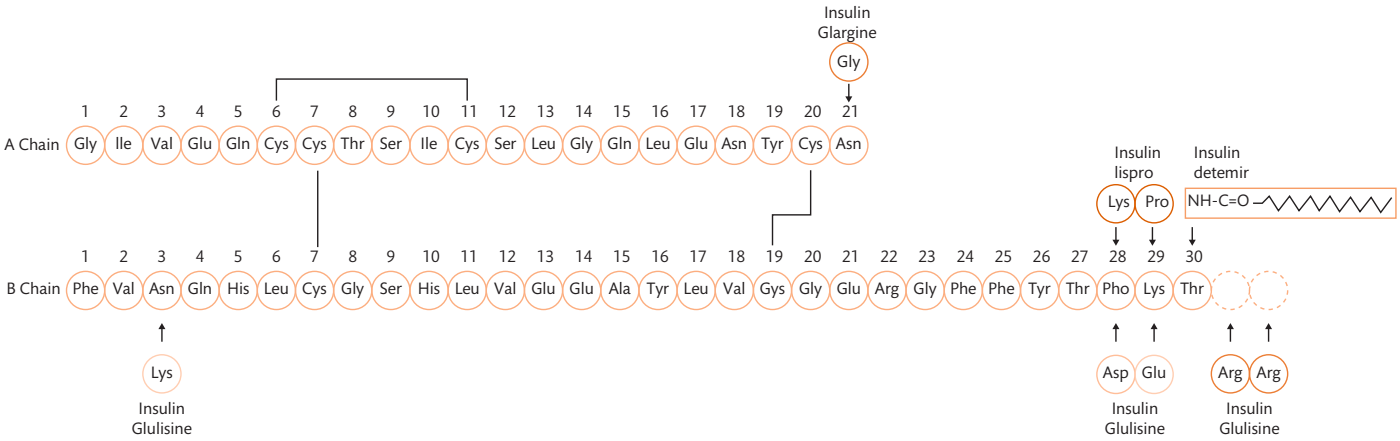

Figure 15.5.3.2 Amino acid structure of insulin. Insulin analogues are created by substitution of amino acids, or insertion of a new group on either the A or B chain at specific sites. Aspart–aspartate replaces B28 proline. Glulisine–lysine replaces B3 asparagine and glutamate replaces B29 lysine. Lispro–lysine replaces B28 proline and proline replaces B29 lysine. Detemir–myristic acid moiety replaces B30 threonine binding directly to B29 lysine. Glargine–glycine replaces A21 and two arginines bound to B30 threonine.

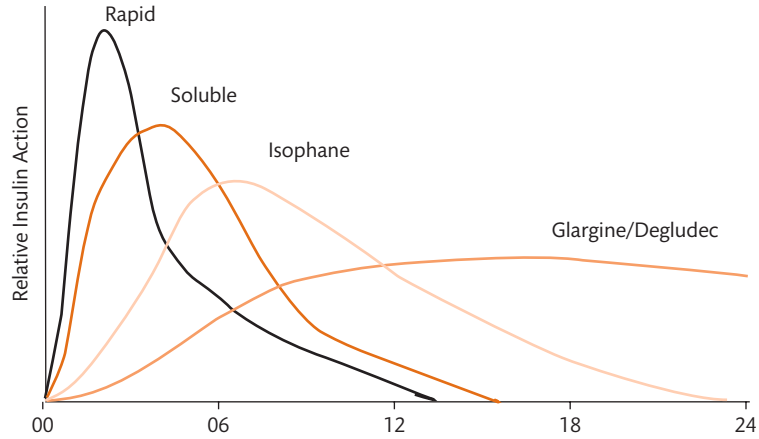

Figure 15.5.3.3 Relative insulin activity following a single subcutaneous injection of each insulin.

to low blood glucose (hypoglycaemia). A very small number of patients continue treatment with bovine or porcine insulins, but these treatments have been superseded and will not be discussed further here.

Prandial Insulins

Soluble human insulin is a synthetic insulin manufactured using recombinant DNA technology and has the same amino acid structure as native human insulin. It aggregates into hexamers at higher concentrations and thus when injected subcutaneously has a delayed onset of 30–60 minutes, peak effect after 2–4 hours and prolonged duration of action (6–8 hours) (Table 15.5.3.1). Evidence suggests that soluble insulin should be injected up to 30 minutes before eating to control postprandial excursions and reduce the risk of late hypoglycaemia [5]. Its long duration of action continues to predispose to a risk of late hypoglycaemia with between meal carbohydrate-containing snacks often required. There is significant interdose variability in absorption and duration of action may be prolonged with larger injection volumes impacting on reliability.

Table 15.5.3.1 Comparison of insulin action profiles for commonly used insulins

Insulin	Time to onset	Peak activity	Duration of action
Prandial insulin			
Soluble human insulin	30–60 min	2–3 min	6–8 hr
Rapid-acting analogues	15 min	30–90 min	4–6 hr
Faster aspart	5–15 min	30–90 min	3–5 hr
Basal Insulin			
Isophane	2–4 hr	4–10 hr	12–14 hr
Detemir	1–2 hr	6–12 hr	Up to 24 hr
Glargine	2–4 hr	Peakless	Up to 24 hr
Degludec	2–4 hr	Peakless	Up to 42 hr

Rapid-acting insulin analogues were designed to minimize the need for early preprandial injections and to reduce the risk of hypoglycaemia late after the meal. Insulins lispro, aspart and glulisine were created by substituting amino acids at key residues at the end of the insulin B chain to rapidly reverse hexamerization following injection. With lispro, the amino acids proline and lysine at positions B28 and B29 of the insulin β-chain are reversed. To create aspart the B28 proline is exchanged for aspartic acid. Finally, with glulisine, the asparagine at B3 is altered to lysine and the B29 lysine replaced with glutamic acid. The resulting insulins all have similar pharmacokinetic profiles with onset time of 5–15 minutes and a duration of action of between 4 and 6 hours [6]. Crucially, the peak insulin concentration and the peak insulin effect may still be 40–60 minutes or 120 minutes post-dose, respectively [5]. With these data, patients should still be advised to inject 15–20 minutes before a meal when it is safe to do so. Despite clear advantages for the user, the published data suggest only modest HbA1c improvements of –0.1% compared to soluble insulin [7]. Reductions in total number of hypoglycaemic episodes, number of severe hypoglycaemia events and nocturnal hypoglycaemia were seen in the analogue group but due to differences in trial design clear comparative analysis was not possible. A more recent RCT looked specifically at hypoglycaemia rates in high risk patients with more than two severe hypoglycaemic events per year. This found a significant reduction in the rate of hypoglycaemia when using rapid-acting insulin analogues in comparison to soluble insulin [8]. Benefit of rapid-acting analogue insulins in T2D is less clear [7].

There are a some 'ultra-fast' acting insulins in development, with faster acting insulin aspart (FiAsp®) now clinically available. In this preparation, nicotinamide (Vitamin B3) has been added, intended to enhance absorption by encouraging insulin monomerization, together with L-arginine which is purported to enhance insulin stability. The aspart amino acid structure is unchanged, so that once in the bloodstream the effect is identical to regular aspart. These modifications shift the insulin action curve 5–10 minutes to the left, providing greater insulin action within the first 30 minutes [9]. In clinical trials, better postprandial control was associated with lower overall HbA1c and similar hypoglycaemia rates in type 1 diabetes [10]. Although there was a reduction in postprandial glucose, there was no reduction in HbA1c in type 2 diabetes [11].

Basal Insulins

The treatment of insulin with protamine (isophane insulins) or its co-injection with zinc (Lente insulin series), provided basal insulin treatment for many years. Isophane insulins have persisted as a treatment option, predominantly because of lower acquisition cost in comparison to newer basal analogues. Due to a duration of action of 12–14 hours, isophane is best used twice daily in T1D, but may be used once daily as part of T2D management. There are two major limitations with the use of these 'cloudy' suspensions however, variability in both peak action and duration. Studies have shown variable rate of absorption of isophane insulin on a day-to-day basis of 25–35% which may lead to variable control and risk of hypoglycaemia when aiming for good control [12]. Additionally, the pharmacokinetic profiles of isophane insulins show a peak in action at 4–6 hours which may predispose to hypoglycaemia, particularly when administered before bed, necessitating a suppertime long-acting carbohydrate snack. Duration of action may be injection volume dependent and variable with the same dose on different days.

Analogue Basal Insulins

Subsequently, analogue basal insulins were introduced in which modifications to the insulin chain lengthened the duration of action. The first basal analogue was insulin glargine which was created by adding two basic arginine amino acid residues onto the B chain and substituting a glycine for an asparagine residue on the A-chain (Figure 15.5.3.2). This molecule is soluble at acidic pH, but once exposed to the neutral subcutaneous environment it crystallizes. Its duration of action is long at 18–24 hours and in many people can be used as a once daily insulin, however others may experience pre-dose hyperglycaemia and require twice daily administration. It is described as 'peakless' (Figure 15.5.3.3) and has an onset of action 2–4 hours after injection. Insulin detemir has a fatty acid chain (myristic acid) bound to a lysine amino acid on the B chain of the insulin molecule. This slows down its absorption and allows greater binding to subcutaneous and serum albumin where it is chemically inert. Detemir similarly has onset of action 2–4 hours after dose but duration of action of 16–18 hours and is thus commonly administered twice daily in T1D.

A direct, head to head, non-inferiority study comparing detemir and glargine showed comparable results between the two [13]. Thus, each insulin could legitimately be chosen according to user preference. Those with more variable lifestyles could choose detemir allowing dose down-titrations on days when exercise or alcohol might increase the risk of nocturnal hypoglycaemia whereas glargine might be preferred in those who desire stability and once daily injection. A meta-analysis has suggested that long-acting insulin analogues are superior to intermediate acting insulin but at greater acquisition cost [14].

More recently new insulin analogues have been introduced to the market. A biosimilar insulin glargine is available and has been demonstrated to be non-inferior to standard insulin glargine in both type 1 and type 2 diabetes [15, 16]. Insulin degludec is another modified insulin where hexadecanedioic acid is conjugated to the lysine amino acid at position B29. This modification reduces absorption and enhances protein binding in a similar fashion to detemir but gives insulin degludec a very long duration of action of 42 hours. It therefore allows once daily administration with some variability in daily timing of dose. In T1D and T2D statistically significant reductions in the rate of hypoglycaemia are seen in comparison to glargine [17, 18].

Premixed Insulins

Premixed insulins contain rapid-acting and basal insulin in a predefined ratio. Historically, most patients would 'free-mix' a variable amount of soluble and isophane insulin twice a day. For example, a mixture of soluble and intermediate insulin in the morning would allow a child to get through the school day without needing an injection at school. Certainly, premixed insulins as part of a biphasic regime may be useful in patients where adherence or patient preference for fewer injections dictates treatment decisions such as in children or adolescents. Evidence for their use is stronger in T2D where a meta-analysis has shown that greater than 50% of people can achieve good glycaemic control on a biphasic regime although patients who can manage a basal-bolus had better control with a similar hypoglycaemia rate [19].

Numerous premixed insulins are available and there are important differences between them. Until recently the combinations included either soluble insulin or rapid-acting analogue with isophane. The ratio of short to long-acting insulin varies between preparations but is usually between 25% to 50% short/rapid acting. The 30/70 mixtures (with 30% soluble and 70% isophane insulin) are the most widely used, but in cultures with high carbohydrate intake, 50:50 mixtures have been shown to provide better glucose control [20]. Nomenclature varies around the world and prescribers should be familiar with the terminology used in their country. Due to the pH dependent crystallization of insulin glargine, premixed insulins with analogue basals have not been available. This has changed with licensing of a combination of aspart with degludec.

The limitation of the premixed insulin is the in-flexibility of dosing schedule. The peak of the soluble component is designed to cover the immediate meal, and the peak of the isophane component that arrives 4–6 hours later is designed to cover a second meal. However, if that meal is delayed or of a different carbohydrate content, this could predispose to hypo or hyperglycaemia. For this reason, these fixed combination insulins are best used in those with fixed daily habits.

Different Strengths of Insulins

In some markets, different strengths of insulin are available. The most commonly available insulin is U100 that contains 100 IU of insulin/ml. In some markets, more dilute insulin is available (U40–40 IU/ml) that can be used especially in very young children. It is key to know which insulin is being used and use the appropriate delivery device that is calibrated to the strength of insulin being delivered. In the 1980s it was recognized that the numerous different strengths of insulins contributed to hypoglycaemia [21]. Poor understanding of the different strengths among doctors, pharmacists, and patients together with unclear labelling of insulin syringes compounded the problem. Insulin production and sale in most western markets was consequently restricted to production at a fixed strength (U100).

The obesity epidemic has caused increased rates of insulin resistance and a new need for higher-strength insulins. Higher insulin concentration and hence, smaller dose volumes have lower

variability in dose absorption, duration of action, and have the advantages of single rather than multiple injection with higher doses. U500 insulin is available comprising 500 IU of insulin/ml and can be used in extremely insulin resistant patients [22]. A concentrated insulin lispro U200 (200 units/ml) was introduced to the market in 2015. Both are soluble or prandial insulins.

There are currently two concentrated basal insulins available. Insulin degludec is available as a U200 formulation (200 units/ml) and insulin glargine is available as U300 (300 units/ml). The pharmacokinetic profiles indicate that glargine U300 has a longer duration of action with lower peak activity [23]. In T2D there was a small but statistically significant reduction in hypoglycaemia (particularly at night) when using U300 [24] and it may be considered in patients where this is a particular concern. There was no difference between Glargine-U100 and Glargine-U300 in T1D trials [25].

Prescribers and pharmacists must have a good awareness of the differences between these insulins and patients must be educated appropriately to prevent dose errors. If we can overcome these barriers higher-strength insulins may play a significant role in optimized diabetes treatment [26].

Insulin Delivery Devices

Historically, insulin was drawn up from a vial and injected via a specific insulin syringe with marked graduations allowing the correct volume and dose of insulin delivery. In the early days, these were glass syringes that required regular cleaning and sterilization. Devices such as the Palmer Injector were developed to make things easier, although these were not widely used. In the 1980s, manufacturers developed insulin pens that come as pre-filled disposable pens, or as re-usable pens in which cartridges can be changed [27]. Insulin pens remove the need to draw up insulin which can reduce error, making them more convenient, more discreet, and easier to handle. They require disposable needles that can be of different lengths. Insulin users describe pens as more acceptable and greater satisfaction can be achieved with them while achieving improved HbA1c and reduced hypoglycaemia rates [28].

Key differentiators between pens are differences in the manual dexterity and force required to use them and ease of delivery. Newer pen devices offer the ability to synchronize with a mobile application featuring a bolus advisor, enabling convenient insulin dose tracking and more accurate bolus advice [29].

There has long been an interest in needle-free injection devices, as the use of a needle is a major barrier for many patients who need insulin therapy. There have been some needle-free 'jet' injector devices available on the market, but these are not widely used as they often cause pain or bruising and have less predictable delivery [30].

It is clear that, whatever the preferred method of insulin delivery, high quality education and support from the multidisciplinary diabetes team is crucial in delivering best outcomes [31].

Inhaled Insulins

The possibility of absorption of insulin via inhaled devices offers a clear advantage to some patients (particularly those with phobia of injections and extreme variability in the action of insulin administered subcutaneously). A key benefit is the rapid onset of action with associated reductions in postprandial spikes, but this is offset by reduced and variable bioavailability together with short duration of action.

Initial attempts at development were beset with problems including variable bioavailability and concerns around effects of insulin on lung function. This ultimately led to withdrawal of all drugs from development for some time [32]. More recently, insulin adsorbed to porous Technosphere particles has been developed. Technosphere insulin (TI) has been shown to have more rapid absorption and onset of action (10 minutes) compared to rapid-acting analogues. It has peak action after 30–60 minutes and short duration of action (2–3 hours). Despite this, a meta-analysis has shown greater reductions in HbA1c with subcutaneous insulin compared to TI, albeit with a greater propensity to severe hypoglycaemia and weight gain [33]. Given this, TI may be considered for use when subcutaneous prandial insulin injection is not possible.

Continuous Subcutaneous Insulin Infusion (CSII)

Insulin pumps can be used to deliver rapid-acting insulin continuously into the subcutaneous compartment and were first used in clinical studies in the 1970s [34]. The pump has an electromechanical motor and a reservoir of insulin, usually rapid-acting analogue insulin. The patient and clinician preprogramme different basal rate profiles into the pump that allow basal insulin delivery that can be varied through the day in response to the known circadian profile of insulin sensitivity [2]. In health, basal insulin delivery is lower overnight and rises immediately before the patient wakes up, often called the 'dawn phenomenon' [35]. Pump users can program the pump with different basal rate profiles to accommodate changes in insulin requirements with work, weekends, or illness (Figure 15.5.3.4). Crucially, this basal insulin delivery can also be temporarily increased or decreased using a 'temporary basal rate' in response to exercise, illness, or alcohol.

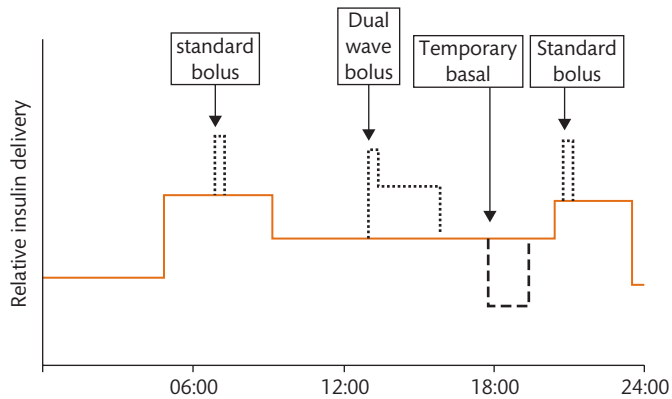

Figure 15.5.3.4 Demonstration of several features of insulin pump insulin delivery.

The flat line indicates continuous insulin delivery. An example alternative basal profile is superimposed with low rate of insulin delivery overnight to prevent nocturnal hypoglycaemia and greater delivery in the morning and evening to combat hyperglycaemia at times of physiological insulin resistance. Finally at meal times, boluses are delivered 15 minutes before meals to cover breakfast and the evening meal as well as a dual wave bolus at lunchtime to cover a high protein/fat meal.

When a bolus of insulin is required to cover carbohydrate intake or to correct hyperglycaemia, the user presses a button to deliver the desired bolus. Boluses can be delivered immediately, or over a prolonged duration (square or dual wave boluses) to cover high fat meals that produce sustained hyperglycaemia. Most pumps have software (bolus calculators) that perform the calculations required for boluses using preset insulin to carbohydrate ratio (ICR) and insulin sensitivity factor (correction factor). One of the key benefits of insulin pumps is the ability to easily deliver multiple boluses to cover all carbohydrate intakes, and take small corrections when needed, as well as the ability to rapidly adapt the basal profile as required. These features allow better matching of insulin requirement to insulin delivery, facilitating improved diabetes control in terms of lower HbA1c as well as less hypoglycaemia.

Observational data show that CSII therapy is associated with significant improvements in HbA1c and hypoglycaemia. A meta-analysis of CSII studies demonstrated a 4-fold reduction in rates of severe hypoglycaemia requiring third party assistance, and a reduction in HbA1c [36]. Benefits in both hypoglycaemia and in glucose control were dependant on baseline. Most studies have shown significant improvements in quality of life, which is an important factor for a lifelong, chronic condition. Initially developed in the United Kingdom and the United States, the uptake of insulin pump therapy is markedly different in different countries, varying from above 40% of people with T1D in the United States to about 20–30% in many European countries and under 15% in the United Kingdom. This can be explained by the cost of these devices, and the perceived complexity, and increased education required for safe and effective use. Cost aside, the potential benefit in motivated and well-educated people with T1D with either sustained hyperglycaemia or troublesome hypoglycaemia is clear. The best results with CSII are demonstrated in specialized centres with access to a highly trained staff group for education and support of insulin pump users.

The REPOSE RCT enrolled patients who did not have a clear preference or indication for pump therapy and compared the outcomes of a structured education programme with or without pump therapy. Both arms showed modest improvements in HbA1c with no differences in hypoglycaemia rates, but with clear improved satisfaction in those with pump therapy. Interestingly, a post-hoc per-protocol analysis showed that when patients who crossed over from pump to MDI or vice versa were analysed according to the treatment they actually received, there was a significant benefit of pump therapy on HbA1c. Similarly, the HypoCOMPaSS study in patients with impaired awareness of hypoglycaemia found that when provided intensive support, there was no incremental benefit of pump therapy over the control arm using injections, although again, there was a clear benefit in quality of life [37, 38].

A recent randomized controlled trial of insulin pumps in patents with type 2 diabetes and high insulin requirements demonstrated improved diabetes control with lower insulin requirements when using insulin pumps [39].

Types of CSII Insulin Pump

Broadly speaking, there are two common insulin pump types that are in use today: tethered pumps and patch pumps. The key difference is the presence or absence of tubing between the pump and the skin.

Tethered pumps deliver insulin via tubing to a cannula inserted subcutaneously. The cannula itself usually looks like a small disc and is placed 4–8 mm deep using an insertion needle. The pump is usually powered by domestically available batteries and can be carried in a comfortable, convenient position in pockets or pouches as decided by the user. The principle control of the pump is generally via an interface on the pump itself, although some may be controlled via a remote device. This allows the user to control the pump unobtrusively. However, some people do not like to be attached to the tubing, finding that the tubing can catch on things and get ripped out, or have deeper-seated body image issues decreasing acceptability of pump therapy.

Patch pumps are directly attached to the skin for the duration of use and have the convenience of no tubing but have the disadvantage of being dislodged if knocked. Control of the pump is generally achieved by a wirelessly connected remote device which usually also functions as a blood glucose meter. There is no particular advantage of one type of pump over the other, apart from patient preference [40].

Most currently available pumps allow data including basic settings, blood glucose values, and insulin doses delivered to be stored. These can then be downloaded by users or healthcare professionals to allow periodic review of control.

Advanced Features of Pumps

The delivery of basal insulin can be set up in numerous ways. Some teams prefer to start with a 'flat' basal that is usually 40–50% of the total daily insulin (Figure 15.5.3.4). Other groups use a circadian profile, or a modified circadian profile that can be programmed using a template, allowing the basal insulin delivery to match the normal circadian profile of insulin requirement. It is important to recognize that overnight insulin requirements vary by up to 200% in the same person between nights [41], and so patients still need to adjust their insulin levels based on review of their blood glucose data.

The basal insulin delivery can be temporarily increased or decreased by either a percentage of the current basal rate or by a fixed amount for a fixed duration, termed a 'temporary basal rate'. This is particularly helpful when the patient needs to reduce basal insulin delivery in response to exercise or alcohol, or increase it in response to illness. Changes in basal rates can take time to impact on plasma insulin, and so these features are most useful when the increase or decrease is required for a longer period.

Different Types of Bolus

High fat or protein content in meals can cause a carbohydrate independent rise in glucose levels. This may be due to temporary insulin resistance caused by fat, or gluconeogenesis stimulated by protein intake. High fat meals can lead to late hyperglycaemia that can last up to eight hours after a meal. Insulin pump users can program square or dual wave insulin boluses that can cover this delayed increase in insulin requirement.

Bolus Advisors

Most insulin pumps currently available have integrated bolus advisors. These are calculators that can perform simple calculations required to deliver precise amounts of insulin taking into consideration factors such as ICR, insulin sensitivity factor, and insulin

action time. The ICR is the amount of carbohydrate that is covered by a single unit of insulin. This can also be expressed as the amount of insulin required to cover a fixed amount of carbohydrate (usually a carbohydrate exchange which can be 10 or 12 grams). This usually varies between 8 and 12 grams per unit of insulin, although for insulin sensitive patients this can be higher and for insulin resistant patients, this can be as low as 2 or 3 grams per unit of insulin.

The use of bolus advisors offers greater accuracy in dosing and some studies have shown that they help reduce glucose variability and improved glucose control [42]. Additionally users report this technology saved time, improving confidence in the dose given [43].

Sensor Augmented Pumps (SAP)

With the advent of real time continuous glucose monitoring systems, some pumps can connect with integrated continuous glucose monitoring (CGM) systems allowing display of glucose values on the pump (see Chapter 15.5.2, 'Glucose Monitoring and Sensing'). The user can utilize these data to make frequent small adjustments in insulin dosing via the pump. Ultimately SAPs could provide complete 'closed loop' control that functions like an 'artificial pancreas'.

The first step along this pathway was systems that used 'threshold suspend' of insulin. These systems can automatically suspend insulin delivery for a fixed duration (usually for up to 2 hours). For example, if the 'low threshold' is set at 3.6 mmol/L (65 mg/dl), the system alerts the user when the glucose reaches this threshold, and if there is no response from the user, it will automatically suspend insulin delivery for up to 2 hours. These types of system do not actually prevent hypoglycaemia, but can minimize the impact of prolonged low glucose and in randomized controlled trials have been shown to significantly reduce duration of nocturnal hypoglycaemia [44].

The next generation of SAP systems proactively aim to prevent hypoglycaemia, by automatically suspending insulin delivery when hypoglycaemia is predicted. Often these systems will suspend insulin delivery while glucose is still in the normal or desirable range, based on the trajectory of glucose. They can also restart insulin once the glucose is back above a safe level and rising. These systems offer progressive improvements in protection against hypoglycaemia [45]. Similarly, the devices can alarm if glucose levels are too high, prompting the user to take appropriate corrective action.

Closed Loop 'Artificial Pancreas' Systems

Over the last 10 years, various closed-loop systems have been developed and tested in different environments (see Chapter 15.8.2, "Closed Loop" Insulin Delivery). A closed-loop system includes three main components. The first is a continuous glucose sensor that detects glucose levels including direction of change. The second is an algorithm that can be housed on a portable computer, a mobile phone, or even the insulin pump itself. This controller calculates the insulin required at any given time point to maintain glucose levels as close as possible to the target glucose. Often the calculation is overseen by safety modules that govern the maximum amount of insulin that can be given and may adjust the calculation if food or exercise are detected. The third component, the insulin pump, delivers the insulin as advised by the algorithm.

Closed-loop systems have been shown to be relatively safe in clinical trials, providing improved glucose control with reduced hypoglycaemia compared to standard treatments. A major challenge for closed-loop systems is the delay in glucose sensing (changes in interstitial glucose often occur 5–10 minutes after blood glucose), which means there is a delay before a rise due to food or glucose fall due to exercise is sensed. The other issue is the relative slowness of currently available 'fast' acting analogues that have a delayed peak and prolonged duration of action, especially when compared to portally secreted endogenous insulin.

A key issue for closed-loop systems is their ability to deal with unannounced meals or exercise. Current insulin kinetics require rapid-acting insulin to be dosed 10–15 minutes before a meal. This is obviously a problem for a truly closed-loop system which requires no input from the user. One solution is a 'hybrid' closed-loop system that requires 'meal announcement' from the user. The more precise this is, the greater the degree of post-meal glucose control.

Another problem is unannounced exercise. Even though systems can be programmed to reduce insulin delivery when exercise is detected, the prolonged action of current insulin preparations and delivery through the subcutaneous route mean that even after complete suspension of insulin there is considerable risk of hypoglycaemia with unannounced exercise.

One hybrid closed-loop system is currently available, the Medtronic Minimed™ 670 g Insulin Pump System with others in development.

Continuous Intraperitoneal Insulin Infusion (CIPII)

A very small number of people use an insulin pump where insulin is continuously delivered into the peritoneum and absorbed preferentially into the portal blood via peritoneal blood vessels [46]. There are two methods for CIPII: fully implanted pumps or external pumps with intraperitoneal delivery.

Implantable pumps have been used in a small group of patients, predominantly in France for many years. An insulin pump is inserted into a pocket in the abdominal wall and a catheter tunnelled to the peritoneal cavity [47]. CIPII has been shown to improve HbA1c and reduce number of hospital admissions in a series of complex patients [48]. It is limited by the need for pump refills and system flushes in addition to potential for 'pocket' infection so cannot be considered a mainstay of treatment [46].

An alternative technology is the DiaPort system in which an external insulin pump is connected to an intraperitoneal delivery system. This has been shown to reduce severe hypoglycaemia in a complex group of people with T1D [49] albeit with problems of port site infections. This has been addressed in a more recent clinical trial without fully published results, but in which many of the infections were managed conservatively [50]. Both implantable technologies require insulin specifically manufactured to prevent aggregation within the pump [51].

Treatments on the Horizon

Glucose-responsive 'smart' insulins are being developed in which the insulin activity depends upon the serum or tissue glucose level [52]. Several strategies for achieving this are being investigated. They include incorporating insulin within a polymer or matrix which has the capacity to release insulin according to glucose concentration. Another strategy is to modify the insulin molecule to allow glucose-dependent action or conformational change which inhibits binding to the insulin receptor during hypoglycaemia.

Micro needles in a patch may offer a method of delivering insulin intradermally with faster absorption due to the greater vascularity of the dermal space. Systems for combining this mode of therapy with glucose-responsive elements are in development [53, 54].

As well as offering a more acceptable route of administration, insulin absorbed through the gut offers more physiological delivery to the vasculature. Absorption into the portal veins allows highly concentrated action on the liver, with relatively little acting systemically providing potentially lower hypoglycaemia rates. With ongoing research into this field, oral insulins may come to the market as a viable treatment option in the coming years.

15.5.4 Non-Insulin Glucose-Lowering Agents

Clifford J. Bailey and Melanie J. Davies

Introduction

This chapter will focus on non-insulin therapies to treat hyperglycaemia in type 2 diabetes. Glycaemic control is an important part of the management of type 2 diabetes, which is a complex process due to the diverse, variable, and progressive nature of the disease pathogenesis, clinical complications, and societal impact (**Box 15.5.4.1**). Care should be individualized, flexible, and realistic, with provision for patient education and empowerment to enable optimal benefit from the guidance and interventions offered by healthcare professionals. Patient preference should be considered with a focus on

Box 15.5.4.1 Multiple features of type 2 diabetes mellitus that make this a complex disease to treat

- Polygenic susceptibility
- Multiple environmental impositions
- Variable endocrine defects (e.g. insulin resistance and islet dysfunction)
- Diverse metabolic disturbances
- Progressive natural history
- Extensive complications and comorbidities (e.g. cardiovascular and renal diseases)
- Many concurrent therapies usually involved
- Substantial patient education, empowerment, and commitment required
- Impacts family, friends, and work colleagues
- Many different healthcare disciplines implicated

choices which optimize adherence to and persistence with therapy. Relief of acute symptoms and attention to long-term complications and comorbidities often preoccupy and sometimes overwhelm the treatment process. However, early and sustained remediation of endocrine and metabolic disturbances, in combination with containment of modifiable cardiovascular risk factors, prevents the onset, and limits the severity of chronic pathology.

Glycaemic Management

Glycaemic control serves as a valuable indicator of metabolic status, and we re-emphasize that good glycaemic control can reduce both micro- and macrovascular complications. Reductions in microvascular disease have been confirmed in almost all trials of intensive glycaemic control, whereas improved cardiovascular outcomes may only emerge after several years, being more evident in younger patients with better control from the time of diagnosis [1]. Moreover, the closer that long-term glycaemic control approaches to normoglycaemia, the fewer the complications (Figure 15.5.4.1), excepting that overintensification of treatment to cause persistent or severe episodes of hypoglycaemia must be avoided [2]. There is also evidence that some glucose-lowering agents offer independent benefits against the major cardiovascular and renal complications of type 2 diabetes.

The post-trial follow-up of the United Kingdom Prospective Diabetes Study (UKPDS) has provided clinical confirmation of the so-called 'glycaemic memory' or 'legacy effect'. This effect, which probably reflects the accumulated damage from glucotoxicity, renders individuals with poor glycaemic control during earlier stages of the disease at much higher risk of complications in later life, even if their control is subsequently improved [3]. Thus, available evidence supports the early use of blood glucose-lowering therapy to attain and maintain a level of glycaemic control as close to normal as safely practicable and commensurate with the circumstances of the patient.

Guidelines

The many guidelines and consensus statements regarding pharmacological therapies to control blood glucose in type 2 diabetes show a considerable degree of conformity [4–6] (Figure 15.5.4.2).

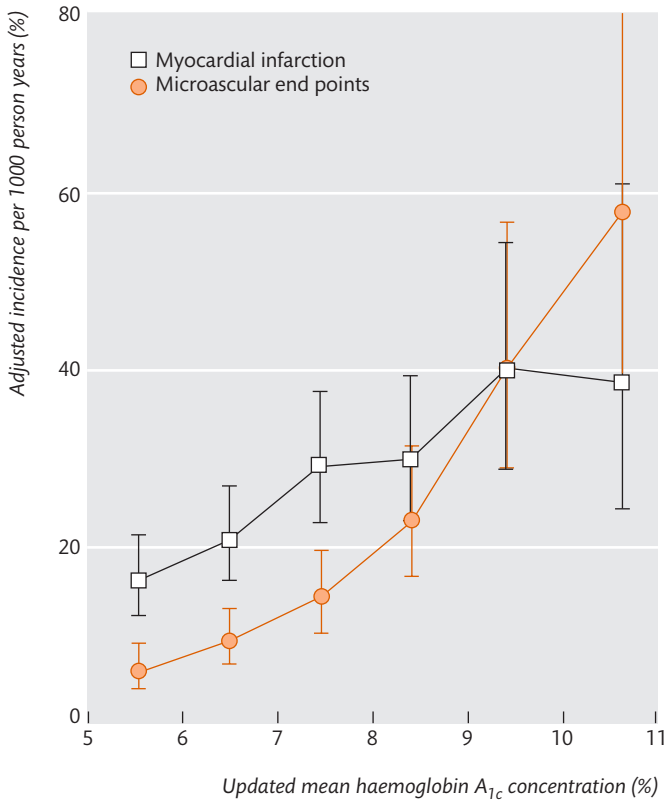

Figure 15.5.4.1 Improved glycaemic control as measured by a lowering of average HbA1c over 10 years during the UKPDS was associated with reductions in microvascular complications and myocardial infarction.
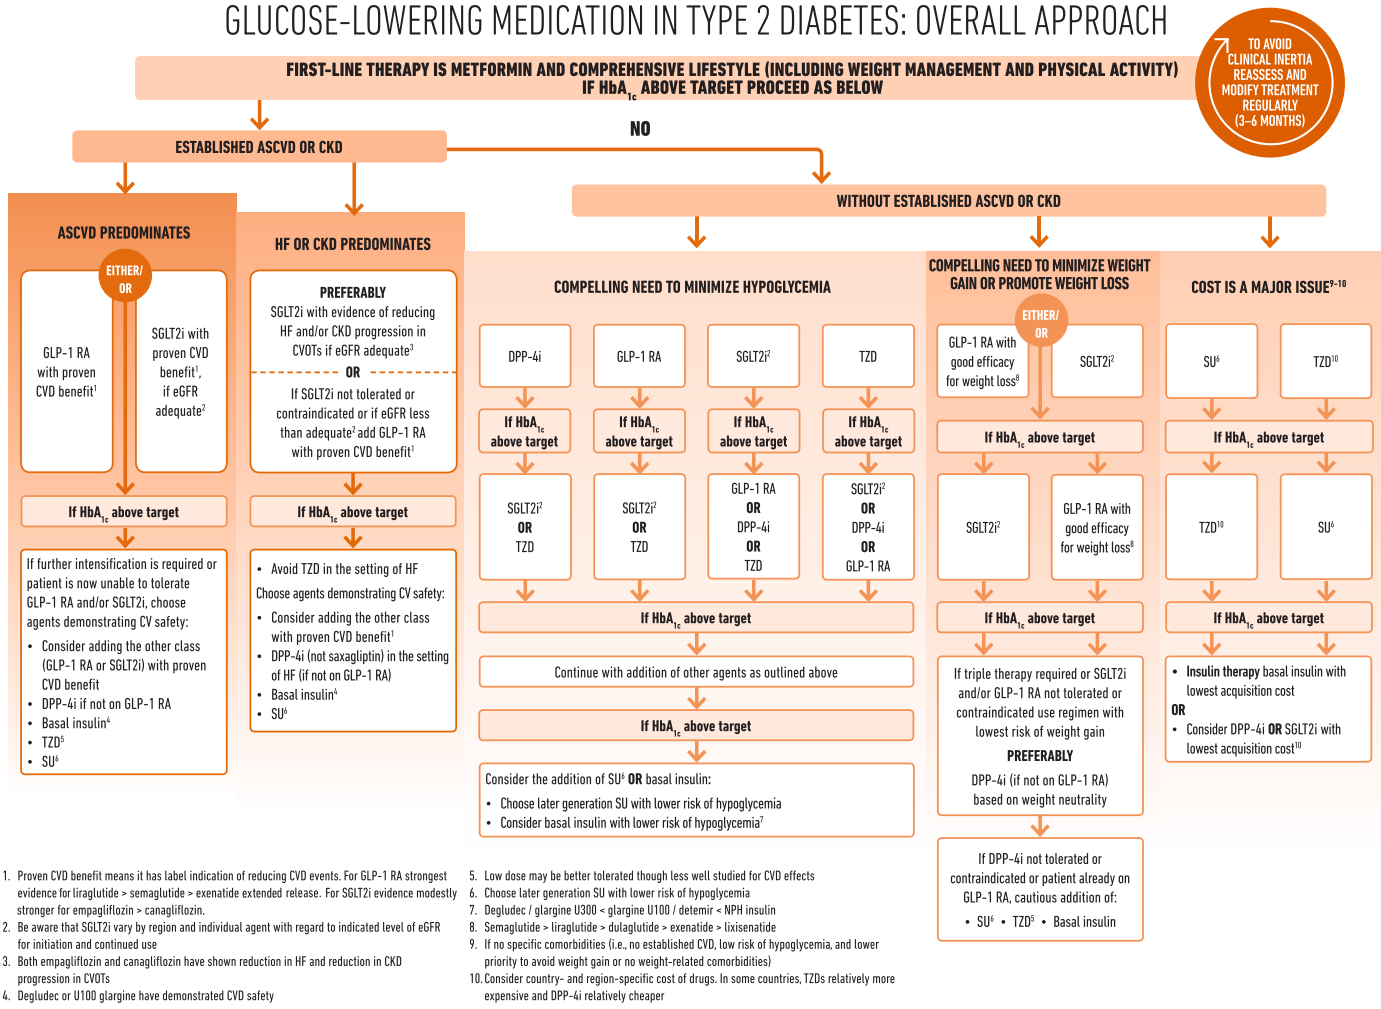
Reproduced with permission from Stratton et al, *Br Med J* 2000; **321**: 405–12, ref 2.

Lifestyle measures invariably form the foundation for management of type 2 diabetes, especially diet and exercise for weight control, cardiovascular wellbeing, and psychosocial health [4–8]. Pharmacological therapies are added to achieve and sustain the desired glycaemic target, generally starting with one oral agent. If the target is not achieved or maintained by increasing the doses, a differently acting oral agent or injectable agent is added. If this combination is unable to prevent disease progression, a third agent is added. The selection of agents at each stage will be strongly influenced by the presence of comorbidities, including CVD, obesity, renal or hepatic impairment, age, and personal circumstances. Submaximal doses of two or more agents may be preferred to enhance efficacy and reduce side effects that are sometimes encountered with a large dose of one agent. Insulin is customarily reserved for patients in whom a combination of other agents does not provide continuing control, but insulin may be introduced earlier if patients are severely hyperglycaemic and substantially symptomatic with comorbidities that deter the use of other therapies.

Synopsis of Therapies

The main orally administered blood glucose-lowering therapies are metformin, sulphonylureas, meglitinides, dipeptidyl peptidase-4 (DPP-4) inhibitors (gliptins), sodium/glucose cotransporter-2 (SGLT-2) inhibitors, thiazolidinediones (TZDs), and α -glucosidase inhibitors (AGIs). Bromocriptine and colesevelam also have an indication



1. Proven CVD benefit means it has label indication of reducing CVD events. For GLP-1 RA strongest evidence for liraglutide > semaglutide > exenatide extended release. For SGLT2i evidence modestly stronger for empagliflozin > canagliflozin.
2. Be aware that SGLT2i vary by region and individual agent with regard to indicated level of eGFR for initiation and continued use
3. Both empagliflozin and canagliflozin have shown reduction in HF and reduction in CKD progression in CVOTs
4. Degludec or U100 glargine have demonstrated CVD safety
5. Low dose may be better tolerated though less well studied for CVD effects
6. Choose later generation SU with lower risk of hypoglycemia
7. Degludec / glargine U300 < glargine U100 / detemir < NPH insulin
8. Semaglutide > liraglutide > dulaglutide > exenatide > lixisenatide
9. If no specific comorbidities (i.e., no established CVD, low risk of hypoglycemia, and lower priority to avoid weight gain or no weight-related comorbidities)
10. Consider country- and region-specific cost of drugs. In some countries, TZDs relatively more expensive and DPP-4i relatively cheaper

Figure 15.5.4.2 Algorithm for the management of hyperglycaemia in type 2 diabetes as set out in the 2020 consensus report by the American Diabetes Association (ADA) and the European Association for the Study of Diabetes (EASD) [4]. This algorithm takes account of emerging evidence of the properties of individual agents in relation to particular patient groups, particularly those with renal impairment or cardiovascular diseases. A decision to treat high-risk individuals with a GLP-1 receptor agonist or SGLT2 inhibitor to reduce major adverse cardiovascular events, hospitalisation for heart failure, cardiovascular death or chronic kidney disease (CKD) progression should be considered independently of baseline HbA1c or the individualised HbA1c target. Also, GLP-1 receptor agonists can be considered in patients with type 2 diabetes without established cardiovascular disease but with the presence of specific indicators of high risk. SGLT2 inhibitors are recommended in patients with type 2 diabetes and heart failure, particularly those with heart failure with reduced ejection fraction, as well as patients with CKD (eGFR 30 to ≤60 ml/min/1.73 m^2 or urinary albumin-to-creatinine ratio >30 mg/g. HbA1c target is usually <6.5%-7.5% (<48-58 mmol/mol), but will vary with patient circumstance.
ASCVD, atherosclerotic cardiovascular disease; CKD, chronic kidney disease; CVD, cardiovascular disease; DPP-4i, dipeptidyl peptidase-4 inhibitor; GLP-1RA, glucagon-like peptide-1 receptor agonist; HbA1c, glycated haemoglobin; SGLT-2i, sodium/glucose co-transporter-2 inhibitor; SU, sulphonylurea; TZD, thiazolidinedione.

for use as glucose-lowering agents in some countries (not Europe) (9). The parenterally administered agents are glucagon-like peptide-1 (GLP-1) receptor agonists and insulin: pramlintide injections are indicated for glucose lowering with insulin in some countries (not Europe). The main actions, typical efficacy, and important cautions for agents other than insulin are summarized in Table 15.5.4.1.

Starting Pharmacological Therapy

If hyperglycaemia is severe, or initial lifestyle measures do not achieve desired glycaemic control after one to two months, pharmacological therapy is indicated. Many guidelines advise immediate prescription of metformin at the same time as instituting lifestyle change. In theory, a pharmacological agent might be chosen to address a predominant underlying pathogenic factor, such as insulin resistance or beta-cell dysfunction. In practice, however, it is often difficult to determine the relative impact of different pathogenic factors, and any safe and effective agent to improve glycaemic control may need to be considered. Indeed, therapies may be prescribed on the basis of local protocols, patient preference, or what is left when preferred options are excluded by contraindications or tolerability [4–9]. The suitability of a treatment for an individual requires consideration of the risks of the disease, risks of other agents, and risk of the proposed agent compared with the potential benefits for the current and likely future circumstances of that individual.

Table 15.5.4.1 Synopsis of the main actions, typical reductions in HbA_{1c} effects on body weight, key adverse effects, exclusions, and precautions for glucose-lowering agents other than insulin

Class *with examples*	Main mode of action	HbA_{1c}	Body wt	Main adverse events	Main exclusions and precautions
Oral					
Biguanide Metformin	Counters insulin resistance[a] ↓ hepatic glucose output, ↑ peripheral glucose utilization	↓ ~ 1–2% (~ 11–22 mmol/mol)	–/↓ Mostly weight neutral	GI intolerance Lactic acidosis (rare)	Renal impairment Any hypoxic condition
Sulphonylureas Glibenclamide (glyburide) Gliclazide Glimepiride Glipizide	Increase insulin secretion[b] Direct effect on pancreatic β cells	↓ ~ 1–2% (~ 11–22 mmol/mol)	↑ ~1–4 kg	Hypoglycaemia	Choice restricted by severe liver or renal disease, or porphyria
Meglitinides Nateglinide Repaglinide	Increase insulin secretion[b, c] (Prandial administration: rapid onset, short duration of action). Direct effect on pancreatic β cells	↓ ~ 0.5–1.5% (~ 5–16 mmol/mol)	↑/– ~1–2 kg	Hypoglycaemia (fewer and less severe than sulphonylureas)	Liver or severe renal disease
DPP-4 inhibitors Alogliptin Linagliptin Saxagliptin Sitagliptin Vildagliptin	Potentiate nutrient-induced insulin secretion[b] Inhibit DPP-4 to increase endogenous incretin activity	↓ ~ 0.5–1.5% (~ 5–16 mmol/mol)	– Mostly weight neutral	Possible risk of pancreatitis	Severe renal or liver disease Caution if history of pancreatitis
SGLT-2 inhibitors Canagliflozin Dapagliflozin Empagliflozin Ertugliflozin	Increase renal glucose elimination	↓ ~ 0.5–1.5% (~ 5–16 mmol/mol)	↓ ~2–3 kg	Dehydration, urino-genital tract infections. Atypical ketoacidosis and fractures[d]	Renal disease
Thiazolidinediones Pioglitazone Rosiglitazone	Increase insulin action[a] Stimulate PPARγ , to increase adipogenesis and adjust the glucose-fatty acid cycle	↓ ~ 1–1.5% (~ 11–16 mmol/mol)	↑ ~2–3 kg	Oedema and heart failure, anaemia, Fractures	Cardiac disease, Fluid retention, Severe liver or renal disease
α -glucosidase inhibitors Acarbose Miglitol	Slow carbohydrate digestion[e]	↓ ~ 0.5–1.0% (~ 5–11 mmol/mol)	– Mostly weight neutral	–	Intestinal diseases, Severe kidney disease
Dopamine D2 agonist Bromocriptine	Neurally mediated ↓ hepatic glucose output, other effects not clear[a]	↓ ~ 0.5–0.8% (~ 5–9 mmol/mol)	– Mostly weight neutral	Fibrotic reactions, hypotension	Psychotic disorders
Bile acid sequestrant Colesevelam	Increase incretin secretion and ↓ hepatic glucose output	↓ ~ 0.4–0.8% (~ 4–9 mmol/mol)	– Mostly weight neutral	May increase triglyceride	Intestinal obstruction
Subcutaneous injection					
GLP-1 receptor agonists Dulaglutide Exenatide BD QW Liraglutide Lixisenatide Semaglutide	Potentiate nutrient–induced insulin secretion[b], Suppress glucagon secretion, Satiety effect	↓ ~ 0.5–2% (~ 5–22 mmol/mol)	↓ ~3 kg	Possible risk of pancreatitis	Caution if history of pancreatitis Severe liver, renal or intestinal disease
Amylin analogue Pramlintide[f]	Slow gastric emptying, Suppress glucagon secretion, Satiety effect	↓ ~ 0.3–0.6% (~ 3–6 mmol/mol)	↓ ~1–2 kg	Risk of hypoglycaemia when used with insulin	Gastroparesis, Other medications affecting GI motility Hypoglycaemia unawareness

↑ increase; ↓ decrease; ~ approximately;—no change

Most agents have rarely caused sensitivity reactions.

[a] Efficacy requires presence of circulating insulin.
[b] Efficacy requires presence of a functional β cell mass.
[c] Taken with meals, fewer and less severe hypoglycaemia than sulfonylureas.
[d] Possible increased risk of amputation with canagliflozin.
[e] Taken with meals rich in complex carbohydrate.
[f] Usually used in conjunction with insulin.

Not all blood glucose-lowering agents are available in all countries, and they do not always carry the same indications for use, e.g. pramlintide and rosiglitazone are not available in Europe and gliclazide is not available in the USA, while bromocriptine and colesevelam are not indicated for glucose-lowering in Europe. The same drug may be named differently in different countries, e.g. glibenclamide (Europe) is glyburide in the USA, although the formulation is different. Similarly named drugs may also have different formulations in different countries, e.g. glipizide. The exclusions, precautions, and monitoring requirements may also vary, e.g. pioglitazone is excluded for New York Heart Association (NYHA) categories I–V in Europe, but III-IV in the USA. Maximum doses are sometimes different between countries, e.g. maximum daily dose for metformin is 3000 mg in Europe and 2550 mg in the USA. Many countries introduce local restrictions, e.g. in England the National Institute for Health and Clinical Excellence (NICE) recommends that a GLP-1 receptor agonist should only be continued if its use is associated with a reduction in HbA1c of ≥ 11 mmol/mol [1.0%] and weight loss of ≥3% of initial body weight in 6 months. Also, individual agents within a class can vary in their glucose-lowering efficacy and effects on body weight which affects their suitability for individual patients. For these reasons, it is not possible to be fully prescriptive or inclusive in this chapter, and prescribers are urged to check national and local formulary restrictions before administering pharmacological therapies.

Starting pharmacotherapy assumes that a chosen agent is not precluded by comorbidity, potential interactions with other medications, or incompatibility with lifestyle, and that appropriate information and support are offered to the patient. Note baseline glycaemia and begin therapy with a low dose. A summary of individual agents with pharmacokinetic information is given in Table 15.5.4.2. Titrate up at intervals of one to two weeks for metformin, sulphonylureas, meglitinides, and AGIs. Some GLP-1 receptor agonists (administered by subcutaneous injection) have two or three dosage strengths through which titration can be made, usually two-weekly to monthly. Intervals of at least one month are usually required for a thiazolidinedione. DPP-4 inhibitors and SGLT-2 inhibitors do not usually require titration. Continue to

Table 15.5.4.2 Summary of dose and pharmacokinetic information for individual glucose-lowering agents other than insulins[a]

Class/agent	Dose range[b] mg (except where stated)	Starting dose[b] mg (except where stated)	Duration of action hr[c]	Plasma protein bound	Metabolites[c]	Elimination
Oral						
Biguanide						
Metformin Meformin XR/SR	500–2550/3000	500–850 od 500–1000 od	6–18 12–24[d]	<12%	–	u ~ 100%
Sulphonylureas

[a] Availability of some agents, dose range, indications for use, exclusions, and contraindications vary between countries. Prescribers are urged to check national and local formulary restrictions before administering pharmacological therapies.
[b] All doses in mg except exenatide bd, lixisenatide and pramlintide, in µg.
[c] Different formulations affect pharmacokinetics, timing of doses, and duration of action. In this table metabolites are considered to be 'active' if they make a significant contribution to the overall pharmacodynamic effect of the agent.
[d] Slow-release formulations of metformin (XR/SR) have a duration of action up to 24h; recommended maximum dose 2000 mg od.
[e] Not usually used to initiate sulphonylurea therapy.
[f] Some slightly active metabolites.
[g] Discontinued in Europe in 2010.
[h] Not indicated for glucose-lowering in Europe.
[i] Taken before the main meal of the day.
[j] Not available in Europe.

Many single-tablet fixed-dose combinations of two differently acting glucose-lowering agents are available. These may be used as a convenient way to reduce the pill burden. Fixed-ratio combinations of a basal insulin with a GLP-1 receptor agonist in the same injection are also available. These are titrated in the same way as insulin but the presence of the GLP-1 receptor agonist increases the glucose-lowering effect at a lower dose of insulin, off-sets the weight gain associated with insulin therapy and reduces the risk of serious hypoglycaemia.

titrate until the desired level of glycaemic control is achieved. If intolerance supervenes, reduce a dose level and attempt titration again later. If a titration step does not provide any additional benefit, return to the previous dosage and, if significant adverse events are experienced, consider discontinuation and switching to another class of agent. Switching within class is rarely helpful, except when contraindications develop that can be circumvented by different pharmacokinetics. Appropriate monitoring, which may extend beyond glycaemic parameters, and reinforcement of lifestyle compliance, should be undertaken as required.

Many single-tablet fixed-dose combinations of two differently acting oral agents are available. These include combinations of metformin with each of a sulphonylurea, meglitinide, thiazolidinedione, DPP-4 inhibitor, or SGLT-2 inhibitor. There are also fixed-dose combinations of a DPP-4 inhibitor with an SGLT-2 inhibitor. Single-tablet fixed-dose combinations may be used as a convenient way to reduce the pill burden. Bearing in mind the progressive nature of type 2 diabetes, additional therapy to address deteriorating control, or switching therapy to accommodate emerging comorbidity, is an expected part of the treatment process. Rapidly advancing hyperglycaemia in patients with long-standing diabetes, often with unintentional weight loss, is generally an indication of substantial beta-cell failure, signalling the need for insulin replacement therapy. Reassessment of diabetes therapy is required when renal or liver function deteriorates, or patients experience cardiovascular events. Glucose-lowering therapy may require alteration during certain investigations, such as the use of contrast media, and during cultural and religious events during which dietary intake is substantially changed. Fixed-ratio combinations of a basal insulin with a GLP-1 receptor agonist in the same injection are now available: these are titrated in the same way as insulin but the presence of the GLP-1 receptor agonist increases the glucose-lowering effect at a lower dose of insulin, off-sets the weight gain associated with insulin therapy and reduces the risk of serious hypoglycaemia.

Metformin

Three biguanide drugs (metformin, phenformin, buformin) were introduced in the late 1950s. Their origins relate to the glucose-lowering effect of guanidine that was identified in *Galega officinalis*, a plant used to treat diabetes in traditional herbal medicine [10]. Due to a high incidence of lactic acidosis, phenformin and buformin were withdrawn by the late 1970s. Metformin (Figure 15.5.4.3) carries negligible risk of lactic acidosis, if appropriately prescribed, and has since become the preferred first-line agent in most guidelines and the most used oral glucose-lowering agent worldwide.

Actions

Metformin lowers blood glucose concentrations without risk of serious hypoglycaemia and without weight gain. This involves several different actions, mostly serving to counter insulin resistance (Table 15.5.4.3). Some of these actions are achieved through enhanced insulin sensitivity, while others are independent of insulin, but the glucose-lowering efficacy of metformin requires the presence of at least some circulating insulin [9, 11].

Hepatic glucose output is reduced by metformin, particularly the suppression of gluconeogenesis, but with low potency such that the counterregulatory response is not impeded when glucose levels fall below the normal range [12]. Metformin also modestly enhances insulin-stimulated glucose uptake and glycogenesis by skeletal muscle, associated with increased deployment of glucose transporter type 4 protein (GLUT4) in the cell membrane

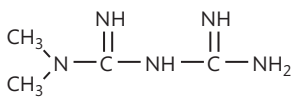

Figure 15.5.4.3 Structure of metformin (dimethyl biguanide).

Table 15.5.4.3 Key insulin-dependent and independent effects of metformin that contribute to its glucose-lowering efficacy

	Insulin dependent	Insulin independent
Liver	↓ Gluconeogenesis	↓ Gluconeogenesis

Gut		↑ Anaerobic glycolysis
		↓ Respiratory chain complex 1

↑, increase; ↓, decrease; AMPK, adenosine monophosphate-activated protein kinase; IR-TKA, insulin receptor tyrosine kinase activity, G-6-Pase, glucose-6-phosphatase; GLUT4, glucose transporter isoform 4. GPD, glycerophosphate dehydrogenase.

(Figure 15.5.4.4). Anaerobic glucose metabolism in the walls of the intestine is increased by the presence of high concentrations of metformin, probably due to suppression of respiratory chain activity at complex 1. This increases glucose–lactate turnover, which may contribute to futile cycling and increased energy dissipation that helps to prevent weight gain.

Efficacy

The glucose-lowering efficacy of metformin has been affirmed in many studies, typically reducing HbA1c by 1–2% (11–22 mmol/mol). The lack of weight gain and low risk of hypoglycaemia have contributed to the general preference for this agent as initial monotherapy, especially in patients who are overweight or more vulnerable to hypoglycaemia. Metformin does not stimulate insulin secretion and generally reduces basal insulin concentrations in hyperinsulinaemic patients. A small improvement in the lipid profile is often seen and reductions in plasma triglyceride and free fatty acids (FFA) are not uncommon. Evidence for a vasoprotective effect of metformin has also contributed to its positioning as initial therapy. Use of metformin reduced the risk of myocardial infarction (by 39% over 10 years) in the UKPDS independently of the glucose-lowering effect, and this benefit persisted during the post-trial follow-up for more than eight years [3]. Metformin has been shown to improve a range of vascular risk markers (e.g. reducing plasminogen activator inhibitor 1 (PAI-1) and increasing fibrinolysis) and surrogate measures such as reducing carotid intima-media thickness and increasing vasoreactivity. Metformin does not appear to affect blood pressure, although a lowering of blood pressure may coincide with reduced body weight [12, 13].

Metformin provides additive efficacy when combined with most other glucose-lowering agents. When used in conjunction with insulin therapy, metformin can reduce insulin dose requirement, improve glucose profile, and reduce hypoglycaemic episodes and weight gain. Hence, metformin is frequently continued when patients with type 2 diabetes start insulin therapy.

Cautions

The main tolerability issue with metformin is gastrointestinal symptoms. Diarrhoea may limit dose titration in some patients, although it is usually transient, reduced by temporary dose reduction and by taking after meals. Symptoms can also be reduced by switching to a slow-release formulation, but around 5–15% of patients do not tolerate titration of metformin.

Since metformin is eliminated unchanged in the urine, it is important to check renal function before and at intervals during therapy to avoid drug accumulation, as this may predispose to

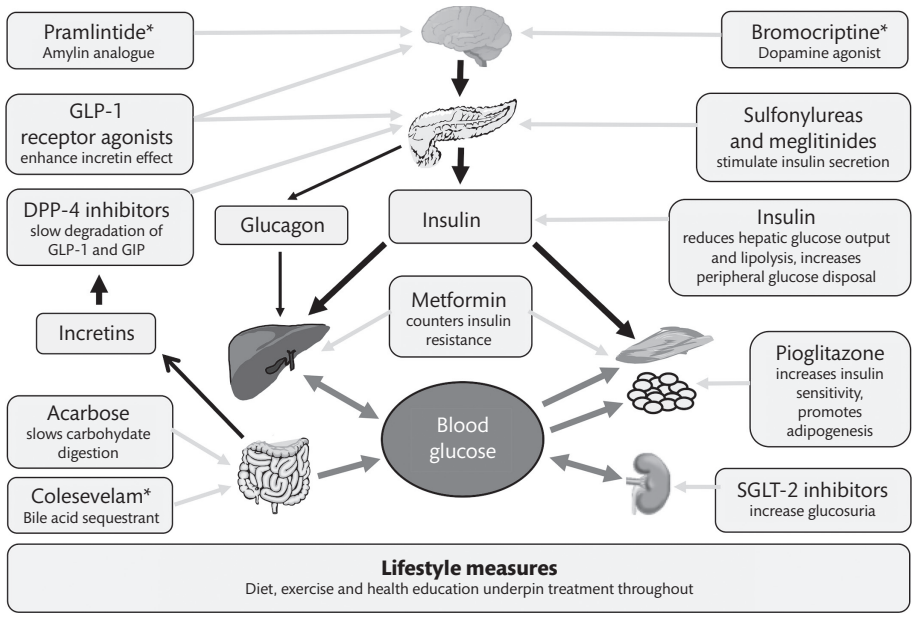

Figure 15.5.4.4 Main sites of action of blood glucose-lowering agents. *Pramlintide, bromocriptine, and colesevelam are not indicated for glucose-lowering in Europe. DPP-4, dipeptidyl peptidase-4; GLP-1, glucagon-like peptide-1; SGLT-2, sodium/glucose cotransporter-2.

lactate accumulation [14]. The renal exclusion criteria, which vary slightly between countries, typically recommend reviewing the dose if the estimated glomerular filtration rate (eGFR) is <60 ml/min/1.73 m², preferably limiting the dose to 1000 mg/day if the eGFR is <60 ml/min/1.73 m², not initiating metformin therapy if the eGFR is <45 ml/min/1.73 m², and stopping metformin if the eGFR is <30 ml/min/1.73 m². Most cases of metformin-associated lactic acidosis are due to failure to respect or recognize deteriorating renal function. Although such cases are rare (variously estimated at 0.03–0.09 per 1000 patient years of treatment), 30–50% are fatal. Treatment should be started immediately, usually with intravenous bicarbonate, and haemodialysis may be helpful to remove excess metformin.

While metformin therapy assists in the prevention of cardiovascular events, it is noted that metformin is contraindicated in conditions of hypoxaemia, which include cardiac or respiratory insufficiency, septicaemia, or hypotension. Also, metformin is contraindicated by alcohol abuse, previous history of metabolic acidosis, or severe cirrhotic liver disease. Nevertheless, with suitable caution, metformin may benefit patients with non-alcoholic fatty liver disease (NAFLD). Metformin is sometimes used to treat the insulin resistance in polycystic ovary syndrome, where it can assist ovulation and conception. Metformin has not been shown to have adverse effects on embryonic or fetal development, and may indeed reduce spontaneous abortion and the risk of maternal gestational diabetes. Since metformin may reduce vitamin B_{12} absorption, it is advised to check haemoglobin occasionally. Metformin should be stopped temporarily during use of contrast media until normal urine flow returns.

Sulphonylureas

Sulphonylureas were developed in the 1950s following an observation that sulfonamide drugs could cause hypoglycaemia. Since the introduction of sulphonylureas, many members of this class have received extensive use worldwide, and they remain the second most used oral glucose-lowering agent (Figure 15.5.4.5).

Actions

The glucose-lowering effect of sulphonylureas is attributed almost entirely to increased insulin secretion resulting from a direct action on the pancreatic beta-cells. Sulphonylureas bind to the so-called sulphonylurea receptor 1 (SUR1), which is part of a transmembrane protein complex with the ATP-sensitive potassium (K_{ATP}) channel [15]. Binding of a sulphonylurea to SUR1 closes the K_{ATP} channel. This prevents K^+ efflux, depolarizes the membrane, and opens adjacent voltage-dependent L-type calcium channels. The resulting increase in cytosolic calcium activates calcium-dependent signalling proteins that regulate the secretion of insulin from pre-formed granules (Figure 15.5.4.6).

Sulphonylureas initiate insulin secretion independently of the glucose concentration. Hence, sulphonylureas can increase insulin secretion at all times, including periods when glucose concentrations are low. They therefore predispose to hypoglycaemia. Sulphonylureas may produce a small decrease of glucagon secretion, and there have been reports of minor glucose-lowering activity that is independent of effects on the pancreas.

Efficacy

The variety of sulphonylureas (see Table 15.5.4.2) with different pharmacokinetic properties enables choice for the onset and duration of action, as well as the mode of metabolism and elimination [16, 17]. Typically, sulphonylureas reduce HbA1c by 1–2% (11–22 mmol/mol) although desensitization may occur along with disease progression to reduce efficacy during prolonged use. Sulphonylureas are effective as monotherapy, and in combination with most other glucose-lowering agents (excepting

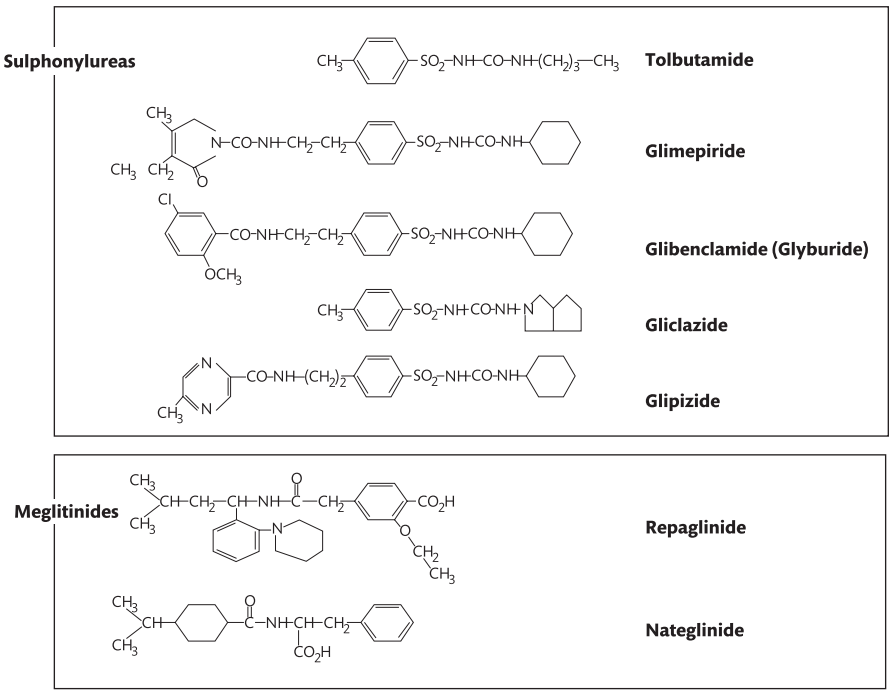

Figure 15.5.4.5 Structures of sulphonylureas and meglitinides.

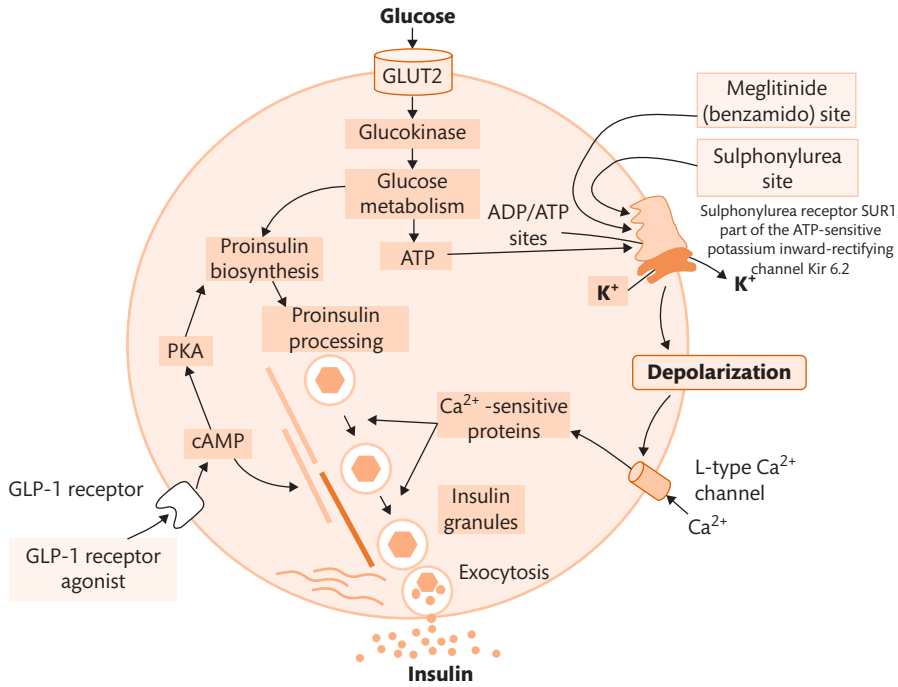

Figure 15.5.4.6 Schematic representation of the control of insulin secretion by a pancreatic beta-cell.

meglitinides, and there is little gain when used in combination with a DPP-4 inhibitor). While there is residual beta-cell function, sulphonylureas can also usefully supplement insulin treatment in type 2 diabetes. By increasing the portal delivery of endogenous insulin, sulphonylureas help to reduce hepatic glucose output, especially during meals: this complements the predominantly peripheral effect of subcutaneously administered insulin. Sulphonylureas have not significantly affected lipids or blood pressure in most studies.

Cautions

Sulphonylureas are prone to cause weight gain, usually 1–4 kg that stabilizes by about 6 months [16, 17]. This is probably due to the anabolic effect of extra insulin and the reduced loss of glucose in the urine. Tolerability is generally good and facilitated by the choice of sulphonylureas available.

Hypoglycaemia is the main serious adverse event associated with sulphonylurea therapy, requiring vigilant glucose monitoring by patients who drive and especial consideration of vulnerability in the elderly and frail. It is important to start with a low dose and titrate in concert with blood glucose monitoring, harmonizing drug therapy with other aspects of lifestyle. It is also necessary to educate patients to recognize and respond to early warning symptoms of hypoglycaemia, and to prevent hypoglycaemia wherever possible. One or more episodes of hypoglycaemia are likely to occur in up to 20% of sulphonylurea-treated patients annually, although severe episodes occur in only about 1% of patients and the mortality risk has been reported at 0.014–0.033 per 1000 patient years. Severe sulphonylurea-associated hypoglycaemia may initially require intravenous glucose, and glucose supplementation should be continued with appropriate monitoring for more than 24 hours to prevent a recurrence, which can occur if longer-acting or more slowly metabolized agents are involved. Treatment of hypoglycaemia with glucagon is discouraged in type 2 diabetes patients, as this is itself an insulin secretagogue.

Meglitinides

Meglitinides are short-acting (prandial) insulin releasers developed after the observation that the benzamido compound meglitinide, which is a component of some sulphonylurea molecules, can stimulate insulin secretion. Two meglitinide agents (repaglinide and nateglinide) were introduced in the late 1990s/early 2000s (see Figure 15.5.4.5).

Actions

Meglitinides bind with the benzamido site on the beta-cell SUR1 receptor [15], setting in motion the same sequence of events described for stimulation of insulin secretion by sulphonylureas (see Figure 15.5.4.6). The main differences are pharmacokinetic: meglitinides are rapidly absorbed, rapidly acting, but with a shorter duration of action than sulphonylureas, making them suitable for administration to coincide with the period of meal digestion.

Efficacy

The main application of meglitinides is to increase prandial insulin secretion to coincide with demand and reduce postprandial glucose excursions [18]. There is typically a carry-over effect to reduce basal glycaemia, but the reduction in HbA1c is usually slightly less than with sulphonylureas. Meglitinides are appropriate for individuals with irregular lifestyles with unpredictable or missed meals. Meglitinides are conveniently used with metformin or a thiazolidinedione, and to supplement insulin therapy in type 2 diabetes.

Cautions

Although meglitinides can precipitate hypoglycaemia, such episodes are fewer and less severe than with sulphonylureas. Weight gain is generally less than with sulphonylureas, although there is

little noticeable effect when switching between a sulphonylurea and meglitinide, or when combined with metformin. A drug interaction between repaglinide and gemfibrozil should be noted. Also multiple daily dosing means that meglitinides are not a practical option for many patients.

GLP-1 Receptor Agonists

GLP-1 receptor agonists enhance the incretin effect which is the extra insulin response to nutrients generated during meal digestion beyond that caused by the increase in circulating nutrients alone. The incretin effect is produced by the hormone GLP-1 and other endocrine (e.g. glucose-dependent insulinotropic polypeptide; GIP) and neural pathways from the intestinal tract [19]. The incretin effect is reduced in type 2 diabetes, but the capacity of GLP-1 to potentiate nutrient-induced insulin secretion (and suppress excess glucagon secretion) is largely retained, hence the therapeutic application of GLP-1 to improve glycaemic control in type 2 diabetes. However, GLP-1 is rapidly degraded in the circulation (half-life, <2 minutes) by the enzyme DPP-4 which breaks peptides with an Ala or Pro residue at position N2 (GLP-1 has an Ala residue in this position). Accordingly, several analogues and formulations of GLP-1 have been developed to avoid or reduce degradation by DPP-4 in order to sustain the incretin effect (Figure 15.5.4.7).

Exenatide, introduced in 2005, was the first GLP-1 receptor agonist. It is synthetic exendin-4, a peptide identified in the saliva of the Gila monster lizard *Heloderma suspectum*. Exenatide has 53% homology with human GLP-1, and lixisenatide is an analogue of exendin. Other GLP-1 receptor agonists have a much closer structure to human GLP-1 with only one to three amino acid residues altered (notably alterations in the N2 position) and/or a fatty acid side chain added for attachment to albumin: these are designed to prevent degradation by DPP-4 and enable formulations with different durations of action.

Actions

GLP-1 is secreted by L cells located throughout the intestine but mostly in the ileum and colon. GLP-1 interacts with G-protein-coupled receptors on the pancreatic beta-cells, potentiating distal steps in the nutrient-induced insulin secretion pathway as well as activating protein kinase A to promote insulin biosynthesis (Figure 15.5.4.6). Additionally, GLP-1 interacts with receptors in the portal system to trigger neural reflexes that affect other pancreatic, gastrointestinal, and metabolic functions. These include the suppression of excess glucagon secretion by pancreatic alpha-cells, as well as slowing gastric emptying, and augmenting meal-induced satiety. GLP-1 can increase pancreatic beta-cell mass in animal models, but an effect on beta-cell mass in human type 2 diabetes has yet to be confirmed, although the durable efficacy of GLP-1 receptor agonists has been encouraging. Many further physiological effects of GLP-1 have been reported which impact cardiovascular, renal, neural and inflammatory activity [19–21].

The pharmacokinetic properties of the various GLP-1 receptor agonists include preparations with different affinities for the GLP-1 receptor and different durations of action which afford different administration schedules (Table 15.5.4.4). As all GLP-1 receptor agonists bind to the GLP-1 receptors to produce the glucose-lowering effect, it is likely that each will exert additional GLP-1 receptor-mediated effects.

Efficacy

GLP-1 receptor agonists typically reduce HbA1c by 1–2% (11–22 mmol/mol), associated with substantial reductions (by ~4 mmol/l or 72 mg/dl) in postprandial glycaemia. Durability of the glucose-lowering effect has been observed over several years, mostly as add-on to metformin. Adding a GLP-1 receptor agonist to other oral glucose-lowering agents as dual or triple therapy is similarly effective provided there is adequate residual beta-cell capacity. Use of a GLP-1 receptor agonist is usually associated with a reduction in body weight of about 3 kg over 6–12 months. However there is considerable heterogeneity in the glucose-lowering and

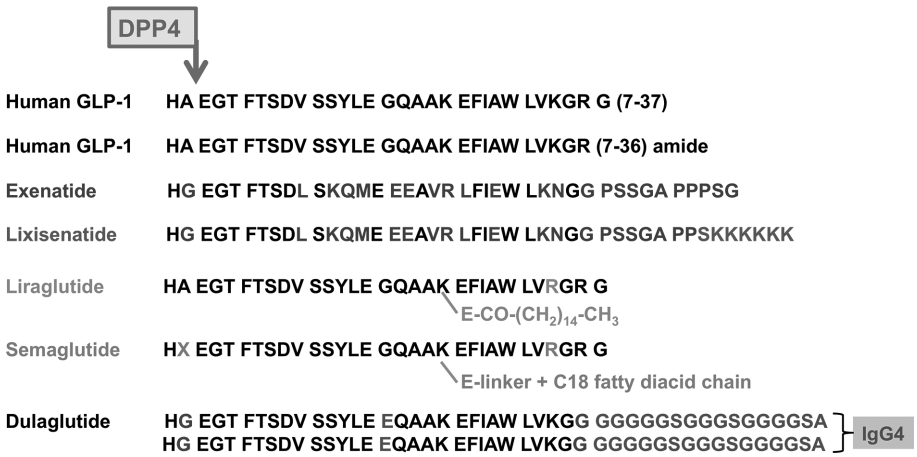

Figure 15.5.4.7 Structures of the incretin hormone GLP-1 (glucagon-like peptide-1) and the GLP-1 receptor agonists exenatide, liraglutide, lixisenatide, dulaglutide, and semaglutide. Dulaglutide comprises two GLP-1 analogue molecules covalently linked to a modified human immunoglobulin G4 (IgG4) heavy chain fragment (Fc) by a small peptide linker.

[Semaglutide is additionally available as an oral formulation.] X, alpha-aminoisobutyric acid. Note that the N2 position of the biologically active GLP-1 peptides 7–37 and 7–36 amide is the same as the N8 position of the fully translated sequence.

Table 15.5.4.4 Characteristics of GLP-1 receptor agonists

Drug	Brand	Structure (sequence homology)	IC_{50} (nM)	Dose	Admin	C_{max}	T_{max}	Half-life
Exenatide *twice daily*	Byetta	Exendin-4 (53%)	0.55	5 µg, 10 µg	BD	~160–250 pg/ml	2–3 h	~3.5 h

weight-lowering efficacy of individual agents and in the responsiveness of individuals. There is also debate regarding the effectiveness of twice-daily versus once-daily versus once-weekly administration, but head-to-head studies have reported generally similar effects over 6–12 months [9]. For reasons unknown, a minority of individuals do not respond to GLP-1 receptor agonists, even when there is evident beta-cell capacity remaining. GLP-1 receptor agonists can be used effectively in combination with basal (long-acting) insulin, and there are fixed-ratio combinations of a GLP-1 receptor agonist with a basal insulin in the same subcutaneous injection which can be titrated in the same way as insulin alone. A fixed-ratio combination of liraglutide with insulin degludec (IDegLira) confers greater blood glucose-lowering at a lower dose of insulin and with less weight gain and no increased risk of hypoglycaemia compared with degludec alone. A fixed-ratio combination of lixisenatide with insulin glargine offers similar efficacy.

Most studies with GLP-1 receptor agonists have noted a small reduction of systolic blood pressure, although there is often a small increase in heart rate. Large prospective outcome studies have reported either no significant changes or beneficial reductions in a composite of major adverse cardiac events (CV-related deaths, non-fatal MI and stroke) during use of a GLP-1 receptor agonist [22]. Accordingly, some guidelines have offered recommendations for the use of particular GLP-1 receptor agonists in patients with cardiovascular diseases or at high risk of cardiovascular disease [4]. Lower rates of development and progression of albuminuria have also been noted in some long-term studies with GLP-1 receptor agonists.

Cautions

A limiting factor for the use of GLP-1 receptor agonists is initial nausea, presumed to reflect a reduced rate of gastric emptying which may affect the absorption of concomitant oral medications. The nausea is usually transient and ameliorated by introducing therapy at a low dose for several weeks. Administration to patients with severe gastrointestinal disease, including gastroparesis, should be avoided. GLP-1 receptor agonists carry little risk of severe hypoglycaemia when used as monotherapy or combination with agents that do not raise insulin concentrations, but the risk of hypoglycaemia should be appreciated when used in combination with insulin and insulin-releasing agents. Dose reduction or avoidance should be considered in patients with moderate to severe renal disease, although liraglutide, semaglutide, and dulaglutide can be used in renal patients (except end-stage renal disease) without dose adjustment. It is advised to discontinue these agents in pregnancy. Although some patients develop antibodies to exenatide, these do not usually have a noticeable effect on efficacy, and reactions at the injection site are seldom problematic. A possible increased risk of pancreatitis in patients receiving GLP-1 receptor agonists remains unclear, but it is advised that these agents are discontinued if pancreatitis is suspected or diagnosed. Caution is also suggested in patients with thyroid disease.

DPP-4 Inhibitors

Several dipeptidyl peptidase-4 (DPP-4) inhibitors (also terms gliptins) have become available since 2007, namely sitagliptin, vildagliptin, saxagliptin, linagliptin and alogliptin which are taken once daily (or twice-daily for vildagliptin) (**Figure 15.5.4.8**). In Japan there are long-acting once weekly DPP-4 inhibitors (e.g. omarigliptin and trelagliptin). DPP-4 inhibitors act by increasing the endogenous incretin effect.

Actions

Each of the DPP-4 inhibitors produces almost complete inhibition of DPP-4 activity for 12–18 hours, and >80% inhibition for the remainder of a 24h period. This slows the proteolytic degradation of the two main incretin hormones GLP-1 and GIP. The rise in active GLP-1 concentrations is about 2–3-fold compared with >10 fold increased concentration after administration of a GLP-1 receptor agonist. Thus, DPP-4 inhibitors exert similar effects to GLP-1 receptor agonists but to a lesser extent. Adequate residual beta-cell capacity is required for DPP-4 inhibitors to potentiate

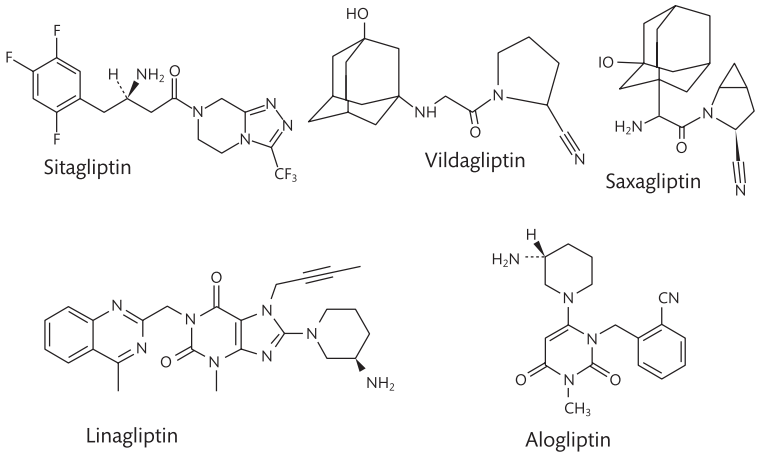

Figure 15.5.4.8 Structures of the dipeptidyl peptidase-4 (DPP-4) inhibitors sitagliptin, vildagliptin, saxagliptin, linagliptin, and alogliptin.

nutrient-induced insulin release and they may also reduce excess glucagon, although GIP tends to raise glucagon which diminishes the glucagon-lowering effect of GLP-1. Neural and gastrointestinal effects of DPP-4 inhibitors are also less marked than with GLP-1 receptor agonists [19, 23, 24].

Efficacy

As monotherapy, DPP-4 inhibitors reduce postprandial glucose concentrations (by about 3 mmol/l or 54 mg/dl) and basal glycaemia (by about 1–1.5 mmol/l or 18–27 mg/dl). This typically achieves a reduction in HbA1c of 0.7–1% (8–11 mmol/mol). Because the increase in insulin secretion is glucose dependent, the release of extra insulin does not occur when glucose levels fall to normal basal values, thereby reducing the risk of interprandial hypoglycaemia. DPP-4 inhibitors do not cause weight gain and they may assist a small amount of weight loss: they seldom reduce the rate of gastric emptying to a clinically significant extent (so nausea is not a problem), and they do not produce a clinically demonstrable satiety effect. DPP-4 inhibitors can give added efficacy when used in combination with agents that improve insulin sensitivity and with SGLT-2 inhibitors. They are approved for use with other glucose-lowering agents such as sulphonylureas, meglitinides, GLP-1 receptor agonists, and insulin, although the extra effects are generally modest with these combinations.

Although DPP-4 inhibitors might theoretically slow the degradation of some vaso-active peptides, large prospective trials with saxagliptin, alogliptin and sitagliptin have confirmed the cardiovascular safety of these agents in type 2 diabetes patients who are at high cardiovascular risk. However these trials did not identify cardiovascular benefits, and a small increase in heart failure hospitalization was noted with saxagliptin. Use in renal disease requires dose reduction of DPP-4 inhibitors except linagliptin which is eliminated mostly via the bile. A reduction in some markers of kidney function suggests a possible slower progression of diabetic renal disease with some DPP-4 inhibitors [23].

Cautions

DPP-4 inhibitors have shown a commendable safety profile: several large studies have indicated a small increased risk of pancreatitis, and DPP-4 inhibitors should be discontinued if pancreatitis is suspected or diagnosed. The DPP-4 enzyme is also the CD26 T-cell activator, but inhibition of the dipeptidase activity does not interfere with the immune function of the molecule, and DPP-4 inhibitors have not been reported to exert any immunological effects.

Sodium/Glucose Transporter-2 Inhibitors

Sodium/glucose transporter-2 (SGLT-2) inhibitors were introduced in 2013: they lower blood glucose by increased elimination of glucose in the urine (glucosuria). The development of SGLT-2 inhibitors arose from the glucosuric effect of phlorizin, a natural phenolic glycoside isolated from apple tree bark [25]. Current members of the class in Europe and North America are canagliflozin, dapagliflozin, empagliflozin and ertugliflozin (Figure 15.5.4.9). Further SGLT-2 inhibitors (ipragliflozin, luseogliflozin, and tofogliflozin) are available in Japan. A dual SGLT-1/SGLT-2 inhibitor (sotagliflozin) is advanced in development.

Actions

SGLT-2 in the first segment of renal proximal tubules is responsible for reabsorption of most of the glucose filtered by the kidney. SGLT-1 in the third segment of renal proximal tubules also contributes to glucose reabsorption, and SGLT-1 in the brush border of enterocytes is responsible for the intestinal absorption of glucose (Figure 15.5.4.10). Competitive inhibition of SGLT-2 reduces the renal threshold for glucose, and in individuals with substantial hyperglycaemia (e.g. blood glucose concentrations >10 mmol/L) SGLT-2 inhibitors can eliminate 80–100 g of glucose/day into the urine. Depending on its specificity and kinetics an SGLT-2 inhibitor may slightly reduce the activity of renal SGLT-1 transporters. The glucosuric effect is self-limiting such that at low glucose concentrations entering the renal filtrate (e.g. <4 mmol/l), 'unblocked' transporters can reabsorb most of the glucose. Also SGLT-2 inhibitors do not compromise the counterregulatory mechanism, making the risk of hypoglycaemia unlikely when these agents are used alone or in combination with

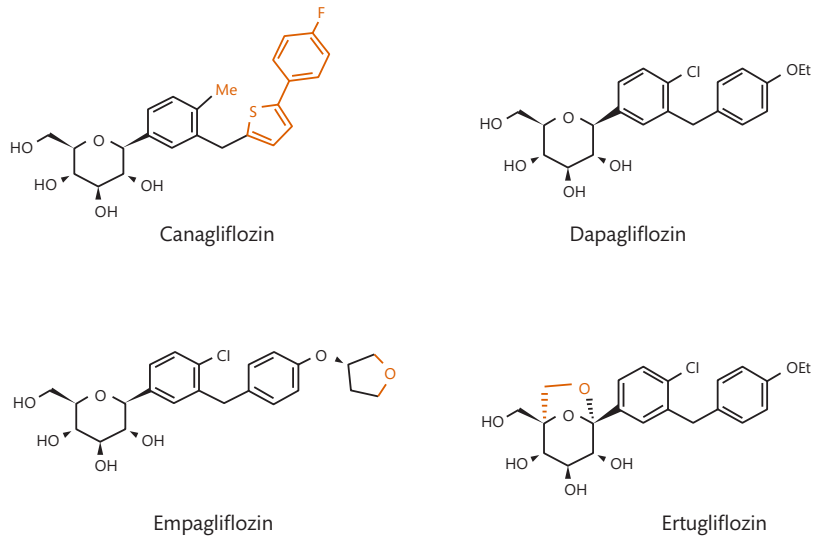

Figure 15.5.4.9 Structures of the SGLT-2 inhibitors canagliflozin, dapagliflozin, empagliflozin, and ertugliflozin.

other low risk agents. The effects of SGLT-2 inhibitors are independent of insulin: hence their efficacy is not affected by the extent of insulin resistance or insulinopenia, but it is appreciated that sufficient insulin must be present to address the underlying endocrine pathogenesis. The caloric loss associated with the glucosuria assists weight reduction, and the mild osmotic diuresis generated by the glucosuria is likely to contribute to a reduction of systolic blood pressure with SGLT-2 inhibitors. Lowering of blood glucose with reduced glucotoxicity during use of an SGLT-2 inhibitor can improve insulin sensitivity and glucose sensitivity of pancreatic beta-cells, assisting the extent and durability of the glucose-lowering effect. The unique mode of action of SGLT-2 inhibitors enables their use in combination with any other class of glucose-lowering agent.

The inhibition of SGLT-2 in the proximal tubules is anticipated to allow more sodium into the loop of Henle and to deliver more sodium to the macula densa. Through the tubular-glomerular feedback mechanism this would constrict the afferent glomerular arterioles, reducing intraglomerular pressure and reducing the risk of hyperfiltration. This could account for emerging evidence

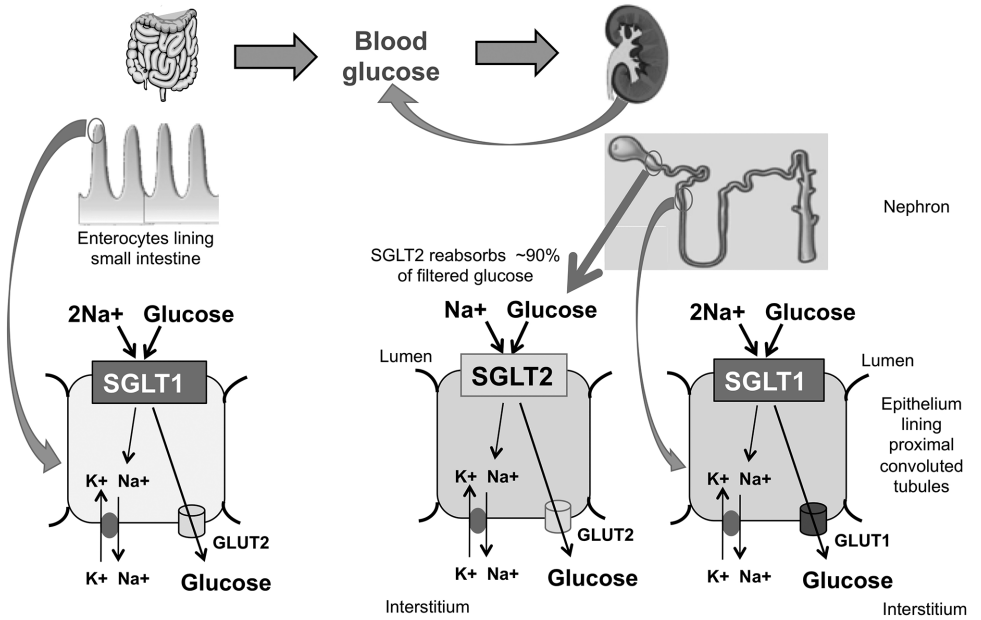

Figure 15.5.4.10 SGLT-2 inhibitors act mainly by competitive inhibition of SGLT-2 transporters in the renal proximal tubules and possibly by slight inhibition of renal SGLT-1 transporters. SGLT-2 transporters are low-affinity, high-capacity glucose transporters that normally reabsorb most of the filtered glucose.

Reproduced with permission from Bailey CJ, Day C. *Br J Diabetes Vasc Dis* 2010; 10 193–9.

that SGLT-2 inhibitors exert a renoprotective effect in diabetes by slowing the rate of long-term decline in glomerular filtration and slowing the onset and progression of albuminuria.

Efficacy

The prompt glucosuric effect of SGLT-2 inhibitors causes a rapid reduction of blood glucose that is approximately proportional to the extent of hyperglycaemia provided there is an adequate glomerular filtration rate (GFR). Reductions in HbA1c are similar whether an SGLT-2 inhibitor is used as monotherapy or add-on to any other glucose-lowering agent(s) as a double or triple combination including insulin. From a baseline HbA1c of around 8% (64 mmol/mol) the reduction in HbA1c is typically ~0.7–1.0% (8–11 mmol/mol) and durability has been observed over several years provided kidney function is maintained [9, 25–27]. Risk of hypoglycaemia is negligible unless used with an agent that increases circulating insulin. Body weight reductions with SGLT-2 inhibitors are usually in the order of 2–3 kg after 6–12 months, which is less than might be predicted in the long term from the amount of glucosuria. This is possibly due to an increase in metabolic efficiency and to a compensatory increase in feeding. In 'real world' observational studies the reductions in HbA1c have been similar to the prospective controlled trials, although the weight reductions have generally been >3 kg. Reduction in systolic blood pressure are typically 2–5 mmHg and there are reductions in uric acid.

Cardiovascular outcome trials to-date have noted a reduced composite of major adverse cardiac events (CV-related deaths, non-fatal MI, and stroke) and consistent demonstration of fewer hospitalizations for heart failure during use of SGLT-2 inhibitors. The rapid emergence of these effects suggests that they are unlikely to reflect weight loss or reduced atherogenesis and may be due in part to reduced plasma volume and blood pressure. It is also possible that SGLT-2 inhibitors can act directly on the myocardium to improve energy metabolism and reduce activity of the Na^+/H^+ exchanger.

Cautions

Though labels vary between region and compounds it is generally recommended that SGLT-2 inhibitors should not be initiated in patients with eGFR <60 ml/min/1.73 m^2, although patients who are already receiving and tolerating an SGLT-2 inhibitor can be continued down to an eGFR of 45 ml/min/1.73 m^2. An initial drop in glomerular filtration often occurs after introduction of an SGLT-2 inhibitor, but this will usually return to pretreatment levels by 3–6 months. Indeed trials have consistently shown reductions in a renal composite end point with SGLT-2 inhibitors [28–30]. The main tolerability concern with SGLT-2 inhibitors is genital infection, particularly women with a history of these infections, and there is a small increased risk of urinary tract infections. Potential for volume depletion, dehydration, and hypotension should be appreciated and patients are usefully reminded to ensure that fluid intake is adequate, especially in hot climates. Those who regularly self-monitor blood glucose, particularly if insulin-treated, may equate a decrease in blood glucose with a lesser need for other glucose-lowering therapies. Any reduction of insulin should be cautious to avoid underinsulinization which can lead to increased lipolysis, increased ketone production, and risk of an atypical form of ketoacidosis that presents without severe hyperglycaemia and sometimes with euglycaemia. Slightly increased risks of fractures and possibly of amputation in individuals with severe peripheral vascular disease have not been excluded.

Thiazolidinediones

TZDs were introduced at the turn of the century. Of three original class members (troglitazone, rosiglitazone and pioglitazone), troglitazone was withdrawn globally due to idiosyncratic hepatotoxicity, and rosiglitazone was withdrawn in Europe and given restricted use in some countries due to reports of increased cardiovascular risk. Pioglitazone remains in use in most countries but was withdrawn in some European countries due to reports of a possible association with bladder cancer (Figure 15.5.4.11) [9].

Actions

TZDs produce most of their antidiabetic activity by activation of a nuclear receptor, peroxisome proliferator-activated receptor-gamma (PPARγ). This receptor forms a heterodimeric complex with the retinoid X receptor (RXR), and, when a TZD and retinoic acid are bound to the complex, repressors are shed and coactivators recruited [31]. The activated receptor locates a nucleotide sequence termed the 'peroxisome proliferator response element' within the promoter regions of a range of genes. Many of these genes are insulin sensitive, and others promote complementary effects on glucose and lipid metabolism that improve insulin sensitivity. PPARγ is highly expressed in adipose tissue, and modestly expressed in other key tissues involved in nutrient homeostasis. Stimulation of PPARγ promotes adipogenesis through the differentiation of

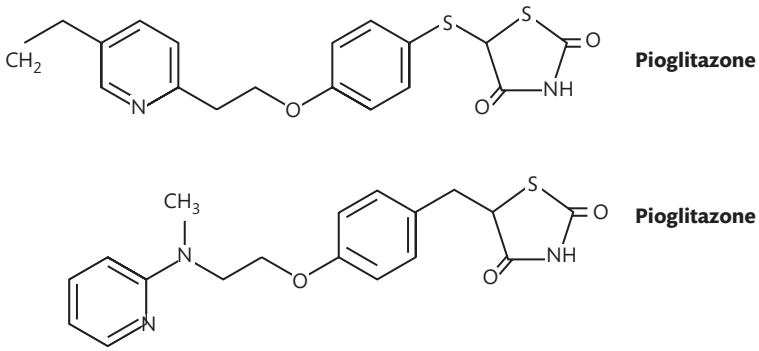

Figure 15.5.4.11 Structure of the thiazolidinediones pioglitazone and rosiglitazone.

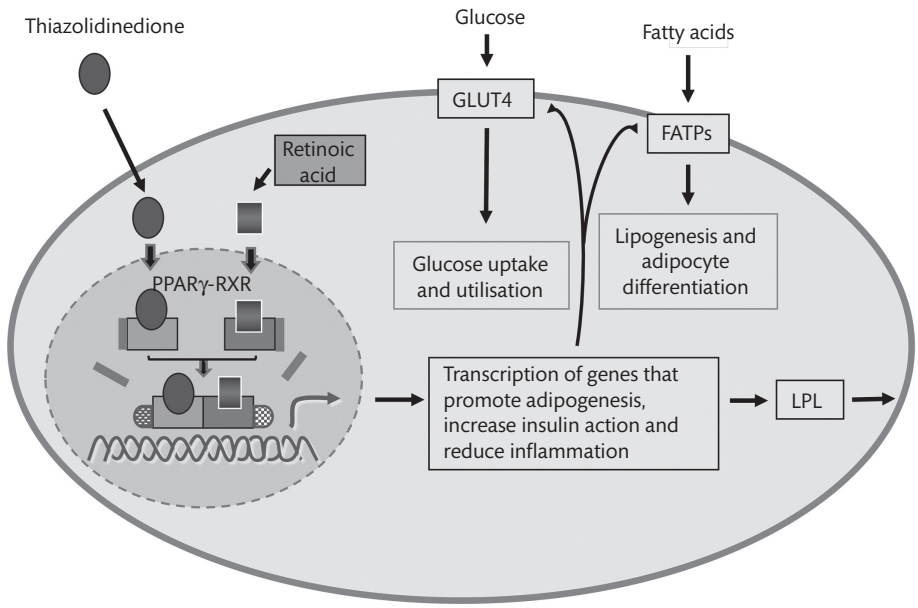

Figure 15.5.4.12 Cellular mode of action of thiazolidinediones via activation of peroxisome proliferator-activated receptor-gamma (PPARγ). FATPs, fatty acid transport proteins; GLUT4, glucose transporter isoform 4; LPL, lipoprotein lipase; RXR, retinoid X receptor.

preadipocytes into new, small, insulin-sensitive adipocytes, mainly in subcutaneous adipose depots (Figure 15.5.4.12). These take up fatty acids, decrease circulating fatty acid concentrations and rebalance the glucose-fatty acid Randle cycle to favour glucose utilization, reducing fatty acid availability as an energy source for hepatic gluconeogenesis. TZDs also reduce the accumulation of lipids in muscle and liver, and increase glucose uptake into skeletal muscle and adipose tissue through increased availability of GLUT4.

Additional and diverse ('pleiotropic') effects of TZDs include reduced production of several pro-inflammatory cytokines by adipose tissue, notably tumour necrosis factor-alpha (TNFα). TZDs also increase adiponectin production, improve vasoreactivity, and tend to reduce blood pressure, with beneficial effects on a range of cardiovascular risk factors and markers.

Efficacy

TZDs exert a slowly generated glucose-lowering effect, typically decreasing HbA1c by ~1% (11 mmol/mol). This generally requires 2–4 months to achieve full efficacy, reflecting the predominantly genomic mechanism of action: hence dose titration may be a prolonged process [32, 33]. However, durability of action has been longer than with sulfonylureas. TZDs do not stimulate insulin secretion, and they do not cause hypoglycaemia. They can be used as monotherapy, or in combination with most other types of glucose-lowering agents. Pioglitazone exerts some PPARα agonism and generally reduces triglycerides and often increases HDL. It also increases the proportion of larger and more buoyant (less atherogenic) LDL particles, and long-term trials have noted a reduction in risk of MI and recurrence of stroke.

Cautions

Use of TZDs is typically associated with weight gain, often more than with sulphonylureas. This is mainly an increase in subcutaneous adipose tissue, but rapid and marked weight gain may be due to fluid retention, and development of oedema after initiation of TZD therapy is usually accompanied by a modest dilutional reduction in the circulating haemoglobin. Although TZDs reduce several markers of cardiovascular disease, they are contraindicated in individuals with manifest cardiovascular disease. TZDs carry a risk of increased heart failure and their use is contraindicated by New York Heart Association I-IV (Europe) or III-IV (USA). Impaired liver function is also a contraindication, although pioglitazone has been used cautiously to reduce hepatic triglycerides in NAFLD. Improved insulin sensitivity with TZDs can restore ovulation in polycystic ovary syndrome (PCOS), but TZDs should be discontinued in pregnancy. Risk of bone fracture is increased with a TZD, especially in postmenopausal women, and individuals with low bone density or osteoporotic disease are not recommended for a TZD. Pioglitazone is not recommended in patients with current or previous bladder cancer, pending ongoing debate over a possible link.

α-Glucosidase Inhibitors

Following evidence that metabolites from cultures of actinomycete fungi could inhibit cell surface glucosidase enzymes, specific AGIs were developed as glucose-lowering drugs. The first, acarbose, was introduced in the early 1990s, followed by miglitol. Another, voglibose, is available in some countries (Figure 15.5.4.13).

Actions

AGIs bind to α-glucosidase enzymes with high affinity, acting competitively to prevent the binding and cleavage of disaccharides and oligosaccharides into monosaccharides [34]. This impedes the final step of carbohydrate digestion. AGIs do not specifically affect the glucose absorption process, but the delay in carbohydrate digestion can defer and slow the appearance of glucose in the circulation, significantly reducing the postprandial glycaemic excursion when there is substantial complex carbohydrate in the diet. The

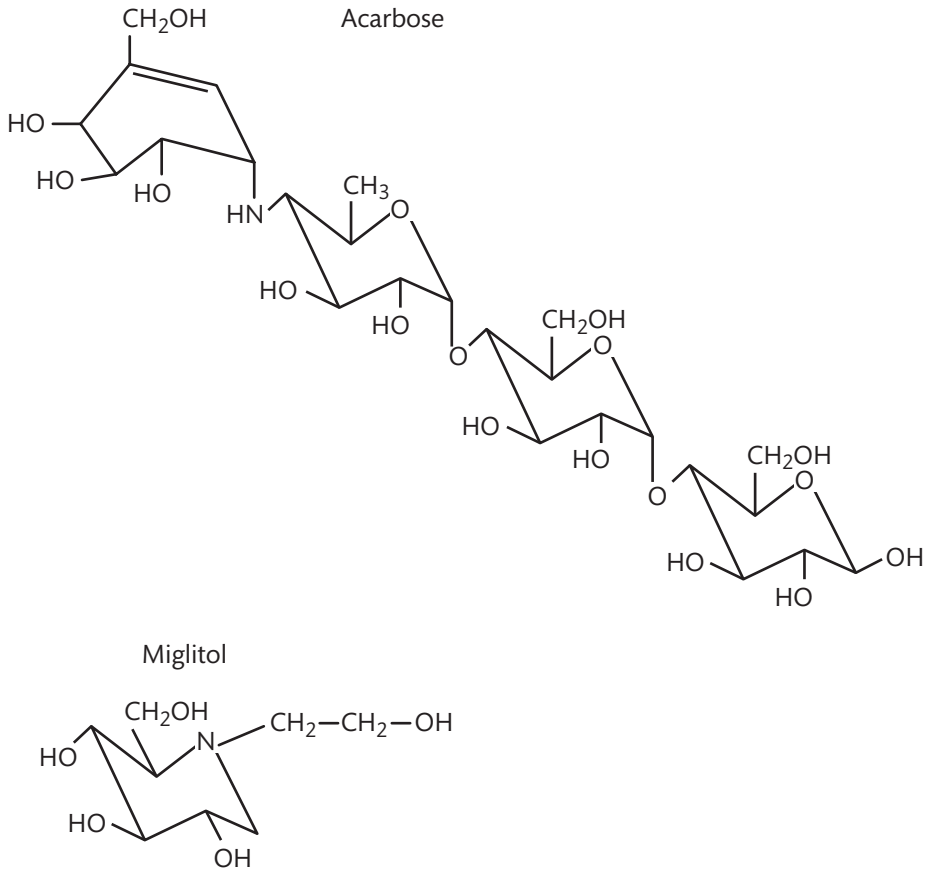

Figure 15.5.4.13 Structures of the α -glucosidase inhibitors acarbose, miglitol, and voglibose.

activity profiles of acarbose and miglitol vary slightly: acarbose has a greater affinity for glucoamylase than sucrase, whereas miglitol has a stronger inhibitory effect on sucrase.

Efficacy

AGIs act mainly to reduce postprandial hyperglycaemia, and their effects are generally modest, reducing HbA1c by about 0.5% (5 mmol/mol), although this can be greater in individuals consuming mainly a carbohydrate-rich diet. Usefully, an AGI can be added in to any other therapy, and this is not usually associated with risk of hypoglycaemia. Indeed, by extending the duration of meal digestion, AGIs can reduce the risk of interprandial hypoglycaemia in individuals receiving insulin or an insulin secretion initiator. Also, AGIs do not cause weight gain, and some individuals may show a reduced postprandial triglyceride profile. It has been suggested that, by extending carbohydrate digestion to more distal regions of the intestine, AGIs might increase GLP-1 secretion. However, postprandial insulin concentrations are commonly reduced by an AGI, commensurate with the lowering of postprandial glycaemia. There have been reports of fewer cardiovascular events in patients receiving an AGI, but a large long-term prospective trial in people with impaired glucose tolerance found no significant effect on major adverse cardiovascular events [35].

Cautions

AGIs are prone to cause some carbohydrate malabsorption. Undigested carbohydrate passing into the large bowel is fermented and can create considerable flatulence. Thus, AGIs should be given with appropriate meals and titrated slowly to minimize this effect. AGIs are contraindicated in individuals with gastrointestinal conditions: caution is needed with any agents affecting gut motility, and liver function should be checked in individuals receiving a high dose of acarbose, since increased alanine transaminase levels have been noted very occasionally.

Pramlintide

Amylin (islet amyloid polypeptide, IAPP) is synthesized and cosecreted with insulin from the pancreatic beta-cells. Precipitates of IAPP within the islets in type 2 diabetes have been ascribed a pathogenic role in beta-cell demise, although the extent of involvement remains uncertain. Amylin exerts central effects that independently affect nutrient metabolism: to retain these effects without detrimental effects on the islets, a non-precipitating amylin analogue (pramlintide) was developed and introduced in the USA in 2005, but is not available in Europe [36].

Actions

Pramlintide (Figure 15.5.4.14) acts centrally to complement the effects of insulin in the control of postprandial glucose homeostasis. It acts predominantly via the area postrema in the brain stem, which communicates with the hypothalamus and activates neural pathways to suppress glucagon secretion by pancreatic alpha-cells.

Amylin KCNTAT CATQRL ANFLVH SSNNF GAILSS TNVGSNTY-(NH_2)

Pramlintide KCNTAT CATQRL ANFLVH SSNNF GPILPP TNVGSNTY-(NH_2)

Figure 15.5.4.14 Structures of amylin (islet amyloid polypeptide, IAPP) and pramlintide.

By reducing glucagon, pramlintide reduces hepatic glucose output. Additionally, via a central route, pramlintide decreases the rate of gastric emptying and reduces the secretion of gastric juice, which slows the rate of digestion with resultant slowing of nutrient absorption. Pramlintide also acts centrally to reduce food intake, which may, in the long term, assist weight control.

Efficacy

Pramlintide is typically used to reduce the insulin dose and prevent weight gain associated with higher doses of insulin, while improving glycaemic control. It is injected before meals in patients with type 1 or type 2 diabetes who are already receiving insulin therapy, and has been shown to improve the glycaemic profile with reductions in HbA1c of about 0.3–0.6% (3–7 mmol/mol) and reductions in body weight of 1–2 kg. Since these effects of pramlintide are usually achieved with a reduction in the insulin dose, it is generally advised to reduce the pre-meal short-acting insulin dose by about half when initiating pramlintide therapy, to avoid risk of hypoglycaemia. The pH difference between insulin and pramlintide precludes the combination of these agents in the same syringe.

Cautions

The most common side effect of pramlintide is nausea, which is usually transient and minimized by gradual dose titration. Since pramlintide is used with insulin, it increases the risk of hypoglycaemia unless appropriately titrated in conjunction with suitable meals and a reduced insulin dose. A drawback to the use of pramlintide is the need for an injection before each main meal, which is additional to the injection required for insulin therapy. Antibodies to pramlintide have been detected in some patients, but this does not appear to have interfered with efficacy.

Bromocriptine

Bromocriptine received an indication for glucose-lowering in the USA in 2009 but is not indicated for this purpose in Europe. Its antihyperglycaemic potential had been appreciated through studies decades earlier, and through experience during use in the treatment of Parkinsonism and pituitary tumours.

Actions

Bromocriptine is a dopamine D2 receptor agonist that lowers glucose concentrations without stimulating insulin secretion [37]. Taken in a low dose early in the morning it appears to assist the normal diurnal periodicity of glucoregulation, acting centrally to stimulate neural pathways that reduce hepatic glucose output.

Efficacy

Low-dose bromocriptine reduces HbA1c by about 0.5–0.6% (5–7 mmol/mol). It can be used as monotherapy or in combination with other oral agents, is unlikely to cause severe hypoglycaemia and is not associated with weight gain.

Cautions

Experience with bromocriptine during use for other indications suggests that risk of respiratory and pericardial fibrosis, hypotension, and exacerbation of psychotic disorders should be borne in mind, and appropriate monitoring should be undertaken. Also, interactions can occur with dopamine antagonist therapy, drugs that are highly protein bound, and other drugs that are metabolized by or induce the P450 isoform CYP3A4 (cytochrome P450, family 3, subfamily A, polypeptide 4). Use in pregnancy is not recommended.

Colesevelam

The bile acid sequestrant colesevelam, used in the treatment of dyslipidaemia, received an indication for glucose-lowering in the USA in 2008, but is not indicated for this purpose in Europe.

Actions

Colesevelam is a non-absorbed allylamine polymer. Its glucose-lowering mechanism is unclear, but by transferring bile acids distally along the intestine colesevelam may facilitate bile acid stimulation of GLP-1 secretion by L cells. Also, by reducing bile acid recirculation to the liver, colesevelam might decrease gluconeogenesis by preventing activation of hepatic farnesoid receptors.

Efficacy

In trials, colesevelam reduced HbA1c by about 0.3–0.5% as add-on to metformin, sulphonylurea, or insulin, without changing body weight or increasing the risk of hypoglycaemia [38].

Cautions

Colesevelam should be taken with plenty of water, and avoided in patients with gastrointestinal motility disorders. Use is associated with risk of increased triglyceride concentrations, possible decreased absorption of fat-soluble vitamins and delayed absorption of other medications.

Conclusions

Managing the progressive and variable natural history of type 2 diabetes with its emergent complications and comorbidities continues to present a formidable therapeutic challenge. Diet and other lifestyle measures are fundamental throughout, supplemented with a series of oral and injectable glucose-lowering agents, as appropriate, eventually requiring insulin in many patients. Individualization and flexibility of therapy to suit the particular needs and circumstances of the patient are important to the

management process, and must be complemented with adequate education and empowerment.

15.5.5 Hypoglycaemia in the Treatment of Diabetes Mellitus

Stephanie A. Amiel

Introduction

Hypoglycaemia (low blood glucose concentration) is the most important acute complication of the pharmacological treatment of diabetes mellitus. Low blood glucose impairs brain function, may precipitate cardiac arrhythmias, and is associated with an inflammatory stress response. The brain has minimal endogenous stores of energy, with small amounts of glycogen in astroglial cells, and is therefore largely dependent on circulating glucose as the substrate to fuel cerebral metabolism and support cognitive performance. If blood glucose concentrations fall sufficiently, cognitive dysfunction occurs. In health, efficient glucose sensing and counterregulatory mechanisms exist to prevent clinically significant hypoglycaemia. These are impaired by diabetes and by its therapies. Patients with diabetes rank fear of hypoglycaemia alongside fear of chronic complications such as nephropathy or retinopathy [1]. Fear of hypoglycaemia, hypoglycaemia itself and attempts to avoid hypoglycaemia limit the degree to which glycaemic control can be intensified to reduce the risk of chronic complications of diabetes, both for type 1 and type 2 diabetes.

Definition and Classification of Hypoglycaemia

Truly good metabolic control in diabetes can only be defined as maintenance of near-normal blood glucose concentrations, reflected by measures of medium-term glycaemic control, such as glycated haemoglobin (HbA_{1c}), associated with least risk of microvascular complications, *plus* absence of troublesome hypoglycaemia. This two-item definition matters not only in optimizing diabetes management for people with diabetes, but also in the assessment of the relative efficacy of new treatments for diabetes coming to market, where superiority of performance may be claimed on the basis of lesser risk of hypoglycaemia.

Hypoglycaemia may be defined clinically as an episode in which the low blood glucose results in a characteristic symptom complex or in the presentation of signs. Whipple's triad, in which an event requires symptoms consistent with hypoglycaemia, a measured low plasma glucose concentration and relief of symptoms by administration of glucose to be defined as hypoglycaemia, was devised originally for surgeons to diagnose spontaneous hypoglycaemia in pathological hyperinsulinism [2]. It remains valid for diabetes management today, if we add 'or signs' to the 'symptoms' to allow inclusion of episodes of asymptomatic hypoglycaemia, and can agree on a biochemical value for hypoglycaemia. In theory, the latter should be a simple statement of the plasma glucose concentration that is lower than values seen in health, traditionally defined as under 3.5 mmol/L, but this has been controversial, as some counterregulatory responses can be detected at higher glucose concentrations, and there is no evidence for actual harm until lower values are reached.

Expressing hypoglycaemia prevalence rates or an individual's hypoglycaemia experience using symptoms alone to define an episode is obviously dependent on subjective awareness of hypoglycaemia and the affected person's memory. Many symptomatic mild episodes will not be recalled, while normoglycaemic episodes with symptoms mimicking hypoglycaemia may be recorded. Nevertheless, symptom-based definitions are useful clinically. They categorize episodes by degree:

- severe hypoglycaemia, in which third-party intervention is required, because cognitive dysfunction is so impaired that the patient cannot either perceive or make logical response to the hypoglycaemia; useful subgroups of this may be episodes requiring parenteral therapy (intravenous glucose or intramuscular glucagon) and those resulting in coma or seizure (which may include episodes for which third-party intervention was not available), or for health economic assessments those requiring ambulance call out, hospital attendance, or admission. It is worth noting that some people with diabetes, particularly those with type 1, count only this category as 'hypoglycaemia', which will lead to underestimation of their experience and missed opportunities for prevention unless more specific questions are asked. It is also worth noting that in paediatric practice, children will often need assistance to understand and treat their hypoglycaemia, so the need for assistance is a poor marker of the severity of the hypoglycaemia itself. However, by stressing the presence of cognitive impairment as the reason for the requirement for help, the paediatric definition of severe hypoglycaemia has been harmonized and is given as having 'severe cognitive impairment (including coma and convulsions) requiring external assistance by another

person to actively administer carbohydrates, glucagon, or take other corrective actions'. Again, events associated with a seizure or loss of consciousness are recognized as a subgroup [3].

- non-severe hypoglycaemia is then any episode which is self-recognized and self-treated. The term 'non-severe' is recommended in preference to the term 'mild', as such episodes, while medically safe, can be experienced by the patient as unpleasant precisely because they may be very symptomatic. Some authorities include an intermediate category of 'moderate', where the patient can perceive and self-treat the episode, but where the symptoms and/or the treatment cause significant disruption of normal activity, but there are obvious problems with consistency of this definition, leaving division into 'non-severe' and 'severe' solely by ability to self-treat the favoured option.

This simple and widely accepted categorization assumes that every documented episode is true hypoglycaemia and is either symptomatic or otherwise clinically obvious. A 2013 consensus statement from the American Diabetes Association (4) classifies hypoglycaemia as follows:

- severe, as just defined (although without explicitly including episodes for which help was not available);
- documented symptomatic in which typical symptoms are experienced in the presence of a low measured plasma glucose and, by distinction from severe, the event is self-treated;
- asymptomatic, a biochemical episode not accompanied by typical symptoms, describing episodes in which the hypoglycaemia was only detected because someone other than the patient recognized it and/or where it was detected because of a coincidental blood test, i.e. not being done because the patient was aware of being low;
- probable symptomatic, in which the patient experiences symptoms but does not have a confirmatory biochemical measurement;
- pseudo-hypoglycaemia, formerly defined as relative hypoglycaemia, in which the patient experiences typical symptoms of hypoglycaemia, but with a measured blood glucose that is not in the hypoglycaemic range. This is likely to occur in patients accustomed to running high blood glucose concentrations because endogenous hypoglycaemia sensing is programmed by recent glycaemic experience and so may trigger responses at normal or even high values. Furthermore, there is a still a strong clinical impression, not entirely supported by experimental evidence [5, 6], that rate of glucose fall can be important in determining symptomatic hypoglycaemia.

The ADA classification depends on defining a biochemical cut-off for hypoglycaemia, quoted in the 2013 document as 3.9 mmol/L (70 mg/dl) or less, and certainly hypoglycaemia should be definable solely biochemically. Frequency will then be dependent upon frequency of monitoring. As just intimated, there is however no universally agreed threshold glucose concentration for defining biochemical hypoglycaemia. Use of capillary, venous, venous arterialized (sampling from a distal venous cannula in a heated hand) or arterial samples will introduce variability, as will measurement of concentration in either whole blood or plasma. However, international consensus has recently been achieved on the biochemical definitions of important low blood glucose [3, 7] (**Figure 15.5.5.1**), in which a plasma glucose reading of 3.9 mmol/L (less than 70 mg/dl) is recognized, not as hypoglycaemia *per se*, but as the lower limit of a desirable target range for diabetes therapies. Consequently, plasma glucose values below this are defined as a 'hypoglycaemia alert', a value that should be treated to prevent hypoglycaemia; while values <3 mmol/L (<54 mg/dl) are recognized as being associated with negative medical outcomes, including cognitive impairment, cardiac arrhythmia and generation of impaired awareness of hypoglycaemia (IAH), and therefore identify a serious, clinically important hypoglycaemia to be avoided. The term 'severe hypoglycaemia' is retained to denote an episode including severe cognitive impairment requiring external assistance for recovery, or in which there is loss of consciousness or seizure, not requiring a biochemical value. These definitions, proposed in 2017, have been accepted by the American Diabetes Association and the European Association for the Study of Diabetes with simultaneous publications in their respective journals, although it should be noted that that original document used 3.9 mmol/L or less as the hypoglycaemia alert, based

on the earlier recommendation from the ADA, and subsequent discussion has accepted <3.9 mmol/L (<70 mg/dl) for consistency. This is because 3.9 mmol/L (70 mg/dl) is the quoted lower limit of the recommended target range for diabetes therapies intended to minimize risk of future complications and so using <3.9 mmol/L for the hypoglycaemia alert avoids defining a value of precisely 3.9 mmol/L in two ways. The scheme (Figure 15.5.5.1) has been endorsed by a multidisciplinary group including patient advocates and people with diabetes [8]. Important for clinical practice, there is evidence that those who perceive their own hypoglycaemia at plasma glucose concentrations of 3 mmol/L (54 mg/dl) or higher are at significantly lower risk for severe hypoglycaemia than those who perceive symptoms of hypoglycaemia at plasma glucose concentrations below 3 mmol/L (54 mg/dl) or who do not perceive their hypoglycaemia at all [9] (see 'Impaired Awareness of Hypoglycaemia', to follow).

Definitions for hypoglycaemia in continuous glucose monitoring data are also uncertain, with no clear clinical correlates for different values, given that the readings are made in interstitial fluid, not plasma, although equilibrated to plasma glucose concentrations, and there is an inevitable time lag between interstitial and plasma concentrations [10]. An early definition of 'low interstitial glucose' or 'LIG' described low glucose readings lasting at least 20 minutes at values of less than 3 mmol/L (54 mg/dl, LIG_3) or less than 2.2 mmol/L ($LIG_{2.2}$) [11]. More recently, an international consensus came to an agreement in line with the consensus on plasma glucose readings, and defined a CGM reading of <3 mmol/L (54 mg/dl) for at least 15 minutes as clinically significant hypoglycaemia, retaining the range from 3 to <3.9 mmol/L (54 to <70 mg/dl) as a hypoglycaemia alert [12]. Most episodes of asymptomatic, usually nocturnal, hypoglycaemia detected by CGM with the wearer of the device unaware of the event in fact last much longer than this and the clinical significance of the shorter duration episodes remains uncertain. That such episodes are seen in non-diabetic individuals is not necessarily helpful, as hypoglycaemia in the presence of an intact feedback loop including endogenous insulin and glucagon may be very different from hypoglycaemia during which the plasma insulin concentrations are artificially maintained. Nevertheless, there has been recent validation for a nocturnal value of <3 mmol/L (54 mg/dl) as having clinical consequences, with no indication yet for problems for any specific values between 3.0 and <3.9 mmol/L (54 to <70 mg/dl) [13].

Incidence of Hypoglycaemia

Even allowing for the differences in definition, reported incidence of hypoglycaemia—even severe hypoglycaemia—varies considerably. The first major considerations are the type and duration of the diabetes and the diabetes therapy being used. Tables 15.5.5.1 and 15.5.5.2 give some estimates from the literature for incidence of severe hypoglycaemia in type 1 and type 2 diabetes respectively. Lifestyle and insulin sensitizing or glycosuric agents used alone carry virtually no risk of severe hypoglycaemia and the nature of the hypoglycaemia reported in such treatments (e.g. [42]) is not

[a] These population-based studies only recorded events that were reported to the emergency services or required hospital admission.
[b] This study defined serious hypoglycaemia as that requiring hospitalization/emergency department admission or bringing about death associated with a blood glucose of <2.8 mmol/l. bd, twice daily pre-mixed insulin (given before breakfast and evening meal); CSII, continuous subcutaneous insulin infusion; INS, insulin therapy; MDI, multiple daily insulin injection therapy; Prandial, fast-acting analogue given before meals only; OHA, oval hypoglycaemic agent; SU, sulphonylurea therapy.

clear. The nature of the population will affect the prevalence—a specialist clinic population may have particular characteristics not shared by people not attending that clinic, while questionnaire surveys of large populations, which may be thought to be more representative of the population at large, may suffer from bias in that people interested in the topic are more likely to respond. Large database surveys can be helpful, especially for health economic analyses, but the data collected may be imperfect. Another important consideration is whether the data are collected retrospectively by questionnaire from patient recall, or prospectively, and the duration of time over which the data are collected. Rates also vary by country. In one recent large global study of people using insulin therapy and estimating rates from a 4-week prospective recording, the Hypoglycaemia Assessment Tool (HAT) study, rates of severe hypoglycaemia ranged from 2.1 to 10.8 events per person per year (global mean 4.9) for type 1 diabetes and 1.3–3.7 (global mean 2.5) for type 2, and noted that the percentage of people reporting at least one episode of any hypoglycaemia ranged from 54% to 87.4% and from 30.1% to 53.8% for types 1 and 2, respectively [30]. The study importantly showed no link with HbA1c, in contrast to randomized controlled trials of intensified insulin therapy, where higher rates of severe hypoglycaemia are associated with the lower HbA1c seen in groups allocated to intensive therapy [31, 42, 44–46]. The rates reported by the HAT study are high. A much smaller, focused study of a clinic population of adults with type 1 diabetes reported an annual severe hypoglycaemia rate of 1.3 episodes per patient per year, but very importantly showed that only 40% of people experience a severe hypoglycaemia during a year and 10% of the population contribute nearly 70% of all episodes [24].

People with type 2 diabetes are at much lower risk for hypoglycaemia than those with type 1. However, the type 2 population is heterogeneous. As the disease progresses, insulin deficiency becomes more profound. The insulin-deficient late type 2 patient behaves more as a patient with type 1 diabetes, including in terms of hypoglycaemia risk. The UK Hypoglycaemia Study Group reported both patient-reported episodes and episodes in which circulating glucose, monitored as interstitial tissue glucose calibrated to capillary plasma continuously over 96 h, fell below 2.2 mmol/L for 20 min or more. This prospective study found low rates of hypoglycaemia in participants with type 2 diabetes on sulphonylurea therapy and in those who had been on insulin for less than 2 years, but the rates in participants who had been on insulin for more than 5 years were higher and not different from rates in participants with type 1 diabetes of less than 5 years' duration (**Figure 15.5.5.2**) [11]. People with type 1 diabetes of more than 15 years' duration had much higher rates than the other groups. One contributor to the differences is duration of diabetes *per se* and increasing insulin deficiency over time. It is likely that the patients with type 2 diabetes who are treated with insulin secretagogues and those in the early stages of insulin therapy, are relatively protected from hypoglycaemia by residual ability to suppress endogenous insulin secretion and therefore, also respond to hypoglycaemia with endogenous glucagon. As insulin deficiency progresses, these primary counterregulatory mechanisms are lost and, as already suggested, one hypoglycaemic episode diminishes the defences against and therefore, increases the risk for another in the near future. Importantly, despite the lower rates of severe hypoglycaemia compared to rates in people with type 1, patients

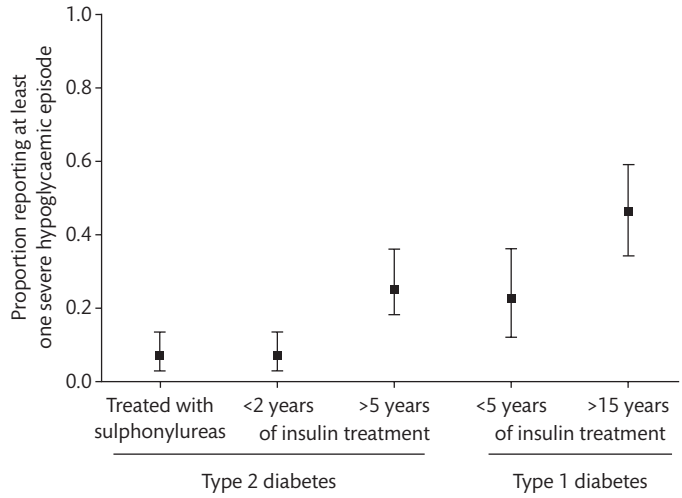

Figure 15.5.5.2 Graph showing relative frequency of severe hypoglycaemia in different groups of people with diabetes.

with type 2 diabetes may account for almost the same number of presentations to emergency services, because of the much greater prevalence of the disease [22]. Nevertheless, a meta-analysis of studies of people on sulphonylureas conducted in 2014 suggested only about 5% of people on such therapies experienced severe hypoglycaemia [47].

Physiological Responses to Hypoglycaemia

The response to hypoglycaemia is a generic stress response. As with other stressors, it involves activation of the hypothalamic–pituitary–adrenal axis and the autonomic nervous system. It is primarily driven centrally, although there are important local responses in the pancreas and liver (see next three paragraph) and modulating influences from peripheral sources, such as hepatic portal glucose sensors [48]. The brain's glucose-sensing apparatus is part of a complex system for control of energy balance. Despite vast fluctuations in energy intake and expenditure in normal daily living, in health, these mechanisms preserve plasma glucose concentrations within an extremely narrow physiological range. In health, hypoglycaemia sufficient to cause significant impairment of cognitive function does not occur.

The physiological responses to hypoglycaemia have been examined experimentally in human and in animal models by creating hypoglycaemia with insulin. This can be done by unopposed insulin injection, as in the insulin-tolerance test, or infusion, but, in human studies, a commonly used experimental technique is to infuse relatively high doses of insulin and control the hypoglycaemia with a simultaneous glucose infusion. This applies a very controlled hypoglycaemic challenge that allows comparisons of the responses to be made between different populations. It should be recognized that the counterregulatory responses to hypoglycaemia will normally be stimulated in a different physiological state but much useful information has been achieved with the technique.

Any change in plasma glucose concentration is detected by neurones in the brain stem and hypothalamus, which respond to changes

in blood glucose by altering their firing rate. The cellular and molecular mechanisms whereby these glucose responsive neurones are activated have recently been reviewed [49, 50]. The glucose-sensing neurones use many of the same mechanisms as the insulin-secreting cells of the pancreas, which release insulin in proportion to intracellular glucose metabolism and thus directly in response to the glucose supply to the cell. In the neurones, the likely response is a change in firing rate and neurotransmitter release. These eventually drive changes in endogenous glucose production from the liver and kidney and in peripheral glucose uptake by muscle and fat to sustain glucose concentrations in the circulation.

The first hormonal responses to a falling blood glucose concentration in the non-diabetic are cessation of pancreatic insulin release and stimulation of glucagon release (**Figure 15.5.5.3**). Hepatic glucose output rises as a result of glycogenolysis (which can sustain circulating plasma glucose for about 6–8 hours after the last food intake) and, later, gluconeogenesis. The role of hepatic autoregulation, in which hepatic glucose production rises in response to a falling blood glucose level independently of hormonal stimulation, is unclear. It is likely that changes in insulin and glucagon alone can protect against hypoglycaemia during normal daily living, with the balance between these processes maintaining circulating glucose concentrations despite wide changes in glucose availability (fed vs. fasting) and utilization (rest vs. exercise). If however glucose concentrations do fall, a stress response, including adrenaline secretion and sympathetic nervous system activation [51], further stimulates hepatic glucose output both directly and indirectly by peripheral effects on lipolysis and proteolysis to increase hepatic delivery of gluconeogenic precursors, such as alanine, glycerol, and lactate. Stimulation of the autonomic nervous system is reflected by changes in circulating noradrenaline and pancreatic polypeptide. Sympathetic activation directly stimulates endogenous hepatic glucose production, shuts down insulin secretion, and stimulates glucagon release. Growth hormone and cortisol also rise in hypoglycaemia, later or at slightly lower glucose concentrations. They are probably of secondary importance in acute counterregulation, but are important in sustaining euglycaemia, acting predominantly to reduce peripheral glucose utilization and provide precursors for gluconeogenesis. Other endocrine changes during hypoglycaemia include increased plasma renin activity and rises in prolactin, vasopressin, oxytocin, and β-endorphin. The role of these hormones in glucose regulation is uncertain.

The stress response to hypoglycaemia just described is associated with a characteristic symptom complex. This occurs at a lower glucose concentration than the stimulation of pancreatic glucagon and cessation of insulin secretion, and is not usually important in counterregulation in health, although subjective awareness has been reported in healthy volunteers during experimental hypoglycaemic induction studies at arterialized plasma glucose concentrations ranging from 2.8 to 3.6 mmol/L [51, 52]. The classical symptoms of hypoglycaemia are traditionally divided into autonomic (pounding heart/palpitations, shaking/tremor, hunger, sweating) and neuroglycopenic (drowsiness, difficulty speaking, incoordination, difficulty concentrating/confusion), either on the basis of the known aetiology of the symptom (e.g. sweating due to cholinergic sympathetic outflow) or by using statistical techniques. Groups of symptoms that tend to cluster together can be identified by principal component analysis, either during experimental hypoglycaemia, or from population-based studies in people with diabetes (**Table 15.5.5.3**) [53]. Hunger is a particularly useful symptom, since it both warns of hypoglycaemia and promotes eating and restoration of glucose levels. Symptoms of early hypoglycaemia become key in defence against more profound falls in circulating glucose concentrations in people with diabetes, *qv.*

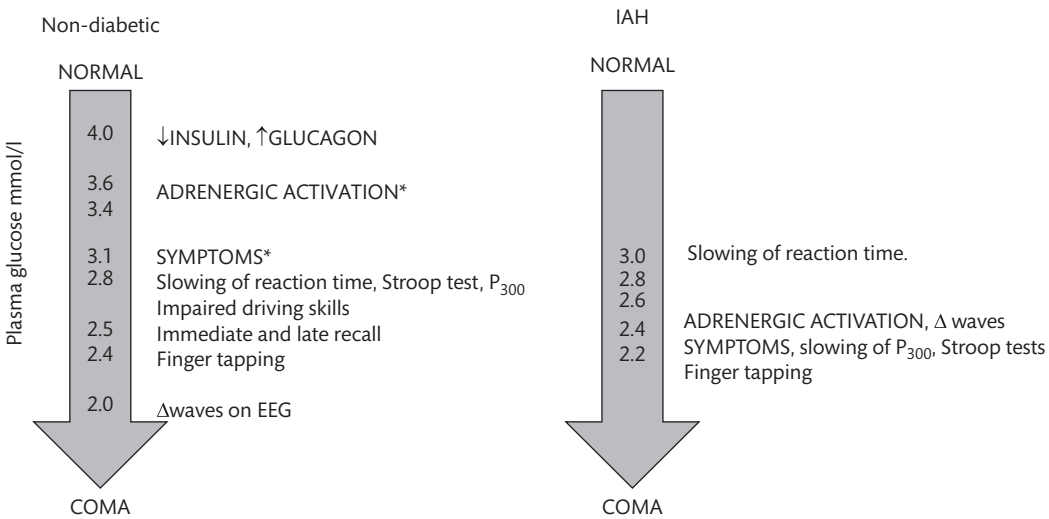

Figure 15.5.5.3 Counterregulation to hypoglycaemia. The arrow on the left shows the normal protective hierarchy of responses against progressive hypoglycaemia in with autonomic and humoral responses (upper case) occur before any detectable evidence of cognitive dysfunction (lower case). Of these, the Stroop test measures speed of reading lists of names of colours in appropriately, and, later, inappropriately coloured ink; P300 is an evoked potential recorded in response to a stimulus by scalp electrodes. * = In some studies of people with poorly-controlled diabetes, these parameters have been found to change at even higher glucose concentrations. Arterialized venous plasma glucose concentrations are given in mmol/L. On the right, the responses of a person with diabetes and impaired awareness are shown. The ability to regulate insulin and glucagon is lost and the glucose concentration for the onset of the rest of humoral response has fallen below the glucose concentration at which cognitive function is detectably deteriorated.

Table 15.5.5.3 Symptoms of acute hypoglycaemia

Autonomic	Neuroglycopenic	Other	Miscellaneous
• Sweating • Tremor • Warmth • Anxiety • Nausea	• Dizziness • Confusion • Tiredness • Difficulty in speaking • Headache	• Hunger • Blurred vision • Drowsiness • Tiredness	• Palpitations • Shivering

Impaired cognitive function, particularly changes in reaction time tasks, is noted in healthy volunteers undergoing experimental hypoglycaemia at glucose concentrations of between 2.6 and 3.2 mmol/L [52, 54], depending on the circumstances of the study and the age of the participants. Impairment of multiple memory functions has been shown at around 2.5 mmol/L [55], although the impact of lesser degrees of hypoglycaemia on memory in non-diabetic subjects has not been studied. Older people show evidence of cognitive decline at slightly higher glucose concentrations compared to young adults, and a later onset of symptoms [52]. In theory, if glucose levels are lowered far enough, brain function becomes further impaired, so that drowsiness and even seizures or coma may eventually develop. This cannot, of course, be done in experimental settings, but it has been well described in insulin shock therapy in treatments for severe depression in the nineteenth century. Outside this, hypoglycaemia sufficient to cause significant cognitive dysfunction does not occur in health, except in extreme circumstances such as prolonged vigorous exercise. Starvation, for example, does not cause loss of consciousness, especially as the brain can use non-glucose fuels, such as ketones and lactate, to support its function.

Responses to Hypoglycaemia in Diabetes

In diabetes, endogenous protection against hypoglycaemia is impaired. With loss of endogenous insulin secretory capacity comes loss of the ability to reduce insulin release during hypoglycaemia, a problem compounded by artificial elevation of the circulating insulin from injected insulin, or as a result of the action of insulin secretagogues or meglitinides. The glucagon response to hypoglycaemia is also lost, as the alpha-cell response is apparently driven by signals from adjacent β-cells. The loss of the glucagon response to acute hypoglycaemia is seen within the first five years of type 1 diabetes [56]. The primary neurohumoral defenWEWce against hypoglycaemia is then adrenaline and autonomic activation. Defects in the former have been shown in otherwise healthy subjects with diabetes, associated with longer disease duration [56]. People with diabetes are, therefore, peculiarly dependent upon subjective recognition of early degrees of hypoglycaemia and voluntary ingestion of carbohydrate to compensate for the failure of endogenous responses. As gastric emptying is accelerated during hypoglycaemia, oral carbohydrate ingestion results in a rapid rise in circulating glucose (see 'Treatment', to follow).

The symptoms of hypoglycaemia early in diabetes are similar to those reported by healthy volunteers made hypoglycaemic in experimental protocols but are influenced by many factors, including the age group of the person. Studies have been made in children with type 1 diabetes, who may experience symptoms that they cannot report, and manifest signs, often behavioural, that are detected by their parents [57]. By the age of nine, children become able to detect and describe their own hypoglycaemia [57]. Symptoms of hypoglycaemia also wane with ageing and elderly patients with diabetes and treated with insulin report more lightheadedness. Unsteadiness incoordination/disarticulation symptoms become important [58]. Diabetes duration is also relevant, with many people reporting a weakening of particularly autonomic symptoms over time [59]. It is possible that treatment modality affects the glucose concentration at which symptoms of hypoglycaemia are reported—one study showed earlier symptom perception in people with type 2 diabetes using sulphonylureas, vs. insulin [60], and although an impact of the different degree of insulin deficiency is likely between patients on the different treatment modalities, a direct effect of the sulphonylureas cannot be ruled out. Agents that impact on sulphonylurea receptors have been investigated for their ability to enhance subjective awareness of hypoglycaemia. Antecedent glycaemic experience has a major impact, with evidence for the ability of antecedent hypoglycaemia to reduce the glucose concentration for symptom and neurohumoral responses to subsequent hypoglycaemia demonstrated experimentally in both non-diabetic people [61, 62] and in people with diabetes [63–65] and evidence also for prior hyperglycaemia, as seen in type 2 diabetes, to elevate the glucose concentrations associated with onset of counterregulatory responses [66].

Glucose thresholds for cognitive impairment during acute hypoglycaemia are not so obviously impacted upon by the presence of diabetes. Deterioration in task performance during experimentally induced controlled slow reduction in plasma glucose has been seen at a mean of between 3.2 and 2.6 mmol/L in all studies, irrespective of type of diabetes or its treatment [54, 60, 67, 68]. Performance of simpler tasks may be slightly better preserved during hypoglycaemia and glucose concentrations for some tasks may show some adaptation to antecedent hypoglycaemia, but this effect if present is small [63]. Importantly, one study in young people with type 1 diabetes who performed brief cognitive tasks prior to measuring plasma glucose demonstrated preservation of ability at glucose concentrations of 3–3.9 mmol/L but significant impairment at lower values, as well as at values of over 22.2 mmol/L [69].

Impaired Awareness of Hypoglycaemia

Because of their lost ability to make an appropriate insulin or glucagon response to a falling plasma glucose, people with insulin-deficient diabetes are dependent on subjective recognition of the start of a fall in order to arrest it by ingestion of rapidly absorbed carbohydrate and avoid severe hypoglycaemia with significant cognitive impairment. Between 20% and 40% of people with type 1 diabetes have impaired awareness of hypoglycaemia (IAH), in which they fail to be able to recognize their own hypoglycaemia in timely fashion [9, 70]. This increases their risk of severe hypoglycaemia sixfold [70]. The prevalence of IAH in type 2 diabetes is less well studied but there is evidence that 10% of people using insulin will have IAH, with a 17-fold increased risk of severe episodes [71].

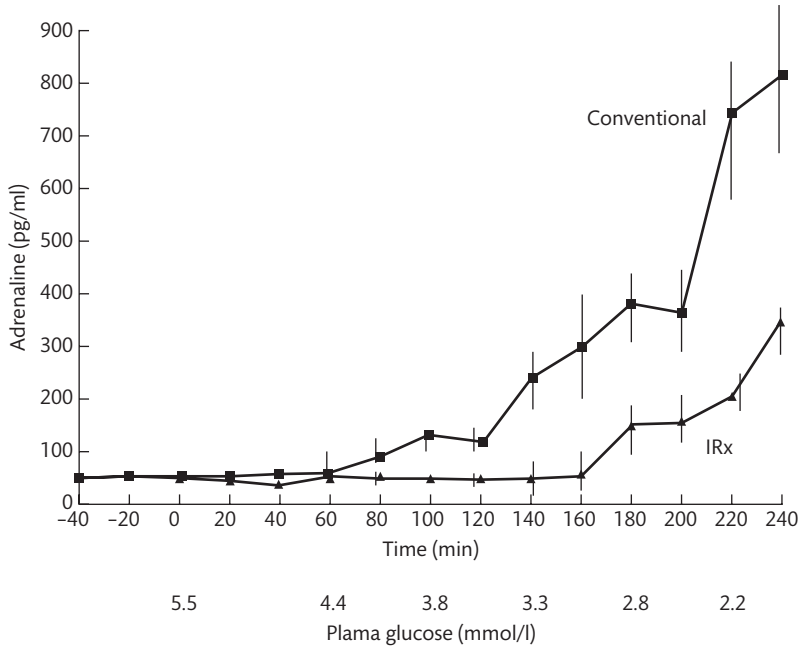

Figure 15.5.5.4 Delayed and diminished adrenaline responses to hypoglycaemia after institution of intensified insulin therapy in the mid-1980s. The samples were collected during controlled hypoglycaemia established by the insulin clamp technique, so the adrenaline responses are to the same hypoglycaemic challenge, applied before and after intensification of therapy in a small group of people with type 1 diabetes.

IAH is associated with defects in the normal counterregulatory responses to acute hypoglycaemia, additional to the inability to regulate insulin secretion or mount a glucagon response. The neurohumoral responses are delayed in onset to lower glucose concentrations (Figure 15.5.5.3) and diminished in magnitude at any given concentration (Figure 15.5.5.4) [72]. The glucose concentration at which cognitive dysfunction is first detectable is, however, not lower [67]. Performance in some cognitive tasks may be preserved at slightly lower plasma glucose concentrations, but the change is small and much less than the change seen in glucose concentrations associated with symptoms or catecholamine responses [73]. For some tasks, there is no change at all and the protective window between the glucose concentration for subjective awareness and hormonal responses and the onset of cognitive function is lost [67, 74]. By the time the stress response starts, the patient may have too much cognitive deficit to be able to recognize or respond to it. The major contributor to this situation is prior exposure to low blood glucose concentrations, with the impact on symptomatic and hormonal responses to subsequent hypoglycaemia alluded to above [63, 65, 68]. It is not clear whether some people are genetically more resistant to this phenomenon, or to the cognitive decline of hypoglycaemia, but, in general, people frequently exposed to plasma glucose readings of <3 mmol/L will develop impaired awareness of hypoglycaemia and experience more severe episodes [9]. Equally, avoidance of such exposure can restore awareness [75–77].

The mechanisms of IAH induction are not certain. Postulated mechanisms include increased glucose uptake by neuronal cells in response to hypoglycaemia exposure, and alterations in the brain's ability to utilize non-glucose fuels (e.g. [78]). Neuroimaging studies have failed to confirm that loss of response to hypoglycaemia is associated with increased brain glucose uptake, a phenomenon that has been well described in animal models and in early human studies, but have shown that hypoglycaemia is associated with altered responses in brain regions, including in the brain stem and hypothalamic and pituitary regions, involved in energy balance, glucose sensing, and stress responses, balance and coordination, and also in brain regions that are involved in desire to eat, emotional salience and recall [79, 80]. These differences in brain response to hypoglycaemia may be relevant not just to the reduced perception of symptoms, but also to the difficulties some patients experience in avoiding hypoglycaemia in the future, a strategy that can restore awareness to the unaware.

Nocturnal Hypoglycaemia

Hypoglycaemia at night has important specific features and is the topic of a recent review [81]. The counterregulatory response is greatly attenuated during deep sleep and people with diabetes experiencing hypoglycaemia during such sleep will not wake up, or be aware, and may also show no external signs. They may also sleep through alarms generated by continuous glucose monitors. Symptomatic hypoglycaemia at night may only occur if the hypoglycaemia is still present or occurs during lighter sleep. Nocturnal hypoglycaemia may thus continue for several hours. Risk of nocturnal hypoglycaemia is increased because the early hours of the morning are the time of maximum insulin sensitivity (because of diurnal variations in counterregulatory hormone secretion) and may also coincide with peak action of insulins injected to provide overnight cover. Hypoglycaemia in the night does not appear to impair cognitive performance next day but can be associated with low mood. It confounds the laying down of memory [82] and may be enough to reduce the stress response to hypoglycaemia the next

day [63]. Symptoms of an unsuspected hypoglycaemia in the night range from none at all to temporary neurological deficit (Todd's paresis), although a headache in the morning may be a result.

Contributory Factors to Hypoglycaemia

Hypoglycaemia in patients with diabetes is driven by exogenous insulin and insulin secretagogue therapy, with the loss of endogenous control of insulin secretion. Such therapies are inevitably associated with times of insulin excess and loss of glucagon responses to hypoglycaemia consequent upon the loss of β-cell function increases the risk. Additional risk occurs with defective responses in other elements of the normal stress response, most notably with the development of IAH. Risk of severe hypoglycaemia rises as insulin deficiency, marked by C-peptide deficiency, advances; with increasing age and diabetes duration and, most robustly, with a history of severe hypoglycaemia in the past [24]. A relationship between increased hypoglycaemia and desirable HbA1c is not inevitable. Most recent studies fail to find a higher incidence of severe hypoglycaemia with a lower HbA_{1c}, at least in type 1 populations [23, 26], although one recent study has shown increased risk in type 2 patients attending primary care with HbA1c below 53 mmol/mol [83]. Rates of severe hypoglycaemia are always higher in the intensive treatment arms of research trials [31, 44–46] but in type 1 diabetes, improving patients' ability to manage their own insulin regimen flexibly through structured education lowers HbA1c and risk of hypoglycaemia (e.g. [9]). In type 2 diabetes, there is no risk for severe episodes with lifestyle therapies or insulin sensitizing therapies (during which the patient is using endogenous insulin only) and minimal risk with incretin-based therapies, or glycosuric agents, when used alone. The risk is restricted to insulin secretagogue therapies and highest with longer-acting agents, such as first- and second-generation sulphonylureas [83]. This is not to suggest that such agents should not be used, as the absolute risk remains small and they are well-tested, effective, and familiar agents, but care should be taken in their use, especially in elderly patients and in those with other comorbidities, such as renal impairment or coexisting cognitive dysfunction, now that newer agents with lower hypoglycaemia risk are available.

Exogenous insulin can cause hypoglycaemia because it is not under endogenous control; it is delivered systemically, rather than into the portal circulation, creating a relatively high peripheral-to-portal gradient; its absorption is unpredictable, depending on factors such as skin blood flow (and, therefore, site of injection, local lipohypertrophy, exercise of underlying muscle, or physical disruption of the injection site by rubbing, ambient temperature) and because of intrinsic variability in the absorption, which affects time to peak action and duration of the effects of an injection. Whether the absence of C-peptide leaves the patient lacking in a specific defensive action, or is simply a reflection of the complete inability to achieve any lowering of insulin effect by shutting off an endogenous supply or influencing the glucagon response, is not known.

Often, a single episode of hypoglycaemia can be attributed to a likely precipitant. Exercise, missed meals/snacks, treatment errors, and alcohol are the most commonly reported (Box 15.5.5.1). Exercise causes immediate hypoglycaemia as it drives insulin and insulin independent muscle glucose uptake and glucose oxidation. Unaccustomed, vigorous, or prolonged exercise (all relative to the exerciser's accustomed exercise level) will continue to lower blood glucose over the next 12–24 hours as expended muscle and liver glycogen stores are replaced. The possibility that exercise may cause hypoglycaemia many hours later is often not appreciated. Extreme exercise, by producing a stress response, may alleviate this and one paper has suggested a sprint at the end of a period of less intense exercise may provide some protection in the immediate post-exercise phase [84], but not the delayed hypoglycaemia [85] which needs to be addressed by reduced insulin administration.

Alcohol increases the risk of delayed severe hypoglycaemia, by inhibiting the gluconeogenesis needed to maintain blood glucose levels after fasting. The hypoglycaemia typically occurs in the early hours of the morning after drinking in the evening; or even after breakfast the next day. Alcohol also causes neglect of self-care of diabetes (affecting compliance with medical treatment and dietary regimens), decreases perception of symptoms of early hypoglycaemia and may impair the ability to take appropriate action to recover from a low glucose.

Box 15.5.5.1 Risk factors for hypoglycaemia and problematic hypoglycaemia

Common contributors to an individual episode of hypoglycaemia

- Missed or inadequate meals/snacks
- Exercise
- Drug or insulin dose error
- Alcohol
- Change in absorption from injection, e.g. hot bath, sauna, change in injection site
- Overcorrection of a high glucose reading, e.g. postprandial, during action of earlier correction dose

Risk factors for experiencing severe hypoglycaemia:

- History of severe hypoglycaemia
- Hypoglycaemia unawareness/deficient counterregulation
- Long duration of diabetes
- C-peptide deficiency
- Under 5 years of age
- Nocturnal hypoglycaemia
- Intensified glycaemic control (insulin or drug treatment)
- Inappropriate insulin/drug regimen, e.g. long-acting sulphonylurea in elderly patients
- Comorbidities and polypharmacy

Other factors increasing risk for recurrent, problematic hypoglycaemia

- Failure of glucose counterregulation
  - Cortisol and/or growth hormone deficiency
- Failure of insulin or sulphonylurea clearance
  - Renal failure
  - Liver failure
  - Hypothyroidism
  - Insulin-binding antibodies
- Failure of endogenous glucose production
  - Liver failure
  - Glycogen storage diseases
- Failure of exogenous glucose supply
  - Malabsorption, including coeliac disease
  - Gastroparesis
  - Eating disorders, especially dieting or anorexia
- Postpartum/breast feeding
- Manipulation of therapy (includes suicide/parasuicide and obsessive fear of hyperglycaemia)

Presence of insulin-binding antibodies may interfere with the pharmacodynamics of any given insulin, and has been associated with increased risk of severe hypoglycaemia, especially when present in high concentrations in patients using older, less pure insulin preparations [56]. Insulin antibody levels are higher with genetically modified insulin analogues and with inhaled insulin, but, so far, have not been shown to have the same impact. In autoimmune disease, both insulin-binding and insulin-receptor antibodies have been known to cause hypoglycaemia in the absence of insulin therapy. Similarly, there are reports of hypoglycaemia occurring in the prodrome to type 2 diabetes, thought to be due to an exaggerated second-phase insulin response, brought on by early hyperglycaemia associated with loss of the first-phase insulin response.

Comorbidities, perhaps particularly in the elderly patient with type 2 diabetes, are well established to increase risk of severe hypoglycaemia. Renal failure and hypothyroidism (by decreasing insulin clearance) and hypoadrenalism from Addison's disease or hypopituitarism and growth hormone deficiency (by reducing insulin antagonism) are rare causes of recurrent hypoglycaemia. Anecdotally, insulin-treated patients on adrenal replacement therapy may be more safely managed on longer-acting agents, e.g. prednisolone rather than hydrocortisone, to avoid periods of very low corticosteroid levels at night, although this should be the subject of research. Drugs that have been reported to increase hypoglycaemia risk in treated diabetic patients include angiotensin-converting enzyme (ACE) inhibitors in patients with type 1 diabetes, any hypertensive therapy in patients with type 2 diabetes (possibly reflecting more active medical management, rather than a direct effect of a particular drug), antithyroid treatment, and cessation of steroid treatment. Other drugs that can cause hypoglycaemia include quinolones, pentamidine, quinine, β-blockers, and insulin-like growth factor [86]. Recurrent hypoglycaemia, or mixed hypoglycaemia/ketoacidosis, occur in some subjects labelled as having 'brittle diabetes'. Psychosocial factors may contribute to this presentation. Some patients may choose to run their blood glucose at near-hypoglycaemic levels, overcorrecting minor or transient high glucose concentrations.

Anecdotal reports of loss of hypoglycaemia awareness and increased risk of severe hypoglycaemia associated with conversion from one insulin species to another, most particularly after switching from animal to human insulin, were not confirmed in randomized trials. However, insulins do differ in terms of pharmacokinetics and lipid solubility. The randomized trials cannot exclude idiosyncratic or very small differences that might be clinically relevant to susceptible patients. Caution should always be exercised in converting patients from one insulin regimen to another and patient preference should be respected.

Hypoglycaemia may become a particular problem in pregnancy, where women with diabetes strive for very tight control, often introduced urgently. The therapeutic targets are tighter. Insulin sensitivity may be increased in the first 12 weeks of pregnancy, and, importantly, the insulin resistance of pregnancy stops immediately placental function ceases, so that protocols for insulin administration during delivery must anticipate and account for this (see Chapter 15.10.4, 'Diabetes in Pregnancy'). Loss of hypoglycaemia awareness and severe hypoglycaemia are common in pregnancy and can create a significant problem for the mother, although with no apparently negative impact on the fetus. Because of the attention to very tight glucose targets, including postprandially in pregnancy, review of eating patterns and, perhaps, introduction of routine between-meal snacking, may be necessary. The insulin resistance of late pregnancy resolves with delivery of the placenta, and labour ward protocols for blood glucose control should reflect this, allowing reduction in insulin administration immediately postpartum, to avoid maternal hypoglycaemia. Because of the imperfections in our ability to control blood glucose in the diabetic mother, their babies are at risk of hypoglycaemia, probably secondary to fetal hyperinsulinaemia before and during labour. Breast feeding is an energy-consuming activity and maternal insulin doses may need further reduction during lactation.

There is some controversial evidence for a genetic predisposition to IAH and severe hypoglycaemia, with the deletion (D-) allele of the ACE insertion/deletion (I/D) polymorphism and polymorphisms in or near the genes for the β1 and β2 adrenergic receptor implicated in adults with diabetes (e.g. [87–89]), although other studies, including one in young people have been negative [90, 91].

Consequences of Hypoglycaemia

Acute Effects

Acute episodes of hypoglycaemia resulting in cognitive impairment may result in embarrassing incidents, errors of judgement or performance, and accidents. Altered behaviour may manifest as aggression, or may mimic alcohol intoxication. If glucose levels fall low enough, drowsiness, coma, and/or epileptic seizures may result in injury and/or hospital admission.

Hypoglycaemia is a particular risk when undertaking activities that require concentration and fast reactions. Driving is a particular issue, usefully reviewed in [92]. In many countries, risk of hypoglycaemia is taken into account by driving licensing authorities and this has led to underreporting [93]. In the United Kingdom, hypoglycaemia is not accepted by courts as a valid medicolegal explanation for driving offences and the onus is on the individual to ensure that hypoglycaemia does not occur behind the steering wheel. Cox has found a relationship between experience of hypoglycaemia-related road traffic accidents and risk-taking behaviours in general [94]. Patients with a current history of severe hypoglycaemia while awake, or asymptomatic hypoglycaemia with high risk of severe hypoglycaemia, must be advised not to drive at all, and steps should be taken immediately to attempt to restore hypoglycaemia awareness and protection. While the UK licensing authorities suggest any normal blood glucose (5 mmol/L or more) is acceptable before driving, we advise patients with any degree of impaired awareness not to drive with a blood glucose less than 7 mmol/L, as there is evidence that blood glucose falls during driving. If a driver does suspect that he or she is hypoglycaemic during driving, he/she should stop the car, get out of the driver seat, and treat the hypoglycaemia. Because of evidence of delayed restoration of cognitive function after hypoglycaemia, driving should not be resumed for at least 45 minutes after an event.

Acute hypoglycaemia impairs formation of memory for events occurring at the time of the hypoglycaemia [95], and may impair consolidation of memory during sleep [82]. Prolonged hypoglycaemia may result in seizure [96]. Nocturnal hypoglycaemia may

also impair awareness of hypoglycaemia the next day [62, 63]. It may result in transient neurological sequelae, such as hemiplegia, which may mimic a cerebrovascular event (hemiplegic hypoglycaemia). Rarely, hypoglycaemia may be followed by cerebral oedema. Persistent neurological damage may follow very severe and prolonged hypoglycaemia, usually after a major insulin overdose.

Cardiac arrythmias are detected at plasma glucose concentrations of under 3 mmol/L (54 mg/dl) and may be associated with the autonomic activation, adrenaline responses and/or hypokalaemia that accompany insulin-induced hypoglycaemia [97, 98]. Prolongation of the qQTc interval is detected. The suggestion that some people may be predisposed to certain arrhythmias in hypoglycaemia raises the possibility of screening for risk in future [99].

Mortality resulting from acute hypoglycaemia is difficult to quantify accurately. Each year, 25–30 deaths are recorded in the United Kingdom as being directly related to hypoglycaemia. Population studies suggest that the actual rate may be higher. While diabetic ketoacidosis remains the main cause of acute diabetes-related death in young people, Cryer has quoted data reporting between 4% and 10% of deaths in people with type 1 diabetes are due to hypoglycaemia, but it is important to recognize that all the studies were in young people, with low rates of death from other causes [100]. A history of severe hypoglycaemia is associated with a significant increased mortality but not necessarily from hypoglycaemia itself in type 1 or type 2 diabetes, such that hypoglycaemia may be a marker of frailty and high risk of death from other causes [101, 102]. Nevertheless, recent studies show that death from hypoglycaemia, at least in people with type 1 diabetes, continues to occur probably at a stable rate. 'Dead in bed' syndrome, the event of a sudden, presumed cardiac, death occurring during sleep without evidence of seizure, was recently reported as accounting for 5% of deaths in young people with type 1 diabetes, very similar to the 4% originally described in 1991 [103].

In type 2 diabetes, and/or with elderly patients, presentations with severe hypoglycaemia have been associated with stroke and heart attack, although it cannot be established which event came first.

The costs of hypoglycaemia are difficult to calculate, as many episodes even of severe hypoglycaemia, are managed without involvement of emergency services. Furthermore the hidden costs in terms of loss of working time, for either the person with diabetes or his/her carers, and additional self-monitoring or contact with healthcare professionals are not easily recorded. One recent estimate of the direct and indirect costs of episodes of severe hypoglycaemia that led to hospitalization was approximately £1180 (US $1505) medical costs per person per episode, and £485 (US $620) additional indirect costs in terms of lost work [103]. There are no significant costs associated with non-severe episodes [104].

Chronic Effects of Hypoglycaemia

Neurological

The chronic effects of recurrent hypoglycaemia, from which apparently full recovery is made at the time, are unknown. Other repeated brain insults (e.g. trauma in boxers) may lead on to irreversible brain damage and it is known that neonatal hypoglycaemia (not usually diabetic) is associated with impaired brain function later. The developing brain is more susceptible to the effects of hypoglycaemia than the adult brain, and severe hypoglycaemia before the age of seven does seem to have impact on later performance of cognitive tasks [105, 106]. In contrast, in adolescents, as well as in adults, prospective studies of intensified therapy, with its associated increased risk of severe hypoglycaemia, have failed to show any cognitive deficit in those with recurrent hypoglycaemia [107], which is important information when deciding appropriate therapies to offer to minimize all complications of diabetes and its therapies, including cognitive performance. At the other end of the age range, one recent study has reported a high rate of impaired cognitive performance in older adults with type 1 diabetes, and impaired performance was associated with recent severe hypoglycaemia and impaired awareness of hypoglycaemia [108] and a study in older people with type 2 diabetes also links impaired performance and cognitive decline with hypoglycaemia [109]. However, the type 1 data also confirm earlier studies showing associations with chronic hyperglycaemia and microvascular complications, and the direction of any link between impaired cognitive function and hypoglycaemia remains unknown—certainly people with dementia struggle to adjust insulin regimens effectively and poor cognition may be a cause of problematic hypoglycaemia. A meta-analysis of seven studies in adults, with diabetes, comparing those with and without a history of severe hypoglycaemia, indicates impaired memory functions and impaired speed of processing in type 2 diabetes only, while other cognitive functions remain intact [110]. Anecdotally, people with hypoglycaemia often complain of poor memory, and animal studies of profound hypoglycaemia show damage in the hippocampus, but it is possible that the failure to make or consolidate memory mentioned earlier may be as much to blame as permanent damage. Depression and anxiety deteriorate performance of cognitive function tests.

Cardiovascular

Hypoglycaemia is a risk marker for cardiovascular mortality. Apart from acute effects, the stress response of hypoglycaemia is accompanied by a coagulopathy, with elevated circulating inflammatory markers, adhesion molecules, and altered platelet and endothelial function. These changes do not resolve immediately, but persist and it is hypothesized that they may contribute to vascular damage and increase the risk of macrovascular events [111]. The hypothesis is very plausible but remains to be proven.

Societal and Psychological

Experience of hypoglycaemia can have long-term impact on quality of life, both of the person with diabetes and their families. There is evidence for absenteeism after severe hypoglycaemia, with some evidence for reduced work attendance after non-severe hypoglycaemia, although those data are currently soft. As already discussed, recurrent exposure to plasma glucose values of <3 mmol/L (54 mg/dl) reduces awareness of subsequent hypoglycaemia, increasing risk of severe episodes. Both IAH and severe hypoglycaemia can cause embarrassment at work, or worse, with accidents and trauma, and may lead to loss of driving privileges and in severe cases access to children and dependents. Fear of hypoglycaemia is higher in people with experience of severe episodes but may be high even in people not at particularly high risk [112] and can of itself impair quality of life [113]. Healthcare professionals may have higher concern about

hypoglycaemia than people with diabetes and such fears may lead to reduced enthusiasm for intensifying diabetes treatments to minimize long-term diabetes complications. The impact of IAH and severe hypoglycaemia on family members can be devastating as they thrust the family into an extreme carer role [114].

Management of Hypoglycaemia

Any person taking insulin or an insulin secretagogue is at risk.

Management

Most acute episodes are self-managed with oral carbohydrate; 15 g is usually adequate and rapidly absorbed carbohydrate must be used. Glucose tablets, such as dextrosol (3.1 g/tablet), or 200 ml fresh fruit juice, are widely recommended, but any palatable sources of concentrated glucose can be used. A glycaemic response should occur within 10–15 minutes and treatment should be repeated after 15 min if glucose concentrations are still below 3.9 mmol/L. If refined glucose is used, most authorities recommend a starchy snack should also be ingested to avoid glucose levels dropping again after rapid absorption of available glucose from the stomach. This may be achieved by expediting the next meal or by deliberately ingesting 20 g complex carbohydrate on recovery. In children who may be reluctant to eat or drink, concentrated glucose preparations, such as Glucogel (32 g/100 ml), or honey can be squeezed inside the cheek. The absorption of this is probably by the concentrated glucose trickling back down the oropharynx, inducing reflex swallowing. Such therapies should not be attempted in the unconscious, when parenteral glucose or glucagon should be used.

Glucagon can be given by intravenous, subcutaneous, or intramuscular injection, with nasal glucagon being developed as an effective substitute. Glucagon mobilizes hepatic glycogen. It may be ineffective in liver disease, malnutrition, after repeated episodes of hypoglycaemia and extreme exercise, where there may be inadequate hepatic glycogen stores. It is available as a 1 mg injection pack for emergency intramuscular injection by a third party at home. The effect will be short-lived, so the recovered patient should take oral carbohydrate to prevent glucose levels from falling again. Intravenous glucose injection (70 ml of 20% glucose, or 125 ml of 10%) will rapidly elevate blood glucose levels and is the standard emergency department treatment for hypoglycaemia that cannot be managed by oral intake. 25 ml 50% glucose may be used if a central venous line is in place and fluid load is a concern. Having treated the acute episode, an attempt should be made to identify the underlying cause (missed meals, exercise) and to give advice/education as appropriate.

Patients who become hypoglycaemic on sulphonylurea therapy will require monitoring, and, probably, additional glucose support for up to 48 hours, as the hypoglycaemia is recurrent and prolonged. Advice for self-treating hypoglycaemia with ingestion of simple sugar should be reiterated, perhaps especially for patients also using alpha glucosidase inhibitors, in whom the ability of which to break down and absorb glucose from complex carbohydrate will be retarded. If there is a history of repeated hypoglycaemia and/or unawareness of hypoglycaemia, the patient should be formally reviewed by a specialist diabetes team.

Avoidance of Hypoglycaemia

The first step towards minimizing hypoglycaemia risk is to identify and quantify it. Documenting hypoglycaemia experience and hypoglycaemia awareness should be part of every annual review for anyone using exogenous insulin or an insulin secretagogue. The International Hypoglycaemia Study Group has produced a Red-Amber-Green rating for risk for use by healthcare professionals and one for use by people with diabetes (ihsgonline.com) The healthcare professional should establish how often the patient experiences severe, non-severe, and asymptomatic (from relatives and friends and from home records showing readings <3 mmol/L [54 mg/dl]) episodes and if there are times of particular risk. Nocturnal hypoglycaemia should be sought by asking the patient to check blood glucose occasionally at around 03.00 h (3 a.m.), the time of maximum insulin sensitivity and, in regimens using conventional background insulins (NPH and isophane), the time of peak insulin action. Hypoglycaemia awareness should be formally measured using one of the published validated questionnaires identifying people at high risk of severe hypoglycaemia [9, 70, 71, 115, 116]. Of these, the Gold score, asking the person to rate their awareness on a numeric scale from 1 to 7, and the Dose Adjustment For Normal Eating (DAFNE) tool asking if symptoms are usually perceived at or above a plasma glucose of 3 mmol/L (54 mg/dl) vs. below this value or not at all, are single item questionnaires, the latter being less subjective. Impaired awareness with either (defined as a score of 4 or more on the Gold score, or usual detection being at under 3 mmol/L or not occurring at all) predict significantly increased risk of severe hypoglycaemia in both type 1 (Figures 15.5.5.5 and 15.5.5.6) and in type 2 diabetes [71].

Inspection of home blood glucose monitoring records can help identify times of particular risk of hypoglycaemia, and it is worth going over recent records with the patient to confirm impressions and to ascertain awareness status. Using continuous glucose monitoring or intermittently monitored, retrospective ('Flash') glucose monitoring can also help identify hypoglycaemia patterns, especially overnight. Short-term use of blinded CGM has been used diagnostically, although not of proven utility.

Identification of risk factors may be made through a careful history and examination. Duration of diabetes, duration of insulin therapy, and degree of insulin secretory failure reflected by C-peptide concentrations are not amenable to treatment, but indicate someone at increased risk for severe hypoglycaemia, as do comorbidity and frailness. Discussing with the patient the timing of seminal activities, such as rising, insulin administration, eating, exercise, and alcohol ingestion, can identify possible contributors to non-physiological insulin replacement strategies. Intercurrent illnesses that might enhance hypoglycaemia risk, such as other hormone deficiencies, other drugs, malabsorption, etc., should be eliminated or treated.

Thereafter, there is a clear pathway for reducing hypoglycaemia risk [117]. In patients with type 2 diabetes, not dependent on insulin, review of medication, with consideration given to replacing insulin secretagogues with insulin sensitizers, incretin-based, or glycosuric therapies. For patients requiring insulin, particularly those with type 1 diabetes, structured education around flexible insulin use and self-adjustment of doses to achieve pre-meal

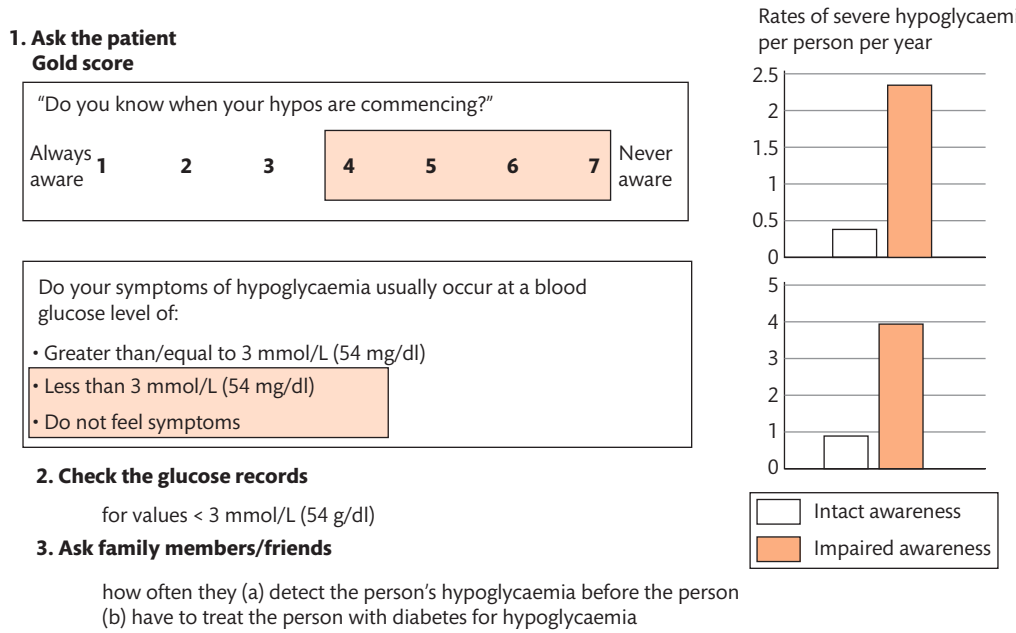

Figure 15.5.5.5 Two tools for assessing awareness of hypoglycaemia in people with diabetes by asking the patient. In the top panel, the Gold score is illustrated, below it the DAFNE tool. With each tool, the patient answers that define impaired awareness are shaded in grey. On the right the grey bars in each graph show the rates of severe hypoglycaemia in people scoring for impaired awareness with each tool compared to the rate in people who do not score for impaired awareness in white.
Data taken from references 70 and 9.

target blood glucose in the near-normoglycaemic range (most particularly stressing the lower limit of the desired range, normally 4 mmol/L (72 mg/dl)) has been reliably shown to reduce severe hypoglycaemia, with evidence for many such programmes, some specifically focused around hypoglycaemia avoidance, others more generally targeting improved glycaemic control and flexibility of lifestyle, demonstrated in a systematic review [118]. Such programmes depend on teaching about insulin pharmacodynamics, how to administer insulin flexibly around meals to be eaten, and common precipitants of hypoglycaemia such as exercise or alcohol. Patients may increase their carbohydrate intake (e.g. 30 g before and at 30-minute intervals during moderate exercise) and/or adjust insulin doses before and after exercise to avoid low blood glucose. During the exercise, continuation of some, perhaps reduced, basal insulin replacement is usually needed, but meal doses can be reduced considerably. Unaccustomed, vigorous, or prolonged exercise necessitates a further reduction in the overnight insulin dose (e.g. by between 15% and 50% in a well-controlled patient). Alcohol, with its ability to cause delayed hypoglycaemia, taken with exercise (e.g. dancing and drinking at parties) may be particularly

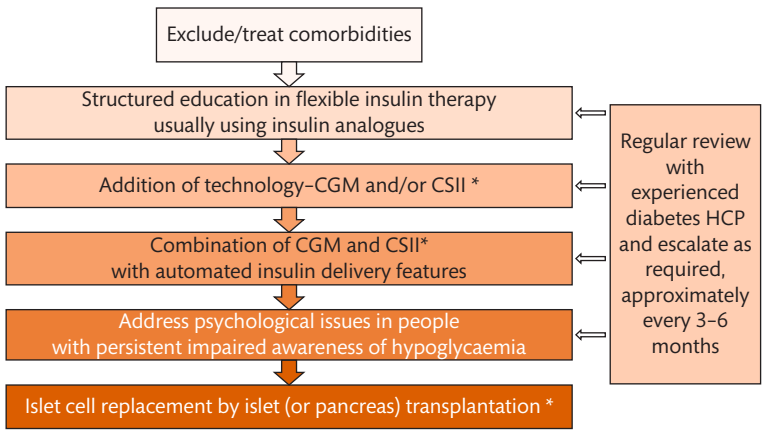

Figure 15.5.5.6 Treatment pathway for people with type 1 diabetes experiencing recurrent severe hypoglycaemia and with impaired awareness of hypoglycaemia. The patient should be carefully assessed and progressed along the pathway, with the option to increase a stage in between reviews if there is clearly no benefit. CSII = continuous subcutaneous insulin infusion; MDI = multiple daily insulin injection; SMBG = self-monitored blood glucose (finger pricking); RT-CGM = real-time continuous glucose monitoring with alarms. * psychological issues may play a role and psychological assessment and/or treatment may be appropriate at any stage when clinically indicated.

Evidence-informed clinical practice recommendations for treatment of type 1 diabetes complicated by problematic hypoglycemia. *Diabetes Care*. 2015 Jun;38(6):1016–29.

dangerous. In insulin-treated patients, consideration of the insulin kinetics will identify times of high risk of hypoglycaemia (e.g. 2–3 hours after meals and in the early hours of the night). Use of the short-acting insulin analogues for meals may help achieve good postprandial glucose levels without hypoglycaemia before the next meal, and, for some, reintroduction of between-meal snacking may need to be considered. Avoidance of postprandial administration of insulin is key—even with the fastest currently available insulins for subcutaneous use, a 15-minute gap between insulin administration and food ingestion gives optimal results [119, 120]. For nocturnal hypoglycaemia, use of fast-acting analogues for evening meals, 'peakless' analogues for background control, or, where conventional NPH or isophane insulins are used, taking the bedtime dose as late as possible or resuming a bedtime snack (including, perhaps, uncooked cornstarch) may all help. Use of the ultralong acting insulin degludec is associated with reduced hypoglycaemia, compared to other insulins, and although this lacks the flexibility of twice daily insulin detemir, many patients do not use this facility and for them, degludec may effectively reduce even severe hypoglycaemia risk (see Chapter 15.5.3, 'Insulins and Insulin Delivery Devices').

Adoption of technology is the next step, if the hypoglycaemia persists after proper education. The prior use of education is key, as this alone can be very beneficial and may account for some of the benefits originally ascribed to technology [121]. Use of automated insulin dose advisors linked to home glucose monitoring and in receipt of information about earlier insulin doses can reduce behaviours such as stacking (repeat 'correction' doses of fast-acting insulin in quick succession, or shortly after carbohydrate ingestion, without allowing the first correction dose to have worked—a minimum interval of two hours is recommended) but the strongest evidence, in people with type 1 diabetes, is for either continuous glucose monitoring (see Chapter 15.5.2, 'Glucose Monitoring and Sensing'), or for infusing background insulin using continuous subcutaneous insulin therapy (for more on insulin pump therapy, see Chapter 15.5.3), followed by sensor augmented pump therapy, in which the pump's insulin delivery is suspended automatically, when the sensor predicts a hypoglycaemic event. Recent studies indicate that use of real-time continuous glucose monitoring alone reduces severe hypoglycaemia risk, and such systems can be added to multiple daily injection therapy with benefit [122]. Interestingly, there is no evidence that such systems result in restored hypoglycaemia awareness, so the protection is only effective when the devices are being worn [123]. If all else fails, islet or whole organ pancreas transplantation provide protection from severe hypoglycaemia while islet function persists (see Chapter 15.6.4, 'Transplantation'). Such therapies cannot be undertaken lightly, but are available for patients with intractable problems.

The described pathway can be very successful in reducing risk of severe hypoglycaemia but there remain a few patients who fail to benefit. These are people with apparently treatment resistant IAH and recurrent severe hypoglycaemia and there is evidence that they have abnormal cognitive responses to hypoglycaemic events, as just described, that create barriers to their engaging successfully with the treatment pathway. Fears of hyperglycaemia and failure to prioritize treatment of hypoglycaemia are key cognitions which may need to be addressed through targeted psychological support before this group of people can successfully reduce their hypoglycaemia experience [124].

Summary

Hypoglycaemia is the most important acute complication of pharmacological therapies for diabetes that either replace or artificially drive endogenous insulin secretion. Awareness of all hypoglycaemia provides the patient using such therapies with essential protection against severe hypoglycaemia, in which the circulating glucose concentrations fall too low to support full, normal, cognitive function. Defects occur in the normal defences against hypoglycaemia as soon as therapies are started and progress over time. Exposure to mild hypoglycaemia can cause defective responses to and subjective recognition of, subsequent hypoglycaemia. Severe hypoglycaemia has associated adverse outcomes, which range from the embarrassing to the disastrous. Healthcare professionals should regularly check each patient's hypoglycaemia experience and adjust therapies to maximize the patient's ability to defend themselves. Avoidance of hypoglycaemia is, therefore, an important goal for diabetes therapies and can be achieved without deterioration of overall glycaemic control. To achieve this, however, requires good systems for patient education and engagement of the patient in these.

Evidence-Based Management of Type 1 Diabetes

15.6.1 Strategies for the Management of Type 1 Diabetes

Peter Hammond and Fiona Campbell

Introduction

The person living with type 1 diabetes has to meet the challenge of integrating glucose self-management with everyday life 24/7 in order to ensure optimal glycaemic control, which not only reduces their risks of long-term complications but enhances their quality of life and allows them to maximize their potential.

The components of this self-management strategy are use of an appropriate insulin regimen, timely and effective glucose monitoring, and training to allow the person with diabetes to adjust their management in response to daily events which impact on blood glucose levels, such as diet, alcohol, exercise, stress, and illness. This self-management training will also need to be provided to parents and carers for children and adults who require support.

Supporting the person with diabetes to implement their self-management strategy requires the input of all members of the specialist multidisciplinary team, ideally comprising a diabetes consultant, diabetes specialist nurse, specialist dietitian, and psychologist with training in diabetes. Similar but separate teams will be needed to support adults and children with diabetes and appropriate local arrangements will be needed to ensure seamless transition for the person with diabetes between children's and adult services. Appropriate benchmarking can assess the performance of individual services. Regional, national, and international benchmarking schemes have been shown to improve overall biomedical outcomes.

Insulin Regimens

The cornerstone of effective blood glucose self-management is intensive insulin therapy or flexible insulin therapy with either multiple daily injections or insulin pump therapy. The aim of treatment is to allow the person with diabetes to target an HbA1c of 6.5% while minimizing the risk of hypoglycaemia.

A multiple daily injection, or basal-bolus, insulin regimen is the favoured starting injection regimen for the newly diagnosed adult or child with diabetes, although in some cases the newly diagnosed child may be started immediately on insulin pump therapy. The multiple daily injection regimen is designed to mimic as closely as possible, given the limitations of the subcutaneous route of administration, a physiological insulin profile, with a long-acting insulin providing the basal, or background, circulating insulin, and a rapid-acting insulin being used for bolus insulin to cover glucose excursions following meals or snacks, and to correct high glucose levels at any time.

Long-acting analogue insulins are preferred for people with type 1 diabetes as they deliver a more reliable diurnal insulin profile with less intraindividual variation in circulating insulin levels when compared to human insulin preparations. A once daily dosing regimen for the long-acting analogue insulin is often preferred by the person with diabetes to minimize the number of daily injections, but a twice-daily injection regimen potentially provides greater flexibility for those with a more varied lifestyle. This is reflected in NICE guidance for adults with type 1 diabetes which advises favouring a regimen using twice-daily insulin detemir over once daily insulin glargine. The twice-daily insulin detemir approach is being increasingly used in children. Since publication of this guidance there is more evidence to support the use of once daily insulin degludec, particularly in reducing the risk of nocturnal hypoglycaemia.

For an adult with type 1 diabetes the starting basal insulin dose can be estimated as:

- 16–24 units depending on the size of the individual, or
- 0.3 units/kg body weight.

A lower dose should be considered in the elderly and where intravenous insulin has been used prior to starting an injection regimen and the individual appears to be very sensitive to insulin. In the latter scenario ½ the units of intravenous insulin administered over the previous 24 hours can be used as a starting basal insulin dose.

In children, the dose and frequency of the long-acting analogue insulin varies depending on the child's age and weight. Smaller children are more sensitive to insulin. Children who are pubertal require increasing amounts of insulin. However, insulin dosages are very individual and two children of the same age or same weight often need quite different amounts. For children under 5 years, if insulin pump therapy is not considered appropriate, then a basal insulin dose of 0.25 units/kg/day, administered once daily, could be considered as a starting dose of insulin detemir.

Children between 5 and 10 years of age could be started on 0.3 units/kg/day. Children aged 11 years and above are often prescribed 0.4 units/kg/day insulin detemir, at this age given in two divided doses.

Rapid-acting insulin analogues are preferred as the bolus insulin for people with type 1 diabetes, the more reliable circulating insulin profile and shorter duration of action compared to soluble human insulin resulting in a lower postprandial glucose peak and less risk of late post-meal hypoglycaemia.

If the newly diagnosed person receives training, and subsequently develops an understanding of carbohydrate counting, then they can be trained to give rapid-acting insulin according to the amount of carbohydrate ingested. To do this they will need to know an insulin: carbohydrate ratio (ICR), the amount of insulin to be administered per 10 g carbohydrate or 1 carbohydrate portion (CP). In most adults, a reasonable starting point is an ICR of 1 unit: 10 g, with 1 unit: 5 g for those who are insulin resistant or are obese, and 1 unit: 15 g for those who are very insulin sensitive. Where this training takes place at a later date, fixed mealtime insulin doses can be used, with the total daily bolus dose equating to the total daily basal dose and divided according to the reported relative carbohydrate content of each meal. In children, an ICR of between 1unit: 5 g to 1 unit: 50 g may be required depending on the child's age, weight, and pubertal status.

Rapid-acting insulin can also be used to correct high blood glucose levels and the individual will need to determine by how much 1 unit insulin reduces blood glucose levels. This is called the insulin sensitivity factor (ISF). In adults, a starting point of 1 unit to bring blood glucose by 2.5–3 mmol/L is typical. In children, an ISF of between 1:2 and 1: 25 may be required depending upon the child's age, weight, and pubertal status,

Established rapid-acting insulin analogues represent modifications of the structure of human insulin. Recently faster-acting insulin aspart has become available, using the adjuvant nicotinamide to accelerate the absorption of insulin from the subcutaneous depot. There is no definitive evidence to indicate superiority of this insulin over other rapid-acting analogue insulins in a multiple daily injection regimen, but it may be considered for those people with diabetes who, despite giving bolus insulin 15 to 20 minutes pre-meals, are struggling with postprandial blood glucose spikes or late post-meal hypoglycaemia.

In certain circumstances a simpler insulin regimen may be considered:

- In the months after diagnosis the person with diabetes may go through a honeymoon phase where insulin requirements fall significantly, and on occasion, for a short time, insulin may not be needed at all. This typically lasts for 6 to 12 months, although rarely can last longer than this. During this honeymoon phase there may be a need for only basal or bolus insulin. However, it is important that the person with diabetes is aware that this is a transient phase and that their maintenance regimen is with multiple daily injections.
- The use of a twice-daily regimen using either a fixed pre-mixture of short and long-acting insulin or a free mixture of these insulins performed by the person with diabetes has been favoured in the past as a starting regimen for people with diabetes before improvements in insulins and glucose monitoring allowed for more effective and widespread use of multiple daily injection regimens. Now, use of a twice-daily regimen using pre-mixed insulin is reserved for those who would struggle to manage a multiple daily injection regimen, particularly those dependent on carers, such as people with learning difficulties, the frail elderly, or young people who are having significant difficulty adhering to this intensive insulin regimen. Such regimens are likely to achieve satisfactory blood glucose control only if the individual maintains a relatively unvarying lifestyle with consistent mealtime carbohydrate intake.

The alternative to a multiple daily injection regimen is continuous subcutaneous insulin infusion or insulin pump therapy. This therapy offers potential advantages over multiple daily injections as a method of delivering intensive insulin therapy. Insulin can be delivered more flexibly via the pump. In particular this includes a variable rate of basal insulin delivery, different types of bolus insulin profiles and an ease of giving bolus doses which favours more frequent use of correction boluses. Insulin pump therapy has been shown to be potentially superior to multiple daily injection therapy in reducing HbA1c and at the same time reducing the frequency of hypoglycaemia in both adults and children, but its use is limited by cost considerations and to a lesser extent personal preference. In one meta-analysis [1], that included 22 studies comparing insulin pump therapy with multiple daily injections, severe hypoglycaemia was reduced on pump therapy compared to injection therapy, with a rate ratio of 2.89 for randomized controlled trials and 4.34 for before/after studies. The mean difference in HbA_{1c} between treatments was 0.21% for randomized controlled trials and 0.72% for before/after studies. The greatest reductions in severe hypoglycaemia were seen in those with the highest baseline incidence and the higher the starting HbA1c the greater the reported reduction. Studies reporting long-term outcomes of pump therapy [2–3] indicate that sustained reductions in HbA1c averaging around 1% for at least 10 years are seen in those who start HbA1c because of inability to reach target HbA1c on multiple injection therapy.

In England and Wales NICE guidance for insulin pump therapy [4] recommends it should be used:

- For children younger than 12 years of age where multiple daily injection therapy is considered to be impractical or inappropriate

- For adults and children 12 years and older where:
  - Attempts to achieve target HbA1c levels with multiple daily injections result in the person experiencing disabling hypoglycaemia, the repeated and unpredictable occurrence of hypoglycaemia that results in persistent anxiety about recurrence and is associated with a significant adverse effect on quality of life, or
  - HbA1c levels have remained high at 8.5% (69 mmol/mol) or above on multiple daily injection therapy despite a high level of care

On the basis of the recommended criteria for using insulin pump therapy the expectation is that in time over 20% of adults and up to 50% of children with type 1 diabetes should be using this technology.

Safe and effective use of insulin pump therapy requires a significant commitment to self-management either by the person with diabetes or their carer and so there should be regular review to ensure that the insulin pump user is demonstrating adequate engagement with the therapy. While the user may choose to discontinue pump therapy themselves or it may be withdrawn due to an absence of clinical benefit, consideration should be given to discontinuing pump therapy if the user is not monitoring blood glucose levels adequately as this will prevent them identifying unrecognized pump failure. If pump therapy is withdrawn due to safety concerns, this should be done in a supportive way, with educational and psychological support provided and an option to restore pump therapy again if appropriate. In reality insulin pump therapy is rarely discontinued with reported continuation rates in excess of 95%.

Glucose Monitoring

Self-monitoring blood glucose is essential for ensuring that insulin dosing is optimized and the risk of hypoglycaemia is mitigated for the person with diabetes. A minimum of 4 capillary blood glucose tests per day is recommended, based on 3 pre-meal and 1 pre-bed test. In reality a greater number of tests is likely to be needed, for example to ensure safety when driving or exercising and to inform the person with diabetes or their carer about the impact of external factors such as alcohol and stress on blood glucose levels.

The NICE guidance for adults with type 1 diabetes [5] recognized this need for additional testing with a recommendation to support testing up to ten times a day if any of the following apply:

- The desired target for blood glucose control, measured by HbA1c, is not achieved
- The frequency of hypoglycaemic episodes increases
- There is a legal requirement to do so, such as before driving, in line with the Driver and Vehicle Standards Agency guidance
- During periods of illness
- Before, during, and after sport
- When planning pregnancy, during pregnancy, and while breastfeeding
- If there is a need to know blood glucose levels more than four times a day for other reasons, such as impaired awareness of hypoglycaemia or taking part in high-risk activities

In certain circumstances more than ten blood glucose tests per day may be required because of the person's lifestyle, for example driving for a long period of time, undertaking high-risk occupations, during long-distance travel, or if the person has impaired awareness of hypoglycaemia. There is good evidence that a greater frequency of blood glucose testing is associated with a lower HbA1c [6].

The NICE guidance for children with type 1 diabetes [7] recommends that an explanation should be given to children and young people with type 1 diabetes and their family members or carers (as appropriate) that an HbA1c target level of 48 mmol/mol (6.5%) or lower is ideal to minimize the risk of long-term complications. They should also be advised to routinely perform at least five capillary blood glucose tests per day [8].

Target blood glucose levels recommended by NICE [5, 7], based on achieving target HbA1c of 48 mmol/mol (6.5%) are:

- Fasting plasma glucose level (on waking) of 4–7 mmol/L for children, 5–7 mmol/L for adults
- Plasma glucose level of 4–7 mmol/L before meals at other times of the day
- Plasma glucose level of 5–9 mmol/L post-meals if checked after at least 90 minutes
- Plasma glucose level of at least 5 mmol/L when driving

The use of subcutaneous interstitial fluid glucose sensing allows an alternative to conventional self-monitoring of capillary blood glucose. These sensors allow glucose levels to be conveniently checked at any time and provide information as to the direction of change in blood glucose that is not evident when taking isolated capillary glucose readings. Two options for interstitial fluid glucose testing are available:

- Flash glucose monitoring—glucose levels are available when the sensing device is scanned
- Continuous glucose monitoring—glucose levels are continuously relayed to a display device and alarms/alerts can be set to warn of existing or impending hypo- or hyperglycaemia

Flash glucose monitoring is relatively inexpensive compared to continuous glucose monitoring and therefore can be regarded as a substitute for self-monitoring of blood glucose. It should be considered for all children with diabetes or for adults with diabetes needing to test eight times a day or more, or whose HbA1c remains high despite adequate blood glucose self-monitoring or who cannot perform capillary testing due to physical or psychological issues.

The indications for adding continuous glucose monitoring into the management strategy are similar to the indications for pump therapy. A meta-analysis of individual patient data from six randomized controlled trials [9] showed a mean difference in HbA1c of 0.3% in favour of those using continuous glucose monitoring rather than capillary glucose self-monitoring, and as for pump therapy the higher the baseline HbA1c the greater the reduction in HbA1c when using continuous glucose monitoring. Clinical trials indicate that in order to get the desired impact from continuous glucose monitoring it should be used at least 70% of the time.

In England and Wales NICE recommend continuous glucose monitoring [5, 7] should be:

- Offered to children and young people with diabetes who have:
  - Frequent severe hypoglycaemia, or
  - Impaired awareness of hypoglycaemia associated with adverse consequences (e.g. seizures or anxiety), or

  - An inability to recognize, or communicate about, symptoms of hypoglycaemia (for example, because of cognitive or neurological disabilities)
- Considered for children and young people with diabetes in the following situations:
  - Neonates, infants, and preschool children
  - Children and young people who undertake high levels of physical activity (e.g. sport at a regional, national, or international level)
  - Children and young people who have comorbidities (e.g. anorexia nervosa) or who are receiving treatments (e.g. corticosteroids) that can make blood glucose control difficult
- Considered for adults with diabetes who despite optimal use of insulin therapy and conventional blood glucose monitoring have:
  - More than one episode a year of severe hypoglycaemia with no obviously preventable precipitating cause
  - Complete loss of awareness of hypoglycaemia
  - Frequent (more than two episodes a week) asymptomatic hypoglycaemia that is causing problems with daily activities
  - Extreme fear of hypoglycaemia
  - HbA1c of 9% (75 mmol/mol) or higher that persists despite testing at least ten times a day. For this indication real-time continuous glucose monitoring should only be considered if HbA1c can be sustained at or below 7% (53 mmol/mol) and/or there has been a fall in HbA1c of 2.5% (27 mmol/mol)

The final recommendation is based on a cost-effectiveness analysis so cheaper continuous glucose monitoring would allow it to be used for lesser degrees of hyperglycaemia and require less stringent glycaemic targets for ongoing usage.

In addition to blood glucose monitoring the person with type 1 diabetes needs a way of monitoring for ketones in the event of high blood glucose levels. While urine ketone testing is feasible, the preferred option is capillary blood glucose testing for its accuracy and predictive value. Generally capillary blood ketones should be checked when blood glucose levels are greater than 15 mmol/l, with a level of 1.5–3 mmol/L mandating action such as administering an insulin correction bolus and increasing fluid intake, and a level of >3 mmol/L the threshold for considering hospital admission.

Combining Technologies for Optimizing Control

A strategy for introducing and combining technologies for optimizing blood glucose control is illustrated in Figures 15.6.1.1 and 15.6.1.2.

The use of sensor-augmented pump therapy, combining an insulin pump and continuous glucose monitoring, is of greatest benefit to the person with problematic hypoglycaemia, particularly impaired awareness of hypoglycaemia. The diabetes team should ensure that all people with type 1 diabetes are assessed at least annually for hypoglycaemic problems by recording the frequency of severe hypoglycaemia and identifying impaired hypoglycaemia awareness using the Clarke or Gold score.

Continuous glucose monitoring alone can alert the user to the existence or imminence of hypoglycaemia but automation of insulin delivery can protect against hypoglycaemia. A sensor-augmented pump system using a predictive low glucose suspend algorithm to temporarily stop insulin delivery when the sensor glucose trend indicates there is a likelihood of hypoglycaemia developing within 30 minutes, has been shown to prevent over 80% of probable hypoglycaemic episodes [9]. A hybrid closed-loop insulin delivery system, using the same technology, with a different algorithm which adjusts basal insulin delivery according to sensor glucose values, is now available in the United Kingdom and may be an option for the person with type 1 diabetes who has a persistently high HbA1c despite optimal use of insulin pump therapy or multiple daily injections supported by continuous glucose monitoring.

Structured Education

The person with type 1 diabetes needs training to effectively use intensive insulin therapy with appropriate blood glucose monitoring.

There is mixed evidence for the value of structured educations for adults with type 1 diabetes. While meta-analysis has failed to show that structured education based around carbohydrate counting has a consistently positive impact on HbA1c [10], the DAFNE (Dose Adjustment For Normal Eating) course is of proven benefit with a reduction in HbA1c of 1% (11 mmol/mol) 6 months after attending the course [11]. Longer-term follow-up shows HbA1c remains lower but to a lesser extent, but quality of life improvements are maintained [12]. It is possible that refresher education courses may help maintain the benefit from the initial course.

The NICE guideline for adults with type 1 diabetes [5] concluded that a structured education course based on the principles of the DAFNE course should be offered to all people with type 1 diabetes between 6 and 12 months after diagnosis. Carbohydrate counting training alone could be offered while awaiting more comprehensive structured education. The NICE guideline for children with type 1 diabetes [7] recommends that children and young people with type 1 diabetes and their family members or carers (as appropriate) are offered a continuing programme of education from diagnosis.

The NICE guideline for adults [5] gives specific criteria for an acceptable structured education course (described in greater detail in Chapter 15.5.1). The structured education course should cover at a minimum the following aspects of self-management:

- Nutrition, including carbohydrate counting, alcohol, healthy eating, and weight management
- Insulin dosing for meals, including insulin to carbohydrate ratios and correction doses
- Hypoglycaemia/hyperglycaemia management
- Exercise and blood glucose control
- Sick day rules
- Complications of diabetes
- Pregnancy and contraception
- Driving and travel

The group approach to structured education appears to have significant benefits over one-to-one training both in terms of efficiency for the diabetes educator and learning for the person with diabetes.

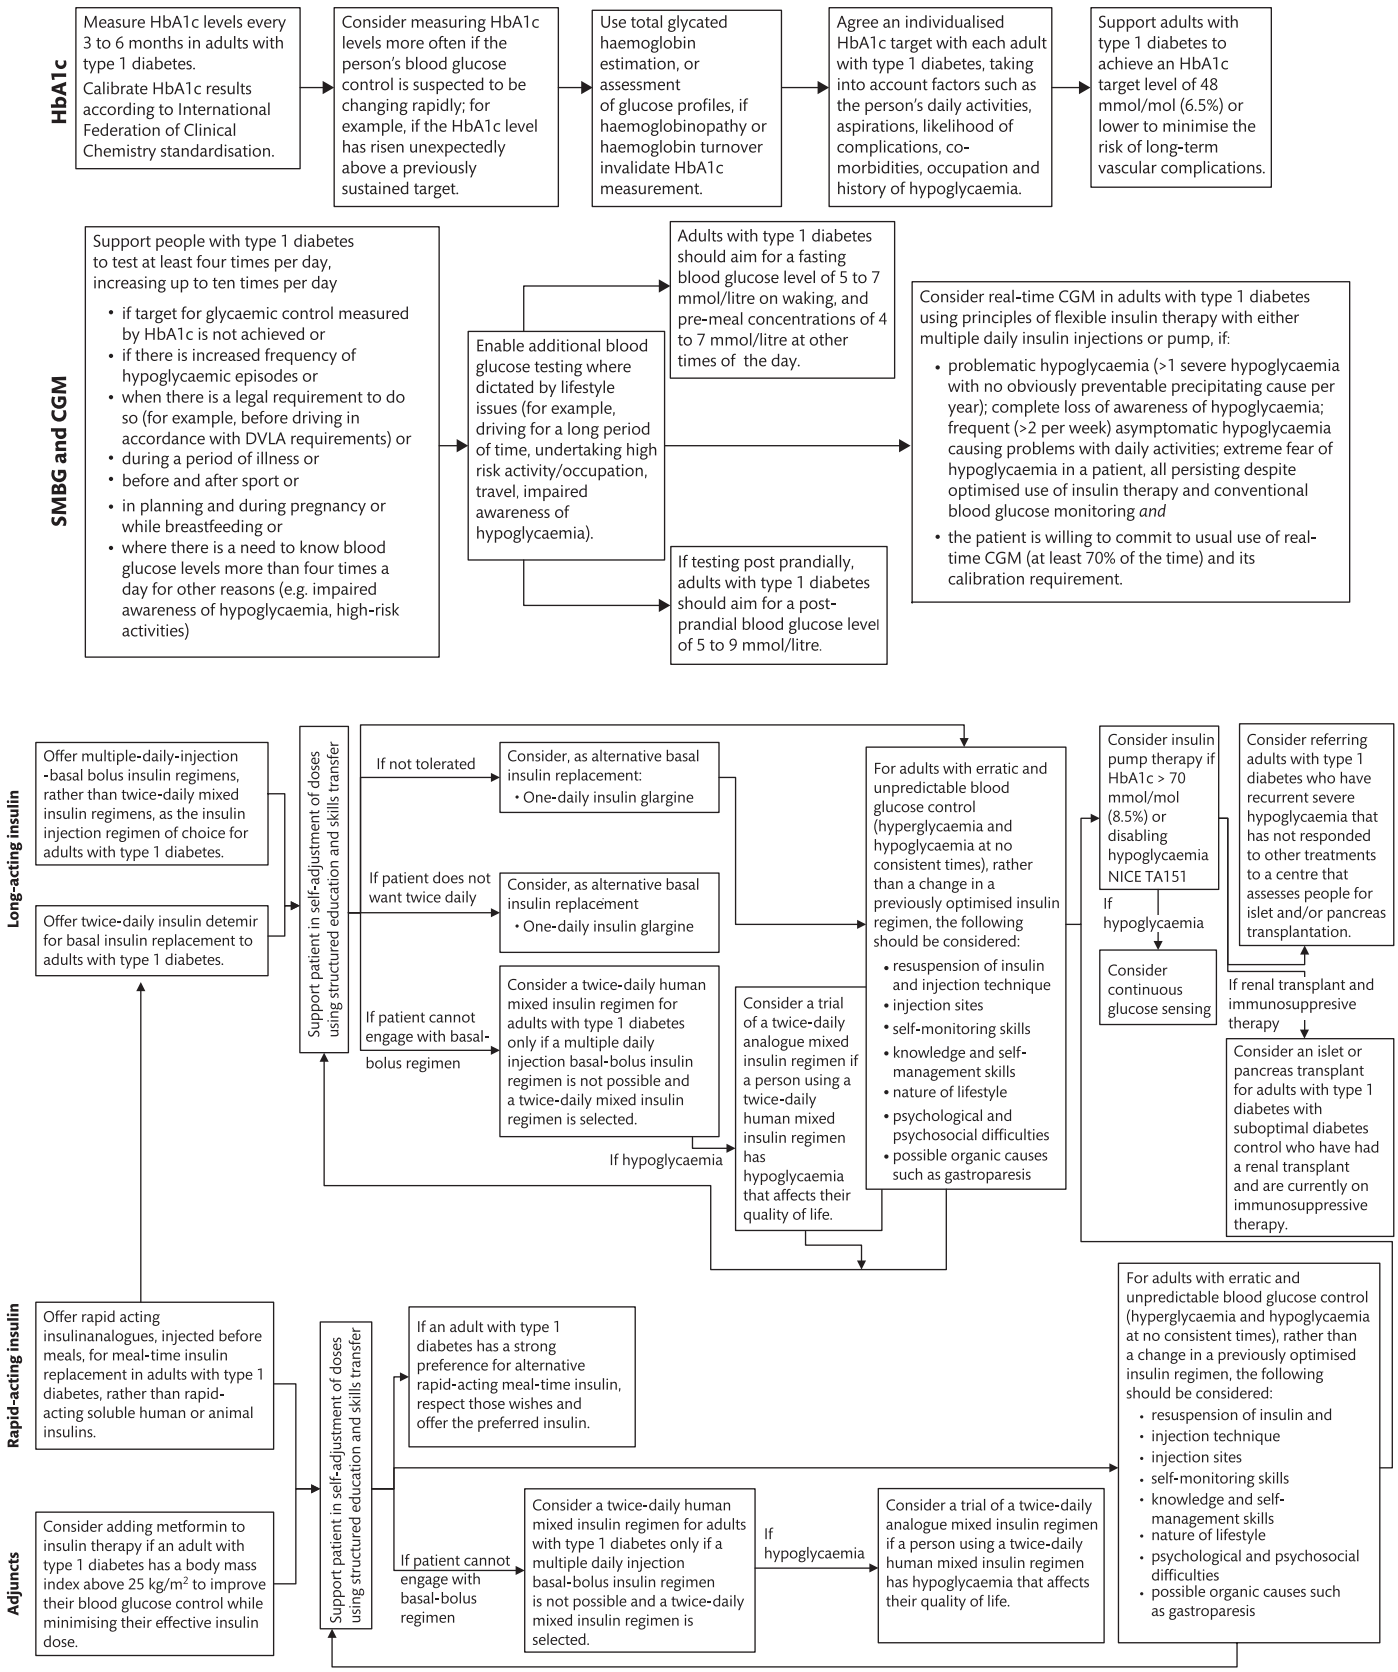

Figure 15.6.1.1 NICE guidance (NG17) for adults with type 1 diabetes (2015): (a) monitoring glycaemia; (b) choice of insulin regimen.

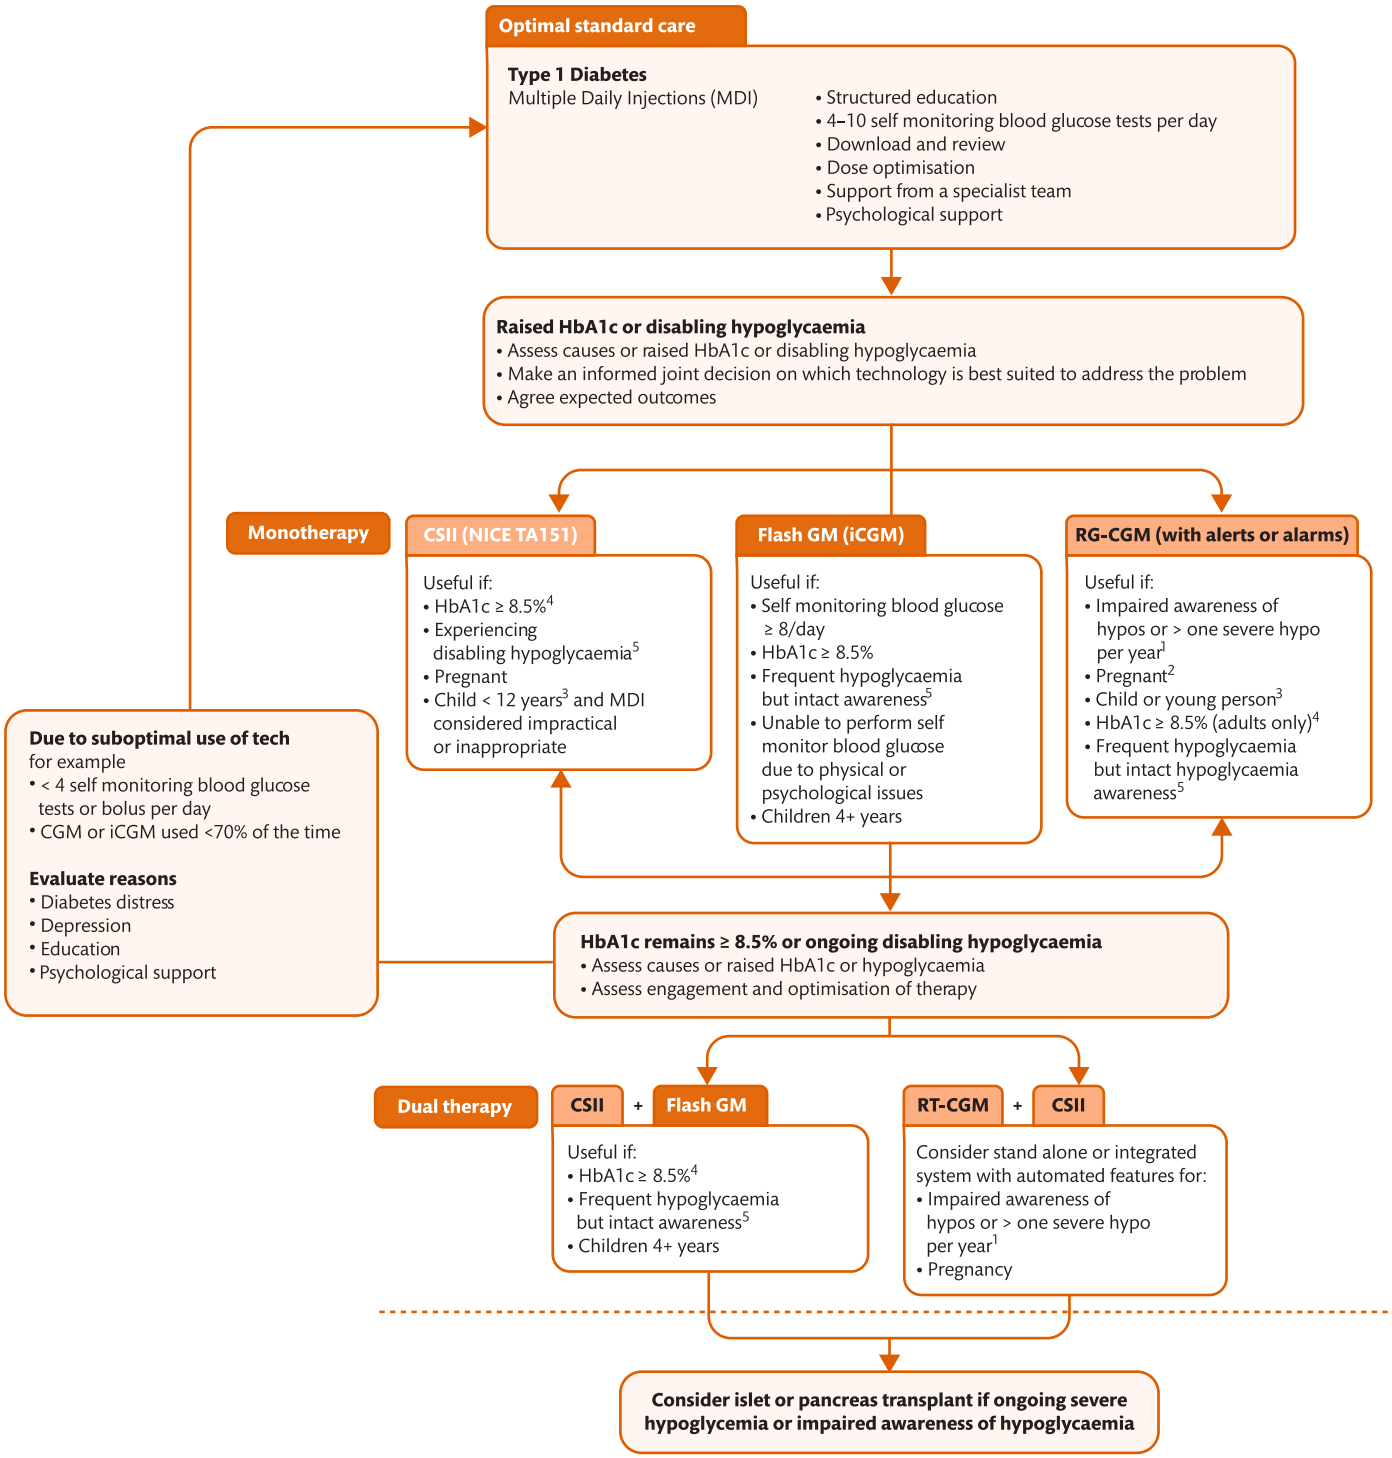

Figure 15.6.1.2 Diabetes UK algorithm for the use of technology for type 1 diabetes (2018)—includes flash glucose monitoring which was not considered in the NICE guidance (NG17).

Reproduced with permission from Type 1 Diabetes Technology: A Consensus Guideline. June 2018. https://www.diabetes.org.uk/resources-s3/2018-06/Diabetes%20UK%20consensus%20guideline.pdf

Certain subgroups may benefit from further education in specific areas:

- Preconceptional counselling has been shown to benefit women with type 1 diabetes preparing for pregnancy
- The person with diabetes who is adept at carbohydrate counting may wish to fine tune insulin dosing with meals by gaining an understanding of how fat and protein content additionally impact on post-meal blood glucose levels
- More detailed advice may be helpful for the person with type 1 diabetes who undertakes serious exercise as the impact of factors such as duration of activity, whether activity is aerobic or anaerobic or mixed, and whether competition is involved, will influence

the strategy for managing glucose levels and the balance between adjusting insulin doses and taking additional carbohydrate
- A DAFNE-pump course has been developed for adults so that pump users can be taught the same self-management principles as applied to insulin pump therapy
- Users of insulin pump therapy and/or flash/continuous glucose monitoring will benefit from training in uploading data from their device and retrospectively analysing the information obtained in order to make adjustments to insulin therapy and consider the impact of external factors, such as nutrition, exercise, and stress on blood glucose levels

People with type 1 diabetes suffering from problematic hypoglycaemia may benefit from specific behavioural training to help avoid hypoglycaemia

Trained educators supported by the wider diabetes multidisciplinary team should deliver these components of structured education and advanced training in diabetes self-management.

The Multidisciplinary Team

The multidisciplinary diabetes team is central to providing the necessary support for the individual person with diabetes to implement their self-management strategy.

The key individuals in this team are:

- Consultant trained in management of type 1 diabetes
- Diabetes specialist nurse
- Diabetes specialist dietitian
- Clinical psychologist with expertise in the management of long-term conditions, and preferably specialist expertise in the management of diabetes
- A diabetes educator, who is likely to be either a diabetes specialist nurse or dietitian

These team members will be the same for adult and paediatric services but the expertise will be either in adult or paediatric diabetes care, with the only overlap occurring at the transition between paediatric and adult services, which usually covers age 16 to 19 years.

Other non-core team members may include:

- Diabetes service administrator
- Diabetes pharmacist
- Diabetes podiatrist
- Diabetes technician, for supporting technology use
- Diabetes youth worker
- Diabetes family support worker
- Diabetes social worker

The multidisciplinary team should meet regularly, probably weekly, in order to discuss complex decisions about individual people with type 1 diabetes. This could include for example:

- People being considered for insulin pump therapy or continuous glucose monitoring
- People who are suffering from problematic hypoglycaemia
- People who are pregnant or planning to conceive
- People who have a persistently high HbA1c
- People who are repeatedly failing to attend the service
- People on insulin pump therapy who fulfil criteria for pump withdrawal
- People who are new to the diabetes service
- People who have been in-patients with diabetes-related complications
- People who have safeguarding related concerns

The multidisciplinary team should oversee improvements in service delivery, provision of appropriate structured education and audit/benchmarking activity.

The amount of contact that the individual with type 1 diabetes has with the multidisciplinary team will vary depending on their age, their degree of education and experience, the effectiveness of their blood glucose self-management, and whether they are using specific technologies.

Most guidance supports all people with type 1 diabetes being under the care of the multidisciplinary specialist team, even if they only make contact once a year. The paediatric best practice, year of care tariff in England mandates at least quarterly face-to-face contact with the team and a minimum of an additional eight contacts with the young person between clinic visits. There is no such mandated contact for those aged over 19, however NICE guidance clearly states standards of care that should be met for young people preparing to transition from paediatric to adult care:

- Allow sufficient time for young people with diabetes to familiarize themselves with the practicalities of the transition from paediatric to adult services because this improves clinic attendance.
- Agree specific local protocols for transferring young people with diabetes from paediatric to adult services.
- Base the decision about the age of transfer to the adult service on the young person's physical development and emotional maturity, and local circumstances.
- Ensure that transition from the paediatric service occurs at a time of relative stability in the young person's health and is coordinated with other life transitions.
- Explain to young people with type 1 diabetes who are preparing for transition to adult services that some aspects of diabetes care will change at transition.

In adult care, following pump therapy initiation, there are best practice guidelines [13] that provide a template for the first year's follow-up and NICE guidance for the pregnant woman [14] with diabetes advises an appropriate schedule of clinic follow-ups.

Contact with the multidisciplinary team is likely to evolve with greater use of technology to support self-management for the person with type 1 diabetes. The ability to upload insulin delivery and blood glucose monitoring data to the cloud, using platforms such as Glooko/Diasend, Tidepool, and Carelink and to communicate remotely can allow for more timely intervention to support changing insulin regimens when problems with blood glucose control occur. There is likely to be rise in remote advice giving, including use of virtual clinics, as the uptake of these technologies becomes more widespread, and healthcare professionals and users become more skilled in interpreting the information obtained from uploaded data.

Benchmarking and Audit

There is good evidence that benchmarking networks and regional, national and international audit programmes can help improve performance of services supporting the person with diabetes in implementing their self-management strategy.

The National Paediatric Diabetes Audit (NPDA) [15] is now in its fourteenth year and is used to compare the care and outcomes of all children and young people with diabetes receiving care from Paediatric Diabetes Units (PDUs) in England and Wales. There is 100% participation in this audit. It has been commissioned by the Health Quality Improvement Partnership (HQIP), funded by NHS England and the Welsh Government, and is managed by the Royal College of Paediatrics and Child Health (RCPCH).

The audit's aims are to monitor the incidence and prevalence of all types of diabetes among children and young people receiving care from a PDU in England and Wales and to establish which key care processes are being received by children and young people with diabetes. The audit enables benchmarking of performance against standards of care specified by the National Institute for Health and Care Excellence (NICE) guidance at PDU and national level and determines the prevalence and incidence of diabetes-related complications among children and young people with diabetes.

Although the NPDA has demonstrated marked improvements in paediatric diabetes outcomes in England and Wales over the last 8 years, it is felt by those working in the field of paediatric diabetes that in order to maintain the momentum towards the best international results and to meet current NICE Standards, new initiatives are required. As a result, the RCPCH has recently commenced the delivery of a high quality 3-year renewable programme of Peer Review and Quality Improvement involving all the diabetes units in England and Wales. The programme is a partnership between the RCPCH and the National Children and Young People's Diabetes Network, which has been supported by HQIP and NHS England and it complies with the Peer Review Framework from NHS Wales.

The programme comprises four elements:

- **An annual programme of self-assessment** against nationally-agreed measures which, alongside existing NPDA data provide a complete picture of a unit's compliance with national standards and good practice
- **A process of external verification** which provides assurance as to consistency and credibility of the assessments
- **A three-year cycle of peer review** visits providing consistent, authoritative assessment of every unit's achievements and practical challenges in improving the care for children with diabetes
- **A cascading managed programme of Quality Improvement** transforming whole diabetes teams and through them their network colleagues

It is hoped that by introducing this Quality Programme more rapid improvement in the variation of standards of care and outcomes will be achieved.

In adult practice the National Diabetes Audit has in recent years been extended to specialist secondary care diabetes services and has started to allow comparison between centres in terms of outcome for people with type 1 diabetes and the uptake of technology in these centres. There is considerable variation across England and Wales, for example the uptake of insulin pump therapy ranging between centres from 3% to over 30% of adults with type 1 diabetes [16] while evidence from the audit demonstrates that greater uptake of technology is associated with better outcomes for the person with diabetes. Given the potential improvements in care that could be facilitated by action to improve a centre's performance in the National Diabetes Audit, participation in such national audit programmes should be mandated for all centres providing specialist type 1 diabetes care.

15.6.2 Psychological and Behavioural Aspects of Type 1 Diabetes Management

Christel Hendrieckx and Jane Speight

Introduction

Type 1 diabetes is the most common chronic condition of childhood—but it can develop at any age, and around half of cases are diagnosed in adulthood. Age of onset can affect the individual trajectory in adapting to life with diabetes [1]. An adult who developed diabetes in childhood may not have memory of the diagnosis and its initial impact on life. While in adulthood, a diagnosis has been shown to have an immediate disruptive effect on physical and psychosocial aspects of life [2]. At any age, type 1 diabetes and its management is challenging, but there are also particular transitions in life that can impact on diabetes management and outcomes and vice versa. For example, puberty/adolescence [3] and pregnancy [4] often coincide with unstable glucose levels and elevated emotional distress, and conversely diabetes impacts negatively on the experience of these key life stages.

This chapter focuses on the behavioural implications and diabetes-related emotional problems that are commonly experienced by people with type 1 diabetes. Adequate assessment of the psychological impact informs the most effective treatment strategies. Also, these are best addressed by diabetes health professionals, as they are associated with diabetes self-care and outcomes.

Managing Type 1 Diabetes is Complex

The aim of type 1 diabetes self-care is to maintain glycated haemoglobin (HbA1c) within an individualized target range (e.g. <53 mmol/mol; <7%). This requires proactive self-management, including adjusting insulin according to glucose levels (checked several times a day) and the nutritional content of meals or snacks. Planning and adjustments are needed for physical activity (e.g. sports, walking, gardening) to avoid extreme glucose levels. However, many other factors affect glucose levels, including several beyond the person's control—e.g. hormones, weather, stress, illness—and the limitations of current treatments. The individual needs to develop advanced self-care knowledge, skills, and confidence, as well as acceptance of the need for relentless decision-making and lifelong perseverance in performing multiple daily self-care tasks. Therefore, managing glycaemic excursions is relentless and places a considerable behavioural burden on the individual.

Diabetes technologies (e.g. insulin pumps and continuous glucose monitoring) may reduce this burden and can offer greater flexibility of lifestyle and choice in treatment modalities. But such benefits are associated with the person's level of engagement and optimal use of the devices [5]. Also, technologies are not an option for all. This is partly due to their financial implications (both initial outlay and ongoing consumables, either for the individual or their healthcare service) and to personal preferences. These can relate to body image concerns (not wanting to be attached to a device), and that the devices currently require significant interaction to maintain 'control' and do not negate the need for human input. The 'human factor' is one reason why not all people with type 1 diabetes benefit from these novel technologies, which is evidenced by the substantial number not achieving HbA1c at target [6]. Despite significant advances in treatments, technologies, and screening procedures, type 1 diabetes can still lead to serious acute complications (e.g. hypoglycaemia, ketoacidosis), long-term complications (e.g. amputation, blindness), remains associated with a shorter life expectancy, and can have a significant psychological impact.

The relentless efforts and frustrations of managing type 1 diabetes are often underestimated by health professionals. Often their approach is still largely driven by the acute biomedical model of care in which the health professional's role is to prescribe treatment and the patient's role is to 'comply' with the prescriptions. This is a wholly inappropriate model of care for type 1 diabetes, which at the least needs to be replaced with a bio-psycho-social model of care [7]. Although health professionals are becoming more aware of the psychological impact of diabetes management and outcomes, there is still a gap between the holistic support people with diabetes expect and what they receive from their health professionals [8, 9]. If an analogy is needed, perhaps that of a mountain climber, supported by an expert team is appropriate—as health professionals can advise but, ultimately, the daily efforts of self-care to achieve individualized targets rest with the person.

Type 1 Diabetes Affects Emotional Well-Being

Emotional responses to the diagnosis, daily burden of self-care, and progress of the condition can be a barrier to achieve optimal

self-care, health, and quality of life. The individual's emotional reactions may be related directly to diabetes and its management (e.g. diabetes-specific distress or fear of hypoglycaemia). People with type 1 diabetes may also experience more general mental health problems such as depression, anxiety, or eating disorders. While these may or may not be caused by type 1 diabetes, these psychological problems can certainly impact on how the person manages their diabetes.

Diabetes Distress

Diabetes distress is a common emotional reaction to living with diabetes [10]. It is not a diagnosable mental health condition. If left unchecked, diabetes distress can become severe and/or place the person at risk of developing depression. Although there is some similarity between diabetes distress and clinical depression, they are distinct constructs and require different treatment strategies [11]. Due to the overlap between symptoms of depression and signs of suboptimal diabetes management (e.g. tiredness and lack of energy), it could well be that people with diabetes are diagnosed with depression, while they actually experience hyperglycaemia or diabetes distress [10]. With appropriate psychological assessment tools, this distinction can now be established [11].

Diabetes distress is defined by its content and severity, which can fluctuate from mild to severe. Around 20–30% of adults with type 1 diabetes experience severe diabetes distress [12]. Sources of diabetes distress in people with type 1 diabetes include, but are not limited to, feeling powerless, food/eating, hypoglycaemia, negative social reactions [13]. The impact of these stressors should not be underestimated because they affect the emotional and physical well-being of the person with type 1 diabetes. Greater diabetes distress is associated with suboptimal diabetes management (e.g. reduced physical activity, unhealthy eating, no or limited self-monitoring of glucose levels) and, as a consequence, elevated HbA1c and severe hypoglycaemia.

Few interventions have been developed specifically to reduce diabetes distress among people with type 1 diabetes—most were designed for people with type 2 diabetes or to reduce diabetes distress as a secondary outcome [14]. There is evidence that structured type 1 diabetes education programmes [15, 16] and psychological interventions [17, 18] are effective in reducing diabetes distress, particularly in those with greater baseline distress. Diabetes distress is reduced after completing the Dose Adjustment For Normal Eating (DAFNE) programme, and further analysis shows this to be driven by reductions in regimen-related distress [16]. In mixed samples of people with diabetes, monitoring diabetes distress routinely with a validated questionnaire and acting on the outcomes in clinical consultations reduced severe diabetes distress and improved general emotional well-being [19]. Finally, positive psychological factors such as optimism, self-esteem, self-efficacy, have been identified as protective against distress and elevated HbA1c [20].

Fear of Hypoglycaemia

Hypoglycaemia is an acute complication of some blood glucose lowering medications, particularly insulin, and is a real concern for people with type 1 diabetes and their families [8, 21]. It can occur unexpectedly, often overnight, with debilitating physical and cognitive symptoms and social embarrassment. *Fear* of hypoglycaemia is the specific and extreme fear arising from the risk and/or experience of hypoglycaemia. This differs from *concerns* about low glucose levels, which are constructive in keeping the person attentive to the early warning signs of hypoglycaemia.

Fear of hypoglycaemia can be triggered by impaired awareness of hypoglycaemia or experiencing a severe episode, which may have caused a trauma (e.g. a car accident or injury). Sometimes, a person's fear is disproportionate to their actual risk [22]. This may be due to limited understanding, skills, and confidence in preventing, recognizing, and treating low glucose levels. It may also coincide with personality traits, such as neuroticism or elevated trait anxiety [23].

To manage their fear, affected individuals may develop compensatory behaviours, such as reducing or omitting insulin doses, or continually snacking. These strategies are effective in reducing fear but when they become a habit, the consequence is persistent hyperglycaemia and increased risk of long-term complications. Other strategies include avoiding being alone or restricting activities that could lead to hypoglycaemia (e.g. refraining from exercise or travelling), which may be detrimental to their quality of life. Underlying reasons may include safety concerns and the fear of embarrassment in public. Furthermore, it is not uncommon that a severe hypoglycaemic event is mistaken for alcohol or drug abuse by those who are not familiar with diabetes, and this results in perceived or experienced stigma [24].

Fear of hypoglycaemia is often not recognized and addressed by health professionals. People with diabetes may not report experiencing hypoglycaemia for valid reasons [25]. They may blame themselves for not being able to prevent hypoglycaemia or fear the potential implications for their driving licence or work. Pathways to address hypoglycaemia and the associated fear include treatment optimization [26] and fear reduction strategies [27]. Psychoeducational intervention—addressing unhelpful beliefs and upskilling the person in their understanding of, and response to, early and personal symptoms of low glucose—has also been shown to be effective [28, 29].

Fear of Hyperglycaemia

At the other end of the spectrum is extreme concern about elevated glucose levels. Affected individuals may strive to keep their glucose levels in a very narrow range, by correcting even slightly elevated glucose levels. Clinical observation suggests that this strategy may be associated with 'perfectionist' tendencies. Such fear may also be a reaction to experiencing unpleasant symptoms of elevated glucose or extreme concerns about developing diabetic ketoacidosis or long-term complications. Irrespective of the cause, without an appropriate level of concern about low blood glucose, hyperglycaemia avoidance appears to be a risk factor for recurrent severe hypoglycaemia [30]. Fear of hyperglycaemia [31] and lack of concerns about hypoglycaemia or impaired awareness [30], have only recently been investigated and underlying mechanisms are not yet fully understood.

Clinical Implications

The psychological burdens just described are real, common and, moreover, a natural consequence of living with this lifelong, self-managed condition. They are barriers to optimal self-care and, as such, are likely to impact on diabetes outcomes. For these reasons,

these are best addressed, in first instance, by the diabetes health professionals as part of holistic individualized care [32].

Health professionals often believe that talking about emotions will divert the conversation from the medical agenda and that it will take up much more time. However, it is crucial to understand how a person is translating professional advice into their daily self-management plan, the barriers they are facing, their beliefs about what does and does not work for them, their preferences and satisfaction with treatment modalities (including use of technologies), and how they feel about their life with diabetes. Only in this way can a mutually agreed, personalized care plan be established and implemented with maximum benefit to the person with type 1 diabetes. Often, simply acknowledging these issues and showing empathy can ease diabetes distress [13] and strengthen the individual's engagement with their self-management.

Diabetes Management or Psychological Approach?

As noted earlier, negative emotions may result from a limited understanding of diabetes and its management, self-care skills, and/or confidence. In this case, the first-step approach should focus on diabetes education and training (preferably a structured programme with a person-centred philosophy and proven effectiveness, such as DAFNE), to enhance these skills and in turn reduce diabetes distress and/or fear of hypo/hyperglycaemia.

However, if the emotional problem (e.g. low/high fear unrelated to actual risk of hypoglycaemia) is due to inappropriate health beliefs or a personality trait, a psychological approach is recommended in parallel with continuous support from the diabetes team. Also, when diabetes-specific emotional problems coincide with other complex issues (e.g. anxiety disorder, eating disorder and/or social problems), it will require an integrated multidisciplinary approach including diabetes health professionals and mental health professionals.

Conclusion

This chapter has highlighted the relentless '24/7' behavioural burden and common negative emotional reactions experienced by people living with type 1 diabetes, which have significant implications for both their health and quality of life. Consequently, such problems need to be acknowledged and addressed, preferably in the first instance by the diabetes healthcare team supporting the individual. For those who experience negative emotional reactions, the intensity can vary over time. However, attentive observation by a concerned clinician is recommended, to enable early detection and addressing of psychological problems when these occur. Finally, it is important to note that the majority of individuals living with type 1 diabetes are coping well and enjoying life, albeit with the added complexity of also managing their condition.

15.6.3 Immunotherapy for Type 1 Diabetes

Colin Dayan and Danijela Tatovic

Introduction

It is now well-recognized that the appearance of multiple antibodies to beta-cell antigens in otherwise normoglycaemic individuals marks the start of the process that will eventually lead to clinical type 1 diabetes (T1D) [1, 2]—see Figure 15.6.3.1. This period of several years represents a window of opportunity for immunological intervention in order to halt the autoimmune process and preserve beta-cell function (see online only Figure 15.6.3.2). The most rapid loss of beta-cell function happens in the first 12 months after diagnosis [3], which represents a further opportunity for interventions leading to effective beta-cell preservation.

The Risk–Benefit Balance of Immunotherapy in T1D

Many diabetologists have been unwilling to consider immunotherapy as they believe the risks outweigh the benefits versus insulin therapy. However, with the new era of therapies that are very well-tolerated, the risks remain largely theoretical and need to be set against the shortcomings of even advanced insulin therapy. Even with optimal management, less than 30% of children and adults with T1D achieve a level of HbA1c which protects them from long-term complications (<7% (53 mmol/mol)) and for certain groups, such as teenagers, compliance and metabolic control is even worse. And even these levels of control are only achieved by acceptance of a level of hypoglycaemic events that impairs quality of life.

Most individuals have 10–20% of beta-cell function remaining at the time of diagnosis of T1D. Preservation of even 5% of beta-cell function has been shown to lower HbA1c by 1%, permit over 50% of people to reach target glycaemic levels, reduce hypoglycaemic risk by >50% and reduce long-term complications by 50% [4, 5]. Immunotherapy has the potential to preserve endogenous beta-cell function and thereby improve metabolic control even in poorly compliant individuals, with less hypoglycaemia and the possibility of intermittent rather than daily therapy [6–8].

Mechanisms of Immunomodulation

Non-Antigen-Specific Interventions

Generalized immunosuppression of the kind used in transplantation provides the evidence that immunotherapy can be effective in preserving beta-cell function [9, 10], but is rarely used in diabetes immunotherapy nowadays because the risk profile cannot generally be justified versus treatment with insulin alone. Selective immunosuppression (non-antigen-specific) disables selected immune pathways relevant to progression of T1D (see Figure 15.6.3.3). Using modern-day low-risk biologic therapies that target specific cell subsets or cytokines, this can now be achieved with limited side effects and little evidence of generalized immunosuppression. As a result, these agents are now widely used to treat other autoimmune conditions such as rheumatoid arthritis, iritis, psoriasis, and multiple sclerosis (see Table 15.6.3.1).

At the time of writing, six therapeutic interventions have shown positive results when given over a short-term period in recent-onset

Stage	Health	Stage 1	Stage 2	Stage 3
Risk factors	YES	YES	YES	YES
Antoimmunity	NO	YES	YES	YES
Metabolic status	Normal	Normal	Dysglycaemia	Diabetes
Symptomatic	NO	NO	NO	YES

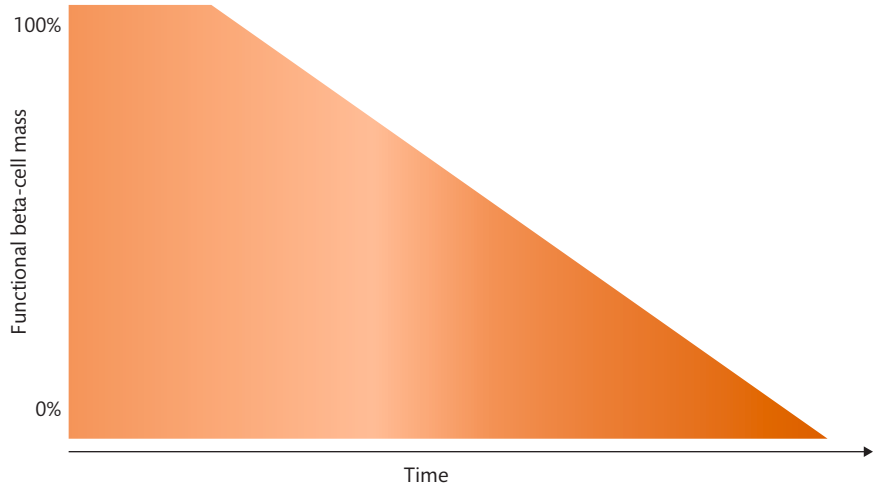

Figure 15.6.3.1 Immunotherapy of type 1 diabetes.

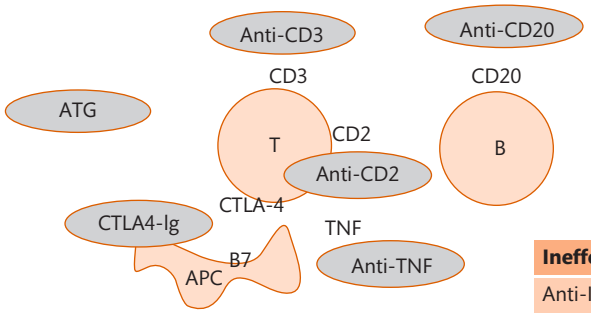
T1D, while others were ineffective (Figure 15.6.3.3). They target various molecules involved in the immune process—Figure 15.6.3.3 [11]—delaying C-peptide loss by 8.2–15.9 months in new-onset T1D [1]. The earlier cell depleting therapies—anti-CD3, anti-CD20 and antithymocyte globulin (ATG) are associated with infusion reactions and cytokine release, that are not apparent with anti-CD2, CTLA4-Ig, and anti-TNF.

Targeting T Cells—Anti-CD3, Antithymocyte Globulin (ATG)

Anti-CD3 monoclonal antibodies target CD3 molecules expressed on the surface of T cells as part of the T-cell receptor (TCR) complex. These antibodies have been successfully used to prevent transplant rejection, but had the significant side effect of causing cytokine storm [12]. Their modification to reduce Fc receptor binding affinity led to the reduction in side effects, but retained immunosuppression [13]. Two of these antibodies have been developed for use in immune interventions: teplizumab and otelixizumab.

Early phase studies of teplizumab showed promising results in slowing the loss of beta-cell function, in both children and adults, that extended up to 2 years of follow-up with most of the effect observed in patients with recent T1D onset [14–16]. The same effect was replicated in a larger study, although the trial did not meet its endpoints, which were focused on diabetes control (HbA1c level and insulin requirement) that is, unlike C-peptide level, dependent on manipulation by physicians and patients [17]. However, younger



Ineffective
Anti-Il-1
MMF+Daclizumab
IL-2 + Rapamycn
Interferon alpha

Figure 15.6.3.3 Agents with evidence of efficacy in T1D.

Table 15.6.3.1 Different types of immunotherapy

Treatment	Example	Risk of side effects
General immunosuppression	Drugs use for organ transplants	High
Selective immunosuppression/ immunoregulation	Includes newer drugs used for example in arthritis, skin diseases	Low
Antigen-specific immunotherapy	'Vaccines', depletion of autoantigen-specific T cells or boosting specific Treg	Very low

Source data from Rigby MR, Harris KM, Pinckney A, DiMeglio LA, Rendell MS, Felner EI, *et al.* Alefacept provides sustained clinical and immunological effects in new-onset type 1 diabetes patients. *The Journal of clinical investigation*. 2015;125(8):3285–96.

patients with good metabolic control and higher C-peptide levels had better therapeutic benefit [18].

Low-dose otelixizumab failed to show benefit in beta-cell preservation in a larger study [19], despite promising results at a higher dose in a smaller cohort, extending up to 18 months of follow-up after a single treatment, probably because the low dose was subtherapeutic [20, 21].

Low-dose ATG depletes T cells and has also been shown to preserve C-peptide in two separate studies (+/– G-CSF) [22, 23] although administration is associated with infusion reactions and transient serum sickness.

Targeting Effector Memory T Cells—Anti-CD2

Alefacept targets CD2 cell surface protein expressed on effector memory cells that are likely responsible for the autoimmune targeting of the pancreatic beta-cells. Indeed, Alefacept preserved C-peptide production (see online only **Figure 15.6.3.4**), lowered insulin use, and reduced hypoglycaemic events by 50% (see online only **Figure 15.6.3.5**) in patients with newly diagnosed T1D [24]. The effect extended over the 12 months after cessation of therapy [25].

Targeting T-Cell Costimulatory Signals—Anti-CTLA4

This approach is based on the observation that stimulation of T cells through the TCR complex without costimulation (interaction between CD28 on T cells and B7 molecules on antigen-presenting cells (APC)) leads to T cell inactivation. Modulating costimulation would, in theory, affect only T cells that have their antigen-specific receptors engaged. This is the basis of trials studying the CD28 homologue, cytotoxic T-lymphocyte antigen 4 immunoglobulin (CTLA4-Ig), also known as Abatacept. It selectively binds the B7 molecules on the APC, interfering with APC–T-cell interaction and inhibiting T cells.

Indeed, when Abatacept was trialled in patients with recent-onset T1D it slowed reduction in beta-cell function over 2 years [26]. The effect of this costimulation modulation was sustained for at least 1 year after cessation of treatment (i.e. 3 years after diagnosis of T1D [27]).

Targeting B Cells—Anti-CD20

The success of Rituximab, a monoclonal anti-CD20 antibody directed against B cells, in rheumatoid arthritis indicated the possibility of its use in diabetes. The rationale for this approach is to target a large population of cells with antigen-presenting properties, such as B cells. It slowed decline in C-peptide over 12 months in subjects with recent-onset T1D [28]. The rate of C-peptide decline shifted by 8.2 months in Rituximab-treated subjects [29].

Anti-TNF—TNF Receptor (Etanercept)

Etanercept is widely used to treat rheumatoid arthritis and other diseases and in a small study showed benefit in T1D [30]. Larger confirmatory studies are awaited.

Antigen-Specific Interventions

Antigen-specific immunotherapy (ASI), in which autoantigen molecules, or peptide epitopes derived from them, are delivered to patients to promote immune tolerance, is an attractive approach to treatment of antigen-specific autoimmune diseases as it offers the possibility of slowing the disease process without systemic immunosuppression The aim is to boost immunoregulation, by expanding antigen-specific regulator T cells, although some ASI appears to act predominantly by deleting or anergizing antigen-specific effector cells [31–33].

One of the first trials in the field of ASI interventions was a glutamic acid decarboxylase (GAD)–alum trial, in which the GAD65, one of the major autoantigens in T1D, was combined with an aluminium hydroxide adjuvant called alum, known to preferentially induce Th2 responses [34] and promote Treg expansion [11], with potential benefit in T1D reversal. Despite positive effects shown in early phase trials in patients treated within 6 months of diagnosis [35], the effect was not confirmed in subsequent larger studies [36–38]. A more recent study of intralymphatic administration appears promising [39].

Studies based on the autoantigen proinsulin—using either proinsulin DNA or T-cell target peptides derived from proinsulin have recently shown some promise but require replication [40, 41].

Currently, no immunotherapies are licensed for use in T1D, but results of many ongoing trials [42, 43] and networks have been established to increase recruitment of newly diagnosed and at risk individuals into trials (https://www.trialnet.org, http://www.address2.org, https://www.innodia.eu, https://www.type1diabetesresearch.org.uk).

For almost a hundred years, treatment for T1D has not advanced beyond insulin replacement. We are now on the brink of fundamentally changing the management of this devastating disease by using immunotherapy to preserve endogenous beta-cell function and make metabolic control substantially easier. It seems likely that non-antigen-specific therapies will be licensed first, but antigen-specific therapy may follow, offering the possibility of treating T1D in the preclinical phase and delaying or preventing the need for insulin therapy.

15.6.4 Transplantation (Islet and Solid Organ)

Anneliese Flatt, Martin Drage, Chris Callaghan, and Peter Senior

Historical Perspectives and Context

The first reports of unsuccessful attempts at transplantation in the treatment of diabetes, initially with fragments of pancreas from sheep and later from human cadavers, predate the discovery of insulin when death from ketoacidosis was inevitable (reviewed by Shapiro, 2007 [1]). After the discovery of insulin, type 1 diabetes was no longer fatal but chronic complications and hypoglycaemia emerged as, and remain, key care gaps and areas of focus for beta-cell replacement therapy.

In the 1960s pancreas transplantation evolved with progress in solid organ transplantation including advances in effective immunosuppression. The first deceased donor vascularized pancreas transplant was performed in combination with a kidney transplant at the University of Minnesota in 1966 with the goal of protecting the donor kidney in a patient with type 1 diabetes and diabetic nephropathy. Technical advances have addressed the high morbidity and mortality due to graft thrombosis, sepsis and anastomotic leaks which were common after early procedures [1].

Successful clinical translation of islet transplantation took longer. The use of enzymatic digestion to isolate islets effectively and identification of the intrahepatic portal site as optimal for transplantation by Moskalewski and Lacy were key milestones paving the way for the first clinical islet transplant performed by Sutherland in Minnesota in 1974. Refinement of isolation techniques including Ricordi's semi-automatic digestion chamber improved islet yield (potency) and purity (safety). Early results of islet allotransplantation for type 1 diabetes were far surpassed by outcomes of islet autotransplantation following pancreatectomy, highlighting the dual challenges of overcoming auto- and alloimmunity [1]. Prior to 2000, insulin independence rates at one year following pancreatic islet allotransplantation were only 8% [2]. The 'Edmonton Protocol' demonstrated improved outcomes through transplantation of sufficient islet mass from 2 to 4 donor pancreases over several procedures, using steroid-free immunosuppression to achieve one-year insulin independence in the first seven consecutive subjects [3]. Longer term results were less impressive with 5-year insulin independence rates of only 10%, although persistent graft function (C-peptide positivity) afforded ongoing clinical benefit through improved glycaemic control, reduced variability and liberation from previously disabling hypoglycaemia [4].

Restoration of endogenous insulin secretion through islet or pancreas transplantation can achieve glycemia superior to that shown to protect against both micro- and macrovascular complications of diabetes without any risk of significant hypoglycaemia [5]. The current rationale for beta-cell replacement is restoration of normoglycaemia and the prevention of hypoglycaemia and progressive complications of diabetes when best medical approaches have failed [6, 7].

Transplant Options in Type 1 Diabetes

Although both pancreas and islet transplantation have similar objectives, they are often considered for distinct populations, albeit with some overlap. Because donor supply is limited and major abdominal surgery is required, pancreas transplants are often restricted to younger, fitter recipients. Islet transplantation is generally indicated to reduce risk of hypoglycaemia and/or improve glycaemic control and most are performed in subjects with preserved renal function or after kidney transplant [8]. Some of the similarities and differences are described in Table 15.6.4.1 [8–13].

Table 15.6.4.1 Comparison of pancreas and islet transplantation

	Pancreas transplant	Islet transplant
Indications	Suboptimal glycaemic control or metabolic instability End stage renal disease (SPK) or functioning renal transplant (PAK)	Recurrent severe hypoglycaemia with impaired awareness of hypoglycaemia Severe glycaemic lability Progressive microvascular complications
Cautions	Current smoking Alcohol/drug use Non-adherence with medical therapy	Alcohol/drug use Non-adherence with medical therapy High body mass index/insulin requirement
Contraindications	Untreated infection or malignancy High cardiovascular risk	Untreated infections or malignancy Liver disease Portal hypertension/portal vein thrombosis
Recipient selection	Good cardiovascular health, younger recipients	Less stringent requirements for cardiovascular health
Renal status		
CKD 4–5	Simultaneous pancreas-kidney transplant indicated	Islet transplant deferred until after kidney transplant (IAK) or less commonly as simultaneous islet kidney
CKD 1–3	Pancreas alone transplants have inferior outcomes and are being performed less frequently	Most islet transplants performed as Islet Transplant Alone in individuals with preserved kidney function
Organ availability	Highly selected donors, with preference for young, lean donors	Less stringent donor selection (older, higher BMI). Islet yields often higher in heavier, middle aged donors
Procurement	Adequate preservation of vessels and an intact pancreatic capsule	Intact pancreatic capsule
Number reported to international registry	48 000 procedures between 1966 and 2014 [9]	2150 infusions between 1999 and 2015 [10]
Surgical procedure	Major abdominal procedure, general anaesthesia	Minimally invasive, local anaesthesia
Length of hospital admission	1–2 weeks	≤1 week
Procedural risks	Bleeding, pancreatitis, anastomotic leak, re-laparotomy, pancreatic thrombosis	Bleeding, portal vein thrombosis, abdominal pain
Immunosuppression		
Steroids	Often used short term Dose minimized/avoided in longer term when possible	Avoided
Maintenance	Required long-term	Required long-term
Beta-cell Mass/secretory capacity	Robust	Minimal/marginal

SPK, simultaneous pancreas kidney transplant; PAK, pancreas after kidney; IAK, islet after kidney transplant.

Pancreas Transplantation

Surgical Procedure

Advances in organ procurement and surgical technique have improved pancreas transplant outcomes. Pancreas grafts are often placed in the right lower quadrant, with a side-to-side anastomosis of the duodenal stump to a loop of ileum permitting exocrine drainage (not usually to the bladder which was used historically). Vascular anastomoses are often with the iliac vessels although portal venous drainage is used by some surgeons. Technical and anatomical considerations may be most important since no clear advantages of portal drainage have been found. Anticoagulation seems to reduce the risk of pancreatic thrombosis which has been a leading cause of early graft loss [14].

Types of Pancreas Transplant

The vast majority of pancreas transplants have been performed in association with renal transplants, with 90% of cases as a simultaneous pancreas kidney transplant (SPK) [9].

Demand for renal transplantation exceeds supply and suitable pancreatic donors are even more limited. Renal transplant recipients have a survival advantage over dialysis with best outcomes achieved with living donor kidneys [15]. Pancreas after kidney transplantation (PAK) may attain the benefits of improved glycaemic control while reducing time on dialysis [11]. SPK with maintained pancreas graft function reduces cardiovascular mortality risk in comparison to living donor kidney transplant alone [15].

Pancreas transplantation alone (PTA) performed in individuals with well-preserved renal function is reserved for metabolic instability in type 1 diabetes, defined by recurrent severe hypoglycaemia, hyperglycaemia, or diabetic ketoacidosis. PTA represents a small minority of pancreas transplants and the benefits of improved glycaemic control and insulin independence must be weighed against the procedural risk, with islet transplantation providing a lower risk alternative [11].

Islet Transplantation

Islet transplantation is a minimally invasive procedure performed with local anaesthesia with/without sedation which generally employs a percutaneous, transhepatic approach to access the portal vein using fluoroscopic guidance. The major procedural risks are related to either bleeding (intrahepatic or intraperitoneal) as a result of the hepatic puncture; or thrombosis of branches of the portal vein. The use of highly purified islet preparations with low tissue volume (below 5 ml)

minimizes elevations of portal vein pressure, and together with use of heparin, reduces the risk for thrombosis. Skilled operators can rapidly access the portal vein with a single pass, and the tract can be ablated to minimize the risk of bleeding, using a paste made from collagen flour and contrast medium or a haemostatic sponge [16, 17].

The success of the Edmonton Protocol was attributed initially to a sufficient mass (a total of >10 000 islet equivalents per kg body weight (IEQ/kg)) of high quality, freshly isolated islets [3]. Most centres now perform islet transplantation after brief periods of islet culture (24–48 hours). This has a number of practical advantages including the opportunity to administer conditioning immunosuppression and schedule transplants during regular hours with experienced staff. While some islets are lost during culture, islet purity generally increases (and tissue volume decreases) as exocrine tissue is preferentially lost [10, 16]. Unfortunately, large numbers of islets are lost in the first few hours after transplantation as a result of the instant blood mediated inflammatory response [13]. Insulin independence can be achieved occasionally with single infusions of <10 000 IEQ/kg, but may not be achieved in all cases despite exceeding this threshold after several infusions [18]. Suffice to say that in the majority of islet recipients, the mass of engrafted islets is substantially lower than in a healthy individual [13, 19].

Successful islet transplant programmes are highly dependent on the skill and expertise of their islet isolation teams to consistently provide high quality preparations. Islet transplant outcomes can vary substantially between sites, with better outcomes achieved by more experienced, high volume centres—emphasizing the importance of effective multidisciplinary teams for achieving optimal outcomes [18].

While insulin independence was the focus of early reports and (with sufficient islet mass) can be achieved in almost all cases, long-term insulin independence may not be maintained [10]. Protection from severe hypoglycaemia can be maintained in the long term such that the major indication for islet transplantation alone (ITA) is recurrent severe hypoglycaemia and impaired awareness of hypoglycaemia and/or glycaemic lability [18]. Islet after kidney transplantation (IAK) is performed less frequently to improve metabolic control with the expectation that this will protect the donor kidney. Simultaneous islet-kidney transplantation has been reported relatively infrequently [10] but has recently been made available within the UK integrated programme as an alternative to SPK in those with insufficient cardiorespiratory fitness. The TRIMECO multicentre randomized trial demonstrated the benefits of islet transplantation (ITA or IAK) over medical therapy for improved metabolic control and prevention of hypoglycaemia [20].

Immunosuppression

Induction with lymphodepleting therapies (thymoglobulin, alemtuzumab) is commonly used in both islet and pancreas transplant [9, 10]. Use of lymphodepletion has been an important factor associated with improved islet transplant outcomes [10]. Maintenance immunosuppression commonly uses combinations of tacrolimus or sirolimus with mycophenolate. While prednisone use is widespread early after pancreas transplant [9], it is avoided in islet transplantation because of adverse metabolic effects believed to negatively impact islet engraftment [3].

While short-term side effects of immunosuppression are common, these can generally be mitigated by dose adjustment. The major concern is the risks of long-term immunosuppression, particularly infection and neoplasia [10]. With careful monitoring, these risks can be minimized, but cases of opportunistic infection do occur. Recently, cases of post-transplant lymphoproliferative disease have been reported in islet transplant recipients [21]. While solid organ tumours are somewhat increased in transplant recipients, skin cancers are significantly more common and seem to progress more rapidly in those on immunosuppression [22].

Outcomes

Patient and Graft Survival

Patient and graft survival reported by international registries are shown in Table 15.6.4.2. Pancreas graft survival is defined by insulin independence with islet graft survival defined by the presence of C-peptide secretion [23–25].

Metabolic Function and Protection from Hypoglycaemia

Both pancreas and islet transplantation can restore counterregulatory response to hypoglycaemia [19]. However, while marginal graft function protects against severe hypoglycaemia [26], more substantial beta-cell mass, routinely provided by successful pancreas transplantation, is required for insulin independence. Despite insulin independence, pancreas transplant recipients may have dysglycaemia [27], although detailed metabolic assessments are not reported routinely. Registry data for islet and pancreas transplant metabolic outcomes are summarized in Table 15.6.4.3 [28].

Table 15.6.4.2 Islet patient survival data from CIT-07 trial. Islet graft failure reported from NHSBT annual report on pancreas and islet transplantation 2017/2018 with 1-year survival data for islet transplants between 2013 and 2017, and 5-year survival for transplants between 2008 and 2017

	Patient survival (%)			Beta-cell (pancreas or islet) graft survival (%)		
	1 year	5 years	10 years	1 year	5 years	10 years
SPK	97.4†	90††	76††	91.3†	73††	56††
PAK	97.9†	87††	71††	86.0†	64††	38††
PTA	97.0†	90††	82††	85.7†	53††	36††
ITA	100%	100%		84%	48%	

†Analysis of transplant outcomes from UNOS and IPTR report for US transplants performed between 2010 and 2014[9].
††Analysis of IPTR outcomes for US transplants with reported 5-year survival outcomes for transplants 2008/2009 and 10-year outcomes for transplants between 2004/2005.

Table 15.6.4.3 Metabolic outcomes after pancreas and islet transplant. Islet data obtained from 10th CITR Annual report with assessment of outcomes 1- and 5-years post last infusion. Pancreas data from UNOS[9]. In pancreas transplants, a return to exogenous insulin has generally been viewed as graft failure, and it is uncommon for HbA1c and severe hypoglycaemia to be assessed routinely

	Pancreas transplant		Islet transplant	
	Short term (1 year)	Long-term (5 years)	Short term (1 year)	Long term (5 years)
Insulin independence	>90%	53–73%	50%	~30%
Reduced insulin dose	Insulin independence expected	Expected, unless explanted or recipient develops insulin resistance/PTDM	Expected, unless C-peptide negative	Sustained, if C-peptide positive
Absence of severe hypoglycaemia	Expected	Expected	95%	>90%
HbA1c <7% (53 mmol/mol) and no severe hypoglycaemia	Expected	Expected	~70%	~50%

PTDM, post-transplant diabetes mellitus.

Impact on Diabetes Complications

Data from the Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications study (DCCT/EDIC) imply that improved glycaemic control should result in improved microvascular outcomes [5]. Compared with DCCT participants, transplant recipients are older, have much longer diabetes duration and a substantially higher burden of complications [10]. Rodent data suggest that reversal of complications is harder with longer diabetes duration. Some immunosuppressant drugs (calcineurin inhibitors) are nephrotoxic [17]. Thus long-term studies to evaluate the net effect of transplantation are required.

Ten years of normoglycemia after pancreas transplant has shown reversal of histological changes of diabetic nephropathy (without preservation of GFR) and stabilization of diabetic retinopathy [29]. Small studies support a reduced rate of microvascular disease progression following islet transplantation versus medical therapy [30]. Macrovascular disease may also be positively impacted as islet transplantation has been associated with reduced progression of carotid intima-medial thickening [31] and cardiovascular mortality is lower with sustained pancreas graft function after SPK compared with living donor kidney transplant alone [15].

Quality of Life

Improved quality of life is expected with successful pancreas and islet transplantation [32]. Diabetes distress and hypoglycaemia fear are substantially reduced [33].

Can We Meaningfully Compare Beta-Cell Replacement Outcomes, Risks, and Benefits?

A major challenge is the paucity of comparable data regarding outcomes of pancreas or islet transplantation. Most reports in pancreas transplantation are derived from registry data and focus on patient and graft survival. Graft function is defined as no insulin use (often without any assessment of glycaemic control) [9]. In contrast, long-term patient survival data are not yet available in islet transplantation and reports have tended to focus on defined metabolic outcomes and hypoglycaemia (Table 15.6.4.3).

To address this the International and European Pancreas & Islet Transplant Associations have proposed the Igls criteria (Table 15.6.4.4) to standardize assessment of outcomes for beta-cell replacement [6].

Patient Selection and Indications for Transplantation

Informed choices around transplant options necessitate weighing short- and long-term risks and benefits, including the consideration of renal reserve and other comorbidities. Most contraindications are relative and depend on the strength of the indications. Robust early function appears to predict long-term function [34], although achieving insulin independence with islet transplantation may be challenging in heavier recipients [10], or with higher pre-transplant insulin requirement and/or insulin resistance. It is not clear whether strategies prioritizing achievement of insulin independence (several

Table 15.6.4.4 Outcomes of beta-cell replacement therapy: Igls criteria

Beta-cell functional status	HbA1c (mmol/mol)	Severe hypoglycaemia events per year	Insulin requirements unit/kg/day	C-peptide	Treatment success
Optimal	≤48 (6.5%)	None	None	>Baseline	Yes
Good	<53 (7%)	None	<50% baseline use of other OHA	>Baseline	Yes
Marginal	Baseline	<Baseline	≥50% baseline	>Baseline	No
Failure	Baseline	Baseline	Baseline	Baseline	No

OHA: oral hypoglycaemic agents.

Copyright 2018 © Steunstichting ESOT.

islet donors per recipient—Canada) or amelioration of hypoglycaemia in more recipients (maximum two infusions—UK) will prove more effective in the long-term but supplemental islet infusions have been shown to be effective in re-establishing insulin independence in individuals with islet graft dysfunction [35].

Pancreas Allocation and Availability

Because of the limited availability of donor organs efforts should be made to ensure they are used most appropriately and effectively. In some parts of the world (e.g. Canada) organ allocation is determined by local policies, with pancreata first being offered for whole pancreas transplantation (usually SPK), with declined organs then being offered for islet transplantation. This may reflect historical precedence with many established pancreas transplant programmes compared with a small number of islet transplant programmes.

In the United Kingdom, nationally retrieved organs are allocated to pancreas and islet transplant recipients on a shared waiting list. Priority for islet or pancreas transplant is assessed by the weighting of factors including: recipient waiting time; dialysis status; HLA sensitization/donor-recipient mis-match; donor body mass index (BMI); donor-recipient age matching; and cold ischaemic time. The quality of the donor organ has been shown to directly influence the success of islet isolation and graft outcomes. In the UK programme, pancreata from higher BMI donors are preferentially offered for islet transplant. Additional priority is also awarded following first islet transplant towards rapid access to a second transplant when indicated [36].

Clinical Monitoring and Management

Interval monitoring is important to ensure adequate, but not excessive, exposure to immunosuppression with metabolic monitoring to assess graft function. Dysglycaemia can predict islet and pancreas graft failure [27] and may be due to allo-immune rejection, recurrence of autoimmunity, diabetogenic effects of immunosuppression or beta-cell exhaustion [18]. Pancreas rejection can be confirmed by biopsy and may respond to steroids [12] or antithymocyte globulin Currently there are no reliable markers for rejection in islet transplant, and dysglycaemia is most commonly addressed by early use of insulin to reduce metabolic demand and avoid glucose toxicity. DPP4 inhibitors and GLP-1 receptor agonists appear to be safe glucose-lowering agents in islet transplantation. Other non-insulin glucose-lowering agents have not been tested, but consensus guidelines suggest avoidance of insulin secretagogues [8].

Other Indications and Future Directions

Long-term safety and limited organ supply are the two major barriers to broader application of transplantation in type 1 diabetes. Clinical trials of a potentially unlimited supply of beta-cells derived from embryonic stem cells began in 2016 [37]. Advances in immunotherapy and immunobarrier encapsulation may improve the effectiveness and safety of, or potentially obviate the need for, chronic immunosuppression.

No immunosuppression is required in islet autotransplantation following total pancreatectomy for chronic pancreatitis complicated by severe, refractory pain to prevent labile diabetes and may avoid the need for insulin in up to 41% of patients for up to 3 years [38].

Reports of case series of pancreas transplantation for type 2 diabetes have shown that insulin independence can be achieved [39], certainly in the absence of BMI >30, but the efficacy of the marginal mass achieved by islet transplantation in the face of insulin resistance in type 2 diabetes seems questionable. However, given the growing prevalence of type 2 diabetes with end stage renal disease, transplantation (SPK) may be an appropriate and effective therapy [40]. Transplant physicians will continue to carefully balance the risks and benefits for an individual with the optimal use of limited donor pancreata.

15.7

Evidence-based Prevention and Management of Type 2 Diabetes

15.7.1 Strategies for the Management of Type 2 Diabetes

Peter Winocour and Sagen Zac-Varghese

Introduction

Type 2 diabetes is characterized by insulin resistance and inadequate insulin secretion leading to hyperglycaemia. The overarching objectives of antihyperglycaemic therapy are: symptom relief, reduction of microvascular complications, and reduction of macrovascular complications over the longer term. Therapies may reduce insulin resistance, stimulate insulin secretion, replace insulin, reduce glucose production, delay glucose absorption, or increase glucose elimination.

The increasing availability of new antihyperglycaemic agents, while beneficial, has led to increased uncertainty with regards to choice of agent, sequence, suitability, safety, and appropriate combination. Guidelines state that care plans should be individualized. However, opinions on how this is to be achieved are varied. In the future, subcategorization of type 2 diabetes may have an impact on therapy [1].

National guidelines are broadly similar in recommending stepwise increments in therapy. Ultimately a successful treatment regimen would enable a patient to achieve glycaemic control in the absence of weight gain and hypoglycaemia. Some guidelines have reflected cardiovascular and renal benefits of certain agents, and have incorporated these into treatment algorithms.

This chapter looks at the approach to therapy selection and discusses some of the background, theoretical framework, and evidence behind these algorithms.

Socioeconomic Determinants of Health

The socioeconomic determinants of health and cost of therapy are important considerations. Where patients have to pay for their treatments this can lead to non-compliance [2]. Nationally funded healthcare may restrict access to certain agents. Globally, food insecurity could lead to the risk of hypoglycaemia with certain medications. Conversely, the widespread availability of highly processed, refined carbohydrate snacks, and beverages has contributed to the global obesity epidemic.

Lifestyle Measures and Obesity Management

Guidelines advocate healthy lifestyle interventions (diet and exercise) for type 2 diabetes [3, 4]. Weight loss can delay the progression of prediabetes to type 2 diabetes and there is increasing evidence that weight loss has important effects on improving glycaemic control both initially and at later stages of diabetes [5]. The demonstration that remission from type 2 diabetes can be achieved after more extreme weight loss (through an approximately 800 calories/day diet) may preclude the need for medical therapies or at least enable dose reduction or withdrawal of certain hypoglycaemic agents

[6, 7]. However, it is recognized that such an approach is limited by weight regain (after diet cessation) unless a long-term maintenance programme is followed.

American, Canadian and European guidelines reflect the importance of both good glycaemic control and weight management and advocate the use of antihyperglycaemic agents which either promote weight loss or which are weight neutral [3, 4, 8]. Current National Institute for Health and Care (NICE) guidelines do not specifically prioritize the use of these agents [9]. However, the fundamental importance of individualized care is a central theme of that guidance.

Antihyperglycaemic agents that contribute to weight loss include: glucagon-like peptide-1 (GLP-1) receptor agonists, sodium and glucose cotransporter (SGLT) 2 inhibitors and amylin (only available in the United States). Medications with possible benefits or weight neutral drugs include: metformin, dipeptidyl peptidase IV (DPP-IV) inhibitors and α-glucosidase inhibitors (acarbose). Sulphonylureas (SU), meglitinides, and particularly insulin all lead to weight gain (increased adiposity). Weight gain is inevitable with insulin and this is more notable in insulin resistant patients who require higher insulin doses. Thiazolidinediones (TZD) are associated with weight gain due to fluid retention.

A recent meta-analysis concluded that oral antihyperglycaemic agents were equally beneficial irrespective of baseline body mass index (BMI) [10]. However, SU were less effective in obese patients and insulin was not studied. In the UKPDS 49 study, obese patients were more likely to require multiple therapies [11].

The American Diabetes Association (ADA) guidelines recommend specific pharmacotherapy for obesity (either alone or as an adjunct to standard diabetes therapy) [8]. Efficacy may be limited by adverse effects and variable compliance. In contrast, metabolic bariatric surgery leads to marked early improvement in glycaemic control and weight loss. Following bariatric surgery, type 2 diabetes remission is between 30% and 80% depending on the type of surgery performed [12].

Principles of Antihyperglycaemic Treatment for Type 2 Diabetes

Patient empowerment in understanding diabetes and the associated treatments is essential. People with diabetes should be actively involved in therapy selection and in monitoring the response to treatment. The choice of antihyperglycaemic agent is based on a number of factors including:

- individualized glycaemic targets,
- effectiveness of the therapy versus tolerability and side effects,
- comorbidities including renal impairment,
- cardiovascular disease, and obesity,
- the impact of the agent on weight,
- the impact of the agent on renal disease and cardiovascular disease, patient preference,
- risk from polypharmacy,
- appropriateness of tight glycaemic control (risk of hypoglycaemia).

Patient preferences may dictate treatment based on their job (shift work or work involving heavy machinery), driving restrictions and fasting (e.g. Ramadan). This may preclude the use of agents which predispose to hypoglycaemia. Patient comorbidity and concomitant medications, in particular atypical antipsychotics, steroids, and antiepileptic agents may also be associated with unwanted weight gain and hyperglycaemia.

Changes during a lifetime, such as during puberty, during pregnancy and breastfeeding, in older patients, in dementia and at the end of life, can lead to changes in diabetes management with either intensification or relaxation of glycaemic targets and treatment regimes. Type 2 diabetes is increasingly prevalent in older adults who are at increased risk of polypharmacy. It is important to simplify regimes and implement strategies with low risk of hypoglycaemia as elderly patients may not recognize hypoglycaemic symptoms or seek appropriate help. In these patients, the focus should be on symptom control and agents that encourage satiety and weight loss may be undesirable as malnutrition may be an issue. At the end of life, in patients with type 2 diabetes, many treatments can be discontinued [13] (see Table 15.7.1.1).

Initiation of Antihyperglycaemic Agents for Type 2 Diabetes

A patient with type 2 diabetes who is asymptomatic and diagnosed through a screening programme will require a different treatment approach compared to a patient diagnosed due to symptoms, metabolic decompensation, or due to the complications of diabetes. All antihyperglycaemic agents (including insulin) have side effects and the importance of sick day guidance should be reinforced. In general, patients with undiagnosed type 2 diabetes presenting with complications will be less amenable to tight control, especially if associated with obesity, compared to asymptomatic patients diagnosed early in the disease through screening programmes.

Patients with Type 2 Diabetes Presenting With Metabolic Decompensation

In newly presenting patients with symptomatic hyperglycaemia and metabolic decompensation, the type of diabetes may be initially unclear and glycaemic control may be best achieved with increasing doses of either SU or insulin. Insulin would be the treatment of choice where severe osmotic symptoms, ketosis, or weight loss (regardless of HbA1c) raise the possibility of type 1 diabetes, latent autoimmune diabetes of adults (LADA), or insulin deficiency.

Guidelines employ an initial stratification scheme based on the level of glucose and HbA1c (regardless of symptoms). If the HbA1c is <75 mmol/mol initial oral monotherapy is recommended, if the HbA1c is ≥75 mmol/mol dual therapy is recommended (e.g. metformin plus insulin) and at levels ≥86 mmol/mol combination injectable therapy is recommended (e.g. a basal bolus insulin regime) [3, 8, 9]. The Canadian guidelines use individualized glycaemic targets and an algorithm which references percentage deviance from the target [3].

The initial intensive treatment of hyperglycaemia may have some benefit as studies have demonstrated the effects of glycaemic memory which may reflect a reduction in accumulated glucotoxicity [14]. There is also some evidence that early insulin therapy leads to

Table 15.7.1.1 Summarized benefits, side effects, and other considerations for antihyperglycaemic agents

Agent	Weight	Hypoglycaemia	Cardiovascular effects	Renal effects	Side effects	Additional contraindication	Additional benefits
Metformin	Neutral/ loss	No	Benefit	Contraindicated if eGFR < 30	Gastrointestinal, B12 deficiency, lactic acidosis (rare)	Liver failure, hypoxia (acute heart failure, sepsis)	Benefit in NAFLD and PCOS
Sulphonylureas	Gain	Yes	Association with heart failure, RCT—no statistical difference	Risk of hypoglycaemia		Liver failure	
Meglitinides	Gain	Yes	Neutral	Risk of hypoglycaemia		Liver failure	Rapid onset and offset of action. Suitable for erratic meal patterns
Thiazolidinedione	Gain (fluid)	No	Increased risk of heart failure. Benefit in PROactive study	Not recommended in renal failure due to oedema	Fluid, maculopathy, osteoporotic fracture peripheral (and hip) in postmenopausal women	Heart failure, liver failure, bladder cancer (EASD—no significant association)	Benefit in NAFLD/NASH
SGLT-2 inhibitors	Loss	No	Benefit –class effect reduction in hospitalization for heart failure. Reduction in MACE—empagliflozin, canagliflozin	Benefit – dapagliflozin, empagliflozin, canagliflozin eGFR restrictions—variation within class	Urinary tract and genital infections, DKA risk, possible risk of amputation and increased fracture risk (canagliflozin), association with Fournier gangrene, small increase in LDL-C	Liver failure	Reduced blood pressure
DPP-IV inhibitors	Neutral	No	Potential risk—saxagliptin, alogliptin	Renal dose adjustment, variation within class		Previous pancreatitis, angioedema, urticaria	
GLP-1 receptor agonist	Loss	No	Benefit—liraglutide, semaglutide, dulaglutide, albiglutide	Benefit—liraglutide eGFR restrictions—variation within class	Rare cases of acute gallstone disease, gastrointestinal	Previous pancreatitis Black box—risk of thyroid C cell tumours (seen in animal studies only), semaglutide—caution with severe retinopathy	Benefit in NAFLD (liraglutide)
Insulin	Gain	Yes	Neutral	Risk of hypoglycaemia			
Acarbose	Neutral	No	Possible benefit	Avoid in dialysis	Gastrointestinal	Liver failure, gut dysmotility e.g. gastroparesis	

partial beta-cell recovery [15]. Unfortunately, the agents associated with rapid improvement in glycaemic control (insulin and SU) are associated with risk of weight gain and hypoglycaemia.

While high glucose and HbA1c values may prompt insulin initiation, it is important to take a clear dietary history. Intake of high glucose containing drinks to address the osmotic symptoms of type 2 diabetes could lead to hyperglycaemia which could readily improve by their withdrawal and institution of standard dietary advice.

It is also important to reflect on comparative studies and the baseline HbA1c. All therapies will have greater efficacy the higher the starting level of glycaemia. Some have flatter dose response curves and insulin is the most potent glucose lowering therapy on a dose dependent basis.

While several studies have demonstrated reduced microvascular complications with improved glycaemic control, the Action to Control Cardiovascular Risk in Diabetes (ACCORD) study found significantly higher mortality in older patients with prevalent macrovascular disease treated with intensive insulin therapy [16].

It is also recognized that overly rapid correction of HbA1c can lead to deteriorating retinopathy and worsening neuropathy [17, 18]. Currently, there are no recommendations with regards to rate of HbA1c improvement, other than increased retinal screening in patients considered to be at increased risk, i.e. those with baseline moderate to severe diabetic retinopathy and longer duration of diabetes [18]. In the majority of patients, the worsened retinopathy and/or neuropathy are reversible and the benefit of improved glycaemic control outweighs the risk [17, 18]. However, there is still a case for gradual HbA1c reduction in at risk patient groups but the evidence that this will reduce the risk of deterioration is lacking.

Patients with Type 2 Diabetes Presenting Without Metabolic Decompensation

Across all guidelines, metformin is considered the standard first line therapy for type 2 diabetes and there is a long-term accumulation of experience of over 60 years. The benefits of metformin include its efficacy, low risk of hypoglycaemia, weight neutrality (or slight weight loss), potential cardiovascular benefits, ability to combine metformin with most other agents and its cost [14].

The main contraindication for metformin is renal impairment with eGFR <30 ml/min/1.73 m^2 (see 'Renal Impairment and Choice of Antihyperglycaemic Agent'). There is a potential risk of lactic acidosis in situations of metabolic decompensation. Thus metformin is contraindicated in sepsis, acute coronary disease, hepatic and renal failure, and in the event of concurrent illness (sick day guidance). This guidance is perceived by many as overly cautious and it is not yet clear if metformin is a bystander or active participant contributing to lactic acidosis in these situations. A Cochrane systematic review of metformin found no fatal or non-fatal cases of lactic acidosis with the use of metformin compared to placebo or other antihyperglycaemic agents [19]. The latest ABCD-Renal Association guidelines support the use of metformin for some patients with chronic kidney disease (CKD) stage 4 with dose reduction [20].

In situations where metformin is contraindicated due to significant renal impairment, several other classes of antihyperglycaemic agent may be similarly cautioned (notably SU, TZD, and SGLT-2 inhibitors). If metformin is contraindicated for other reasons, for example, due to gastrointestinal intolerance (including intolerance of modified released metformin), then the European Association for the Study of Diabetes (EASD), Canadian guidelines and ADA suggests initiating any one of the six treatment options: SU, TZD, DPP-IV inhibitors, SGLT-2 inhibitors, GLP-1 receptor agonists or basal insulin [3, 4, 8]. In the ADA and Canadian guidelines these options are given equivalence. The Scottish Intercollegiate Guidelines Network (SIGN) gives equivalence to four treatment options: SU, TZD, DPP-IV inhibitors and SGLT-2 inhibitors [21]. NICE guidelines advocate the use of SU, TZD, or DPP-IV inhibitors as next step therapy. SGLT-2 inhibitors are considered appropriate if these three are not suitable or are contraindicated.

Intensification of Therapy for Type 2 Diabetes

Due to the progressive nature of type 2 diabetes, patients may require additional therapy. All guidelines follow a similar stepwise approach to treatment intensification. An individualized target HbA1c is decided upon and following lifestyle or monotherapy, treatments are sequentially added every 3–6 months until the target HbA1c is achieved. However, this may lead to a degree of therapeutic inertia. In ADA, NICE, and SIGN guidelines, the target HbA1c at diagnosis is initially set at 48 mmol/mol and 53 mmol/mol thereafter if therapy is associated with hypoglycaemia [8, 9, 21]. Higher targets have been suggested for patients with moderate to severe renal failure or reduced life expectancy [8, 20, 22].

Following metformin, the sequence of therapy selection differs in the guidance from the various agencies. NICE guidelines advise adding SU, TZD, or DPP-IV inhibitors. SIGN suggest adding SU, TZD, DPP-IV inhibitors, or SGLT-2 inhibitors. ADA, EASD, and Canadian guidelines base further treatment choice on the presence of atherothrombotic disease, heart failure or renal disease (see 'Cardiovascular Disease and Antihyperglycaemic Agents'), or the effect of the agent on body weight (see **Figure 15.7.1.1**). Individual patient and antihyperglycaemic agent characteristics influence the subsequent choice of antihyperglycaemic agent (see **Table 15.7.1.1**).

Within the NICE and SIGN guidelines, GLP-1 receptor agonists are only recommended in the third intensification of treatment if the BMI is >35 (lower in patients of Asian ethnicity) with obesity-related complications. GLP-1 receptor agonists are also recommended in patients with BMI <35 where insulin use would be restricted or where weight loss would directly benefit obesity-related complications [9, 21].

Insulin is initiated in patients failing to achieve glycaemic targets. Most guidelines advise starting with a basal insulin [4, 8, 9, 21]. If this is ineffective, short acting prandial insulin is added or the patient is switched to a biphasic regime. The 4T study looked at the use of various insulin regimes and found that basal insulin is least likely to induce weight gain and hypoglycaemia [23]. In addition, the AT-LANTUS study comparing clinician-led to patient-led insulin titration algorithms found that the patient-led protocol was associated with a reduced HbA1c without increased hypoglycaemia [24]. This highlights the importance of self-management and patient education. In general, hypoglycaemia can be mitigated with carbohydrate awareness, exercise guidance, and the use of analogue insulins with improved pharmacokinetic profiles. In insulin resistant patients, the concentrated insulins (e.g. U-500) may play a role. However, care needs to be taken with regards to safety of insulin prescription.

ADA guidelines highlight a role for α-glucosidase inhibitors (acarbose), bile acid sequestrants, bromocriptine and pramlintide (an injectable amylin analogue only available for use in the United States). However, the placement of these agents within the algorithm is not clear. These drugs are limited due to their side effect profile and are less commonly used in clinical practice [4].

Combination of Antihyperglycaemic Agents

In contrast to using maximum doses of single agents, there is some evidence that combinations of submaximal doses may be more effective [25]. When combining antihyperglycaemic agents, agents targeting different pathways should be used together. For example, the combination of an insulin secretagogue such as an SU with an insulin sensitizer would be appropriate. However, the combination of two insulin secretagogues (e.g. an SU with a meglitinide) or the combination of two agents that act on the incretin system (e.g. a DPP-IV inhibitor with a GLP-1 receptor agonist) are less rational with limited benefit.

In addition, specific issues arise with drug combinations with similar side effect profiles. For example, canagliflozin and pioglitazone both potentially increase the risk of fracture; thus this combination should be avoided in patients with metabolic bone disease.

Many patients eventually end up with a combination of oral antihyperglycaemic agents and insulin. When metformin is combined with insulin, this is associated with reduced HbA1c and

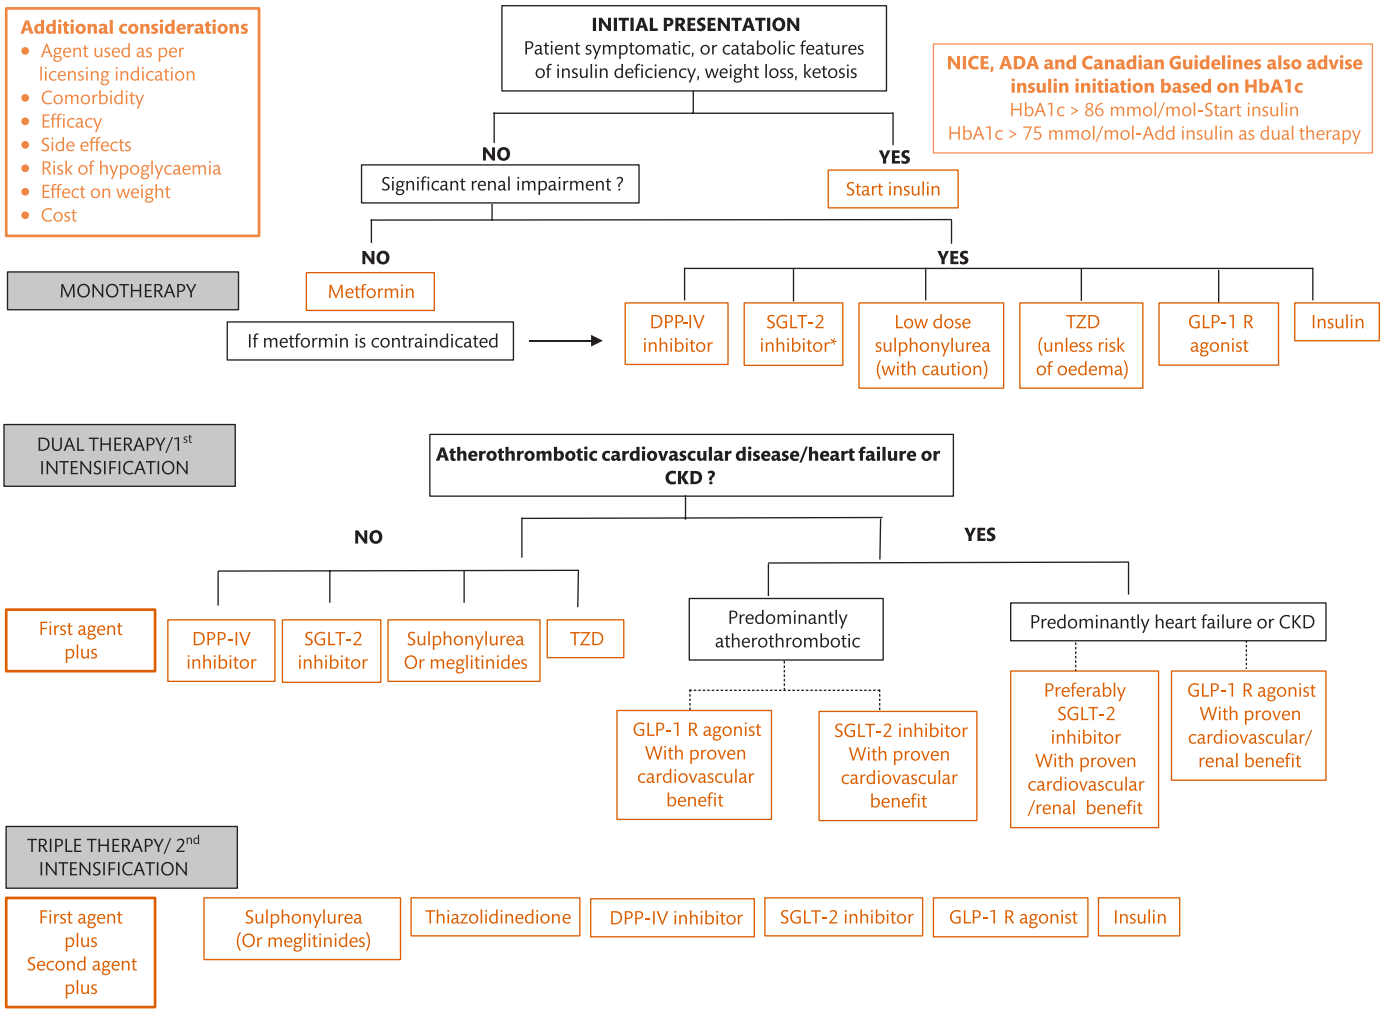

Figure 15.7.1.1 Strategy for choice of antihyperglycaemic agent in type 2 diabetes. *Dependent on eGFR and licensing.

decreased weight gain. However, SU in combination with insulin could increase the risk of hypoglycaemia. It would be reasonable to reduce or discontinue SU after insulin is started (especially if a basal bolus or biphasic insulin regime is used). TZD use alongside high insulin doses can lead to significant weight gain through fluid retention. SGLT-2 inhibitors can be used with insulin and can also lead to weight loss with insulin dose reduction; however, this combination can be associated with increased risk of hypoglycaemia. In general, GLP-1 agonists do not need to be discontinued with insulin.

Cardiovascular Disease and Antihyperglycaemic Agents

In 2008, following cardiovascular concerns regarding rosiglitazone, the Food and Drugs Administration (FDA) advised that cardiovascular outcome trials (CVOT) be performed for all new antihyperglycaemic agents. Since 2008, restrictions on the use of rosiglitazone have been removed and it is currently available in the United States (not licensed in Europe). Pioglitazone (available in United States and Europe) is associated with heart failure; however, paradoxically, pioglitazone was found to improve all-cause mortality, non-fatal MI and stroke in the PROactive study [26, 27].

The Thiazolidinediones Or Sulfonylureas Cardiovascular Accidents Intervention Trial (TOSCA.IT) study looked at the risk of TZD versus SU in patients on metformin monotherapy [28]. This study did not find differences in the primary end point (cardiovascular death, non-fatal MI, non-fatal stroke) between these two agents. However, heart failure was not included in the primary or secondary outcomes and had a relatively high incidence in both arms in the expanded composite outcomes. It is not yet known if pioglitazone has a beneficial role in patients where heart failure is controlled with diuretics.

The UK GP database (observational study) identified an 18–30% increased risk of heart failure with SU [29]. However, randomized control trials demonstrated no statistical difference between SU and metformin [21, 30]. It is possible that SU increase the risk of heart failure, but not of atherothrombotic heart disease.

In addition to TZD and SU, select DPP-IV inhibitors (alogliptin and saxagliptin) have been associated with an increased risk of heart failure. Cardiovascular safety has been established with sitagliptin and more recently for linagliptin in the CArdiovascular safety and Renal Microvascular outcomE study with LINAgliptin (CARMELINA) study [31].

The cardiovascular benefit of metformin was previously suggested in UKPDS [32]. A recent systematic review and meta-analysis of the

effects of metformin has moderated this view. This demonstrated that metformin reduced the risk of all-cause mortality, cardiovascular disease (fatal and non-fatal) and peripheral vascular disease but potentially increased the risk of stroke (although the absolute risk is very small) [33].

Cardiovascular benefit has been demonstrated for empagliflozin, canagliflozin, and dapagliflozin with all three associated with a reduction in hospitalization for heart failure. The EMPA-REG OUTCOME trial demonstrated a reduction in cardiovascular outcome and death with empagliflozin compared to placebo [34]. For canagliflozin, the CANVAS trial showed a reduced risk of cardiovascular death and a reduction in hospitalization for heart failure [35]. This cardiovascular benefit was confirmed in the canagliflozin renal outcome study, CREDENCE, in a high-risk cohort with CKD [36]. CREDENCE demonstrated a reduction in the risk of cardiovascular death, myocardial infarction or stroke and a reduction in hospitalization for heart failure [36]. For dapagliflozin, the Dapagliflozin Effect on CardiovascuLAR Events (DECLARE-TIMI 58) study demonstrated a reduction in hospitalization due to heart failure, a lower rate of cardiovascular death and a neutral effect on major adverse cardiovascular events [37, 38]. Of note, the study populations for these three CVOTs differed and it is of interest that the SGLT-2 inhibitor that demonstrated the largest effect was studied in the highest cardiovascular risk population.

Cardiovascular benefit has been demonstrated in established cardiovascular disease for liraglutide, semaglutide, albiglutide, and dulaglutide. The Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results—A Long Term Evaluation (LEADER) trial demonstrated a reduction in cardiovascular death and death from any cause [39]. The SUSTAIN-6 trial demonstrated that semaglutide, a once-weekly GLP-1 receptor agonist, reduced cardiovascular death, non-fatal MI, and non-fatal stroke [40]. The HARMONY outcome trial comparing albiglutide to placebo found a reduction in a composite primary end point of major adverse cardiovascular events and a significant reduction in myocardial infarction [41]. The REWIND trial looking at dulaglutide demonstrated a reduction in the primary composite cardiovascular outcome compared to placebo [42]. While cardiovascular safety has been established for GLP-1 receptor agonists not all agents have shown superiority. Both the Evaluation of Lixisenatide in Acute Coronary Syndrome (ELIXA) study and the Exenatide Study of Cardiovascular Event Lowering (EXSCEL) study met the primary objective of non-inferiority but without added benefit [43].

The CVOTs for the newer antihyperglycaemic agents (GLP-1 receptor agonists and SGLT-2 inhibitors) have influenced European, American and Canadian guidelines which currently recommend adding one of these agents with proven benefit following lifestyle intervention and metformin in patents with atherothrombotic cardiovascular disease or in patients with clinical heart failure [3, 4].

Renal Impairment and Choice of Antihyperglycaemic Agent

Several antihyperglycaemic agents are untested in patients with moderate to severe CKD and therefore are not licensed or recommended below specific eGFR levels. Uncertainty rather than safety precludes their use. As study data and real-world data accumulates, this may influence licensing and prescribing of these newer agents.

There are several considerations with regards to antihyperglycaemic agent pharmacokinetics and pharmacodynamics in the context of renal impairment and renal failure [20]. This influences the appropriateness and dosage of therapy [44]. It should also be recognized that eGFR is inaccurate in various circumstance such as in obesity. In this group of patients the Cockcroft-Gault formula may be used.

Insulin requirements rise in the early stages of diabetic kidney disease and then fall [45]. Therefore, agents which promote hypoglycaemia (SU, meglitinides, and insulin) should be used with caution. SU and meglitinides are currently not recommended for use in dialysis [22]. Basal bolus insulin regimes are recommended in haemodialysis as these allow greater flexibility [22].

There are a number of other agent specific considerations with regards to the complications related to renal failure. Where renal failure is associated with fluid overload, agents associated with oedema, such as TZD, would be contraindicated. Where oedema is not a concern TZD can be continued without dose adjustment in renal impairment. However, TZD are not licensed for use in haemodialysis and currently not recommended [22].

The Canagliflozin and Renal Endpoints in Diabetes with Established Nephropathy Clinical Evaluation (CREDENCE) trial evaluated the effects of 100 mg canagliflozin in patients with established renal disease and reported a reduction in the primary renal endpoint of 30% in the canagliflozin group [36]. There was a significant reduction in end stage renal failure at a median follow-up of 2.62 years [36]. This was the first study looking at primary renal endpoints in a population with established macroalbuminuria and diabetic kidney disease. In the CANVAS study, the renal outcomes were not considered statistically significant, however, this study complements the CREDENCE study. This showed reduced frequency of progression of albuminuria and reduced frequency of the composite renal outcome (reduction in eGFR, need for renal replacement, or death from renal causes) [35]. The DECLARE-TIMI study suggested similar renal benefit with a reduced frequency of renal events (reduction in eGFR, new endstage renal disease, or death from renal or cardiovascular causes) occurring in the dapagliflozin group [38]. The EMPA-REG OUTCOME trial demonstrated that empagliflozin reduced renal progression (microalbuminuria, doubling of creatinine and initiation of renal replacement) as a secondary end point [34, 46]. Studies looking specifically at the renal outcomes of empagliflozin (EMPA-KIDNEY) and dapagliflozin (DAPA-CKD) are awaited.

SGLT-2 inhibitors are currently licensed for initiation when eGFR >60 ml/min/1.73 m^2 and can be maintained in lower doses when eGFR remains >45 ml/min. These cut-off values are being re-evaluated with a likely reduction in the threshold eGFR for use with increased safety data from the cardiovascular and renal outcomes trials.

GLP-1 receptor agonists have a less evident effect on renal function. In acute illness they have been anecdotally linked with acute kidney injury. However, sustained reductions in albuminuria have been noted with dulaglutide, liraglutide, and semaglutide [40, 47, 48]. Definitive renal outcome studies with hard renal endpoints are awaited.

Hepatic Impairment and Choice of Antihyperglycaemic Agent

Elevation of liver enzymes is common in patients with type 2 diabetes, affecting up to 24% of diabetic patients screened [49]. This is often associated with non-alcoholic fatty liver disease (NAFLD). Hepatic impairment leads to several challenges. Firstly, most oral antihyperglycaemic agents are metabolized in the liver. Secondly, patients with hepatic impairment are at increased risk of hypoglycaemia [50]. Thirdly, hepatic impairment, unlike renal impairment, is less clearly defined and guidance can be misinterpreted.

National guidelines regarding the safety of drugs in hepatic impairment may reflect the paucity of data in these study populations rather than actual risk of harm. Most oral antihyperglycaemic agents can be used in mild chronic liver disease (i.e. where there is no evidence of decompensation, e.g. ascites or encephalopathy). However, caution is advised in moderate disease and most agents are contraindicated in severe disease [50, 51].

NAFLD is characterized by insulin resistance; thus agents, such as metformin, which improve insulin sensitivity may be beneficial in reversing disease pathology. This has also been demonstrated with pioglitazone in patients with biopsy proven non-alcoholic steatohepatitis (NASH) [52]. However, if the ALT levels increase further during therapy (>3× upper limit of normal) then it may be necessary to stop pioglitazone while assessing the aetiology.

SGLT-2 inhibitors undergo extensive hepatic metabolism. They are largely untested in severe liver disease and so while they can be used in mild hepatic impairment, they should be used cautiously and avoided in moderate to severe hepatic disease. However, the SGLT-2 inhibitor dapagliflozin has a documented benefit in fatty liver disease. In addition, in NASH, studies have found liraglutide to be safe with a beneficial effect on liver enzymes [53]. See Table 15.7.1.1.

Conclusion

The strategy for successful management of hyperglycaemia in type 2 diabetes depends on a patient-centred approach with careful consideration of the risks and benefits of the various agents. Currently, metformin is the first line recommended agent. Following this, different classes may be given equal consideration (where cost is not prohibitive). It is useful to consider the impact of the agent on weight given the increasing global prevalence of obesity. The main change in recommendations is due to cardiovascular and renal outcome trials demonstrating cardiovascular and renal benefits of specific agents. The results of further renal outcome trials may also have an impact on recommendations. In the future, long-term effectiveness trials of the newer agents will influence treatment algorithms.

15.7.2 Psychological and Behavioural Aspects of Type 2 Diabetes Management

Timothy C. Skinner and Jane Speight

Introduction

The challenge of type 2 diabetes is that, if individuals wish to minimize their risk of developing long-term complications, then they need to maintain their blood glucose, blood pressure, cholesterol, and their emotional well-being as close as possible to recommended levels [1]. This can be achieved, but only through significant and sustainable changes, including dietary choices, physical activity, taking medication, and monitoring glucose levels; for many, there is the additional challenge of needing to sustain some weight loss (1). All of these are independent risk factors for heart disease, stroke, retinopathy, nephropathy and neuropathy and mortality [2]. Unfortunately, managing these risks is complex and most people do not achieve recommended targets [3]. An important consideration is that biomedical risk factors (blood glucose, blood pressure, cholesterol) are largely asymptomatic, and a lack of biofeedback means little positive reward for optimal diabetes self-management. In the long term, at best, individuals are rewarded with an absence of complications some 10–20 years into the future (i.e. they maintain the status quo). It is little wonder that many people with type 2 diabetes find it challenging to maintain motivation for sustained optimal diabetes self-management.

In the past 20 years, substantial innovations in medical technologies, pharmaceutical agents, and digital technologies have not been matched with comparable improvements in type 2 diabetes outcomes [4]. The reality remains that diabetes is a self-managed condition, and outcomes will not improve until this is acknowledged fully by clinicians, researchers and policymakers [5]. Regardless of healthcare professional advice, people with diabetes make the day-to-day decisions about their food choices and activity levels, taking medications, and monitoring their health, and are in charge of managing *their* diabetes.

Given this, it is unsurprising that many people with type 2 diabetes experience high levels of distress. A recent meta-analysis (55 studies from 16 countries) indicated that 36% of people with type 2 diabetes experience clinically meaningful levels of diabetes-specific distress [6]. This diabetes distress is possibly the main barrier to effective self-management of diabetes. Further, some intervention studies have demonstrated that a reduction in diabetes distress is associated with improved glucose levels [7, 8].

Psychometric instruments have been developed to assess diabetes distress, and there is substantial overlap between scales [9]. For clinical purposes, it can be useful to think of five facets or 'SHADEs' of diabetes distress, and recognize that many people with diabetes feel: Scared, Helpless, Alone, Deprived, and Exhausted.

Scared

Individuals with type 2 diabetes report feeling worried about the future and the possibility of complications, and this is consistently one of the most commonly endorsed problems in diabetes [10]. This can surprise healthcare professionals, who may assume that individuals do not follow 'clear' advice and recommendations because they do not consider diabetes a serious condition—although, underestimation of risk may be the case for a minority.

Many healthcare professionals struggle to communicate balanced and effective messages regarding the seriousness of diabetes while conveying the message that it is possible to prevent complications. When they see that individuals are not making the self-care changes that they advised, they may use fear of complications as the 'stick' with which to motivate behaviour change. However, a review found that people usually overestimate their risk [11], with one study reporting individuals' perceptions of risk for coronary heart disease (CHD) and stroke about 3.5 and 5.5 times, respectively, greater than actual risk [12].

However, fear alone does not motivate action. A recent meta-analysis showed that increasing perceptions of threat (i.e. likelihood and severity of diabetes complications) does not result in behaviour change [13]. More importantly, when individuals have low confidence in their capability to address a health threat, increasing the perceived threat can have a negative impact on their health behaviours and self-care.

Increasing evidence suggests that providing individuals with accurate, personalized information about their complication risk can have positive effects on both emotional well-being and self-care. Randomized controlled trials (RCTs) have demonstrated the efficacy of providing people with type 2 diabetes with their actual cardiovascular risk and a small RCT has used personalized retinal imaging effectively [14–16]. People experience the provision of their actual risk as engaging and constructive. If this is used to support the individual to develop a specific action plan for managing their risk, it may improve blood glucose, pressure, and cholesterol, and reduce diabetes distress.

Helpless

Feeling scared is likely to be accompanied by feeling helpless, and a number of factors contribute to this. First, people with type 2 diabetes are usually given a long list of recommendations that they are told they need to follow. For example: *'eat less sugar, less fat, more fibre, more fruit and vegetables (but not too much fruit), be more physically active, take (up to 10 different) medications at the right time every day, monitor glucose levels, give up smoking, and limit alcohol intake'*.

People with type 2 diabetes usually know all these things—many are common public health messages—but few feel capable to achieve them all. There is little nuance about which are most important/effective actions, or any emphasis on *how* to develop these new healthy habits. So, if the person cannot do all these things, what is their response? Typically, to do none of them. And what is the healthcare professional's response? Typically, they assume the problem to be lack of knowledge—so, they give more advice/recommendations; or to be lack of motivation—so, they scare them a bit more.

Compounding this 'all or nothing' problem, people with diabetes receive different advice from different people, and struggle to know what advice to follow. Healthcare professionals in the same team often do not agree on basic principles of diabetes management [17, 18], and so different professionals in different roles can give conflicting information. This is without considering the advice from well-meaning friends and family, the stigmatizing consequences of well-intended media messages [19], and that written information is frequently incomprehensible to the people for whom it is intended [20, 21].

So, we need to help people appreciate the value of any, small change in reducing risk of complications. If they are even aware of targets, most are fixated on, and demotivated by, unattainable numbers rather than targeting incremental risk reduction. Again, this is where the freely available risk engines can be valuable, to demonstrate the impact of reducing just one risk factor. Critically important, though, is taking the time to appreciate what the individual understands, and what sense they make of all the disparate information to which they are exposed. Without this insight, we simply add to confusion and challenges.

Alone

Many individuals report feeling alone, or unsupported in managing diabetes [22]. In this context, there are several issues to consider: the 'diabetes police', lack of social support, perceived/experienced social stigma and that our words have power.

Nearly everyone living with diabetes has experienced the 'diabetes police'—the family, friends, colleagues, and acquaintances, who may be well-meaning with their comments but are often controlling or undermining [23]. Added to this, studies have now identified social stigma surrounding diabetes, often blaming and shaming people for bringing their condition upon themselves, leading to unwillingness to disclose their condition to others [24, 25], which can have serious implications for self-managing in public.

Added to these challenges, it is important to acknowledge the role that healthcare professionals (and their language) play in leaving people with diabetes feeling unsupported and stigmatized. In recent years, patient advocacy organizations, professional bodies and healthcare organizations have raised awareness that the words we use in diabetes care are often inappropriate, inaccurate, and harmful [26, 27] (**Box 15.7.2.1**).

Many of the words we use, such as 'adherence' or 'compliance', are not only inaccurate and inappropriate [29], they shape and inform a negative relationship with the person with diabetes. Thus, if we wish to reduce the distress that people with diabetes experience, and want them to feel supported in their self-management efforts, then we need to change our own attitudes, approach, and language [26, 29].

Box 15.7.2.1 The inappropriate, inaccurate, and harmful nature of the words we use in diabetes

The NHS England 'Language Matters' guide [28] indicates much of our language can be:

- Stigmatizing, e.g. *'you're in denial'*
- Shaming/blaming, e.g. *'it's your weight that is causing all these problems'*
- Authoritarian, e.g. *'you must take your medications properly in future'*
- Demanding, e.g. *'before you come to see me next, I want you to do 4 blood tests a day for 3 days, so I can check what's going wrong'*
- Disapproving, e.g. *'you aren't meant to take your insulin like that'*
- Discriminating, e.g. *'I don't think they'd get much from a diabetes education class'*
- Stereotyping, e.g. *'people from xx background often dislike the idea of injections'*
- Assumptive, e.g. *'I think you'd cope best with once a day insulin, as it's simpler'*
- Pre-judging, e.g. *'no-one in that family has ever taken much notice of their diabetes, they will be the same'*
- Judgemental, e.g. *'I think you're making the wrong decision'*
- Threatening, e.g. *'If you don't improve your control you will end up on insulin'*

Deprived

While self-managing diabetes is a significant burden, it is made harder by much of the language we use being focused on *not* doing things. *Not* eating sweet foods, *not* eating fat, *not* drinking sugary drinks. The language of reducing, stopping, and not doing creates a sense of deprivation. It is estimated that we make around 200 food/drink-related decisions every day [30]. If the majority of those decisions end up as 'no I can't', 'no I shouldn't' etc., then that is a lot of negativity every day. Therefore, it is unsurprising that many people with diabetes struggle with a sense of feeling deprived of the things that make life enjoyable for them.

This is why, when working with people with diabetes, the goal is to focus on what people *can* do. Many healthcare professionals have heard of SMART goal setting, but few report that A is for Actions, i.e. to focus on the thing someone *will* do, not on the thing they will *not* do, or negative goals such as weight loss, or reducing blood glucose. So, when talking about reducing dietary fat/sugar, the key is to help individuals reframe this, into a positive, i.e. what they are going replace/swap or do instead. Helping people focus on something they *can* achieve (i.e. keeping a focus on R for Realistic) reduces this sense of deprivation.

It is also worth considering some of the behavioural lessons derived from 'mindless eating' [31]. This focuses on how our environment shapes our thoughts, feelings, and behaviour around food. For example, the same amount of food, presented on a smaller plate, is perceived to be a larger portion size, and reported as more satisfying, than the same amount on a larger plate [32]. A wealth of factors shape our eating without our awareness, but these same factors can improve our food choices, if we become aware, and use them to our advantage.

Exhausted

Self-managing diabetes is a '24/7' task—it never goes away, so the effort to effectively manage glucose, blood pressure, and cholesterol, is unrelenting and exhausting. Then there is the challenge of a lack of tangible reward. The best possible outcome from all the person's efforts is that nothing bad happens; they just grow older like someone without diabetes. This means there is no sense of progress, and nothing to re-energize the individual for the continuous effort required to change and maintain that change. Moreover, let's not forget that the individual is trying to maintain healthy behaviours in the context of an 'obesogenic' social and cultural environment [33], which have shaped the person's lifestyle, potentially contributing to their development of diabetes in the first place. Individuals with diabetes are also at increased risk of having a number of sleep problems (see Chapters 1.11, 'Endocrinology, Sleep, and Circadian Rhythms' and 15.11.2, 'Type 2 Diabetes and Psychiatry'), and diabetes itself is associated with feeling fatigued and tired.

Therefore, it is critical to create mechanisms whereby individuals can connect to progress with their diabetes management. This is where self-monitoring plays a major role. A powerful tool to deal with the emotional exhaustion of diabetes management is to support individuals to find creative and informative ways to visualize both the problems and their progress toward a solution, ensuring positive rewards for their efforts. While many studies of self-monitoring of blood glucose appear to show it to be ineffective and burdensome for people with type 2 diabetes who are not using insulin, behaviourally-informed trials have demonstrated that this structured biofeedback improves engagement in medication taking, confidence in self-care, well-being and glucose outcomes [34, 35].

Conclusion

Living with type 2 diabetes (and being the recipient of a biomedical model, rather than a biopsychosocial model, of care) often results in high levels of diabetes distress. Many feel Scared, Helpless, Alone, Deprived, and Exhausted. By providing people with their actual risk of diabetes complications, helping them focus on realistic actions that target their concerns, using constructive and supportive language, helping them use their environment for change, sleep better, and find creative ways to monitor their health and visualize what they have achieved, we can reduce distress and improve both the physical and emotional health of people with type 2 diabetes.

15.7.3 Type 2 Diabetes in Different Ethnic Groups

Nitin Narayan Gholap and Kamlesh Khunt

Introduction

The prevalence of type 2 diabetes mellitus (T2DM) and its associated complications varies significantly between populations, with non-white ethnic populations, indigenous groups, and developing countries bearing a disproportionately higher burden of the disease. High-quality studies examining various aspects of T2DM and its management among diverse non-white ethnic groups remain limited. Furthermore, ethnic disparities in health may vary between countries due to various factors. However, existing evidence has identified common themes across these groups as being key contributors to their greater burden of disease. In the increasingly globalized world, healthcare professionals, and policymakers need to understand ethnic disparities in relation to T2DM and their determinants to provide effective care.

Ethnicity and Health

An ethnic group can be defined as a group of people with shared ancestral, social, cultural, religious, lingual, ideological, *or* homeland background and biological features which are distinctive and maintained between generations. The study of ethnicity in health is important because it allows us to identify patterns of given diseases among people with shared ethnic characteristics, thereby helping us to assess health needs, formulate health policies, develop treatments, plan service delivery strategies, and identify areas for further research.

The Epidemiology of Type 2 Diabetes

Latest estimates from the International Diabetes Federation (IDF) suggest that there are currently 451 million (8.8%) adults aged 20–79 years with diabetes worldwide, compared with 151 million (4.6%) in the year 2000. This figure is expected to increase to 629 million (9.9%) by 2045 [1]. While not differentiating between types of diabetes, these estimates are very much representative of T2DM. However, there is a significant geographical and ethnic variation in prevalence, with the global burden of the disease rising much faster among non-white ethnic groups (see **Figure 15.7.3.1** and **Table 15.7.3.1**) [1–5]. This is reflected in the variation seen in the rates of diabetes across the seven IDF geographical regions (**Figure 15.7.3.1**) and among multiethnic populations in Western countries. The estimated age-adjusted prevalence of diabetes is over 12% in Mexico and some of the Middle East/North African countries, and 9–12% in India, China, and North America, which is higher than in Europe and Australia (**Figure 15.7.3.1**). It is further predicted that differences between the countries will become more pronounced in the future. Between 2017 and 2045, prevalence of diabetes is set to rise by 156% in sub-Saharan Africa, 110%

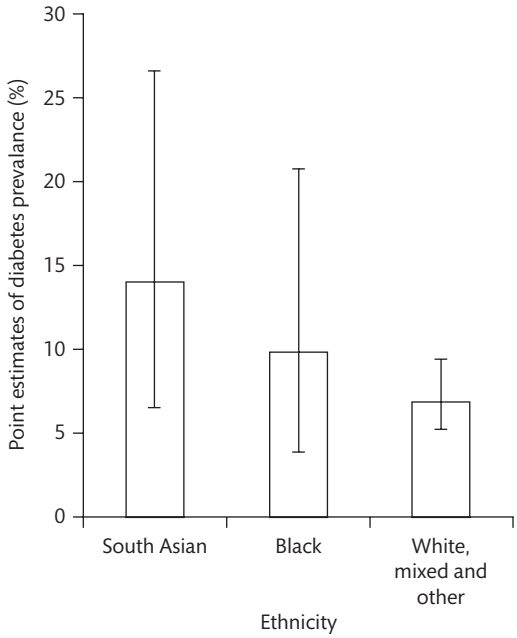

Figure 15.7.3.2 Summary estimates of diabetes prevalence by ethnicity for England in 2010. Error bars show the uncertainty range.

Adapted with permission from Holman N, Forouhi NG, Goyder E, *et al.* The Association of Public Health Observatories (APHO) diabetes prevalence model: estimates of total diabetes prevalence for England, 2010–2030. *Diabet Med* 2011;28:575–82; with data from Hanif W, Khunti K, Bellary S, *et al.* Type 2 diabetes in the UK South Asian population. An update from the South Asian Health Foundation; 2014. Available at: https://www.sahf.org.uk/publications.

in North Africa, and the Middle East, 84% in South East Asia and 62% in South and Central America compared with 16% in Europe (Figure 15.7.3.1).

The UK population comprises 13% of people from ethnic minority groups, with South Asian (people originating from India, Pakistan, Bangladesh, or Sri Lanka) and black African populations forming the two largest groups. The prevalence of diabetes (known and undiagnosed) in the South Asian population in England is 2–4 times higher than the general population, at 14.0% compared with 6.9% in the general population. The corresponding figure for the black African population is about 10% (Figure 15.7.3.2) [2]. Similarly, the incidence of T2DM is about three-times higher in first generation British South Asians (34%) and two-times higher in British black Africans (30%) compared with the native white (14%) population, as seen in the SABRE (Southall and Brent Revisited) study [3]. Higher incidence and prevalence of T2DM have also been reported among different ethnic minority groups in the United States [4], Canada, Australia, and European countries. Disproportionately high rates of T2DM are also seen in certain indigenous populations living in developed countries; for example, Pima Indians in the United States [5].

Among non-white ethnic groups, T2DM is more common in young and middle-aged individuals [5]. In a recent UK study, South Asian, and black African individuals developed T2DM at a mean age of 46 and 48 years respectively, with 31% and 23% developing it below the age of 40 [6]. In contrast, the mean age in white individuals was 58 years and only 9% developed T2DM below 40 years of age [6]. In recent years, there has also been an alarming rise in T2DM and obesity among children and adolescents from indigenous groups in the United States and Australia, and in black African, Hispanic, and Asian populations [7].

Table 15.7.3.2 Top 10 countries with highest number of people with undiagnosed diabetes in 2017

Rank	Country ranking 2017	Number of people with undiagnosed diabetes (millions), 2017	Proportion undiagnosed
1	China	61.3	53.6%
2	India	42.2	57.9%
3	United States	11.5	38.2%
4	Indonesia	7.6	73.7%
5	Brazil	5.7	46.0%
6	Pakistan	4.6	61.5%
7	Russia	4.5	53.7%
8	Mexico	4.5	37.4%
9	Egypt	4.4	53.1%
10	Bangladesh	3.9	56.0%

Adapted with permission from International Diabetes Federation. IDF diabetes atlas, 8th ed. International Diabetes Federation; 2017. Available at: http://www.diabetesatlas.org.

Diabetes remains undiagnosed in about 50% of the population globally; this proportion is much higher in low-to-middle income countries where the proportion of undiagnosed diabetes is 85% (Table 15.7.3.2) [1]. While this can be partly explained by inadequate resources and lack of diabetes screening programmes, undiagnosed diabetes remains high among South Asian and black African populations in countries with free access to care, such as the United Kingdom.

Pathogenesis and Risk Factors

The precise mechanisms behind the excess risk of T2DM in non-white populations remain unclear. However, it is indisputably driven by the heightened adverse impact of rapid economic development and urbanization, especially of physical inactivity, energy-rich diet and obesity, in the background of genetic predisposition [8–14]. Research has not yet identified distinct genetic variants that fully explain the excess risk, and genetic susceptibility accounts for less than 10% of total diabetes risk in any ethnic group [14, 15]. In contrast, epigenetic changes may be more pertinent to excess risk of T2DM in non-white groups as described next [16–19].

Development Origins of Health and Diseases (DOHaD)

The thrifty phenotype [18] and Development Origins of Health and Diseases (DOHaD) [16, 19] postulate that nutritional mismatch between periconception/intrauterine/infancy and adult life significantly increases risk of obesity and T2DM in later life, possibly through epigenetic changes. These epigenetic alterations are mitotically heritable changes in gene expression caused by distinct mechanisms of histone modification and DNA methylation, without involving changes in the DNA sequence *per se* [5, 17]. According to the thrifty phenotype hypothesis, maternal

malnutrition, and low birth weight lead to a programmed tendency towards nutritional thrift, impaired fetal pancreatic development, and beta-cell function, impaired peripheral glucose uptake and insulin resistance [18]. When such individuals undergo rapid weight gain during the postnatal period, especially due to abundance of food and physical inactivity, this can result in disturbances in glucose metabolism and adverse fat deposition [16, 18, 19]. A recent meta-analysis highlighted the inverse relationship between low birth weight and excess risk of T2DM and further found that each 1 kg gain in birth weight reduced the risk by 25% [20]. Apart from undernutrition, intrauterine overnutrition from maternal obesity, hyperglycaemia, or T2DM and resultant high birth weight is also associated with risk of T2DM in offspring at a younger age, mediated again possibly via epigenetic effect [21]. Such phenomena related to early-life nutritional status and intergenerational effect of hyperglycaemia are pertinent to the rapid emergence of T2DM in fast-developing countries, especially in South Asia, China, and the Middle East [1, 5, 22].

Obesity, Insulin Resistance, and Beta-Cell Dysfunction

Non-white ethnic groups tend to develop glucometabolic abnormalities at lower thresholds of obesity [6, 23]. In a study of 490 288 UK Biobank participants, for an equivalent prevalence of T2DM, body mass index—BMI (and waist circumference) was significantly lower in non-white participants (South Asian 22.0 kg/m^2; black African 26.0 kg/m^2; Chinese women 24.0 kg/m^2; Chinese men 26.0 kg/m^2) compared with white participants (30 kg/m^2) [23]. A possible explanation for this is that non-white populations, particularly Asians, have a high total body fat percentage ('thin-fat' phenotype) that is distributed mainly in the abdomen and ectopic areas of the liver and muscles, which could lead to insulin resistance at lower BMI [10, 22–25]. Such ethnic discrepancies have led to recommendations to use ethnic-specific cut-offs for defining obesity or metabolic syndrome. According to emerging evidence, early beta-cell impairment is also a major determinant of increased risk of T2DM in Asian groups [11–13]. This may reflect early beta-cell 'exhaustion' following years of insulin hypersecretion in response to higher degrees of insulin resistance, or reduced beta-cell mass/capacity/function as a consequence of adverse early-life factors or genetic predisposition [11–13].

Lifestyle Habits and Social and Cultural Determinants of Health

The rapid rise in obesity and T2DM in non-white ethnic groups is largely attributed to changes in lifestyle habits. There has been a major shift in nutrition towards consumption of diets rich in calories, sugar (including sweetened beverages), saturated fat and processed meat, and low in fibre and fruit and vegetables. In addition, multiple studies report significantly low levels of physical activity in non-white ethnic groups [9–12, 14]. Unawareness of the benefits of physical activity, lack of time and space, and, for women from Asia and the Middle East, cultural norms are major barriers to engaging in leisure-time exercise [9–11, 22, 24–26]. Additionally, health illiteracy, religious beliefs that attribute disease to being an inevitable 'destiny', and poor socioeconomic [27], educational, and psychological status all contribute to ethnic disparities in T2DM risk and its outcomes.

Mortality and Complications

High-risk ethnic populations and geographical regions are generally at a greater risk of developing associated adverse outcomes. In 2017, diabetes accounted for an estimated 10.7% of total mortality worldwide, with premature and higher mortality rates seen in South Asia, the Middle East, and North Africa, Central and South American regions [1]. In an analysis of pooled mortality data from different time periods from 1991 to 2007 in seven European countries, adjusted mortality rate ratios were about twofold higher in migrants from developing countries compared with the native population, with the highest mortality observed in people from the Caribbean and South Asia [28]. Likewise, in the United States, non-Hispanic black, native Americans and Alaskans, and Hispanic Americans have been found to be 2.1, 1.8, and 1.4 times respectively more likely to die from diabetes compared with non-Hispanic whites [14, 29].

Macrovascular Complications

The prevalence of cardiovascular disease (CVD) and associated mortality among people with T2DM is disproportionately high in developing countries such as India, China, and Russia [1]. Certain ethnic populations, particularly South Asians, suffer from excess overall CVD mortality, likely due to higher burden of insulin resistance, T2DM and related atherosclerotic risk factors [9, 10]. It is also possible that T2DM is more adversely associated with CVD risk in some non-white ethnic groups. In the SABRE study, during a median 20.5-year follow-up, diabetes was associated with a 3.0-fold and 2.5-fold increase in age-adjusted incidence of stroke in British black African and South Asian individuals respectively, compared with 1.3-fold excess risk in the native white group [30]. In the UKPDS (UK Prospective Diabetes Study), at the median 18-year follow-up, the adjusted relative risk was non-significantly high for stroke (1.18 (0.97–1.43)) in black African/Caribbean individuals and for myocardial infarction (1.11 (0.96–1.28)) in South Asian individuals compared with white individuals with T2DM [31]. In a recent retrospective case–control study, the risk of major cardiovascular events (MACE) among patients with T2DM compared with those without T2DM was significantly higher in overweight and obese South Asian patients in comparison with their white counterparts [32]. The risk of coronary heart disease in Chinese and black African individuals with T2DM is generally low compared with white individuals. Similarly, the relationship between ethnicity and peripheral artery disease in patients with T2DM shows rather mixed results, with a higher risk observed in black Africans and a lower risk in Asian populations.

Microvascular Complications

Individuals with T2DM of South Asian, African American, Middle Eastern, Hispanic, Polynesian and from indigenous populations are at a particularly high risk of developing chronic kidney disease (CKD) and its progression to end-stage renal disease (ESRD) [33]. In the UK and elsewhere, Asian and black African patients suffer from increased risk of albuminuria or proteinuria, rapid CKD progression, and higher incidence of stage 4 or 5 CKD [34]. Similarly, a recent systematic review reported a generally higher prevalence of diabetic retinopathy among ethnic minority groups, indigenous populations and developing countries [35]. In a cross-sectional analysis of the DRIVE UK (Diabetic Retinopathy in Various Ethnic

Groups) study, the age-standardized prevalence of any diabetic retinopathy, significant macular oedema and sight-threatening retinopathy was significantly higher in black African and South Asian compared with white patients [36]. The prevalence of diabetic peripheral neuropathy is generally similar among white, black African, and Hispanic populations but low in the Asian population.

Implications for Management of T2DM

Apart from possible genetic predisposition, much of the excess risk of adverse outcomes in non-white ethnic populations can be attributed to poorer diabetes management and control of conventional risk factors [37]. Individuals from non-white groups within and between countries are generally less likely to: adhere to medications and diabetes self-management; engage in physical activity; receive insulin therapy despite poor glycaemia control; and achieve treatment targets for HbA1c, blood pressure, and cholesterol [14, 37, 38]. The major barriers to effective diabetes care in these groups include issues with access and quality of care, lack of cultural adaptation to diabetes management, limited knowledge, and misconceptions about diabetes management including the role of preventative care, cultural health beliefs and behaviours and social determinants of health [14, 27, 37, 39]. In addition, the low participation of non-white ethnic groups in clinical trials has resulted in lack of knowledge on ethnic-specific treatment targets and efficacy of various pharmacological and non-pharmacological interventions. Nonetheless, the available evidence suggests that intensive control of risk factors as per the current targets derived predominantly from the white population are beneficial in non-white ethnic groups [31]. However, challenges remain in the delivery of care. To achieve desired clinical outcomes, a greater emphasis needs to be placed on a comprehensive diabetes management plan that combines pharmacotherapy with culturally adapted diabetes education and advice on self-management, regular exercise, and dietary changes [39, 40]. Additionally, in middle- and low-income countries, more emphasis is needed on developing and implementing national policies and programmes to raise awareness about T2DM and its complications, deliver screening, facilitate early diagnosis, develop prevention strategies for diabetes complications and, to improve organization of overall diabetes care [41]. Such strategies have been successful in significantly reducing rates of diabetes complications such as CVD and all-cause mortality in high-income countries [42]. In addition, wide-scale screening, early detection, and prevention of T2DM through national programmes are equally important in middle and low-income countries to reduce future burden of the disease and associated resources [42]. Any diabetes screening programme needs to use ethnic-specific strategies, for example, screening at a younger age, using lower BMI cut-points, and adopting a more aggressive and culturally adapted approach to diabetes prevention.

Summary

Non-white ethnic populations across the globe are facing an extremely worrying health, economic, and societal challenge from the rapidly growing burden of T2DM. Compared with white populations they have a 2–4-fold higher incidence and prevalence of T2DM. They also suffer from higher rates of certain diabetes-related complications. However, much of the excess burden of T2DM in non-white populations can be attributed to poor control of modifiable risk factors and suboptimum diabetes care. To improve the situation, a culturally adapted and innovative approach to the delivery of diabetes care is needed. This approach should focus on the proactive management of risk factors, address misconceptions about T2DM, and encourage lifestyle behaviour change. Further consideration should be given to early detection, control, and prevention of complications of T2DM and targeting high-risk individuals for prevention of T2DM.

15.7.4 Prevention of Type 2 Diabetes

Nicholas J. Wareham

Introduction

There is a growing body of literature which has unequivocally established that type 2 diabetes is preventable. This chapter reviews that evidence and then proceeds to consider how that evidence should be translated into preventive action. Since this textbook is focused on clinical management, the perspective that will be taken

is predominantly a clinical rather than a public health one. However it is impossible to thoroughly describe the topic of diabetes prevention without considering public health approaches and thus these are described here not least because clinicians are important advocates for this important complementary strategy.

Is Type 2 Diabetes Preventable by Behavioural Interventions and Weight Loss?

A series of randomized controlled trials (RCT) have shown than behavioural interventions aimed at dietary change, physical activity, and weight loss are effective in halving the risk of progression from impaired glucose tolerance to diabetes. The first major RCT was conducted in Da Qing in the North Eastern province of Heilongjiang in China. In this trial, 577 people who had impaired glucose tolerance (IGT) (2-hour plasma glucose 7.8—< 11.1 mmol/L) were cluster randomized to a diet intervention alone, physical activity alone, both interventions together or standard care [1]. The cumulative incidence of diabetes in the control group at 6 years was very high (67.7%) and in an analysis adjusting for baseline differences in body mass index (BMI) and fasting glucose, the diet intervention was associated with a 31% reduction in risk (P <0.03). In the physical activity only group, the risk reduction was 46% (P <0.0005) but there was no evidence of an additional effect of both interventions, as the risk reduction in the combined group was 42% (P <0.005).

The largest prevention trial was the U.S Diabetes Prevention Program (DPP) [2] which randomized 3234 middle-aged adults with IGT and fasting hyperglycaemia (fasting plasma glucose 5.3—<7.0 mmol/L). In addition to these two glucose-based parameters, participants were also selected to be high risk by virtue of other characteristics including age, obesity, and ethnic group. The mean BMI at baseline was 34 kg/m^2 and 45% of those randomized were of African, Hispanic, and Asian or American-Indian origin. Participants were originally randomized to four arms; an intensive lifestyle intervention, metformin (850 mg twice a day), troglitazone, or placebo. The troglitazone arm was discontinued in 1998 because of evidence of hepatotoxicity [3]. The intensive lifestyle intervention which was delivered by individual counselling sessions was focused on achieving a loss of 7% in body weight over 24 weeks through achieving 150 minutes per week of moderately intense physical activity and consumption of a low calorie, low fat diet. The incidence rate of diabetes, assessed by annual oral glucose tolerance tests and measurement of fasting plasma glucose at 6 monthly intervals, was reduced by 58% (95% confidence interval 48–66%) compared to the placebo group. The risk reduction in the metformin arm was less at 31% (95% CI 17–43%) and adherence to this treatment was high, with 72% of the participants in the metformin arm being compliant with therapy as defined by taking >80% of the prescribed medication.

At approximately the same time as the DPP, the Finnish Diabetes Prevention Study (DPS) reported the results of a randomized trial of intensive lifestyle intervention compared to placebo in middle-aged people (mean age 55 years) with IGT [4]. As with the DPP, participants in the DPS were largely overweight or obese (mean BMI 31 kg/m^2) and the intervention aimed to reduce body weight by at least 5% by reduction of consumption of fat, particularly saturated fat, increased consumption of fibre, and increased moderately intense physical activity to 30 minutes per day. As in the DPP, the DPS showed that the reduction in rate of progression to diabetes was 58% (95% confidence interval 30–70%). Subsequent similar intervention trials have demonstrated similar efficacy of lifestyle interventions in other populations including Japanese men with IGT [5] (n = 458) and Asian Indians with IGT [6] (n = 531). In a recent Cochrane systematic review, Hemmingsen *et al.* [7] meta-analysed these trials with a further seven studies [8–14] and reported a summary relative risk of progression to diabetes of 0.57 (95% CI 0.50–0.64).

Are the Benefits of Lifestyle Intervention the Same in All People at Risk?

The question of differential response to preventive interventions can only realistically be addressed in the DPP since only a large study has the power to examine heterogeneity between subgroups. In that study, there were no significant differences in relative risk reduction between subgroups defined on the basis of age, sex, and ethnicity, baseline level of obesity, or fasting glucose. A significantly larger relative risk reduction was, however, observed in those with lower levels of 2-hour glucose. While differences between subgroups in relative risk are interesting from an aetiological perspective, it is differences in absolute risk that matter from a clinical perspective. In general high-risk prevention approaches have their biggest impact when targeted on people at high absolute risk, because in those individuals, for a given relative risk reduction, the absolute risk reduction is greatest. The inverse of the absolute risk reduction is the number needed to treat, which is the parameter that makes sense to individual people who are offered a preventive intervention since it addresses the question 'How many people like me would need to have this intervention for one person to avoid getting diabetes over a particular time period?'. Thus logically, the individual interventions that have been shown to be efficacious in clinical trials ought to be first offered to people who have the highest absolute risk of developing type 2 diabetes. Whether they are offered to a wider set of people at moderate risk is an affordability question. However, the total number of people at moderate risk is considerably greater than those at high risk, since risk is roughly normally distributed, and since those people stand to gain less from a preventive intervention than those at high risk, it is very easy for a prevention programme to become overwhelmed by people who are not those who stand to benefit most. This is one of the challenges of translating trial results in diabetes prevention into real-world programmes.

Do the Benefits of Behavioural Interventions Persist Once the Active Intervention is Discontinued?

Several lifestyle diabetes prevention trials have examined the impact of interventions over the longer term and critically beyond the duration of the active phase of supported behaviour change. In the DPS the hazard ratio in the intervention group compared to placebo during a 9-year post-trial follow-up period was 0.67

(95% CI 0.48–0.95), suggesting that the benefits of lifestyle intervention persist beyond the point at which people were being provided with active lifestyle change interventions [15]. A similar follow-up in the Da Qing study also suggested persistence of the impact on lifestyle intervention with those in a combined lifestyle intervention groups having a 43% lower incidence over 20 years of follow-up [16]. In the follow-up study to the DPP [17], the intervention groups became more similar after the active period of the trial was ended and became unblinded, with the reduction in risk in the lifestyle intervention group compared to the original placebo group in the 10 years since randomization being 34% (95% CI 24–42%). Together these data suggest that there are persistent benefits of lifestyle intervention that go beyond the period of active intervention.

Are There Long-Term Health Benefits of Diabetes Prevention?

Although these landmark trials have shown that behavioural interventions and weight loss reduce progression to diabetes, it has proven very difficult to show that by reducing diabetes incidence there are long-term health benefits, since the trials are underpowered to examine these effects. The Da Qing study showed a 47% reduction in risk of severe retinopathy in the intervention group compared to control but no significant differences in risk of nephropathy or neuropathy [18]. In the DPP after 15 years of follow-up, there was no significant difference in risk of an aggregate microvascular outcome between treatment groups [19]. The only trial that has reported the impact on cardiovascular outcomes is the Da Qing trial which reported a relative risk for cardiovascular disease mortality of 0.59 (95% CI 0.36–0.96) in the intervention group over 23 years of follow-up [20]. From a patient perspective, it may be important not only to consider these long-term outcomes, but also the impact of diabetes preventive interventions on the more immediate outcome of quality of life. In the DPP, the lifestyle intervention improved patients' perception of the functional capability and quality of life compared to placebo, whereas there was no difference between these outcomes for the metformin and placebo groups [21].

Is Type 2 Diabetes Preventable by Pharmacological Intervention?

Beyond metformin, which was reported in the DPP, a whole series of trials have examined the effect of pharmacological therapy on diabetes prevention. Given that diabetes is defined by glucose levels, it is self-evident and effectively tautological to suggest that prescribing glucose lowering therapies to people with pre-diabetes should reduce progression to diabetes. Indeed, the level of relative risk reduction can be predicted by the degree of glucose reduction that an agent causes [22]. Thus thiazolidinediones including troglitazone (before it was withdrawn) [3], pioglitazone [23], rosiglitazone alone [24], or in combination with metformin [25], α-glucosidase inhibitors (acarbose [26, 27] and voglibose [28]), glucagon-like peptide-1 analogues (liraglutide [29]), and insulin secretagogues (Nateglinide [30]) have all been shown to reduce risk of progression to diabetes from IGT. Whether reduction of progression from IGT to diabetes is sufficient evidence to justify pharmacological intervention in people who don't consider themselves to be ill and who often have not even sought help, but may have been offered it as a consequence of being screened, is debatable. Unlike lifestyle intervention, the benefits for pharmacological diabetes prevention don't persist beyond the duration of active treatment, nor do patients being treated pharmacologically feel better or have better functional capability. The evaluation of the benefits of pharmacological diabetes prevention on hard clinical outcomes is the ultimate test of clinical utility of this approach but is a high level of evidence to aspire to and will inevitably require large and long-term clinical trials. In the absence of such evidence, it may be logical to restrict use of glucose lowering treatments in people without diabetes to population groups who have tried lifestyle interventions but without success. This stepwise approach using metformin, for example, has been shown to reduce diabetes incidence by a third in the D-CLIP trial [31].

Translating the Results of Trials into Real-World Interventions

As this chapter has summarized, the trial evidence underpinning individual-level diabetes prevention is extremely strong, showing that interventions are efficacious when assessed under the ideal circumstances of a randomized controlled trial. However, a major question is whether those interventions are as effective when used under the less ideal situations that prevail in the real world. An analysis by Ali and colleagues of 28 studies of real-world interventions in the United States suggested that these interventions achieved an average weight loss at 12 months of 4% of their baseline weight [32]. Since the DPP had established that weight loss was the most important determinant of reduction of diabetes incidence, with that incidence being reduced by 16% for every kilogramme of weight lost, this magnitude of average weight loss is not inconsiderable. Alongside the challenge of average effect size, is the issue of retention. In the MOVE-IT trial, a lifestyle intervention programme was effective in the group of individuals who completed the programme in an intense and sustained manner, but these participants represented less than 1% of the population for whom the intervention was designed [33], creating a massive gap between efficacy and effectiveness [34]. Many agencies in developed and developing countries are working to design programmes that can combine reach, effectiveness, and affordability since an additional challenge of the DPP approach was that it cost $1399 per participant in the first year of intervention. Cheap and scalable interventions may be possible but as yet, there is limited evidence of effectiveness of any programmes [35, 36]. Since the real clinical benefits of a preventive intervention lie not in the relative risk but in the absolute risk reduction, it may be preferable to focus such individual-level approaches to prevention on subgroups of the population who are at demonstrably high absolute risk because for those participants it is possible to get a large absolute risk reduction and a relatively low number needed to treat, the inverse of the absolute risk reduction.

Finding Complementary Strategies for Diabetes Prevention

Striving to deal with the problem of diabetes prevention only through an individual-level strategy is unlikely to result in a major impact on population-level diabetes incidence even though it could be of benefit to participants who are compliant and engaged. Thus an integrated diabetes prevention strategy also needs to take a whole population approach and to reflect the need to deal with the public health problem of type 2 diabetes through public health means. There is no single population-level intervention that is likely to have a major impact by itself on diabetes risk, nor is there likely to be strong evidence of effectiveness before policy action is implemented. Thus multiple policy level interventions have to be encouraged on the basis of observational evidence and modelled long-term health impact, with the effectiveness of approaches evaluated after the event through quasi-experimental approaches. This is the basis, for example, of the evidence that has driven the implementation of sugar-sweetened beverage taxes in multiple countries [37–39]. It is not within the remit of a medical textbook to provide a full discussion of the full range of public health interventions, but perhaps the critical thing for clinicians to appreciate is that the population-level approaches are a complement to more clinical approaches to prevention rather than alternative, that no single intervention is ever likely to have a large effect alone, but that considerable impact can be accumulated by intervening in multiple ways, and above all that the evidence base that underpins such interventions in inevitably different to that that is possible for individual-level interventions.

Emerging Approaches to Restoring Euglycaemia in Diabetes

15.8.1 Regenerative Medicine for Diabetes

Michael G. White, Cara E. Ellis, and Timothy J. Kieffer

Introduction

Both type 1 (T1D) and type 2 (T2D) diabetes are characterized by insulin insufficiency and ultimately beta-cell loss. While T2D is multifactorial, T1D principally results from the selective loss of beta-cells involving autoimmune processes and requiring lifelong insulin replacement therapy to prevent clinical complications including ketoacidosis. Despite substantial improvements in insulin delivery systems and glucose monitoring, insulin therapy remains inadequate to maintain euglycaemia. Moreover, while intensive insulin therapy decreases average glycaemia and thereby reduces long-term complications of T1D, exogenous insulin delivery can also result in episodes of severe hypoglycaemia [1]. Therefore, there is an unmet need for better approaches to insulin replacement.

Beta-cell replacement through islet transplantation can provide restoration of more physiological glycaemic control, almost entirely preventing significant hypoglycaemia [2]. While islet transplantation offers unquestionably superior glycaemic control compared to insulin therapy, widespread implementation is severely limited by the availability of donor tissue. This has fuelled efforts to develop alternative beta-cell replenishment strategies including: (1) derivation of beta-cells from human embryonic stem cells (ESCs)/induced pluripotent stem cells (iPSCs); and (2) induction of endogenous beta-cell regeneration. Since both T1D and T2D are associated with beta-cell mass deficits, these therapeutic strategies could be effective for both forms of the disease.

Generating Beta-Cells from Pluripotent Stem Cells

ESCs and iPSCs are attractive sources of unlimited numbers of beta-cells to treat diabetes because they can self-renew indefinitely and differentiate into all cell types. To coax stem cells to beta-cells, differentiation protocols typically aim to mimic normal developmental processes, with the added challenge of using protocols that can be adapted for industrial scale. The pluripotency of stem cells makes it extremely challenging to achieve homogenous differentiation and undifferentiated cells can form teratomas. Several strategies are being explored to enhance the safety of potential stem-cell products, including cell containment devices and genetic modifications.

Beta-Cells from Embryonic Stem Cells

Building upon knowledge of pancreatic development in animal models and humans, protocols have been developed to differentiate human ESCs to pancreatic endoderm cells [3]. Efforts have focused on the production of cells expressing the key marker proteins PDX1 and NKX6.1, transcription factors that in combination specify pancreatic progenitor cells. Notably, cells at this stage are sufficiently committed to the pancreatic lineage and are fully capable of finishing differentiation and maturation post-implant to produce mixed populations of islet endocrine cells that can regulate glycaemia in rodents [3, 4]. Clinical trials implanting human ESC-derived pancreatic progenitor cells are now underway to assess safety and efficacy in patients with T1D (ClinicalTrials.gov Identifiers: NCT02239354, NCT03163511). Cell differentiation protocols continue to be refined and extended towards preimplant generation of mature beta-cells [5–8]. While not yet fully optimized, such cells can more rapidly reverse diabetes following implantation in mice compared to progenitor cells [5, 6].

Beta-Cells from Induced Pluripotent Stem Cells

The development of technologies to produce iPSCs through reprogramming of patient-derived cells such as fibroblasts [9] offers an alternative pluripotent cell type that addresses some of the ethical concerns related to the destruction of an embryo to generate

ESCs. Directed differentiation of iPSCs towards islet endocrine cells is being pursued using similar approaches as with ESCs [5, 6] but with additional challenges due to variability (including epigenetic) in the donor cells [10] and the need for protocol optimization for individual lines. Also, iPSCs may carry increased risk of teratoma formation compared to ESCs due to the chance of the reprogrammed donor cells acquiring a pro-oncogenic mutation that could be selected for during culture. However, earlier fears that the reprogramming process itself may introduce mutations appear to be unfounded [11]. Patient-derived cells would theoretically not be recognized as foreign by the immune system, but in T1D there is still beta-cell targeted autoimmunity to deal with, and generation of personalized tissues for millions of people with T1D will be prohibitively expensive for the foreseeable future. Alternatives to both ESCs and iPSC sources include creating HLA-matched banks from a subset of donors or creating universal donor cells through genetic editing [12]. A genetic 'safety switch' could also be added, allowing drug-mediated destruction of the implanted cells should the need arise, including in the case of off-target differentiation or teratoma formation.

Graft Encapsulation

Another challenge for the therapeutic application of stem-cell derived beta-cells is a safe and functional implant site. Graft retrievability and immune protection have been the goal stem cell-derived product development and thus clinical trials have not yet been conducted whereby differentiated stem cells are infused into the liver to mimic islet transplant using the Edmonton protocol. PEC-Encap™ is under development by ViaCyte [13, 14] and a phase I/IIa clinical trial began in 2014 (NCT02239354). This and other macroencapsulation devices are designed to contain the cells and physically prevent immune rejection while allowing nutrient exchange and insulin delivery via diffusion. However, results from other macroencapsulation devices implanted in humans suggest that a foreign body response to implanted devices contributing to lack of graft oxygenation may preclude optimal graft function [15]. As a substantial subset of patients with T1D are already on immunosuppression for other transplanted organs, use of a fully immunoprotective barrier may not always be necessary. ViaCyte is now testing PEC-Direct™, a device with holes that are designed to permit direct graft vascularization. A new multicentre phase I/IIa clinical trial began in 2017 (NCT03163511) that will offer important insights for the future direction of encapsulation technology.

An alternative to centimetre-scale immunoprotective devices is to encapsulate cell clusters, producing micrometre-to-millimetre-scale spheres which prevent physical interactions between the recipient immune system and the implanted cells. Moderately promising results from clinical trials (for example [16]) and advances in alginate formulas [17], the most common microencapsulation material, suggest that this technology could be a potential alternative to immunosuppression, although challenges with this approach include retrievability, achieving effective nutrient exchange, implant site, and foreign body responses.

Remaining Challenges for Stem Cell-Derived Beta-Cells

Regardless of the stem cell source, safety, and efficacy of the implanted cells are vital. Having completed maturation, whether before or after implantation, these cells must sense glucose and not only increase insulin secretion when blood glucose levels rise to minimize hyperglycaemia, but rapidly decrease insulin secretion when blood glucose levels drop to prevent hypoglycaemia. Challenges relating to immunosuppression or immune protection have not been completely solved, although many patients would exchange the heavy burden of multiple daily insulin injections for the side effects of immunosuppression if restoration of normal glucose homeostasis could be achieved. Recent encouraging progress suggests that these challenges, though difficult, are not insurmountable, and stem cell-derived beta-cells may be a functional cure for diabetes in the future.

Expanding Endogenous Beta-Cell Mass

Physiological Mechanisms Regulating Beta-Cell Mass

During embryogenesis beta-cells are formed from a population of pancreatic progenitor cells. While beta-cell mass in adults is determined, at least partially, by the size of this progenitor pool [18], it is also heavily influenced by the rapid beta-cell replication that occurs during infancy [19]. Physiological turnover of β-cells in both adult rodents and humans is comparatively slow; however, during pregnancy [20, 21] and excessive weight gain [22, 23], beta-cell mass expands to compensate for the increased metabolic demand. While the mechanisms governing such compensatory responses remain relatively poorly understood, and indeed may differ considerably between species, new beta-cell formation is thought to occur through both beta-cell replication [24] and differentiation from non-beta-cell sources—a process termed neogenesis [25, 26]. It may be possible to target replication and/or neogenesis to restore beta-cell mass and function in patients with diabetes.

Replication of Beta-Cells

Experiments using approaches that label beta-cells and their descendants provided compelling evidence for replication of pre-existing beta-cells as the major source of new beta-cells during adulthood in rodents [24, 27]. During pregnancy in rodents, beta-cell replication has been described as the main compensatory mechanism, predominately mediated by a prolactin-dependent inhibition of the tumour and replication suppressor, menin [20]. Similarly, increases in beta-cell mass observed in obese mice have been attributed to beta-cell replication [22]. Human beta-cells may have less capacity to replicate. While it has been shown that replication-mediated human beta-cell expansion occurs during infancy [19], there is a significant decline in this capacity with no evidence of beta-cell replication in donors aged over 30 [28], perhaps as a result of age-related increase in expression of p16INK4a, an inhibitor of cell–cycle associated activators, including cyclin D3 [29]. While increases in human beta-cell numbers during pregnancy have been reported, there was no evidence for these resulting from beta-cell replication [21]. Rather, increased numbers of small islets and duct associated insulin-positive cells suggest neogenesis as a major source of new β-cells [21], but this conclusion relies on circumstantial evidence from observations in autopsy material. Although it is increasingly clear that adaptive β-cell responses differ between species, evidence for beta-cell replication following human islet transplants into mice supports the hypothesis that human beta-cells have

the capacity, albeit perhaps limited, for proliferation [30, 31], and thus strategies to exploit this potential should be explored.

Inducing Beta-Cell Replication

While seeming an obvious therapeutic approach, inducing human beta-cell replication has proved difficult. Loss- or gain-of-function studies in rodents have yielded critical insights into the importance of cell–cycle molecules, particularly the D cyclins, which act predominantly at the G1/S transition [32]. However, species differences in the expression and localization of these proteins have hindered potential translation to humans [33], and there is evidence of potential beta-cell apoptosis following forced entry into the cell cycle [34]. However, high-throughput screens have identified small molecules that induce human beta-cell proliferation, including harmine [35], 5-iodotubercidin [36], and a series of aminopyrazines [37], all of which target a common pathway affecting DYRK1a and NFAT activity. Further, exendin-4, a clinically used GLP-1 receptor agonist, induced proliferation of juvenile human beta-cells [30]. While these studies demonstrate the feasibility of inducing beta-cell replication, the clinical utility of such compounds will require development of methods to ensure beta-cell specificity, particularly given the potential health implications of unchecked cell proliferation.

Beta-Cell Neogenesis/Transdifferentiation

Despite all pancreatic cell types arising from a common progenitor, evidence for a true adult pancreatic stem cell remains unconvincing, and the existence of facultative progenitors after birth continues to be debated. It is increasingly accepted, however, that pancreatic cells can display significant plasticity. Pancreatic cell types can switch phenotype, either directly (transdifferentiation) [26] or indirectly via a dedifferentiated intermediate [38]. Understanding of these events has been gained through rodent models of pancreatic regeneration including partial pancreatectomy [38], partial duct ligation [39], and targeted β-cell ablation [26]. Lineage tracing within these models reveals endocrine cell neogenesis, demonstrating several potential sources of new beta-cells, including pancreatic ducts and non-beta-cell endocrine cells.

Duct-Derived Neogenesis

Responsible for channelling digestive enzymes to the duodenum, the pancreatic ductal epithelium has long been proposed to harbour a post-natal progenitor cell population for islet cells, with several reports detailing observations of duct-mediated beta-cell neogenesis in response to pancreatic injury. Specifically, lineage tracing of ductal cells and their derivatives demonstrated that ductal cells can give rise to both new islet and acinar cells following partial duct ligation [40]. Characterization of rodent pancreas following 90% pancreatectomy identified several stages to this process, including initial ductal cell dedifferentiation and rapid proliferation, followed by activation of the endocrine progenitor marker neurogenin-3 (Ngn3) and subsequent formation of new beta-cells [38]. The gut hormone gastrin can enhance this series of neogenesis events and increase beta-cell numbers in a pancreatectomy model [41]. Lineage tracing following partial duct ligation also demonstrated the contribution of Ngn3-positive ductal cells to new beta-cell formation [39]. Recently it was reported that subpopulations of cells within the duct differ in their ability to differentiate towards endocrine cells [42], which may explain conflicting reports that refute duct-mediated beta-cell neogenesis in the adult [43, 44]. Analyses of human autopsy samples have provided circumstantial evidence for progenitor cells in the ductal regions, most notably a CD133-positive population [45]. Although this cell population has demonstrated some β-cell differentiation potential *in vitro* [46], overall the existence of such events in humans remains poorly understood and additional research is needed to better understand the translational potential.

Endocrine Cell Transdifferentiation

Forming functional micro-organs within the pancreas, islets consist of four main cell types: beta-cells (insulin), alpha-cells (glucagon), delta-cells (somatostatin), and PP cells (pancreatic polypeptide). While characterized by discrete gene expression profiles at full maturity, each of these endocrine cell types is derived from a common Ngn3-positive progenitor population. Diabetes reversal can occur in rodents following near total beta-cell ablation, mediated by alpha-to-beta-cell transdifferentiation [26]. This specific conversion appears to be age restricted, with recovery of diabetes in young mice (before puberty) resulting from delta-to-beta-cell conversion, without a contribution from alpha cells. The potential occurrence of similar plasticity events in human T1D has been described [47]. Further, it was demonstrated that transdifferentiation was dependent on activation of the G-protein coupled receptor, PAR2, and could be induced by the agonist 2-furoyl-LIGRLO-amide trifluoroacetate salt (2fLI) in both rodent models [48] and human islets [49]. However, there have yet been no lineage tracing studies to define cell transitions in human islets, and the continual autoimmunity associated with T1D must be considered. Despite these caveats, further work in this area may eventually allow the therapeutic induction of new beta-cells harnessing islet endocrine cell transdifferentiation potential.

Interplay Between Islet- and Duct-Cell Plasticity in Beta-Cell Neogenesis

Alpha-to-beta-cell conversion can be induced through genetic manipulation of key transcription factors. Ectopic expression of Pax4 and inhibition of Arx in alpha cells leads to their conversion to functional, neo-generated beta-cells that are capable of rescuing streptozotocin-induced diabetes in mice [50, 51]. Lineage tracing studies revealed activation of Ngn3-positive cells in the pancreatic ducts, which give rise to new α-cells and subsequently beta-cells following α-cell transdifferentiation [50, 51]. These studies may reconcile observations from the varying animal models of beta-cell regeneration, demonstrating a role for ductal and islet cell plasticity in beta-cell neogenesis in rodents. A study by the same group identified the neurotransmitter GABA as an inducer of the same series of events that lead to beta-cell replacement following Pax4 and Arx manipulation, including in human islets both *in vitro* and following transplantation into rodents [52]. In a parallel study, the antimalarial drug, artemisinin, was reported to induce alpha-to-beta-cell conversion in islets from multiple species through $GABA_A$ receptor signalling [53]. However, recent reports contest the impact of GABA and artemisinin on alpha-cell mediated beta-cell neogenesis [54, 55]. More investigation will be required to elucidate and potentially harness the putative plasticity of human islet cells.

Conclusions

Transforming lives of many patients with T1D, the success of islet transplantation has paved the way for development of novel cellular therapies for diabetes. Although in its infancy, substantial advancements have been made in our understanding and application of beta-cell replacement strategies, particularly in the generation and implant of differentiated hESCs. While significant challenges remain, including the development of technology to protect implanted cells from immune attack, emerging and ongoing clinical trials highlight the potential. Although a renewable source of *ex vivo* generated beta-cells is highly attractive, the ultimate regenerative goal in diabetes is to stimulate beta-cell formation *in situ*. The finding that the major pancreatic cell types appear to display a degree of plasticity which may be harnessed to generate new beta-cells has been met with considerable excitement. However, despite encouraging data, the existence of beta-cell proliferation and neogenesis/transdifferentiation in humans remains unclear, and thus whether strategies to enhance them are therapeutically relevant is unknown. Despite this, animal models have facilitated the identification of FDA-approved molecules that may target these potential regenerative pathways. This has led to an increasing number of clinical trials involving patients with T1D, from which the results are eagerly anticipated.

15.8.2 "Closed Loop" Insulin Delivery

Roman Hovorka and Charlotte Boughton

Introduction

Following the Diabetes Control and Complications Trial, focus on intensive insulin therapy has led to increased uptake of insulin pump therapy (continuous subcutaneous insulin infusion, CSII) as it is recognized that CSII delivery can achieve improved glucose control, reduce the risk of hypoglycaemia and improve quality of life in people with T1D (see Chapter 15.5.3, 'Insulins and Insulin Delivery Devices') [1].

Advances in diabetes technology have led to the development of continuous glucose monitoring (CGM) systems which measure real-time interstitial glucose concentration (see Chapter 15.5.2, 'Glucose Monitoring and Sensing'). There has been steady improvement in the reliability and accuracy of CGM systems with the best having an accuracy of below 10% mean absolute relative difference [2]. There remains a known issue with lag between blood and interstitial

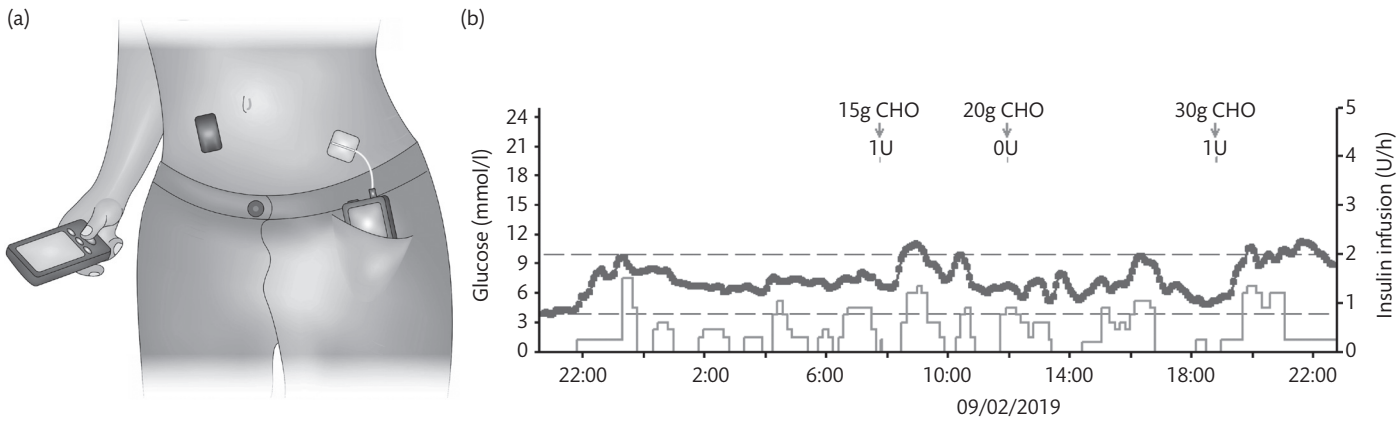

Figure 15.8.2.1 (a) A sensor (black rectangle) transmits information about interstitial glucose levels to a mobile-phone-sized controller (red box located in the hand), which runs a control algorithm and interacts with the user. An insulin pump (blue box) delivers a rapid-acting insulin analogue subcutaneously. Insulin delivery is modulated in real-time by the control algorithm. The communication among system components is wireless. (b) Glucose levels and insulin delivery profiles during a hybrid single-hormone closed-loop study. The bold red line shows the continuous subcutaneous glucose trace. Control algorithm-directed insulin infusion rates during closed-loop are denoted by the thick blue line. Vertical arrows indicate meals and snacks (orange arrows) and blue vertical lines illustrate insulin boluses administered by the user at mealtimes. Horizontal dashed red lines indicate the target glucose range. *For a colour version of this figure, please see colour plate section.*

glucose levels; however, use of CGM is associated with improvements in glucose control and reductions in hypoglycaemia [3].

Insulin pumps can be used in conjunction with real-time CGM, allowing users to manually modify the insulin infusion rate according to CGM values (sensor augmented pump therapy, SAP). Introduction of a low glucose suspend (LGS) feature allowed for automatic insulin infusion suspension when a pre-programmed CGM threshold value is reached or when sensor glucose is predicted to cross the pre-programmed CGM threshold value (predictive LGS). These features are effective in reducing the frequency and duration of hypoglycaemia [3].

Closed-loop insulin delivery (the artificial pancreas) is more sophisticated and combines insulin pump and CGM with *a control algorithm* to deliver insulin in a glucose-responsive manner (single-hormone closed-loop system) by automatically adjusting the insulin infusion rate based on sensor glucose levels. Glucagon or other hormones can also be delivered in a similar glucose-responsive fashion within dual-hormone closed-loop systems. The control algorithm may be embedded in the pump or reside in a separate device (e.g. a smartphone (Figure 15.8.2.1) and these components communicate wirelessly).

Closed-Loop Algorithms

The key component of a closed-loop system is the control algorithm, which directs insulin delivery according to real-time sensor glucose levels while accounting for inter- and intrasubject variability, inherent sensor, and insulin delivery errors as well as kinetic delays. Various algorithms have been developed with the most commonly used being the model-predictive control approach, the proportional–integral–derivative control, and fuzzy logic [4].

Model-predictive control (MPC) algorithms employ an individualized mathematical model of glucose regulation to predict glucose excursions based on input such as subcutaneous insulin. Insulin delivery is calculated by minimizing the difference between model-predicted glucose-concentrations and the target glucose levels over a pre-specified prediction time horizon.

Proportional–integral–derivative (PID) control algorithms continuously adjust the insulin infusion rate by assessing glucose excursions from three perspectives, the deviation from the target glucose (proportional component), the area-under-the-curve between the measured and target glucose level (integral component), and the rate of change in the measured glucose levels (derivative component).

The fuzzy logic control approach modulates insulin delivery on the basis of approximate rules to express the empirical knowledge of diabetes practitioners.

Meta-analysis data suggests that PID algorithms may be associated with less time in target compared with MPC and fuzzy logic algorithms, although the analysis of subgroup differences was not significant [5]. Direct comparison of the performance of comparable PID and MPC algorithms in a cross-over study support this finding [6].

Most control algorithms include additional safety modules to constrain insulin delivery, limiting the amount of insulin on board or the maximum rate of insulin delivery, or suspending insulin delivery when glucose levels are low or decreasing rapidly.

User specific parameters (body weight, insulin requirements) are usually required for initialization. Adaptation of the algorithm to changes in physiological parameters with real-time adjustment of closed-loop control parameters is essential for optimal performance.

Types of Closed-Loop Systems

Hybrid and Fully Closed-Loop Systems

Hybrid closed-loop systems require meal announcements while fully closed-loop systems are entirely automated offering the

advantage of reduced user intervention. There have been relatively few, small in-patient studies of fully automated closed-loop systems in people with T1D. Postprandial hyperglycaemic excursions and late postprandial hypoglycaemia are significant challenges with this approach and glucose control is significantly compromised compared to hybrid closed-loop at present. Ultra-rapid insulin analogues are needed to enable safe and efficacious fully closed-loop systems.

Single and Dual-Hormone Closed-Loop Systems

Impaired glucagon response to hypoglycaemia is characteristic of T1D. Addition of glucagon to closed-loop systems (dual-hormone) is an attractive option to counteract the relatively long duration of action of subcutaneous insulin but also increases system complexity and cost. The potential role of glucagon is further reduction in the risk of hypoglycaemia while optimizing insulin delivery, or to compensate with higher glucagon doses, buffering 'aggressive' insulin delivery.

Addition of glucagon to closed-loop systems is currently limited by the instability of available glucagon formulations at room temperature. These require reconstitution prior to use and exchange of the glucagon depot every 24 hours. Novel glucagon analogues are under development but the full pharmacokinetic and safety profile is to be established. Long-term low-dose glucagon administration has the potential for pleiotropic effects and long-term follow-up safety studies are necessary. The main side-effects of high-dose rescue glucagon include nausea, vomiting, and headaches, but adverse effects of smaller doses of glucagon used in trials of dual-hormone systems were limited to mild gastrointestinal symptoms [7].

Adjuncts

One of the main challenges with closed-loop insulin delivery is postprandial glucose control. Studies have demonstrated short-term efficacy of adjuncts such as synthetic amylin (pramlintide), glucagon-like peptide-1 agonists, and dipeptidyl peptidase-4 inhibitors in combination with closed-loop insulin delivery to reduce postprandial hyperglycaemia, although long-term benefits have not been evaluated.

Clinical Evidence of Closed-Loop Systems

Clinical studies have progressed from those undertaken in highly supervised clinical research facilities to studies lasting several months in unsupervised, free-living conditions. Clinical studies have shown that hybrid closed-loop systems, as compared with CSII or SAP, improve glycaemic control and reduce hypoglycaemia. Closed-loop insulin delivery has demonstrated efficacy and safety in children, adolescents, adults, and pregnant women with T1D and in hospitalized patients with hyperglycaemia.

Closed-Loop in Adults and Children with Type 1 Diabetes

Two recent meta-analyses have evaluated the efficacy and safety of closed-loop therapy in non-pregnant outpatients with type 1 diabetes [5, 8]. The larger of these included 41 studies (1042 participants).

Time in Range

Meta-analysis data from 32 studies has shown that closed-loop systems increase time spent in near normoglycaemia (3.9–10.0 mmol/L) throughout 24 hours by 9.6% compared with controls (140 additional minutes/24 h period). The beneficial effect of closed-loop systems is more evident on the percentage of time spent in near normoglycaemia overnight, which is 15% greater than controls [8]. Increased time in range with closed-loop systems is due to reduced time in hyperglycaemia (>10 mmol/L) compared to controls.

While dual-hormone systems have been associated with a greater improvement in time in target range compared with single-hormone systems, almost all dual-hormone system studies have been relatively short and have been compared to pump therapy alone, whereas almost all single-hormone systems have used SAP as a comparator. Studies directly comparing single- and dual-hormone closed-loop systems have been under supervised conditions and of short duration but observed no difference in the time spent in target glucose range over 24 hours [9].

Hypoglycaemia

Closed-loop systems reduce time spent in hypoglycaemia (<3.9 mmol/L) by 1.5% (approximately 20 minutes/24 h period) compared to control [8]. The incidence of severe hypoglycaemia is very low in clinical studies comparing closed-loop with control so there is insufficient evidence to determine any benefit of closed-loop insulin delivery on severe hypoglycaemia. However, use of closed-loop systems was associated with a decrease in low blood glucose index overnight compared to controls, a measure of the risk of severe hypoglycaemia.

Clinical studies contrasting dual-hormone with single-hormone systems report less time spent in hypoglycaemia and fewer hypoglycaemic events with dual-hormone systems [7]. The reduction in hypoglycaemia was observed with comparable mean glucose levels.

Mean Glucose and HbA1c

Compared to control, use of closed-loop systems has a favourable effect on the mean sensor glucose level over 24h, which is reduced by 0.48 mmol/L in meta-analysis data [8]. These findings are consistent with a reduction in HbA1c of 0.26% observed with closed-loop systems compared with control in studies with a duration per intervention of more than eight weeks.

Glycaemic Variability

In almost all closed-loop studies, glucose variability, measured as the standard deviation and coefficient of variation of the sensor glucose level between days, is lower with closed-loop systems than with controls [10].

Insulin Requirements

Individual studies have conflicting results with respect to the effect of closed-loop systems on daily insulin dose. Meta-analysis data suggests there is no difference between closed-loop and control systems in the mean daily insulin requirement [5, 8].

Closed Loop in Pregnancy

Closed-loop insulin delivery has been shown to be safe and effective in women with T1D during pregnancy. In a randomized, cross-over

study in pregnant women with T1D, overnight closed-loop therapy for 4 weeks resulted in increased time in target range (3.5–7.8 mmol/L) by 15.2 percentage points (74.7% vs. 59.5%) compared to SAP therapy [11]. There was no difference between closed-loop and SAP therapy in the percentage of time in hypoglycaemia. During the continuation phase (up to 14.6 additional weeks including antenatal hospitalizations, labour, and delivery), of day-and-night closed loop until delivery, glucose levels were in the target range 68.7% of the time. The impact of closed-loop insulin delivery on perinatal outcomes has not been established.

Closed Loop in Inpatients

In-patient hyperglycaemia is a marker of poor prognosis associated with increased morbidity, mortality, length of stay, and healthcare costs. In-patient studies have focused on fully closed-loop insulin delivery (without meal announcements) both in the intensive care unit (ICU) and the general wards.

Most closed-loop insulin delivery studies in the ICU have utilized intravenous insulin delivery and venous glucose sampling. These studies have demonstrated efficacy and safety of automated insulin delivery although the requirement for large blood sample volumes has resulted in limited uptake [12]. Use of fully automated closed-loop therapy with continuous subcutaneous glucose monitoring led to increased time in target glucose range (6.0–8.0 mmol/L) compared with control intravenous variable rate insulin (54.3% vs. 18.5%) over a 48 h period in ICU without increasing the risk of hypoglycaemia [13].

In inpatients with type 2 diabetes in the general wards, closed-loop insulin delivery significantly increased time spent within target glucose range (5.6–10.0 mmol/L) compared to conventional subcutaneous insulin delivery (65.8% vs. 41.5%) without any increase in the risk of hypoglycaemia [14].

Psychosocial Aspects of Closed Loop

Long-term usage of closed-loop technology is likely to be influenced by user expectations and experience. Expectations include stable glucose regulation, reduced need for glucose self-monitoring, relief of daily concerns, and timesaving, however, trust in automated insulin delivery is perceived as a potential barrier [15].

Reported benefits, in addition to improved glycaemic control, include reduced fear of hypoglycaemia, reassurance for users and family members, reduced anxiety, improved sleep, confidence, 'time off' from diabetes demands, greater freedom to engage in activity, excitement, and empowerment. Reported burdens included technical difficulties, alarm intrusiveness and interrupted sleep, increased time spent thinking about diabetes, size, and appearance of the equipment, limitations on exercise, and perceptions of deskilling and data obsession.

OpenAPS (Open Artificial Pancreas System) and LOOP lay communities suggest high parental and end-user interests in the technology [16]. The OpenAPS movement includes individuals building alternative non-commercial do-it-yourself (DIY) closed-loop systems from commercially available insulin pumps (sometimes out of warranty), CGM devices, and an open source algorithm.

Individual users have varied levels of engagement (a 'hands-off' approach with minimal input to high levels of engagement and adjustment of the control algorithm to their individual needs) and differing preferences with potential implications for effective long-term usage, associated glycaemic outcomes, and training needs. Clinician attitudes to closed-loop systems have yet to be considered.

Figure 15.8.2.2 Hybrid closed-loop system comprising fourth generation Enlite 3 glucose sensor, MiniMed® 670G insulin pump, with an embedded proportional–integral–derivative algorithm with insulin feedback (Medtronic, Northridge, CA).
Reproduced with permission from Medtronic.

Commercially Available Closed-Loop Systems

The MiniMed® 670G pump (Medtronic, Northridge, CA), approved in 2016 by the U.S. Food and Drug Administration (FDA) for use by people with T1D over 14 years of age, is a single-hormone hybrid closed-loop system with the control algorithm integrated in the insulin pump (Figure 15.8.2.2). The pump basal rate is automated based on a proportional–integral–derivative algorithm with insulin on board feedback. Clinical trial evaluation to assess safety was non-randomized and lacked a control arm therefore statements pertaining to its efficacy are limited [17]. The closed-loop system was used day and night for 3 months by 94 adults and 30 adolescents. No episodes of severe hypoglycaemia or ketoacidosis were observed. Several other hybrid closed-loop systems are being developed for commercial use. Post-marketing studies are ongoing.

Outlook

Future closed-loop systems will utilize improved system components. Sensors with improved accuracy, reduced or factory calibrations, and increased wear time will improve both performance and acceptability. Faster insulin analogues may further improve closed-loop system performance. At present, meal announcement with accurate carbohydrate counting is recommended to achieve optimal glucose control. Algorithms capable of integrating multiple signals may more accurately reflect the rapidly changing insulin

requirements of a person with diabetes than CGM alone. Device interoperability, cloud upload, and remote monitoring capabilities may further increase appeal and acceptability.

Assessment of cost-effectiveness for reimbursement by healthcare systems, and development of adequate infrastructure to support closed-loop users is essential for wide adoption of this technology.

Emergency and Hospital Management of Diabetes

15.9.1 Hyperglycaemic Emergencies

Ketan Dhatariya

Diabetic Ketoacidosis (DKA): Introduction

Diabetic ketoacidosis (DKA) is a frequently encountered acute metabolic emergency most frequently occurring in people with type 1 diabetes mellitus, but increasingly in those with type 2 as well. DKA is a condition, that if not managed correctly in a timely manner it is still associated with an appreciable mortality. The Centers for Disease Control and Prevention in the United States reported that in 2014 there were 168 000 admissions to hospital for this condition, a prevalence of 7.7 per 1000 people with diabetes [1]. These data are broadly unchanged from the late 1970s and early 1980s [2, 3]. In 2014, admissions for DKA represented ~2.3% of all admissions where diabetes was listed as a discharge diagnosis. In 1993, the mortality rate for DKA was reported as 3.9% in the United Kingdom [4], but data from the United States suggests that more recently this has fallen from ~8% to less than 1% [5, 6]. Among children and young adults the long-term standardized mortality ratio for children and young people has also come down from 9.3 to 5.6 between 1965 and 1979 [7, 8]. However, in this age group, DKA remains the most common cause of death with type 1 diabetes.

Pathophysiology

DKA occurs due to absolute insulin deficiency or when the concentrations of counterregulatory hormones (glucagon, catecholamines, cortisol and, to a lesser extent, growth hormone) are high. In these circumstances there is almost no insulin mediated cellular glucose uptake meaning that cells need an alternative energy substrate.

Insulin deficiency results in the generation of free fatty acids due to the increase in hormone-sensitive lipase activity on triglycerides [9]. The fatty acids are β-oxidized to form acetyl coenzyme A (CoA), which usually enters the tricarboxylic acid (TCA) cycle. This excess acetyl CoA entering the TCA cycle overwhelms the enzyme systems, and is converted into ketone bodies in the liver [10]. These ketones provide the alternative energy substrate needed for cellular metabolism to continue, mainly in the form of β-hydroxybutyrate (a hydroxyl acid) and acetoacetate at an approximate ratio of 10:1 [11].

Definition of DKA

To date, there is no recognized 'standardized' definition of DKA. While it may sound obvious, to make a diagnosis of DKA, all three of these criteria must be met. In the absence of large scale clinical studies to help determine the best management of DKA in the United Kingdom, the Joint British Diabetes Societies have produced a widely used national guideline on the management of DKA, used by over 90% of all UK hospitals [12, 13]. The diagnostic criteria they use states that the individual should either have an admission glucose of >11.1 mmol/L (200 mg/dl) or be known to have diabetes—irrespective of the admission glucose (the 'D'); that the plasma β-hydroxybutyrate concentration be ≥3.0 mmol/L, or there be significant ketonuria (>2+ on standard urine ketone sticks) (the 'K'); and the plasma bicarbonate concentration be <15.0 mmol/L *and/or* a venous pH of <7.3 (the 'A') [12].

Probably the most widely adopted guidelines used elsewhere for the management of DKA come from the 2009 American Diabetes Association position statement on hyperglycaemia emergencies [14]. That document uses a slightly different set of diagnostic criteria for DKA: a glucose concentration of >13.9 mmol/L (250 mg/dl); that ketones must be present (in urine or in the blood); and a metabolic acidosis must be present, with a pH of <7.30 (measured on arterial or venous blood) *and* a serum bicarbonate of ≤18.0 mmol/L.

Conflict of interest: Prof Dhatariya has been the lead or coauthor on several of the guidelines on the management of patients with diabetes in hospital produced by the Joint British Diabetes Societies for Inpatient Care, available at https://abcd.care/joint-british-diabetes-societies-jbds-inpatient-care-group
External Funding: None. Prof Dhatariya is a full-time employee of the National Health Service

Recently there has been a call to amend the ADA guideline in the face of emerging concerns about the sodium-glucose cotransporter 2 (SGLT-2) inhibitors and their association with 'euglycaemic DKA', where glucose concentrations may be less than 10.0 mmol/L (180 mg/dl) [15]. This condition may occur in between 3.5% and 15% of all cases of DKA, but because the ADA guideline states that DKA should not be diagnosed unless the glucose is >13.9 mmol/L (250 mg/dl), there is potential room for error in diagnosis, and subsequent management [16, 17].

The ADA also grades DKA into levels of severity depending on pH, bicarbonate concentrations, anion gap and level of alertness [14]. This is important because the available evidence suggests that in patients with mild to moderate DKA, the use of weight based, low dose subcutaneous or intramuscular insulin given every one or two hours offers an acceptable alternative to intravenous insulin [18]. In addition, the use of modern technology can guide whether an individual needs to be admitted for treatment or not [19]. Thus, there is an opportunity to reduce the costs associated with treating DKA, especially where the use of intravenous insulin necessitates mandatory admission to high cost environments such as the intensive care unit.

Incidence and Prevalence of DKA

A recent systematic literature review reported a range for incidence of 0–56 per 1000 person years, and a prevalence of 0–128 per 1000 people [20]. In North America, the prevalence of 168 000 admissions per year equated to an estimated incidence of DKA in at between 1% and 5% per year [1, 3, 21]. Most of these are in people with type 1 diabetes, but in some areas with high ethnic diversity or strong family history, up to 50% of cases occur in those with type 2 diabetes [22, 23]. In other parts of the world the rates vary, with quoted rates of 10 per 100 patient years in the Western Pacific [24]. It is much lower in Northern Europe [25, 26], with rates of 4.8 per 100 patient years being reported in the United Kingdom—an incidence of 3.8% per year [27, 28]. The treatment of DKA is expensive, with costs per admission in the US estimated at ~$17 500 [14], and £2064 in the United Kingdom [29].

Precipitants

Recent data has suggested that DKA is the first presentation for type 1 diabetes in only 3–6% of cases [16, 30], far below the previously quoted figure of ~30% [3, 31–35]. While in many cases no clear cause is found, the other main causes of DKA are infections, poor adherence to treatment, and drug and alcohol related events [16, 36, 37]. As mentioned, DKA—in particular euglycaemic DKA—has been increasingly reported with the use of SGLT-2 inhibitors [38] (and in SGLT1/2 inhibitors [39]) in those with type 1 and type 2 diabetes. More recently, a systematic review has found that lower socio-economic status is also associated with an increased risk of DKA [40].

DKA is still reported as the largest cause of death in children and young adults with type 1 diabetes under 30 years old [8]. However, the mortality rate in adults and in children may be dropping [41]. In 2016 a national survey of DKA management in the United Kingdom reported no deaths due to DKA in over 280 acute admissions [16], compared to previously reported rates of between 1.7% and 3.9% in the United Kingdom and China [4, 42, 43].

Box 15.9.1.1 Factors that should prompt an urgent assessment for care in a Level 2/High Dependency Unit environment in DKA

- Severe ketoacidosis (blood ketones >6.0 mmol/L; serum bicarbonate <5.0 mmol/L; venous or arterial pH <7.1; anion gap >16)
- Hypokalaemia (<3.5 mmol/L)
- Impaired consciousness (e.g. abnormal Glasgow coma score (GCS) or AVPU (Alert, Voice, Pain, Unresponsive) score)
- Oxygen saturation <92% breathing air (if baseline respiratory function normal)
- Haemodynamic compromise (systolic BP <90 mmHg and/or heart rate >100 or <60 beats per minute)

The Management of DKA

The principles of managing DKA centre primarily on replacing the fluid deficit. In addition to enhancing organ perfusion, fluid replacement helps reduce counterregulatory hormones production. Once a fluid replacement regimen has been started, then a weight based, fixed rate intravenous insulin infusion (FRIII) should be administered to suppress lipolysis and ketone production. 50 units of human soluble insulin should be made up to 50 ml with 0.9% sodium chloride solution and infused at a starting dose of 0.1 units/kg/hour. As mentioned previously, the American Diabetes Association guideline suggests grading the severity of DKA allowing for the use of regular subcutaneous insulin should hospital admission need to be avoided [14].

A bolus dose of subcutaneous or intravenous insulin should only be administered if there is a delay in setting up an FRIII. At the same time as the fluid and insulin are being administered, precipitating factors should be sought and treated appropriately. The presence of any of the factors listed in Box 15.9.1.1 should prompt an urgent assessment for care in a level 2/high dependency unit environment

The aim of treatment should be to restore euvolaemia, euglycaemia, and a normal pH without inducing iatrogenic hypokalaemia or hypoglycaemia.

Table 15.9.1.1 gives an example of a fluid replacement regimen.

Hyperkalaemia is common at presentation in DKA, and, if severe, should be treated as an emergency. However, high serum potassium often masks a total body deficiency potassium, and because potassium is driven into cells by treatment with insulin and fluids, serum

Table 15.9.1.1 An example of a fluid replacement regimen in DKA

Fluid	Volume
0.9% sodium chloride 1 L	1000 ml over 1st hour
0.9% sodium chloride 1 L with potassium chloride	1000 ml over next 2 hours
0.9% sodium chloride 1 L with potassium chloride	1000 ml over next 2 hours
0.9% sodium chloride 1 L with potassium chloride	1000 ml over next 2 hours
0.9% sodium chloride 1 L with potassium chloride	1000 ml over next 4 hours
0.9% sodium chloride 1 L with potassium chloride	1000 ml over next 4 hours

Re-assessment of cardiovascular status at 12 hours is mandatory, further fluid may be required

Table 15.9.1.2 An example of a potassium replacement regimen in DKA

Potassium concentration in first 24 hours (mmol/L)	Potassium replacement in mmol/L of infusion solution
Over 5.5	Nil
3.5–5.5	40 mmol/L
Below 3.5	Senior review because additional potassium needs to be given

potassium may fall sharply. Hypokalaemia occurs frequently, and serum potassium should be checked regularly and replaced proactively to avoid hypokalaemia [16].

Table 15.9.1.2 gives an example of a potassium replacement regimen.

Regular clinical and biochemical assessment (ideally hourly initially) should be mandatory to ensure continued improvement after the initiation of therapy. As discussed next, the urine ketone estimation should be avoided, while the use of venous blood gases is strongly encouraged.

Resolution of DKA is defined as a venous pH >7.3, serum bicarbonate >15.0 mmol/L, and blood ketone <0.6 mmol/L.

The early involvement of the diabetes specialist team in the longer-term management of the person with DKA is crucial.

Urinary vs. Plasma Ketones

In addition to the call for changes in the glucose concentration used to define DKA, there has been an increasing focus on the potentially inappropriate use of urinary ketones. There are many reasons for this. Firstly, the predominant ketone in urine is acetoacetate [44]. The urinary concentrations of acetoacetate do not reflect the concentration of plasma β-hydroxybutyrate [11]. Furthermore, as the DKA resolves, β-hydroxybutyrate is converted into acetoacetic acid which is then renally excreted. This leads to the false impression that the DKA is taking longer to resolve than is the case [45]. With the increasing availability of handheld, point-of-care ketone meters, there is call to stop using urinary ketones and to use blood ketones to help diagnose, and guide the management of DKA [17, 45, 46]. This move towards the DKA being 'ketone-centric' rather than 'glucose-centric' is increasingly important given the recognition of the previously mentioned 'euglycaemic DKA'. While it is increasingly being reported with the use of SGLT-2 inhibitors [38] (and in SGLT1/2 inhibitors [39]) euglycaemic DKA can also occur in pregnancy, starvation, and alcoholism [47–49].

Venous vs. Arterial Blood Gases

There is increasing evidence to suggest that the difference between venous and arterial pH is very minor—in the region of 0.02–0.15 pH units, and that the difference between arterial and venous bicarbonate is ~1.88 mmol/L [50–53]. These differences are highly unlikely to change the diagnosis or alter the management of DKA. Given the potential iatrogenic harm that can be caused by an arterial blood gas sample being taken, in the United Kingdom it is felt that it is no longer necessary to use arterial blood to measure acid-base status [12]. Venous blood can be used in portable and fixed blood gas analysers and therefore venous measurements (pH, bicarbonate, chloride, and potassium) are easily obtained in most admitting units. The UK guideline suggests that an arterial line should only be inserted if its use will influence management [12].

Continuation of Subcutaneous Long-Acting Basal Insulin

The use of long-acting basal insulin is now widespread. These can be either human or analogue insulin. They should be continued in patients already taking them, or started at a dose of 0.25 units/kg subcutaneously once daily in those for whom DKA is the first presentation of type 1 diabetes. Continuation of these subcutaneous injections during the initial management of DKA provides background insulin when the intravenous insulin is eventually discontinued, and so avoids any rebound hyperglycaemia [54]. This should avoid extending the length of stay [55]. This only applies to long-acting insulin and does not obviate the need to give short acting insulin before discontinuing the intravenous insulin infusion.

Future Developments

It is likely that there will be several changes in the management of DKA over the next few years. The unexpected finding of DKA with the use of SGLT-2 inhibitors has highlighted some issues with the diagnostic criteria used to diagnose DKA. The DKA event in these trials were not adjudicated, and on closer inspection of the data, it is clear that the definitions used to diagnose the conditions in these trials varied across the world, and even within countries at different institutions. However, despite there being no clear definitions used, licencing authorities have placed warnings on the use of these drugs [56, 57] Because of this, there has recently been a call to ensure that the same diagnostic criteria are used, especially with clinical trials, to ensure that data used to make such decisions are robust [58].

In addition, the awareness that euglycaemic DKA occurs with some frequency, may change the diagnostic algorithm used by the ADA to allow a glucose of lower than 13.9 mmol/L (250 mg/dl) before a diagnosis can be made.

The recent move towards the management being more 'ketone-centric', because of the increasing availability of point-of-care ketone testing equipment, means that there is likely to be a greater call for their use—in diagnosing the disorder and also in guiding its management [45]. And while there remain differences in the management of DKA between the two most commonly used guidelines—those of the United States and the United Kingdom [59]. These differences are likely to become smaller as the evidence base increases and there are changes in the paradigm in how DKA presents [17]. This is important because of the data suggesting that fragmentation of—and by extension—differences in care—is associated with recurrent DKA as well as increased mortality [60].

Finally, recent evidence from a large national survey showed that the current management paradigm used in the United Kingdom was associated with over 27% of patients developing hypokalaemia (a potassium concentration of <4.0 mmol/L) and 55% developing mild (i.e. self-treated) hypoglycaemia (blood glucose <72 mg/dl [4.0 mmol/L]) [16]. While these biochemical abnormalities were not associated with any harm, what remains unclear is whether these were due to staff not following the guidelines, or whether the rate of insulin infusion needs to be reduced to reduce the likelihood of them occurring. Further work needs to be done to determine the best intravenous insulin infusion rates.

Hyperosmolar Hyperglycaemic State (HHS)

Introduction

HHS was initially described as a separate entity causing diabetic coma by Dreschfield [61] and Von Frerichs [62]. Dreschfield and others described three forms of 'diabetic coma'—one of which was the gradual onset of loss of consciousness that occurred most frequently in adults over the age of 40, who were overweight without the characteristic acetone breath or acetone in the urine found in other forms of diabetic coma [61, 63–65]. It was with the advent of post-war technology that the true extent of the metabolic derangement associated with HHS became apparent [66, 67].

Definition and Pathophysiology

While there is no formally accepted definition of HHS, it is a condition characterized by severe dehydration, hyperglycaemia in the absence of ketoacidosis, and hyperosmolarity. The diagnosis is made when there is hypovolaemia, a glucose of >30.0 mmol/L (>33.3 mmol/L in the United States), with a serum osmolality >320 mOsm/kg—in the absence of significant acidosis or ketonaemia [14, 68]. Osmolality should be calculated as or [2 × measured Na (mmol/L) + glucose (mmol/L) + [urea (mmol/L)] or [2 × measured Na (mEq/L) + glucose (mg/dl)/18 + blood urea nitrogen (mg/dl)]/2.8]. HHS is believed to result from the presence of sufficient insulin to suppress hepatic ketone production, but not to suppress gluconeogenesis. The slow onset of progressive hyperglycaemia causes an osmotic diuresis, which itself leads to often severe dehydration. Because the renal losses of water are in excess of sodium and potassium the osmolality rises. Fluid losses are estimated at between 100 and 220 ml/kg. Despite this, patients with HHS may not look dehydrated, because of the redistribution of body water due to blood hypertonicity and preservation of intravascular volume.

Some patients may present with a mixed picture, with a metabolic acidosis and a raised anion gap—this may be due in part to ketonaemia, but also to high lactate concentrations.

Precipitants

The most common precipitant of HHS is infection. Other common causes are omission of glucose lowering agents, other comorbidities, such as acute coronary syndrome, or the addition of high dose glucocorticoid therapy. In only a minority of cases is HHS the first presentation of diabetes [36].

Morbidity and Mortality

HHS tends to occur in individuals who are older than those with DKA. As such, they often have several other comorbidities at the time of presentation. In addition, they are at greater risk of developing other complications, with atherosclerosis, thrombosis, and foot ulceration posing particular risks. Patients with HHS should be offered heel protection—particularly to those with neuropathy, peripheral vascular disease, or lower limb deformity. The feet should be examined daily.

It is likely that the reported mortality of HHS of 5–16% (about 10-fold higher than for DKA) is partly because of these pre-existing comorbidities [69, 70].

Management of HHS

As with DKA, the principles of managing HHS centre primarily on replacing the fluid deficit and lowering glucose concentrations. The two main guidelines used in many parts of the world—the ADA guidelines [14] and the UK guidelines from the Joint British Diabetes Societies for Inpatient Care [68], both advocate the use of 0.9% sodium chloride solution given at an appropriate rate (depending on the presence of cardiac, pulmonary or renal comorbidities) to correct the dehydration and reduce the serum osmolality. The UK guideline advocated that approximately 50% of the estimated fluid loss should be replaced within the first 12 hours, and the remainder in the following 12 hours. There may be an initial rise in serum sodium concentrations but because the glucose and urea concentrations would fall faster than the sodium rise, the overall calculated serum osmolality should fall—ideally by 3–8 mOsmol/kg/hr. The use of 0.45% sodium chloride solution should be avoided initially—except when the osmolality fails to fall despite adequate fluid replacement. Despite the absence of hard data, a decline in serum sodium of 0.5 mmol/L per hour has been recommended for hypernatraemic dehydration. Potassium should be replaced as for DKA (see Table 15.9.1.2).

The only time that insulin should be started before glucose concentrations stop falling in HHS is if, at the time of presentation or anytime thereafter, ketonaemia (>1.0 mmol/L) develops. This would indicate a relative hypoinsulinaemia. Most patients with HHS are insulin sensitive, and the addition of insulin prior to the fluids alone allowing glucose concentrations to fall may lead to a precipitous drop in glucose, causing a rapid lowering of osmolality, potentially leading to central pontine myelinolysis. In addition, the rapid fluid shifts associated with the movement of glucose intracellularly out of the intravascular space, may lead to cardiovascular collapse if the rate of fluid replacement is insufficient, or not possible due to other comorbidities.

Careful and regular monitoring of fluid balance and biochemistry—ideally hourly for the first 6 hours—should be instituted, and the intravenous fluid should be continued until the osmolality stops falling. In addition, once the glucose concentration has stopped falling with fluid administration alone should a weight based, FRIII be initiated at a rate of 0.05 unit/Kg/hour. The aim should be to reduce the glucose concentration at a rate of 5.0 mmol/L/hour, but to maintain it initially between 10.0 and 15.0 mmol/L (according to the UK guideline). As the condition of the patient improves, with the addition of further intravenous insulin, or the use of oral hypoglycaemic agents, the glucose concentration may be reduced further as necessary.

While infusing intravenous fluids, clinical assessment should look for evidence of a precipitating cause, e.g. inflammation, sepsis, or myocardial infarction, or a change in medication, e.g. recently starting steroids. Once fluid resuscitation has been initiated, then the underlying cause should be sought and treated appropriately, while at the same time ensuring the prevention of complications such as arterial or venous thrombosis, cerebral oedema, central pontine myelinolysis, and foot ulceration. Foot examination is mandatory at the time of admission and daily afterwards. Obtunded or uncooperative patients should be assumed to be at particularly high risk.

Box 15.9.1.2 Factors that should prompt an urgent assessment for care in a level 2/high dependency unit environment in HHS

- Difficulty in obtaining intravenous access
- Serum osmolality >350 mOsm/kg and/or serum sodium >160 mmol/L
- Venous/arterial pH <7.1
- Severely deranged serum potassium (<3.5 mmol/L or >6.0 mmol/L)
- Impaired consciousness (e.g. GCS <12 or abnormal AVPU score)
- Oxygen saturation <92% breathing air (if baseline respiratory function normal)
- Haemodynamic compromise (systolic BP <90 mmHg and/or heart rate >100 or <60 beats per minute)
- Hypothermia
- Acute or serious comorbidity (e.g. MI, CCF, or CVA)
- Urine output <0.5 ml/kg/h or other evidence of acute kidney injury

The electrolyte and osmolality abnormalities may take up to 72 hours to normalise.

The presence of any of the factors listed in Box 15.9.1.2 should prompt an urgent assessment for care in a level 2/high dependency unit environment.

Education

For DKA and HHS the key is prevention—educating patients before they develop any complications. For those with insulin treated diabetes, revision of 'sick day rules' should form a part of the annual review.

For those who develop DKA or HHS, assessment by the inpatient diabetes specialist team should be mandatory, to educate the patient and provide a contact for patients and carers for when the patient leaves hospital.

15.9.2 Management of the Inpatient with Diabetes Mellitus

Gerry Rayman

Introduction

The previous edition of this textbook lamented on the general lack of interest in inpatient diabetes care. Since then there has been a significant change, partly brought about by increasing recognition of the significant financial burden of inpatient diabetes, increased lengths of stay, worryingly high levels of patient harms associated with poor control (both hyperglycaemia and hypoglycaemia), and poor patient experience [1, 2]. In England and Wales, the National Diabetes Inpatient Audit (NaDIA—*vide infra*), the world's first national diabetes audit was partially instrumental in highlighting the levels of patient harms and patient dissatisfaction as well revealing the paucity of inpatient diabetes specialists [2]. Additionally, recognizing the need to improve inpatient diabetes care the Joint British Diabetes Societies (JBDS) for inpatient care was formed to produce evidence and consensus based national guidelines to promote better care and reduce variation in practice [3]. Similarly, in 2013, diabetes specialists in the United States formed a consortium for Planning Research in Inpatient Diabetes (PRIDE) to improve inpatient diabetes care [4]. Thus, driven by evidence of suboptimal management and the associated high costs, inpatient diabetes care has now become a major focus for funders, hospital management, clinicians, and patients. The goal should be to ensure that the outcomes for people with diabetes admitted to hospital are no different from those without diabetes by prevention of inpatient hyperglycaemia, hypoglycaemia, and hospital-acquired foot lesions and ensuring early and safe discharge.

Prevalence and Economic Burden

In England, accurate data on bed occupancy by people with diabetes was for the first time available following the first NaDIA in 2010. This annual bedside snapshot audit that takes place on a single day in a week in September, in over 98% of all acute hospitals, surveys of every inpatient to find those with diabetes and then evaluates the care they have received and documents any complications that have arisen during their stay. In the first NaDIA, people with diabetes were found to occupy 14.9% of inpatient beds; higher than expected from the often quoted 10% from Hospital Episode Statistics and three times the prevalence of the condition in the general population [2, 5, 6]. Furthermore, in line with the increasing prevalence in the general population there has been a year upon year increase such that in 2017, diabetes patients accounted for more than one in six inpatient beds in England and Wales (17.9%) [7]. Projecting forward it is estimated that by 2030 more than one in four inpatients will have diabetes. Indeed, in some UK hospitals the prevalence is as high as 30% [7], a prevalence already exceeded in the whole of some American states [8].

In 2011, the NHS in England was estimated to spend £2.3–2.5 billion a year on inpatient care for people with diabetes—around 11% of total inpatient care expenditure and approximately 25% of the total expenditure on diabetes care [1]. Very similar estimates have been made for the French (22%) and American (25%) healthcare systems, both confirming that inpatient care is the largest component of medical expenditure for diabetes [9, 10].

Given the inexorable increase in prevalence, the high cost and associated demands on staffing this has major implications for funding and planning inpatient diabetes care.

Patient Outcomes: Length of Stay, Re-Admissions, and Mortality

Numerous publications based on hospital activity data confirm that patients with diabetes have longer lengths of stay and emergency re-admission compared with people without diabetes [5, 11, 12]. They also have a greater risk of dying in hospital [5]. Reasons include being an older group with more comorbidities, however after correcting for these it has been shown that unstable diabetes control in the form of hypoglycaemia and hyperglycaemia is associated with increased length of stay, morbidity and mortality [5, 12–15]. Recent studies have however demonstrated that focused initiatives can reduce length of stay and re-admission rates, which if replicated on a nationwide basis would result in substantial savings [16, 17].

Bedside Diabetes Care: Lessons from the National Diabetes Inpatient Audit (NaDIA)

Hospital activity data, collected mainly for the purposes of billing, though providing important data on length of stay, re-admissions, and mortality contains no information on the actual care patients receive. The NaDIA is unique in that it provides comprehensive information on bedside care, which includes patient harms, treatment and management errors, structures of care such as inpatient diabetes specialist staffing levels, and direct feedback from patients of their inpatient experience. Uniquely it allows hospitals to benchmark against other hospitals

The key findings of the NaDIA 2017 report, the 7th iteration providing data on 16 010 inpatients with diabetes admitted to 208 hospital sites in England and Wales are summarized in **Box 15.9.2.1**. The provision of specialist diabetes staff remains a concern and has not improved since the audits began. Medication errors and insulin errors have significantly reduced however, as shown in the box remain at unacceptable levels. Inpatient hypoglycaemia and hospital acquired foot ulceration have reduced year on year however, cases of diabetic ketoacidosis and hyperosmolar hyperglycaemic state occurring in hospital remain unacceptably high. Shockingly, 1 in 25 patients with type 1 diabetes experiences diabetic ketoacidosis during their hospital stay due to due to inadequate care. Although exclusive to England and Wales, anecdotal feedback suggests that the experience in many other countries is very similar.

Box 15.9.2.1 Key findings from the National Diabetes Inpatient Audit in 2017

NaDIA 2017 Key messages summary

- 30% of hospitals have no inpatient diabetes specialist nurse
- 30% who should be seen by the diabetes specialist are NOT SEEN
- Less than half of those insulin-treated have a 'good' diabetes day (no BG<4.0 and no more than 2 >11.0 mmol/L)
- 31% experienced medication errors—more frequent on surgical wards
- Insulin errors occurred in 40% of those treated with insulin
- Inhospital DKA occurred 1 in 25 people with type 1 diabetes
- Severe hypoglycaemia occurs in 1 in 4 people with type 1 diabetes
- 1 in 80 of all inpatients with diabetes required injectable rescue treatment
- Patient satisfaction with timing of and meal choice continue to worsen

Glucose Abnormalities on Admission and During the Hospital Stay

All patients admitted to hospital should have a blood glucose measured on admission. Those known to have diabetes with blood glucose levels persistently greater than 7.8 mmol/L require alterations to their diet and medication. In these patients, an admission HbA1c is helpful in determining the diabetes control prior to admission. In those without history of diabetes, persistent glucose results greater than 7.0 mmol/L may signify stress hyperglycaemia, which will resolve after discharge or newly diagnosed diabetes, which will persist after discharge. An admission HbA1c of ≥6.5% is helpful in confirming pre-existing diabetes and <6.5% in indicating stress hyperglycaemia.

In hospital-hypoglycaemia is clinically significant at glucose levels below 3.0 mmol/L; however, clinical staff should be alerted to levels below 4.0 mmol/L as many people with diabetes are symptomatic below these levels. In the NaDIA, mild hypoglycaemia is defined as any glucose level below 4.0 mmol/L and ≥3.0 mmol/L, severe hypoglycaemia as below 3.0 mmol/L and a third category of severe hypoglycaemia requiring injectable rescue treatment (IV dextrose or IV/IM glucagon) was included to indicate life-threatening hypoglycaemia.

The NaDIA revealed concerning levels of hypoglycaemia occurring in UK hospital. In 2011, 25.7% of people with diabetes experienced a hypoglycaemic episode during their admission; 10.6% were severe. Since, there have been year on year improvements; in 2017, the respective figures were 18.4% and 7.0%. Importantly, hypoglycaemic episodes requiring injectable rescue treatment (IV glucose or IV/IM glucagon) have fallen from 2.1% to 1.3%.

Glycaemic Targets in Hospitalized Patients with Diabetes

Over the past decade, inpatient glycaemic management has focused mainly on preventing hyperglycaemia rather than avoidance of hypoglycaemia as the former has been shown to be associated with increased morbidity and mortality, particularly in cardiac and orthopaedic surgery [18–22]. The initial studies of 'tight glycaemic control' (4.4–6.1 mmol/L), were conducted in a single intensive care unit (ICU) where it was possible to very intensively monitor glucose and intravenous insulin infusion rates. The first study in surgical ICU patients demonstrated an impressive 34% reduction in mortality, 34% reduction in septicaemia and 46% reduction in renal failure requiring dialysis by 41% [23]. A subsequent study by the same group in medical ICU patients did not show a reduction in mortality but benefit in length of stay in the ICU [24]. This led to much excitement among intensivists with many adopting strategies to achieve 'tight glycaemic control'. However, subsequent 'real

world' studies across multiple ICUs have not supported these findings and indeed suggest that 'tight control' may be associated with greater mortality possibly related to increased frequency of hypoglycaemia [25–27]. As the vast majority of diabetes admissions are not to critical care units, these studies are not helpful in determining glycaemic targets in general wards where glucose monitoring is less intensive and the patient to nursing/medical staff ratio significantly lower. A meta-analysis aimed at establishing set guidelines in non-critical hospitalized patients concluded that there is no difference in the mortality or macrovascular complications for non-critical patients with diabetes receiving intensive vs. standard glycaemic control but cautioned that the strength of this conclusion is limited by a dearth of literature from the non-critical setting [28]. In the absence of definite evidence for 'tight glycaemic control' and a broad consensus that hyperglycaemia and hypoglycaemia are associated with adverse outcomes, the pragmatic approach is to avoid hypoglycaemia and significant hyperglycaemia. Thus, American Diabetes Association recommends a target glucose range of 7.8–10.0 mmol/L for the majority of critically ill and non-critically ill patients. In the United Kingdom, the JBDS recommend an ideal blood glucose target range of 6.0–10.0 mmol/L (acceptable range 4.0–12.0 mmol/L). More stringent targets may be appropriate in selected groups such as those undergoing cardiac surgery where intensive monitoring is possible and in whom there is good evidence for the benefit of 'tight glycaemic control' [29]. Conversely, higher glucose targets may be appropriate in those who are terminally ill, those with severe comorbidities, and elderly frail patients.

Barriers to Achieving Good Glycaemic Control in Hospital

There are numerous reasons why achieving good inpatient diabetes control is challenging. These include the physiological response to illness and/or surgery, reduction in carbohydrate intake from emesis, interruption of enteral feeding, periods of fasting for procedures, comorbidities such as renal, cardiac, and hepatic disease, and alteration in insulin sensitivity due use of new medications such as steroids. System issues include coordinating meals and insulin, staff knowledge, staffing levels, communication between staff and with the patient, and insufficient frequency of blood glucose monitoring. Importantly, as over 90% of patients with diabetes are admitted for reasons unrelated to diabetes (e.g. pneumonia or a fracture) and are cared for by non-diabetes specialist staff with relatively little experience in insulin dose adjustment, the need to tailor diabetes medications during illness and in the management of diabetic emergencies. Added to this new classes of diabetes medications, new combinations of existing medications and biosimilar insulins with new names has made diabetes management significantly more challenging for diabetes specialists let alone non-specialists. Indeed, one of the largest surveys of junior doctors in the United Kingdom found that a majority felt their diabetes training did not allow them to confidently manage inpatients with diabetes safely, and that only 40% would take the initiative to optimize glycaemic control for patients under their care [30]. For these reasons, systems need to be in place systems to train non-specialist staff in the basic care of people with diabetes in hospital, and they need easy access to guidelines and policies on diabetes management as well as instruction on whom when and how to refer for specialist support. Patient and system factors that increase the risk of hypoglycaemia are listed in Box 15.9.2.2.

Box 15.9.2.2 Factors contributing to hypoglycaemia

Patient factors contributing to hypoglycaemia

- Critical illness (hepatic, cardiac, and renal failure)
- Alterations in medications such as rapid steroid dose reduction
- Reduced CHO intake: vomiting, reduced oral intake, e.g. fasting for procedures: interruption of intravenous glucose infusion, enteral or parenteral nutrition
- Impaired patient awareness and response to hypoglycaemia related to altered mental status due to sedation or illness

System failures resulting in hypoglycaemia

Inappropriate insulin administration and adjustment:

- Unawareness of interaction between timing of timing in insulin administration to meal
- Lack of information of carbohydrate content of meal and corresponding adjustment of insulin dose
- Lack of knowledge on different insulin types
- Errors in insulin prescription, dosage, and administration

Infrequent/missed blood glucose monitoring:

- Suboptimal levels of staff knowledge on the importance of monitoring
- Lack of blood glucose re-testing and reviewing, following a hypoglycaemic episode

Insufficient ward staffing levels and competencies:

- Low staffing levels, especially in specialist staff, overnight and weekends
- General knowledge and hands-on experience of diabetes lacking for nurses and junior doctors, particularly on wards not commonly dealing with patients diagnosed with diabetes
- Non-specialist staff reluctant to seek specialist's help and advice

Point-of-Care Testing and Frequency of Blood Glucose Monitoring

It is recommended that patients on insulin and/or sulphonylurea therapy are monitored prior to meals and before bed. Less frequent monitoring may be appropriate in other groups such as patients who are solely diet treated if initial monitoring suggests satisfactory and stable glycaemic control. The frequency should be intensified in the deteriorating patient or when there is a change of medication known to effect glycaemia (e.g. steroid therapy).

Glycaemic control in hospitalized patients with diabetes requires accurate near-patient glucose monitoring systems. Blood glucose meters for patient use should not be used in the hospital setting as they lack the required accuracy particularly at the lower glycaemic ranges and unlike those designed for hospital may be adversely affected by hypoxia, dehydration, haematocrit, non-glucose sugars, and interfering drugs [31].

Currently, fourth-generation point-of-care BG data management systems are available that connect seamless and bidirectionally with wireless enabled point-of-care BG meters [32]. These can be configured to provide alerts of out of range glucose results to enable early review of hypoglycaemic medication to prevent recurrent hypoglycaemia. Data from such systems have been also been used to investigate patterns of hypoglycaemia and in one study identified nocturnal hypoglycaemia as a particular issue in patients receiving nocturnal basal insulin and/or sulphonylurea therapy [33].

Glycaemic Therapies in Hospitalized Patients

In the United Kingdom as in many other countries, most patients admitted to hospital remain on their usual antihyperglycaemic regimen in contrast to the United States where the American Diabetes Association recommends a basal-bolus regimen for all diabetes admissions irrespective of their pre-admission treatments [34]. This policy has not been adopted in the United Kingdom principally because nurse to patient ratios are a considerably lower, and the provision of diabetes inpatient nurses is insufficient to support the more intensive management required. Indeed, given the high levels of harm related to insulin use already seen in UK hospitals, the widespread adoption of the basal-bolus regime in inpatients with diabetes may be unwise.

On admission, there should be a review of the patient's glycaemic therapy. In certain circumstances some oral hypoglycaemic agents may need to be discontinued (e.g. metformin and sulphonylureas in the presence of acute kidney injury); metformin should be temporarily discontinued in patients with impaired renal function if intravenous contrast material is to be administered. There will also be a need to consider altering the dose of insulin and/or sulphonylurea therapy depending on patient circumstances. Thus, in many patients the evening basal insulin and or/sulphonylurea dose may need to be reduced take into account differences in feeding patterns and nutritional content of the evening hospital meals compared with those usually eaten at home. Incretin therapies can be used but should be avoided in patients who develop heart failure. Glucagon-like peptide 1 agonists may be continued provided gastrointestinal symptoms are not an issue.

SGLT-2 inhibitors, a relatively new group of oral hypoglycaemic agents currently indicated for the treatment of type 2 diabetes but also increasingly used off licence in type 1 diabetes, should be discontinued, as there is a risk of euglycaemic ketoacidosis in ill and dehydrated patients.

A summary example of the adjustments to hypoglycaemic treatments that should be considered on admission in all patients is shown in Table 15.9.2.1.

Patients started on corticosteroid therapy must be closely monitored and where high doses are required it very likely there will be a need to escalate hypoglycaemic treatment. Furthermore, when the dose of corticosteroid is tapered dose reduction guided by frequent blood glucose monitoring is necessary to avoid hypoglycaemia. Detailed guidance for monitoring and managing steroid induced hyperglycaemia in patients with and without pre-existing diabetes is available through the JBDS [3].

Continuous Subcutaneous Insulin Infusion (CSII) Therapy

An increasing number of patients are using CSII. Unless incapacitated, most will be safest remaining on CSII if admitted to hospital. They will know how best to use the device however but they should be reviewed by the diabetes team. If the patient is unable to manage the CSII, and no specialist advice is immediately available, the CSII should be discontinued and a conventional intravenous insulin infusion or S/C basal-bolus insulin regimen.

Intravenous Insulin Infusion

In critically ill patients and those unable to eat or drink, continuous intravenous insulin infusion is the choice method for achieving and maintaining glucose control. However, as intravenous insulin has a half-life of a few minutes, if interrupted

Table 15.9.2.1 Diabetes medicines management on admission card

Diabetes medicines management on admission	Preventing hypoglycaemia in the first 48 hours after admission
• SGLT2 inhibitors (e.g. empagliflozin)—RISK of DKA. Stop for major surgery or severe medical illness. • Metformin—RISK of lactic acidosis in presence of significant kidney, liver, respiratory, or cardiac failure. Stop if any of above or in those with and eGFR <60 undergoing a procedure that requires prolonged fasting, or a diagnostic test requiring radio-opaque contrast material which can impair kidney function. • NEVER stop the patient's basal insulin (e.g. Lantus or Levemir). Continue even when on an insulin infusion. • Gliclazide—RISK of nocturnal hypoglycaemia in renal impairment or where food intake is reduced. Reduce or omit (if already on low dose) evening dose. • All oral diabetes drugs should preferably be administered with food.	• Hypoglycaemia is common within 48 hours of admission; therefore unless admitted with a hyperglycaemic emergency or admission blood glucose > 15 mmol/l: – Basal-bolus regiment—reduce pre-bed basal insulin by 20% (i.e. give 80% of usual dose); – If on a pre-mix insulin (e.g. Humulin M3) reduce evening dose by 20% (i.e. give 80% of usual dose); – Halve or omit (if already on low dose) the evening dose of sulphonylurea (Gliclazide). • Reassess hypoglycaemic therapy the following day.

Note: Never omit insulin after correcting a hypoglycaemic event as rebound DKA may occur.

ketoacidosis can quickly ensue. This can occur if the infusion line becomes blocked or dislodged or the infusion pump is inadvertently switched off, or intentionally stopped but not restarted (e.g. when transferring from the ward to an investigation area). For these reasons, it is recommended the basal insulin be continued during the infusion in those already receiving a basal insulin. It is also essential that patients placed on an intravenous infusion have hourly monitoring. In most circumstances the variable rate intravenous insulin infusion (VRIII) is used. In those already insulin-treated the initial algorithm may be determined by the previous insulin total daily dose, otherwise a mid-range algorithm is used. The blood glucose response to the insulin infusion must be reviewed regularly to determine whether the glucose/insulin algorithm should be altered. Because of the risk of hypoglycaemia an intravenous glucose infusion should be administered either as 5% dextrose with 40 mmol/L KCL at 125 ml/hr if the serum potassium is 3.5–5.5 mmol/L or preferably 0.45% NaCl and 5% glucose with 0.3% KCl (40 mmol/L) at 125 ml/hr if serum K is 3.5–5.5 mmol/L. A fixed rated intravenous insulin infusion (FRIII) is now considered the most effective means of correcting ketosis in patients with diabetic ketoacidosis. Examples of infusion scales for the VRIII as well as the insulin dose calculation for the FRIII are shown in **Table 15.9.2.2**. More detailed information on the use of VRIIIs and FRIIIs is available from the Joint British Diabetes Societies as well as in specials situations such as patients on parenteral nutrition [3].

In addition to diabetic ketoacidosis, hypoglycaemia, fluid overload, hypokalaemia and/or hyponatraemia, and cannula site infection are potential risk of intravenous insulin infusion. Daily electrolyte measurement is recommended. Given these risks, and the discomfort and intrusion of frequent monitoring especially overnight for the patient, intravenous insulin infusions should only be used where absolutely necessary. In the NaDIA 2010, 7.6% of infusions were considered unnecessary, 9.9% continued for too long and in 25.8% of patients, the transfer back to subcutaneous insulin not well managed. Fortunately, the situation has improved and in 2017, the respective figures were 6.1%, 7.1, and 16.4%.

When transferring from intravenous to subcutaneous insulin, it is important that the latter has been given prior to stopping the infusion to prevent insulinopenia and subsequent ketoacidosis. Ideally, basal insulin should have been continued during the infusion. The VRIII should only be discontinued 30 minutes after subcutaneous short acting or mixed insulin has been given and ideally at a mealtime. Transfer should not be done at bedtime where there is less observation by staff.

If the patient is new to insulin the total daily insulin dose can be calculated from the insulin requirement over the last 6 hours on the VRIII. It is prudent to reduce this by 20%. Fifty per cent (50%) is given as basal insulin and the rest divided initially equally for each of the three meals.

An exciting new development in achieving glucose levels within a 'tight' target range without the risk of hypoglycaemia is the use of automated, closed-loop insulin-delivery systems. To date, in inpatients their use has been limited to those with type 2 diabetes and at present they remain at the research stage [35, 36]. Though attractive, considerable expertise in the use of closed-loop technology and the involvement of diabetes staff expert in fitting and calibrating the sensors is essential. Although such systems hold considerable promise, further work is necessary to improve their ease of use before they can be used on busy general wards [37].

Self-Management

All clinicians who talk to people with diabetes are aware that many are deeply unhappy about the care they receive in hospital. The NaDIA reports that patients are disempowered, particularly in their involvement in their own diabetes control; this includes being permitted to being allowed to self-monitor their own blood glucose, self-administer insulin, and contribute to decisions on insulin dose adjustment. They also report significant concerns about the quality, choice and timing of meals in relation to insulin administration [7].

Self-management is appropriate in selected patients and should be encouraged provided the patient is known to successfully manage their diabetes at home and is well enough and not cognitively affected by their illness. With one in 25 people with type 1 diabetes experiencing diabetic ketosis during their hospital admission, far greater than would occur self-caring in the community, it is not surprising that many patients self-discharge in the belief that they are more capable of controlling their diabetes that the staff in the hospital.

Safe Discharge from Hospital and Preventing Re-Admissions

Re-admission rates within 28 days for people with diabetes are between 14% and 20% and are 59% higher than those without diabetes [38]. A proportion of these can be prevented by a 'safe diabetes discharge policy'. This should include a formal review of diabetes therapies before discharge, which can be informed by HbA1c measured on admission. Care should be taken to ensure that the patient or carer is able to recognize and treat hypoglycaemia, has written instruction on insulin doses and their timing and that they leave with all the necessary equipment and treatments (e.g. needles, insulin pens, blood glucose monitoring). Care should also be taken to avoid transcription errors when communicating medication dosages to the patient, carers, and the primary care physician and all should be aware of follow-up arrangements. The inpatient diabetes specialist nurse is often the key member of the team in this discharge policy.

A relatively small cohort of patients with recurrent admissions account for a significant proportion of inpatient stays in people with diabetes. In one study, 30% of patients who had two or more hospital admissions accounted for more than 50% of such hospitalizations [39]. Targeting these patients may decrease re-admissions. This would include provision of psychological support for those with recurrent ketoacidosis and hypoglycaemia related to behavioural problems. Frail elderly and patients from nursing and residential homes are at particular risk of recurrent hypoglycaemic admissions and/or ambulance call outs with over a third of these being repeated events [40]. Support from the diabetes specialist team, in particular focusing on medication de-escalation and setting less stringent blood glucose targets may reduce re-admissions in this group.

15.9.3 Care of Diabetes in ICU and Perisurgery

Jan Gunst and Greet Van den Berghe

Introduction

Evoked by severe physical stress, critically ill patients and patients undergoing major surgery usually develop stress hyperglycaemia, irrespective of their pre-admission diabetes status. Large observational studies have shown that the degree of stress hyperglycaemia relates to poor outcome (Figure 15.9.3.1), with the lowest risk of death being associated with normal or nearly normal age-adjusted fasting blood glucose levels [1, 2]. Remarkably, in critically ill patients with established diabetes, the relationship between hyperglycaemia and mortality is blunted and shifted to the right [1]. Since these associations are derived from observational studies, they do not imply causality. Indeed, sicker patients will develop more severe insulin resistance, with consequently higher blood glucose levels.

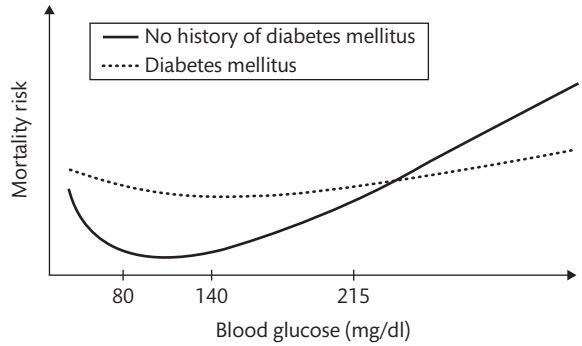

Figure 15.9.3.1 The association of blood glucose concentrations with outcome in critically ill adults. In observational studies, the statistical association between blood glucose concentrations and the risk of mortality follows a J-shaped curve. To convert mg/dl to mmol/L, divide by 18.

A causal relationship can only be derived from adequately powered randomized controlled trials (RCTs).

Tight Glucose Control in the Intensive Care Unit

Over the last two decades, several RCTs—varying in design, study population, size, blood glucose target, and outcome measures—have tested the hypothesis that tight glucose control may improve outcome of critically ill patients [3–8].

The Leuven Studies on Tight Glucose Control in the Intensive Care Unit

In three pioneer studies performed in Leuven, Belgium, tight glucose control improved morbidity and mortality of critically ill adults and children, as compared to tolerating hyperglycaemia up to 12 mmol/L (215 mg/dl) [3–5]. In the intervention group, age-adjusted normal fasting glucose levels were targeted (4.4–6.1 mmol/L for adults [80–110 mmol/L], 3.9–5.6 mmol/L [70–100 mg/dl] for children older than 1 year, and 2.8–4.4 mmol/L for infants [50-80 mg/dl]) and insulin was administered through continuous intravenous infusion (no boluses). As long as an arterial line was present, glucose measurements were performed on arterial blood, using an accurate blood gas analyser, with simultaneous measurement of potassium. All patients received early parenteral nutrition as part of the standard care at that time. The intervention protocol was highly efficient, with >70% of measurements within target and a clear separation in blood glucose levels between the randomization groups.

Importantly, the short-term clinical benefit was maintained on the long-term in both adults and children [9, 10], and the intervention was shown to reduce healthcare costs [11]. Subsequent mechanistic studies attributed the beneficial impact to the avoidance of hyperglycaemia and consequent glucose overload in vital organs, rather than to glycaemia-independent effects of insulin [12].

Subsequent Studies and Possible Contributors to Interstudy Discrepancies

After the Leuven trials, several large implementation studies and small RCTs have confirmed a positive clinical impact of implementing tight glucose control in critically ill patients [13–16].

However, the intervention remains debated, since multicentre RCTs have not reproduced the benefit observed in the pioneer studies [6–8]. The largest RCT, the NICE-SUGAR trial, even found excess mortality by tight glucose control, which was subsequently attributed to the increased risk of hypoglycaemia [7, 17]. Substantial differences in study design may explain these seemingly contradictory results, including differences in blood glucose target, the accuracy of the glucose measurements, the insulin infusion protocol, and the feeding protocol.

In contrast to the Leuven studies, in which tight glucose control was compared to tolerating severe hyperglycaemia, many subsequent studies, including NICE-SUGAR, targeted stricter blood glucose levels in the control group, explained by a shift in standard care after the Leuven studies [3–5, 7]. The outcome effect of lowering blood glucose from less severely elevated to tight blood glucose levels is presumably smaller than with a larger difference in blood glucose target. This is confirmed by a secondary analysis of the Leuven studies, which found a dose-dependent impact of blood glucose lowering on outcome [18].

Second, the accuracy of the blood glucose measurement and the insulin protocol differed among studies. Whereas in the Leuven studies, blood glucose was measured on arterial blood using an accurate blood gas analyser, in many subsequent studies including NICE-SUGAR, a variety of—at that time—inaccurate glucometers were used [19]. Also, subsequent studies allowed capillary glucose measurements, although unreliable in patients with shock [12]. Apart from that, the insulin treatment protocol differed. In Leuven, insulin was only administered through continuous intravenous infusion, in contrast to subsequent studies in which insulin boluses were allowed. Theoretically, inaccurate glucose measurements and insulin boluses increase blood glucose variability and the risk of prolonged and undetected hypoglycaemia, which may have contributed to the harm observed in NICE-SUGAR.

Finally, the feeding protocol differed among studies. In the Leuven studies, all patients received early parenteral nutrition as part of the standard treatment, whereas in NICE-SUGAR and other subsequent studies, patients received less parenteral calories in the acute phase [3–5, 7]. Early parenteral nutrition increases the risk of hyperglycaemia and was subsequently shown to be harmful, even in a context of tight glucose control [20, 21]. A meta-analysis revealed that the mortality impact of tight glucose control related to the amount of parenteral glucose given in the trial [22]. However, this meta-analysis did not adjust for other methodological differences. In contrast, a secondary analysis of the Leuven studies showed that the benefit of tight glucose control was also present in the subgroup who received the lowest amount of parenteral glucose [18]. Hence, it currently remains unknown whether tight glucose control is still beneficial in the absence of early parenteral nutrition.

Intraoperative Tight Glucose Control

Most large RCTs have investigated the effect of tight glucose control in intensive care unit (ICU) patients. However, major surgery *per se* also evokes hyperglycaemia, which has been associated with an increased risk of complications [2]. Several RCTs have investigated whether tight, intraoperative control of blood glucose also improves outcome as compared to tolerating hyperglycaemia. Altogether, these studies showed mixed results. Whereas some RCTs showed benefit in patients undergoing cardiac and vascular surgery, other trials in cardiac and non-cardiac surgery patients were neutral [23–26]. However, as the duration of the intervention was relatively small (mainly the time in the operating room), the benefit the investigators anticipated was probably too large. Hence, several of these RCTs were likely underpowered [27]. Interestingly, the largest RCT, which randomized 2383 elective cardiac surgery patients to intraoperative tight (4.4–6.1 mmol/L [80–110 mg/dl]) or liberal blood glucose control (<10 mmol/L [180 mg/dl]), followed by tight glucose control in all patients once admitted to the ICU, found less postoperative complications with the addition of intraoperative tight glucose control to only postoperative tight control [23]. Likewise, a recent RCT found reduced morbidity and mortality by a hyperinsulinaemic normoglycaemic clamp during elective cardiac surgery, as compared to standard care, which consisted of tolerating hyperglycaemia up to 8.3 mmol/L (150 mg/dl) [28]. As the study combined a hyperinsulinaemic clamp with maintaining normoglycaemia by adjusting the glucose intake, it is unclear whether the clinical benefit is explained by the lower glucose levels, by the higher insulin dose, or by a combination of both. However, as previous RCTs on glucose-insulin-potassium therapy in acute myocardial infarction revealed negative results when targeting normoglycaemia was not part of the intervention protocol [29, 30], it seems plausible that at least part of the benefit of the latter trial is explained by maintaining normal blood glucose levels.

Tight Glucose Control: Which Patients Benefit Most?

Theoretically, the mixed results across the different RCTs on tight glucose control could be explained by a different case mix. However, subgroup analyses could not identify a patient subgroup who responded differently to the intervention than others, with the possible exception of patients with pre-admission diabetes [7, 8, 18]. Indeed, in a secondary analysis of the Leuven RCTs, all patient subgroups showed benefit from tight glucose control, except patients with pre-admission diabetes in whom the intervention was neutral [18]. Likewise, in the large, intraoperative RCT, the benefit of tight glucose control was only present in the subgroup of non-diabetes patients [23]. These findings support observational studies, which revealed a flattened and right-shifted relationship of blood glucose with outcome, especially in patients with poorly controlled diabetes [1, 31] (**Figure 15.9.3.1**). Conversely, in NICE-SUGAR, all patient subgroups were harmed by the intervention, including patients without pre-admission diabetes [7]. Moreover, a large observational study in 5510 diabetic cardiac surgery patients found reduced mortality and infectious complications by implementation of a perioperative glucose control protocol [32].

Tight Glucose Control and the Risk of Hypoglycaemia

Tight glucose control inevitably increases the risk of hypoglycaemia. When severe or prolonged, hypoglycaemia can cause convulsions, coma, and irreversible brain damage, as well as cardiac

arrhythmias. The risk of hypoglycaemia is a concern in critically ill and surgical patients because early hypoglycaemic symptoms are not easily recognized in sedated patients [18]. Multiple observational studies have associated the occurrence of hypoglycaemia with an increased risk of death. However, hypoglycaemia is more prevalent in patients with more severe disease (particularly liver failure and sepsis). It remains unknown whether a short-lasting episode of iatrogenic hypoglycaemia adversely impacts outcome [18]. A secondary analysis of NICE-SUGAR attributed the increased mortality risk by tight glucose control to an increased risk of hypoglycaemia [17]. However, also prolonged hyperglycaemia may cause harm. A 4-year neurocognitive follow-up study of patients included in the paediatric Leuven study showed a better neurocognitive outcome of children randomized to tight glucose control, despite a high incidence of hypoglycaemia [10]. Moreover, a nested case-control study, matching critically ill children who effectively experienced an episode of hypoglycaemia to critically ill children without a hypoglycaemic event, also could not detect any harmful impact of hypoglycaemia on neuronal biomarkers and on 4-years neurocognitive outcome [10, 33]. The fact that overcorrection of hypoglycaemia was carefully avoided in the latter study [5], may have played a role. Indeed, animal data suggest that neuronal death after hypoglycaemia is mainly triggered by activation of neuronal NADPH oxidase, which occurs during glucose reperfusion [34]. Nevertheless, treatment protocols should aim at minimizing the risk of hypoglycaemia. The use of validated computerized treatment algorithms and of near-continuous glucose monitoring may substantially reduce this risk [35].

Summary and Conclusions

Currently, the optimal blood glucose target for critically ill and surgical patients remains unclear and may depend on the context. Tight glucose control has been shown to reduce morbidity and mortality of critically ill patients when performed with accurate glucose monitoring tools and an effective treatment algorithm that avoids insulin boluses in a context of early parenteral nutrition. Analyses of patient subgroups have not shown a differential impact of the intervention, with the possible exception of patients with pre-admission diabetes, who may benefit less from tight glucose control. The impact of tight glucose control in patients in whom early parenteral nutrition is avoided, is unknown. When the logistic context does not allow frequent, accurate glucose monitoring, tolerating higher glucose concentrations appears safer than strictly targeting the healthy fasting range. In any case, the incidence of hypoglycaemia and severe hyperglycaemia should be minimized, which can be achieved by the use of validated computerized treatment algorithms.

MODY

Overview

MODY is a familial form of diabetes with autosomal dominant inheritance that typically presents with non-insulin dependent diabetes diagnosed under the age of 25 years. The term 'MODY' was based on the previous definition of juvenile-onset and maturity-onset diabetes (now type 1 and type 2 diabetes). Although the term MODY is useful as it describes a broad category, cases are more appropriately described by the gene involved when this is known.

MODY is a genetically heterogeneous condition. The commonest causes are due to defects in the transcription factor genes: hepatic nuclear factor-1 alpha (*HNF1A*; ~52%), and hepatic nuclear factor-4 alpha (*HNF4A;* ~10%), as well as the Glucokinase gene (*GCK*; ~32%) [1, 2]. The diabetes phenotype is similar in HNF1A and HNF4A MODY and distinct from that seen in GCK MODY. These are summarized in Table 15.10.1.1.

HNF1A and HNF4A MODY

Clinical Phenotype

Diabetes

HNF1A and HNF4A MODY have a similar diabetes phenotype with progressive hyperglycaemia throughout life [3] (Figure 15.10.1.1). Diabetes characteristically presents in adolescence or early adulthood, in HNF1A MODY 70% develop diabetes by age 25 years, 97% by 50 years. The mean age of diagnosis is similar in HNF1A (20 years) and HNF4A MODY (23 years) [2, 4, 5]. Postprandial glucose values are raised before fasting hyperglycaemia develops and hence, during an oral glucose tolerance test (OGTT), patients typically have an elevated 2-hour glucose with a large increment above the fasting value (>3 mmol/L) [6].

Diabetes-related complications occur frequently and are related to the degree of hyperglycaemia, therefore ongoing monitoring and follow-up is important. There is an increase in cardiovascular morbidity seen in HNF1A MODY. This is despite HDL levels being relatively high, which may appear falsely reassuring [2].

Non-Diabetes Features

HNF1A MODY can sometimes be differentiated from HNF4A MODY by the extrapancreatic features.

In HNF1A MODY decreased renal glucose reabsorption results in a low renal threshold for glucose, causing glycosuria at minimally raised blood glucose levels (<8 mmol/L). Glycosuria may be an early sign of glucose intolerance offering the potential for use as a screening tool in undiagnosed children with an affected parent [2].

In HNF4A MODY apolipoprotein synthesis is altered, resulting in a reduction in HDL, lipoprotein A1, and A2 [5]. Macrosomia also occurs in ~50% (average increased birth weight 800 g) and transient neonatal hypoglycaemia may be present (~15%) with diabetes presenting later in life [2, 7]. A history of marked macrosomia (birth weight >4.4 kg) or prolonged (>48 hours) hypoglycaemia in

Table 15.10.1.1 Comparison between HNF1A/HNF4A MODY and GCK MODY and type 1 and type 2 diabetes

	HNF1A/HNF4A MODY	GCK MODY	Type 1 Diabetes	Type 2 Diabetes
Age at diagnosis	Typically adolescence/early adulthood	When tested	Typically child or young adult	Typically middle or old age
Presenting features	Polyuria, polydipsia, weight loss but may be asymptomatic	Usually incidental Asymptomatic	Polyuria, polydipsia, weight loss	Polyuria, polydipsia but may be asymptomatic
Glycaemia	Progressive deterioration, HbA1c ≥6.5% (48 mmol/mol)	Stable mild elevated fasting hyperglycaemia (5.4–8.3 mmol/L) from birth, HbA1c 5.8–7.6% (40–60 mmol/mol)	Progressive deterioration HbA1C ≥6.5% (48 mmol/mol)	Progressive deterioration HbA1C ≥6.5% (48 mmol/mol)
Low C-peptide (<200 pmol/L)	No	No	Yes outside honeymoon	No
Islet autoantibodies	Negative	Negative	Positive (~80–90%)	Negative
Complications	Frequent microvascular and macrovascular complications HNF1A: Excess cardiovascular morbidity	Very rare microvascular complications—mild if occur, no monitoring required	Frequent microvascular and macrovascular complications	Frequent microvascular and macrovascular complications
Extrapancreatic features	HNF1A: Renal-glycosuria at lower renal threshold HNF1A liver-Raised HDL, adenoma HNF4A: liver-reduced TG, LDL, reduced HDL Macrosomia (56%), neonatal hypoglycaemia (15%)	Fetal size determined by maternal/fetal genotype	None	None
Treatment	Sulphonylurea sensitive 30% ultimately require insulin	Treatment usually neither effective nor needed Consider insulin during pregnancy	Insulin	Diet, non-insulin antidiabetic drugs, Insulin

an infant of a diabetic parent (mother or father) is an indication for sequencing *HNF4A* before the more common *HNF1A* gene [2, 7].

Differentiating HNF1A/HNF4A MODY from Type 1 and Type 2 Diabetes

More than 80% of MODY is not diagnosed in routine clinical practice due to overlapping clinical features with T1D and T2D [1]. The classical criteria (young-onset, family history and non-insulin treatment) only identifies 48% of patients with MODY. However, identifying patients with a high probability of MODY can be greatly improved by using a statistical calculator that takes into account multiple simple clinical factors [8]. The 'MODY Probability calculator' is available as a smart phone application (Diabetes diagnostic) and at https://www.diabetesgenes.org.

HNF1A/HNF4A MODY may be misdiagnosed as T1D due to the young age at symptomatic presentation.

However unlike T1D, in HNF1A/HNF4A MODY, endogenous insulin production (C-peptide >200 pmol/L) is persistent outside the honeymoon period [9] and islet autoantibodies are negative [10]. Therefore, presence of islet autoantibodies and/or C-peptide <200 pmol/L strongly confirms presence of T1D and can be used as a rule-out test for selecting patients for MODY genetic testing.

T2D may be misdiagnosed in patients who are clearly non-insulin dependent. In contrast to T2D, patients with HNF1A/HNF4A MODY are rarely obese, do not have acanthosis nigricans, and the metabolic syndrome is less common. 'MODY Probability calculator' helps to discriminate T2D and MODY [8]. Sulphonylurea therapy may cause hypoglycaemia in HNF1A/HNF4A MODY at the standard doses used in T2D.

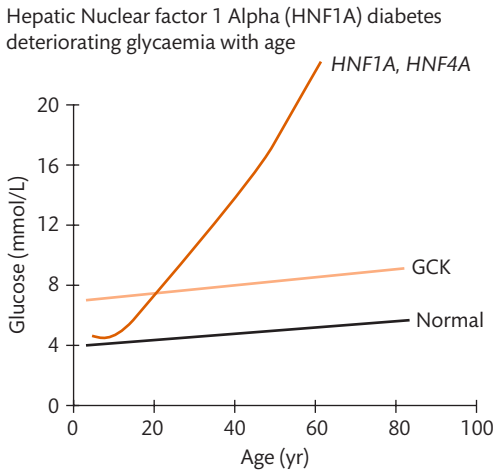

Figure 15.10.1.1 Effect of glycaemia on MODY genotype. In HNF1A/HNF4A MODY, glucose deteriorates with increasing age. In contrast, in GCK MODY, there is little change in glycaemia with age.

Genetics

Over 414 different heterozygous mutations have been reported in the *HNF1A* gene and ~103 have been reported in the *HNF4A* gene [11]. The commonest genetic abnormalities are missense mutations (55% in the *HNF1A* gene). Other mutations include nonsense, insertions, duplications, deletions, insertion/deletions, promoter, and splice site mutations.

Pathophysiology

HNF1A and *HNF4A* genes encode proteins which control gene expression during embryogenesis and in adult life. *HNF1A* and *HNF4A* are expressed in the pancreatic beta-cell and hepatocyte, regulating genes which encode proteins involved in beta-cell development and functioning. They result predominantly in progressive beta-cell failure [3].

Treatment

Patients are very sensitive to the glucose lowering effect of sulphonylurea therapy (five times more than metformin and four times more than in T2D) [3, 12]. This results from both increased insulin secretion and increased insulin sensitivity [12]. Starting doses should be low (e.g. 20–40 mg gliclazide daily) to avoid hypoglycaemia. Alternatively low-dose fast-acting novel agents like repaglinide may be used.

Increasing sulphonylurea doses are required to treat deteriorating glycaemia occurring as the patient gets older. Around 30–40% of patients progress to needing insulin treatment to control blood glucose values, so monitoring glycaemic control is essential. Patients who are misdiagnosed with T1D will be treated with insulin initially and even after several years on insulin the majority (79%) can still be successfully transferred onto sulphonylureas often with improvement in glycaemic control [13].

Due to the excess in cardiovascular morbidity, we recommend treating patients with HNF1A MODY with a statin after the age of 40 years even if HDL levels appear high [2].

GCK MODY

Clinical Phenotype

Diabetes

GCK MODY causes asymptomatic mild fasting hyperglycaemia (usually 5.4–8.3 mmol/L) from birth that deteriorates slightly with age. It is often detected incidentally and depending upon the time of detection can be misdiagnosed as gestational diabetes during routine antenatal screening, T1D or T2D [14].

In contrast to those with HNF1A/HNF4A MODY, patients always have fasting glucose >5.5 mmol/L and a small increment during an OGTT [6, 14]. This is because they have appropriate insulin secretion which is reset at a slightly higher glucose set point. This is also reflected in their HbA1c which ranges from 5.8 to 7.6% (40–60 mmol/mol) [14].

Differentiating GCK MODY from Type 1 and Type 2 Diabetes

A persistently raised mild fasting glucose without further deterioration in glycaemia strongly suggests GCK MODY especially when found in children or young adults (Figure 15.10.1.1). A dominant family history may not be identified unless fasting glucose is tested in asymptomatic family members. Diagnosis is worthwhile to avoid unnecessary treatment. Similar to HNF1A/HNF4A MODY, MODY probability calculator and C-peptide and islet autoantibodies can help to discriminate GCK MODY from T1D/T2D.

Genetics

Nearly 620 heterozygous inactivating mutations (missense, nonsense, frameshift, splice site) have been described throughout the 10 exons of the *GCK* gene [15].

Pathophysiology

GCK is a glycolytic enzyme catalysing the first step in glucose metabolism in the pancreatic beta-cell and hepatocyte (glucose to glucose-6-phosphate). Glucokinase is often referred to as the 'pancreatic glucose sensor' because this rate-determining step is key to detection of ambient glucose and maintaining euglycaemia through appropriate insulin secretion [14, 15]. A reduction in *GCK* activity decreases glucose phosphorylation, which raises the threshold concentration of glucose needed for insulin secretion.

Treatment

Treatment of hyperglycaemia is usually unnecessary outside pregnancy as microvascular complications are rare and glucose homeostasis is maintained [14, 16]. In addition as the fasting glucose level is regulated, low-dose insulin or oral agents do not alter HbA1c except when T2D is also present (HbA1c > 7.5%) [14].

Management in pregnancy depends on growth of the fetus. Growth can be predicted by parental/fetal inheritance. If the fetus and mother both have the mutation, they share a common higher glucose set point resulting in appropriate fetal growth. If there is only a maternal mutation, the fetus will increase its own insulin secretion in response to maternal hyperglycaemia and so there will be increased fetal growth. Reducing maternal hyperglycaemia may be difficult and large insulin doses (at least replacement doses) are often needed and the patient's counterregulation which is also set to the higher level will make achieving normal glucose values difficult. Early delivery may be required for a macrosomic baby. Conversely, a fetus who inherits a paternal mutation may be small for dates because of reduced fetal insulin secretion as the fetal set point is higher than its unaffected mother [17].

Less Common Subtypes of MODY

Other rarer causes of MODY include heterozygous mutations in *PDX1, NEUROD1, ABCC8, INS, KCNJ11*, and *RFX6*. Although *HNF1B* was initially described as a MODY gene and is a hepatic transcription factor it is discussed under monogenic diabetes syndromes since it typically presents with extrapancreatic (notably renal) disease [18].

Neonatal Diabetes

Overview

Neonatal diabetes is a rare (1:100 000 live births) genetically heterogeneous disorder in which diabetes is diagnosed within the first 6 months of life [19]. Around 85% of diabetes diagnosed within the first 6 months of life has a monogenic aetiology [20]. Patients present with diabetes that either persists (permanent neonatal diabetes, PNDM) or remits but frequently relapses later in life (transient

Table 15.10.1.2 Comparison of clinical features of the common genetic subgroups seen in PNDM and TNDM

	PNDM		TNDM	
Genes involved	K_{ATP} channel (~40%)	*INS* (~12%)	6q24 (70%)	K_{ATP} channel (~25%)
Age of presentation in weeks, median (range)	8 (0–40)	11 (0–1144)	Initial: 0.4 (0–4) Relapse:16 years (4–25 years)	Initial: 4 (0–16) Relapse: 5 years (3–15 years)
Birth weight in kg, median (range)	2.7 (1.5–4.2)	2.7 (1.7–3.9)	1.9 (1.6–2.7)	2.6 (1.4–3.6)
Sensitivity to sulphonylureas	85–90%	None	Usually successful on relapse	Usually successful on relapse

PNDM, permanent neonatal diabetes; TNDM, transient neonatal diabetes; K_{ATP} channel genes, *KCNJ11*, *ABCC8*.

neonatal diabetes, TNDM), in approximately equal proportions. There is some overlap in the genes involved. The underlying genetic aetiology determines both the clinical features and the treatment modalities. Those involving the ATP-sensitive potassium channel (K_{ATP} channel) should be treated with oral sulphonylureas. This makes early genetic diagnosis a priority. Diabetes may be present in isolation or associated with other features. Neonatal diabetes can also occur in babies born preterm and they should also have genetic testing. Comparison of the common subtypes of PNDM and TNDM are summarized in Table 15.10.1.2.

Permanent Neonatal Diabetes (PNDM)

Mutations in several genes have been reported giving rise to PNDM, causing abnormal pancreatic development, increased beta-cell destruction, or beta-cell dysfunction.

Common Causes

Activating (gain of function) mutations in *KCNJ11* and *ABCC8* genes account for around 40% of cases [20, 21]. They encode the subunits that make up the K_{ATP} channel of the beta-cell membrane; a 4:4 complex, with an inner pore-forming subunit Kir6.2 (*KCNJ11*) and outer regulatory subunit SUR1 (*ABCC8*). This channel is critical to maintaining glucose homeostasis through insulin secretion by the beta-cell; binding of ATP to Kir6.2 causes channel closure, membrane depolarization, and insulin secretion. The mutated K_{ATP} channel remains open and therefore unable to complete the cascade of steps culminating in insulin secretion [2, 22].

Most patients are born small (mean birthweight 2.7 kg), reflecting fetal insulin deficiency. The typical age of diagnosis is 8 weeks with marked hyperglycaemia (median glucose 33 mmol/L for those with *KCNJ11* mutations) and ketoacidosis with absent or very low C-peptide, all reflecting marked insulin deficiency. Except in a few rare cases, patients are diagnosed under the age of 6 months [21, 22].

The majority of patients have isolated diabetes, but neurological features may be seen in approximately 29% cases with *KCNJ11* mutations, and are less frequent and less marked in those with *ABCC8* mutations (20%) [20]. The neurological features result from a severely mutated K_{ATP} channel affecting the brain, muscle, and/or nerve. There are two patterns of abnormalities described. The DEND syndrome (severe Developmental delay, Epilepsy and Neonatal Diabetes) and the less severe phenotype, intermediate-DEND, in which epilepsy is less severe and less common, and the developmental delay is less marked [2, 19].

K_{ATP} channel mutations usually arise *de novo* (*KCNJ11*: ~80%; *ABCC8*: ~50%), but are typically dominantly inherited although some *ABCC8* mutations are recessive. There is a strong genotype-phenotype relationship for *KCNJ11* mutations although this is not absolute. For example, *KCNJ11* R201H mutations are typically seen in isolated diabetes, while patients with V59M typically have neurological features with the intermediate-DEND syndrome.

The critical reason to make a genetic diagnosis is that it will have a dramatic impact on treatment. Sulphonylureas close the mutated K_{ATP} channel causing membrane depolarization and insulin secretion. After stabilization on insulin, the majority of patients (85–90%) can be transferred on to sulphonylureas with improved glycaemic control, without increased hypoglycaemia that persists up to 10 years [22, 23]. Doses used are 3–4 times higher than those used in T2D. Higher doses (0.4–0.8 mg/kg/day) are typically needed in those with *KCNJ11* compared to *SUR1* mutations. (0.2–0.4 mg/kg)/day) [23]. Choice of sulphonylurea may be important in those who later develop neurological features. Glibenclamide crosses the blood–brain barrier and early treatment may reverse some neurological deficit in some cases [24].

Less Common Causes

Mutations in the *INS* gene, which encodes preproinsulin, accounts for 12% PNDM cases. They tend to be diagnosed later than those with K_{ATP} channel mutations (11 vs. 8 weeks) and require insulin treatment [21].

Rare

Rare causes of PNDM frequently involve extrapancreatic tissues and are listed in Table 15.10.1.3 [19, 20].

Transient Neonatal Diabetes (TNDM)

Commonest Causes

Approximately 70% cases are due to abnormalities in imprinting on chromosome 6q24, causing overexpression of a paternally expressed gene (*ZAC* and *HYMAI*) through different mechanisms; paternal uniparental disomy, paternal 6q24 duplication, and hypomethylation [25]. Of those with a methylation defect, some have been found due to a mutation on an upstream gene (*ZFP57*) which regulates methylation at 6q24 [25]. These patients have a global methylation problem which explains their other clinical features (congenital heart disease, developmental delay).

Irrespective of mechanism, the common phenotype is one of severe intrauterine growth retardation (IUGR) (mean birthweight

Table 15.10.1.3 Causes of neonatal diabetes

	Gene (protein) affected	PNDM/TNDM	Inheritance	Pancreatic agenesis	Common Extrapancreatic features (excluding low birth weight)
Common causes	K_{ATP} channel; *KCNJ11* (Kir6.2) and *ABCC8* (SUR1)	PNDM (50%) TNDM (25%)	AD (KCNJ11) AD/AR (ABCC8)	No	Neurological—developmental delay and epilepsy (29%)
	6q24 abnormality	TNDM (70%)	Variable	No	Macroglossia (30%) Umbilical hernia (9%)
	INS (insulin)	PNDM (12%)	AD (Coding mutation) / AR (promoter mutation)	No	Nil
Less common causes	*EIF2AK3* (eukaryotic translation initiation factor 2-alpha kinase 3)	PNDM	AR	No	Wolcott–Rallison syndrome (spondyloepiphyseal dysplasia, hepatitis, renal failure)
	FOXP3 (forkhead box protein P3)	PNDM	X-linked	No	IPEX syndrome (immunodysregulation, entero-, and endocrinopathy)
	GATA6 (GATA binding protein 6)	PNDM	AD	Yes	Congenital heart malformation, neurological defects, hypothyroidism, gut and hepato-biliary malformation, exocrine pancreatic dysfunction
	GCK (glucokinase)	PNDM	AR	No	Nil
	PTF1A (pancreas transcription factor 1 subunit alpha)	PNDM	AR	Yes	Distal enhancer mutation—isolated pancreatic agenesis; Coding mutation—cerebellar agenesis, microcephaly, exocrine pancreatic dysfunction
Rare causes	*GATA4* (GATA binding protein 4)	PNDM	AD	Yes	Congenital heart malformation, exocrine pancreatic dysfunction
	GLIS3 (GLIS family zinc finger 3)	PNDM	AR	No	Congenital hypothyroidism and glaucoma, liver fibrosis, cystic kidney disease
	HNF1B (hepatocyte nuclear factor 1-beta)	PNDM/TNDM	AD	Yes	Renal cysts, exocrine pancreatic dysfunction
	IER3IP1 (immediate early response 3-interacting protein 1)	PNDM	AR	No	Microcephaly, epilepsy
	LRBA (lipopolysaccharide-responsive and beige-like anchor protein)	PNDM	AR	No	Early onset multiple autoimmune features (e.g. hypothyroidism, autoimmune cytopenia, enteropathy), recurrent infections
	MNX1 (motor neuron and pancreas homeobox protein 1)	PNDM	AR	No	Sacral agenesis, neurological defects
	NEUROD1 (neurogenic differentiation factor 1)	PNDM	AR	No	Cerebellar hypoplasia, sensorineural deafness, visual impairment
	NEUROG3 (neurogenin-3)	PNDM	AR	No	Congenital malabsorptive diarrhoea
	NKX2-2 (homeobox protein Nkx-2.2)	PNDM	AR	No	Severe neurodevelopmental defects
	PDX1 (PANCREAS/ duodenum homeobox protein 1)	PNDM	AR	Yes	Exocrine pancreatic dysfunction
	RFX6 (regulatory factor X6)	PNDM	AR	No	Gall bladder aplasia, gut atresia
	SLC2A2 (solute carrier family 2, facilitated glucose transporter member 2)	PNDM/TNDM	AR	No	Hypergalactosaemia, liver failure
	STAT3 (signal transducer and activator of transcription 3)	PNDM	AD	No	Short stature, early onset multiple autoimmune features (e.g. hypothyroidism, autoimmune cytopenia, eczema), low IgE
	WFS1 (Wolframin)	PNDM	AD	No	Congenital sensorineural deafness, and congenital cataracts

AR, autosomal recessive; AD, autosomal dominant.

Table 15.10.1.4 Monogenic diabetes syndromes (excluding those typically presenting with neonatal diabetes)

A	Inheritance	Cause	Clinical phenotype (median age unless otherwise stated)	Distinguishing features
Wolfram syndrome	AR		DIDMOAD: cranial diabetes insipidus (73%), diabetes mellitus (6 years), optic atrophy (11years), bilateral sensorineural deafness (20 s; 62%) Other features: renal tract anomalies (30 s; 58%), cerebellar ataxia and myoclonus (40 s; 62%), gastrointestinal dysmotility (24%), primary gonadal atrophy, early death (30 years)	Childhood onset diabetes and optic atrophy
MIDD	Maternal	Mitochondrial DNA point mutations (commonly m.3243 A>G)	MIDD: Maternally Inherited Diabetes (slow onset, 20% acute, 8% ketoacidosis; 37 years; range 11–68): and deafness: sensorineural cochlear (75%; range 2–61 years; M>F) Variable phenotypes: MELAS, MERRF, CPEO, KSS, Leigh syndrome Other features: macular retinal dystrophy, myopathy, cardiac abnormalities with risk of premature death, renal disease, endocrine, gastrointestinal	Maternal inheritance Deafness frequently precedes diabetes Stroke <40 years (MELAS) Renal, ophthalmic, and neurological disease Ragged red fibres on muscle biopsy
Roger's syndrome	AR	*SLC19A2* mutations	Thiamine responsive megaloblastic anaemia, cardiac, neurological	Megaloblastic anaemia responds to thiamine, early onset deafness
RCAD	AD *de novo* 1/3	*HNF1B* gene deletions and mutations (encoding transcription factor HNF1B)	Renal developmental disorder (cysts;66%), diabetes; 58% (20 years; 15 days–61 years), genitourinary abnormalities (male 5%, female 14%), hyperuricaemia (20%), hypomagnesaemia (40%), abnormal liver function (13%)	Developmental renal disorder preceding diabetes
DPED syndrome	AD	*CEL* gene deletions	Diabetes and pancreatic exocrine function	Pancreatic exocrine dysfunction

*MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes), MERRF (myoclonic epilepsy associated with ragged red fibres), CPEO (chronic progressive external ophthalmoplegia), KSS (Kearns-Sayre syndrome), Leigh syndrome. *SLC19A2*, solute carrier family2, member 2 gene; CEL, carboxyl ester lipase.

1930 g), diabetes usually in the first weeks of life (median presentation 3 days), remission (typically at 3 months), and relapse in ~55% at around 14 years. Macroglossia (30%) and occasionally an umbilical hernia (9%) may also be present. The genetic mechanism predicts the heritability [25].

Treatment is initially with insulin but on relapse, patients are managed with sulphonylureas or other oral therapy [26].

Patients who have TNDM but do not have an abnormality at 6q24 (~25%) usually (~89%) have a gain of function mutation in one of the K_{ATP} channel genes (*KCNJ11, ABCC8*). In comparison to those with 6q24 abnormalities, patients with TNDM due to K_{ATP} channel mutations have less IUGR (mean birth weight 2.57 vs. 1.95 kg), and present later (4 vs. 0 weeks) indicating less severe insulin deficiency at birth. However, they also enter remission later (35 vs. 13 weeks), and relapse earlier (4.7 vs. 16 years). Similar to K_{ATP} channel mutations causing PNDM, neurological features may be present [27]. These TNDM patients on relapse are treated with low-dose sulphonylureas compared to high-dose sulphonylureas for PNDM patients.

Rare Causes of TNDM

Rare causes of TNDM include mutations in *INS, HNF1B, SLC2A2*, which may also cause PNDM.

Monogenic Syndromes Associated with Monogenic Beta-Cell Disorders

These are listed in Table 15.10.1.4 [2, 18, 28, 29].

Conclusions

There have been considerable advances in our understanding of the molecular genetic aetiology of beta-cell monogenic diabetes. Identifying the aetiological subtypes is crucial for appropriate patient management. Molecular genetics is now key in this area of clinical diabetes and not solely a research investigation.

15.10.2 Lipodystrophies and Severe Insulin Resistance Syndromes

Anna Stears, David B. Savage, and Stephen O'Rahilly

Introduction

The most common cause of insulin resistance, defined by impaired blood glucose lowering by insulin, is obesity. A minority of patients have severe insulin resistance without obesity. These patients, while not contributing significantly to the general prevalence of diabetes, often harbour pathogenic single gene defects affecting insulin signalling or adipose tissue function [1]. This chapter focuses on the resulting severe insulin resistance syndromes.

The normal response of the pancreatic beta-cells to insulin resistance is increased insulin secretion, and hyperglycaemia may not be present, especially earlier in life. Although clinical history and examination may offer clues to the presence of severe insulin resistance, laboratory confirmation should usually be sought. Measurement of insulin concentration is useful, although this is infrequent in clinical practice. Biochemical diagnostic thresholds for severe insulin resistance are arbitrary, and should, ideally, be interpreted in the context of BMI-adjusted normal ranges. However, one set of approximate diagnostic criteria is as follows:

- No diabetes and BMI under 30 kg/m^2 —fasting insulin above 150 pmol/L or peak insulin on oral glucose tolerance testing above 1500 pmol/L.
- Diabetes with absolute insulin deficiency and BMI under 30 kg/m^2 —exogenous insulin requirement above 3 units/kg/day.
- Diabetes with partial β cell decompensation and/or BMI over 30 kg/m^2—insulin levels are difficult to interpret in the context of obesity, while, in established diabetes, glucotoxicity, impaired islet function, and a combination of endogenous and exogenous insulin in the circulation confuse the biochemical picture. In this setting, the clinical history and features such as acanthosis nigricans are important in making a diagnosis of likely monogenic severe insulin resistance.

Causes of Severe Insulin Resistance

In addition to obesity, causes of severe insulin resistance can be categorized into:

1. Inherited or acquired defects in insulin signalling (including insulin receptoropathies)
2. Inherited or acquired impairment of adipocyte triglyceride storage (lipodystrophies)
3. Complex syndromes with associated severe insulin resistance

Insulin resistance of any cause may be exacerbated by puberty, pregnancy, weight gain, or intercurrent illness. Existing clinical nomenclature is variably applied and reflects historical descriptions of the syndromes: type A insulin resistance syndrome was named in the 1970s to discriminate it from the anti-insulin receptor antibody-mediated type B insulin resistance. It denotes acanthosis nigricans, hyperandrogenism, oligo- or amenorrhoea, and a BMI <30 kg/m^2. 'HAIR-AN' syndrome denotes 'HyperAndrogenism, Insulin Resistance, and Acanthosis Nigricans', and is identical to type A insulin resistance syndrome except that it is often used only in women with BMI >30 kg/m^2.

Prevalence of Severe Insulin Resistance

No clear prevalence figures exist for severe insulin resistance syndromes. A recent survey suggested a prevalence of all lipodystrophies across adjudicated electronic medical record databases of 3.07 cases per million (0.23 cases/million for generalized lipodystrophy and 2.84 cases/million for partial lipodystrophy) [2]. It is likely that many patients, especially males, remain undiagnosed. Experience over 5 years in the UK national specialist referral centre found that of 283 patients with confirmed severe insulin resistance and/or lipodystrophy, 14 (5%) had an insulin receptor (INSR) mutation, 1 (0.3%) had insulin-receptor antibodies, 13 (4.5%) had congenital generalized lipodystrophy, and 135 (47%) familial partial lipodystrophy (FPLD). Of the FPLD group 76 (26.5%) had FPLD1, 42 (14.6%) FPLD2 secondary to mutation of the *LMNA* gene, 17 (6%) FPLD3 secondary to mutation of the *PPARG* gene and 36 (12.5%) acquired lipodystrophy (4 generalized).

Generic Clinical Features of Severe Insulin Resistance Syndromes

Severe insulin resistance is often first noticed in patients with persistent hyperglycaemia despite very large doses of insulin. However many cases are unrecognized in the pre-diabetic phase. Indeed, a very common early feature of severe insulin resistance is spontaneous and symptomatic postprandial *hypo*glycaemia. This may dominate the clinical picture for years before hyperglycaemia supervenes, which only occurs in the face of β cell decompensation. The commonest presentation of severe insulin resistance is with acanthosis nigricans, which is nearly a *sine qua non* of all forms of severe insulin resistance. Another common presenting feature in females is hyperandrogenism (which may be severe) and oligo- or amenorrhoea. Partly for this reason, a large preponderance of presenting patients are female. Acanthosis nigricans and hyperandrogenism are common to all known forms of severe insulin resistance, but are not generally seen in insulin-deficient forms of diabetes. It is thus concluded that their pathogenesis depends upon severe hyperinsulinaemia, likely leading to ectopic activation of the insulin-like growth factor 1 (IGF-1) receptor, which is closely homologous to the insulin receptor. This mechanism, while not proven, seems plausible for components of the syndrome that feature cellular hyperproliferation, such as acanthosis nigricans and ovarian hyperthecosis [3].

Clinical Features Which Differentiate Causes of Severe Insulin Resistance

Clinical examination may reveal, in addition to acanthosis nigricans, a paucity or an unusual distribution of body fat, suggesting lipodystrophy. There may be other clinical features in patients with complex syndromes including short stature or signs of premature ageing. Age of onset of clinical features provides diagnostic clues. Fat loss is present from birth in the inherited generalized lipodystrophies, becomes most noticeable at puberty in the inherited partial lipodystrophies and tends to start with

the face and upper body in acquired lipodystrophies. Signs and symptoms often present in puberty in patients with heterozygous insulin-receptor mutations but earlier in childhood in patients with homozygous insulin-receptor mutations. The time course of onset is also important. For example, there is usually a history of rapid weight loss and onset of acanthosis nigricans and diabetes in patients with insulin receptor antibody-mediated type B insulin resistance.

Defects in Insulin Signalling Including Insulin Receptoropathies

Genetic defects in *INSR*, the gene encoding the insulin receptor, produce a spectrum of clinical syndromes: the most severe are autosomal recessive disorders with infant or childhood mortality. Although they form a continuum, the historical labels 'Donohue' or 'Rabson–Mendenhall' syndromes are still commonly used [4, 5]. Both feature characteristic dysmorphism and impaired linear growth. There is poor development of adipose tissue and muscle, which both rely on insulin-stimulated glucose uptake, contrasting with pseudoacromegaloid overgrowth of many other soft tissues. Hypertrichosis and exaggerated growth of androgen-dependent tissues may be particularly prominent. More difficult to diagnose clinically are the milder autosomal dominant insulin-receptor defects leading to type A insulin resistance, HAIR-AN (hyperandrogenism, insulin resistance, and acanthosis nigricans) syndrome, or their male equivalents. These are commonly caused by heterozygous intracellular mutations with dominant negative activity towards the coexpressed wild-type allele [6].

Traditionally, it has been difficult to discriminate patients with type A insulin resistance due to *INSR* mutations from those with other aetiologies for their insulin resistance. However, by exploiting the biochemical differences between receptoropathies and other forms of severe insulin resistance, it is now possible to undertake biochemical triage with a high degree of accuracy prior to genetic testing, expediting genetic diagnosis of affected patients and avoiding unnecessary and expensive sequencing of the large *INSR* gene. Plasma concentration of the adipose tissue-derived protein adiponectin is the most discriminating marker of receptoropathy. In receptoropathy, normal or elevated adiponectin levels are usually found in the face of extreme insulin resistance, unlike the suppressed levels seen in other insulin-resistant states including lipodystrophy [7] (**Table 15.10.2.1**). A further clinical clue to insulin receptoropathy is the absence of dyslipidaemia and hepatic steatosis despite severe insulin resistance [8]. This interesting observation has also led to the inference that this component of the common 'insulin resistance syndrome' actually reflects exposure of intact insulin signalling pathways in at least some tissues to high circulating insulin levels. A similar biochemical profile with normal or raised adiponectin levels and an absence of dyslipidaemia is seen in patients whose insulin resistance is due to mutations in the p85 alpha regulatory subunit of PI3 kinase (see SHORT syndrome, to follow). The biochemical profile of type B insulin resistance, due to anti-insulin-receptor antibodies, is also similar to that of the genetic insulin-receptor defects, but the onset is more acute, with rapid onset acanthosis nigricans and severe hyper and/or hypoglycaemia [9]. Type B insulin resistance is most often, but not exclusively, described in females of African origin.

Table 15.10.2.1 Comparison of biochemical features of insulin receptoropathy with other forms of severe insulin resistance

	Prevalent insulin resistance/ lipodystrophy	Insulin receptoropathy
Insulin	↑↑	↑↑-↑↑↑
Glucose	↑/→/↓	↑/→/↓
Triglyceride	↑-↑↑↑	→
High-density lipoprotein (HDL) cholesterol	↓	→
Adiponectin	↓	↑-↑↑↑
IGFBP-1	↓	→-↑↑
SHBG	↓	→-↑↑

Primary Lipodystrophic Syndromes

Lipodystrophies are a heterogeneous group of conditions characterized by partial or complete absence of adipose tissue [10]. They may be genetic or acquired, and are further classified according to the anatomical distribution of the lipodystrophy [10]. White adipose tissue is required for the storage of excess energy as triglyceride in lipid droplets. Failure to store triglyceride in subcutaneous adipose tissue leads to alternative storage in liver and muscle tissue causing impaired insulin action in these tissues [11]. Insulin resistance therefore is a feature of most, but not all lipodystrophies. As with all forms of insulin resistance, the clinical expression in adults is more pronounced in women.

Congenital Generalized Lipodystrophy

Congenital generalized lipodystrophy (CGL), also known as Berardinelli–Seip congenital lipodystrophy (BSCL) [12], is an autosomal recessive condition characterized by a generalized absence of adipose tissue from birth, increased appetite due to leptin deficiency, accelerated growth, and advanced bone age. Skeletal muscles, peripheral veins, and the thyroid gland are prominent due in part to paucity of subcutaneous fat. Hyperinsulinaemia from early childhood leads to organomegaly, acromegaloid features, and acanthosis nigricans. Diabetes tends to develop in the second decade. Hepatomegaly is often prominent and caused by severe non-alcoholic fatty liver disease (NAFLD), which generally progresses to non-alcoholic steatohepatitis (NASH), and, often, eventually to cirrhosis. Severe hypertriglyceridaemia, eruptive xanthomata, and pancreatitis are common. In the vast majority of cases, CGL is due to biallelic mutations in either the gene encoding 1-acylglycerol-3-phosphate O-acyltransferase 2 (AGPAT2), or the gene-encoding seipin (*BSCL2*), an endoplasmic reticulum protein. AGPAT2 is an essential enzyme in glycerophospholipid and triacylglycerol synthesis. The mechanistic link between seipin and lipodystrophy is more obscure, although seipin has been shown

to be highly expressed in white adipose tissue and to be essential for adipogenesis *in vitro* [13]. It is currently not possible to distinguish clinically between these genetic subgroups with confidence. However, adipose tissue loss in mechanical fat pads, such as the palms, soles, orbits, scalp, and periarticular regions, has been reported as a specific feature of CGL due to seipin mutations.

Familial Partial Lipodystrophies

Familial partial lipodystrophies (FPLD) are both milder and more common than CGL. Indeed, patients with these conditions may exhibit normal, or even increased, whole-body adipose stores. Consequently, indices such as the BMI have little utility in diagnosing FPLD. The abnormality instead lies in the adipose tissue topography, or fat distribution. In particular, head and neck adipose depots are often preserved or increased. Without a thorough clinical examination, it is thus possible to form the erroneous impression of normal or increased adiposity [10]. These disorders most commonly present in peri- or postpubertal women, and the loss of femorogluteal fat is particularly striking. They are difficult to detect clinically in men and in prepubertal children. Metabolic abnormalities range from asymptomatic impaired glucose tolerance and mild dyslipidaemia to severe insulin resistance with type 2 diabetes mellitus and severe dyslipidaemia, eruptive xanthomata, and pancreatitis. NAFLD/ NASH is also common.

Familial Partial Lipodystrophy Type 1 (FPLD1)

FPLD1 (Köbberling syndrome) is characterized by loss of limb fat with preserved (and, frequently, increased) truncal fat, in a pattern reminiscent of that seen in Cushing's syndrome [14]. While some of these patients do have affected family members, many do not, suggesting that not all cases are inherited. No specific genetic defects have been reported in this group and recently it has been noted that patients with FPLD1 are significantly enriched for SNPs associated with increased fasting insulin and lower gluteofemoral fat deposition from 53 distinct genomic regions, suggesting polygenic inheritance [15, 16].

Familial Partial Lipodystrophy Type 2 (FPLD2)

FPLD2 (Dunnigan syndrome) predominantly affects the limbs and gluteal fat depots with variable truncal involvement, but with normal or excess fat on the face, neck, and in the labia majora [17]. A majority of patients with FPLD2 have heterozygous loss-of-function mutations in LMNA, encoding lamin A/C, a structural component of the nuclear lamina which is nearly ubiquitously expressed. Mutations in this gene have also been convincingly linked to several different disorders, including muscular dystrophy and dilated cardiomyopathy. Detailed understanding of the mechanisms underlying the tissue-selective phenotypes associated with LMNA mutations is lacking, but proposed abnormalities include structural defects in the nuclear envelope and altered binding of the nuclear lamina to chromatin or transcription factors.

Familial Partial Lipodystrophy Type 3 (FPLD3)

FPLD3 also features a paucity of limb and gluteal fat; however, abdominal fat is generally preserved and may even be increased, and facial fat is most commonly normal. Insulin resistance and lipodystrophy have been described in prepubertal children, although peripubertal presentation is most common. The very high prevalence of early onset hypertension helps to discriminate FPLD3 from FPLD2. Loss-of-function mutations in the gene-encoding peroxisome proliferator-activated receptor γ (PPARγ)—a nuclear hormone receptor critically required for adipose tissue development and targeted by thiazolidinedione insulin sensitizers—have been described in many patients with FPLD3. All pathogenic mutations described to date have been heterozygous, located in the DNA or ligand-binding domains of the protein, and many display dominant negative activity *in vitro* [18].

Familial Partial Lipodystrophies Types 4–6

FPLD4 (*PLIN1*), FPLD5 (*CIDEC*), and FPLD6 (LIPE) are very rare subtypes of partial lipodystrophy. PLIN1 and CIDEC are involved in triglyceride storage within lipid droplets and are almost exclusively expressed in adipocytes. Rare cases associated with mutations in *AKT2* and *PCYT1A* have also been described.

Acquired Lipodystrophies

Acquired partial lipodystrophies are often associated with autoimmune disorders. The best described is Barraquer–Simons syndrome, with cephalocaudal loss of subcutaneous fat, complement C3 deficiency, C3 nephritic factor and mesangioproliferative glomerulonephritis [19]. Barraquer–Simons is not usually associated with metabolic disturbance due to the sparing of gluteofemoral fat stores. Acquired partial lipodystrophy is increasingly being described following childhood total body irradiation and/or chemotherapy and can be associated with metabolic disturbances including diabetes and NAFLD [20]. 'Late effects' screening should include metabolic screening and clinical examination for lipodystrophy and acanthosis nigricans. Acquired generalized lipodystrophies are very rare and may be associated with low C4 complement levels. Metabolic sequelae are usually severe [21].

Complex Syndromes Featuring Severe Insulin Resistance

There is group of syndromes that exhibit severe insulin resistance disproportionate to total fat mass as part of a more generalized disorder. These include Alström syndrome, primordial dwarfism, mandibuloacral dysplasia, and some forms of progeria. Often in these conditions, acanthosis nigricans is the key clinical clue, and it is important that its clinical significance is recognized and that appropriate endocrine assessment is undertaken at an early stage of evaluation. Some of these complex syndromes are associated with dyslipidaemia and hepatic steatosis but this is not the case in

SHORT syndrome, which arises due to a loss-of-function mutation in the *PIK3R1* gene. SHORT syndrome is also associated with a raised adiponectin concentration.

Principles of Management of Severe Insulin Resistance

Management of severe insulin resistance involves early, intensive use of insulin-sensitizing agents (metformin), and lifestyle modification to include a low-calorie, low-fat diet, and as much aerobic exercise as reasonably possible. Where postprandial hypoglycaemia is symptomatic, a low glycaemic index diet, corn starch/glycoside and acarbose may be efficacious. Dietary measures are particularly important in lipodystrophy, where they are crucial in preventing or improving dyslipidaemia and diabetes [22]. Some patients with lipodystrophy have benefitted from 'metabolic surgery' despite a normal body mass index, with remission of diabetes and reduction in serum triglycerides [23]. Adjunctive use of subcutaneous leptin in patients who have secondary leptin deficiency due to lack of adipose tissue has proved highly effective, especially in patients with generalized lipodystrophy [24]. Recombinant IGF1 or composite preparations have some utility in severe insulin resistance [25]. Clinical management should be introduced based on clinical and biochemical criteria, and establishment of the genetic defect should not influence therapeutic decision making significantly. The FPLDs are minor exceptions to this: it is logical to suppose that use of potent thiazolidinedione PPARγ agonists in patients with *PPARG* mutations may be particularly efficacious; however, despite some evidence for this in the case of particular mutations and novel agonists, this requires further study. Type B insulin resistance can be effectively treated with immunosuppressive regimens [9]. Many patients with severe insulin resistance require very high insulin doses and the use of concentrated insulin formulations and continuous subcutaneous insulin pump therapy is common. The incidence of early microvascular and macrovascular complications is high, especially in patients with lipodystrophy, and close attention should be paid to minimizing cardiovascular risk factors [10, 26]. The psychological burden of severe insulin resistance syndromes can be high, especially when there is severe hyperandrogenism and in patients with lipodystrophy, largely due altered body image [27], but also due to the burden of early complications.

15.10.3 Diabetes Secondary to Pancreatic Disease

Philip J. Weston

Cystic Fibrosis-Related Diabetes

Cystic fibrosis (CF) is an autosomal recessive disorder caused by gene mutations in the cystic fibrosis transmembrane regulator (CFTR) gene. CFTR is a chloride channel responsible for regulation of salt and water across cell walls with mutations leading to increased viscosity of secretions resulting in obstruction and fibrosis of organs including the pancreas [1].

Survival rates for CF patients have increased but this has been associated with the development of complications, the commonest of which is CF related diabetes (CFRD). CFRD occurs in 20% of adolescents and up to 50% of adults with CF. CFRD is associated with female gender, increasing age, exocrine pancreatic insufficiency, and corticosteroid usage. The median age for diagnosis of CFRD is between 18 and 21 years. CFRD has a significant impact on survival rates. Female CF patients with normal glucose tolerance survive up to 16 years longer than those with CFRD. Furthermore, CFRD is associated with reduced pulmonary function, an increase in acute exacerbations of pulmonary disease and poor nutritional status [2]. Effective treatment of CFRD improves pulmonary function [3].

CF leads to exocrine pancreatic failure in up to 85% of patients. Initially beta-cell function is preserved but there is progressive loss of beta- and alpha-cell function. Initially, hyperglycaemia may be seen only at times of acute infection or when the patient is taking corticosteroids (due to associated insulin resistance). As beta-cell function reduces further postprandial hyperglycaemia (but normal fasting glucose) and finally CFRD with fasting hyperglycaemia occurs [4].

CF patients should be screened annually from 10 years of age for CFRD [5]. The American Diabetes Association (ADA) does not recommend HbA1c for screening as it is unlikely to detect the early stages of glucose intolerance that are associated with declining pulmonary and nutritional status of the patient [5]. In addition, HbA1c can be spuriously low in patients with CF owing to increased red cell turnover. The gold standard test for CFRD remains the oral glucose tolerance test (OGTT). The diagnostic criteria for diagnosing impaired glucose regulation in CF patients are the same as in the general population but if pulmonary function is adversely affected the diagnosis of clinically significant glucose dysregulation may need to be individualized. The conventional 2-hour post glucose load OGTT may fail to detect relevant glucose rises between the glucose ingestion and the 2-hour sample. For this reason, in a person with CF who has no symptoms of diabetes and whose respiratory function is stable, an abnormal OGTT should be followed by a period of home blood glucose monitoring. Increasingly continuous glucose monitoring is used in such patients allowing for detailed examination of the abnormality in glucose regulation and tailoring of insulin therapy [4, 5].

Patients with CFRD rarely develop macrovascular disease but patients are now surviving long enough to develop microvascular complications.

The aim of treating CFRD is to maintain/improve lung function and nutritional status as well as reducing the risk of developing microvascular complications. Insulin treatment remains the mainstay and is associated with improved pulmonary function and an increase in body weight [4–6]. For this reason insulin may be initiated in patients with CF and impaired glucose tolerance who are losing weight or who have a persistent decline in their lung function.

To maintain nutrition CFRD patients need an increased calorie intake compared to the non-CF population and dietary carbohydrate is recommended to comprise 40–60% of the total energy intake [4]. While recommendations are for low glycaemic index and high fibre foods, in reality many CFRD patients, particularly those with poor nutritional status, rely on refined sugary food taken in regular quantities.

Insulin regimens need to be individualized based on the patient's home blood glucose monitoring but the majority of patients with CFRD and fasting hyperglycaemia require a multiple dose regimen including a basal insulin. Balancing exocrine replacement therapy with nutritional intake and exogenous insulin replacement is complex and patient education as well as regular review by a multidisciplinary team is essential to ensure adequate nutrition, attain diabetes control, and maintain respiratory function.

Pancreatitis

Acute pancreatitis, most commonly due to gallstones, is associated with transient hyperglycaemia in up to 50% of cases [7]. The severity of hyperglycaemia is a prognostic indicator in patients with acute pancreatitis and is included in a number of disease severity scoring systems. Persistent hyperglycaemia after the acute episode is less common and is associated with the severity of the pancreatitis, obesity, male gender, older age, the presence of chronic liver

disease, hypertension, and a history of alcohol intoxication [8]. If surgical intervention is required for the acute episode of pancreatitis then the risk of diabetes is increased. Glucose tolerance should be assessed in all patients 3–6 months after an episode of acute pancreatitis.

Chronic pancreatitis is an inflammatory disease of the pancreas initially affecting the exocrine pancreas which can, over time, impact on endocrine pancreatic function [9]. The chronic inflammation results in fibrosis and in most cases later calcification. In the United Kingdom most cases chronic pancreatitis are associated with excess alcohol or are idiopathic. It is estimated that up to 60% of patients with calcific pancreatitis develop diabetes. Chronic pancreatitis, especially hereditary pancreatitis, is linked to the risk of developing pancreatic cancer.

Fibrocalculous pancreatic diabetes is due to a form of chronic pancreatitis seen only in developing countries and is not associated with alcohol excess [10]. It affects young adults and is characterized by abdominal pain due to intraductal pancreatic calculi and the development of exocrine and later endocrine pancreatic failure. The aetiology remains uncertain, but micronutrient deficiencies or possible toxins have been proposed. Despite the degree of pancreatic fibrosis, ketoacidosis is rare in those affected. There is a strong association with pancreatic cancer.

Patients with chronic pancreatitis from any cause who develop diabetes are at risk of developing diabetes complications.

The treatment of diabetes secondary to chronic pancreatitis is complex as patients are susceptible to greater glucose variability and are more prone to iatrogenic hypoglycaemia given associated hypoglucagonaemia which results in reduced hepatic gluconeogenesis. This is often compounded by poor nutrition and malabsorption associated with failure of the exocrine pancreas and the limitations of pancreatic exocrine replacement therapy [11]. Continued alcohol excess can lead to further glycaemic instability.

Oral glucose lowering agents may be tried initially provided there is adequate beta-cell reserve but the choice of agents is limited. These patients are often malnourished and underweight so metformin is not favoured. With the continued uncertainty around the risk of pancreatitis with incretin-mimetic agents and DPP4 inhibitors they are best avoided in this group of patients. Similarly, SGLT2 inhibitors should be avoided in view of the possibility of progressive insulin deficiency and risk of developing normoglycaemic ketoacidosis. Sulphonylureas may be effective but long-acting sulphonylureas should be used with caution given the increased risk of hypoglycaemia. Insulin remains the mainstay of treatment for these patients. This may initially be with prandial fast acting insulin but as beta-cell function declines multiple daily insulin doses are needed.

Pancreatic Cancer

Pancreatic cancer is a devastating disease and the fourth commonest cause of cancer-related mortality in men in the United States [12]. The relationship between pancreatic cancer and diabetes is complex and two-way. Patients with pancreatic cancer develop diabetes, with up to 50% of patients with a new diagnosis of pancreatic cancer having associated hyperglycaemia. Conversely, patients with type 2 diabetes are at increased risk of developing pancreatic cancer [13].

The pathophysiology of developing diabetes with pancreatic cancer is far from clear. Although reduced beta-cell mass secondary to tumour-related pancreatitis and fibrosis has been proposed, islet loss may not be sufficient to fully account for pancreas cancer associated diabetes. Other possible factors include a shared association with obesity and insulin resistance, impairment of incretin secretion or earlier loss of beta-cells compared to alpha cells [14].

Haemochromatosis

Primary haemochromatosis is an autosomal recessive condition associated with the *HFE* gene. Patients with primary haemochromatosis chronically absorb iron in excess from the small bowel and the excess iron is deposited in a number of organs, including the pancreas. Identification of the HFE gene has allowed the recognition of milder forms of the disease so the incidence of associated diabetes has fallen over the years from 75% of cases to around 15% dependent on the degree of iron overload [15]. Diabetes is caused by progressive pancreatic fibrosis and other factors and is often present at the diagnosis of severe iron overload.

Diabetes in patients with haemochromatosis is associated with micro- and macrovascular complications and most patients require insulin therapy. Regular venesection to reduce the iron overload is associated with improvements in glycaemic control.

Secondary haemochromatosis occurring in patients with haematological conditions requiring frequent blood transfusions is also associated with diabetes.

Diabetes secondary to pancreatic disease is commonly seen and can present complex management problems which are best managed by a multidisciplinary team. Treating the underlying condition as well as the associated hyperglycaemia is essential.

15.10.4 Diabetes Secondary to Endocrine Disorders

Jeremy W. Tomlinson

Acromegaly

Acromegaly is a rare condition usually caused by a pituitary somatotroph adenoma. It is estimated that up to 40% of patients with acromegaly may develop diabetes and that 20% of patients develop diabetes prior to the diagnosis of acromegaly being made. Diabetes is most likely to occur in those individuals with higher growth hormone (GH) and IGF-1 levels, older individuals, those that have had the condition untreated for longer and also where there is a family history of type 2 diabetes. The development of diabetes in the context of acromegaly may also be associated with an adverse mortality outcome. Diabetes is often diagnosed as part of the diagnostic work-up during an oral glucose tolerance test when glucose excursions can be measured alongside assessing the ability of a glucose load to suppress GH levels. Formal assessment of glucose tolerance should be made in all patients with acromegaly.

Insulin resistance, despite the relatively lean phenotype of patients with acromegaly, is thought to be the major underlying pathophysiological mechanism driving the development of diabetes. Fasting insulin levels are usually elevated and there is impaired glucose disposal. In addition, GH is able to stimulate gluconeogenesis further contributing to elevations in blood glucose. Insulin deficiency and diabetic ketoacidosis are rarely seen [1].

The aims of treating diabetes in patients with acromegaly are not different to those of treating type 2 diabetes in isolation. Normoglycaemia, with restoration of normal insulin and C-peptide levels, can be achieved with normalization of IGF-1 and GH levels following pituitary surgery and occurs in up to 60% of cases.

The use of somatostatin analogues, either as primary therapy or postoperatively, can both improve insulin sensitivity (as a result of lowering IGF-1 and GH levels) but these also impair insulin secretion. As a consequence, they can have a variable impact on glucose homeostasis, but are often reported to have no overall impact on glucose tolerance [2]. However, close monitoring of glycaemic control is advocated. Second-generation somatostatin analogues which possess broader somatostatin receptor activity have a more detrimental impact on glycaemic control. This is thought to arise as a result of a more profound inhibitory action impairing insulin release within the pancreatic islet. In patients who respond clinically to somatostatin analogues, but who have coexistent diabetes, management should be according to current type 2 diabetes consensus guidelines. Agents which stimulate insulin secretion have been used effectively as have GLP-1 analogues, insulin, and insulin analogue therapy. There are limited clinical data available, but the novel GH receptor ligand, pegvisomant, does not appear to worsen, and actually may improve glycaemic control.

Cushing's Syndrome

Cushing's syndrome is defined by circulating glucocorticoid excess due to a pituitary tumour secreting adrenocorticotropic hormone (ACTH) (Cushing's disease); secondary to ectopic ACTH secretion; from an adrenal adenoma or rarely carcinoma. However, the commonest cause of Cushing's syndrome is medically prescribed glucocorticoids; currently it is estimated that 2–3% of the population are prescribed glucocorticoid therapy.

The prevalence of altered glucose homeostasis in Cushing's syndrome is as high as 90%. Overt type 2 diabetes may be present in almost 50% of cases and glucose intolerance in up to 30% [3]. Fasting glucose is more variable, and can be normal in those with diabetes, notably in those with iatrogenic Cushing's syndrome due to prescribed glucocorticoids. Diabetes is more commonly seen in patients with ectopic ACTH secretion who often present with severe and rapidly progressive disease, although the correlations between circulating glucocorticoid levels and abnormalities of glucose homeostasis are variable, probably reflecting interindividual variability in the susceptibility to the adverse effects of glucocorticoids.

The mechanisms underpinning glucocorticoid-induced diabetes and impaired glucose tolerance are complex, but hepatic and peripheral insulin resistance are thought to be crucial. Fasting glucose and insulin levels are elevated in comparison with age-, sex-, and BMI-matched controls. Insulin resistance is thought to be driven, at least in part, through elevated circulating free fatty acid levels which inhibit skeletal muscle and hepatic insulin signalling. In addition, elevated circulating glucocorticoid levels can impair insulin secretion.

Although surgical and pharmacological treatment of Cushing's syndrome to decrease circulating glucocorticoid levels are associated with improvements in glucose homeostasis, the impact of Cushing's syndrome on glucose metabolism can persist for long after the normalization of circulating glucocorticoid levels. As with acromegaly, the second-generation somatostatin analogues with broad receptor affinity can worsen glycaemic control in patients with Cushing's disease and therefore close monitoring of glycaemic control in these patients is needed [4].

There are currently no established guidelines for the treatment of diabetes associated with glucocorticoid excess. All treatment modalities including insulin therapy, sulphonylureas, GLP-1 receptor analogues, and DPP4 inhibitors have been used. The decision to use a specific strategy will rely upon both the degree of impaired glucose metabolism as well as the urgency with which glycaemic control is needed [5].

Hyperaldosteronism

Primary hyperaldosteronism is commonly associated with features of the metabolic syndrome. Insulin sensitivity is reduced in patients with primary hyperaldosteronism in comparison to those patients with essential hypertension. Aldosterone is able to induce insulin resistance in a variety of metabolic target tissues including muscle and adipose tissue. In addition, there is also evidence to suggest that aldosterone can impair insulin secretion. Mineralocorticoid receptor antagonism and surgical removal of an aldosterone secreting adenoma have resulted in improvements in insulin sensitivity and glucose handling in some, but not all, studies [6].

Hypo- and Hyperthyroidism

Both hypo- and hyperthyroidism are associated with glucose intolerance driven by both impaired insulin secretion and insulin resistance. Furthermore, the development of hyperthyroidism may worsen established glucose intolerance or type 2 diabetes.

While the underlying autoimmune aetiology underpins the association between thyroid disease and type 1 diabetes, the association with type 2 diabetes is more complex. Thyroid hormones have been shown to regulate key elements of carbohydrate metabolism, however, variability in glucose control is also associated with increased thyroid-stimulating hormone (TSH) levels which normalize once glucose control is optimized [7].

The mechanisms underpinning these observations have largely been explored in cellular and rodent models. Muscle glucose uptake is impaired in subclinical and overt hypothyroidism and hyperthyroidism (subclinical and overt) is associated with increased gluconeogenesis and impaired glycogen synthesis [8]. Thyroid hormones have been shown to increase the expression of phosphoenolpyruvate carboxykinase (PEPCK), the rate-limiting step in gluconeogenesis. In addition, hyperthyroid-associated hepatic insulin resistance is driven *via* central mechanisms originating within the hypothalamus altering sympathetic stimulation of the liver [9].

The management of impaired glucose homeostasis and diabetes in the context of thyroid dysfunction is not different to those patients without coexistent thyroid disease.

Phaeochromocytoma

Phaeochromocytomas and paragangliomas synthesize the catecholamines norepinephrine, epinephrine, and less frequently dopamine, either in isolation or in combination. Increasingly, these tumours are being recognized as part of hereditary syndromes rather than sporadic occurrences. The prevalence of abnormal glucose handling is highly variable and may occur in up to 75% of cases, but overt type 2 diabetes is relatively rare. Catecholamines inhibit insulin secretion and this is thought to be the main factor driving the development of diabetes although insulin resistance, increased hepatic glucose output, increased glycogenolysis and increased intestinal glucose absorption may all have a role to play [10, 11]. Diabetic ketoacidosis has been reported in a very small number of cases of phaeochromocytomas. Adrenoceptor blockade can improve both insulin secretion and glucose tolerance although even after surgical intervention, abnormalities in glucose homeostasis may persist.

Other Neuroendocrine Tumours

Glucagonoma and somatostatinoma are very rare neuroendocrine tumours. Patients with glucagonoma can present with a constellation of symptoms that include diabetes (in up to 70% of cases), necrolytic migratory erythema, weight loss, stomatitis, anaemia, venous thromboembolic disease, neuropsychiatric disturbances, and diarrhoea [12].

Approximately 75% of patients with pancreatic somatostatinoma develop diabetes (contrasting with 10% of patients who have intestinally located tumours). In addition to the direct impact of local somatostatin excess and its impact upon insulin secretion, replacement of functional endocrine pancreatic tissue may contribute to the high prevalence of impaired glucose handling in this group [13]. The abnormalities in glucose homeostasis are often relatively mild and oral hypoglycaemic agents or insulin can be used therapeutically.

Diabetes is commonly associated with many other endocrine conditions. While the principles of management may not differ (and include treating the underling endocrine disease), the fundamental importance lies in making the diagnosis so that appropriate treatment can be instigated without delay.

15.10.5 Diabetes in Pregnancy

Helen R. Murphy and Jennifer M. Yamamoto

Epidemiology

Globally, 17% of women have hyperglycaemia in pregnancy and 16% of these women have pre-existing diabetes [1]. The prevalence of T2D and gestational diabetes (GDM) in pregnancy is increasing and varies substantially between ethnic groups and locations [1]. The increase in GDM is accompanied by rising rates of maternal overweight and obesity, and excessive gestational weight gain. Obesity may further complicate pregnancy by increasing the risk of fertility problems, excess fetal growth, and maternal hypertensive disorders.

Physiology

There is a normal physiological adaptation of maternal metabolism during pregnancy to ensure growth and development of the fetus. This involves a greater fall in plasma glucose and amino acids, and a greater rise in free fatty acids in response to overnight fasting than in the non-pregnant state ('accelerated starvation'). This is associated with increased hepatic insulin resistance. In later pregnancy, a progressive rise in postprandial glucose and its associated insulin response, associated with decreased peripheral insulin sensitivity, parallels the growth of the fetal placental unit and rapidly reverses after delivery. This 'facilitated anabolism' brings about changes in carbohydrate, amino acid, and lipid metabolism, to ensure adequate nutrients for the developing fetus.

Pathophysiology

Women who lack the necessary beta-cell reserve, either absolutely, as in T1D, or relatively, as in T2D or GDM, still have normal physiological adaptation of carbohydrate, protein, and fat metabolism. Pregnant woman with T1D require sufficient insulin to compensate for increasing caloric needs, increasing adiposity, decreasing exercise, and increasing anti-insulin hormones. The insulin dose to maintain normoglycaemia and prevent maternal ketosis may increase up to threefold during pregnancy in T1D, and women with T2D will usually require insulin treatment in pregnancy, often at high doses often related to obesity and physical inactivity. An understanding of these underlying pathophysiological mechanisms is necessary for the successful management of these women during pregnancy.

Definitions

Internationally agreed definitions of T1 and T2D apply during pregnancy. Screening for overt diabetes in early pregnancy should be performed for those at high risk. The physiologic adaptations of pregnancy, however, affect fasting and 2-hour plasma glucose values as well as HbA1c. This suggests the need for more specific diagnostic criteria pertaining to pregnancy.

GDM is defined as carbohydrate intolerance with onset or first recognition during pregnancy, though its definition remains controversial. A fundamental challenge is that the relationship between maternal hyperglycaemia and adverse pregnancy outcome appears to be continuous. Traditionally, two different schemes have been employed. Both involve an oral glucose tolerance test (OGTT), but differ in the glucose load and interpretation.

The Hyperglycaemia and Pregnancy Outcome (HAPO) trial was a multicentre, multicultural, prospective observational study that examined whether maternal hyperglycaemia, short of diabetes, is associated with adverse maternal fetal outcome [1]. The study comprised 25 000 women who underwent a 75 g OGTT at ~28 weeks'

Table 15.10.5.1 Definitions of gestational diabetes mellitus based on a 75 g oral glucose tolerance test

	Fasting plasma glucose	1 h plasma glucose	2 h plasma glucose
World Health Organization diagnostic criteria			
Any of the following are met or exceeded	5.1–6.9 mmol/L (92–125 mg/dl)	≥ 10.0 mmol/L (180 mg/dl)	8.5–11.0 mmol/L (153–199 mg/dl)
International Association of Diabetes and Pregnancy Study Group			
Any of the following are met or exceeded	5.1 mmol/L (92 mg/dl)	10.0 mmol/L (180 mg/dl)	8.5 mmol/L (153 mg/dl)
National Institute for Health and Care Excellence (NICE) UK Guidelines			
Any of the following are met or exceeded	5.6 mmol/L (100 mg/dl)	–	7.8 mmol/L (140 mg/dl)

gestation with clinicians blinded to the results, unless the fasting glucose was >5.8 mmol/L or the 2-h was >11.1 mmol/L. The results demonstrated a continuum of risk, without clear thresholds, between each of the OGTT glucose measures (fasting, 1 hour, and 2 hours post-glucose load) and each of the four primary outcomes: macrosomia, primary caesarean section, neonatal hypoglycaemia, and fetal hyperinsulinism [1].

Different GDM diagnostic criteria continue to be endorsed by various international guidelines (Table 15.10.5.1) which reflect the controversy in this area. The glycaemic threshold values chosen from the HAPO data are consistent with an odds ratio of 1.75 for large-for-gestational-age, high neonatal body fat, elevated cord blood C-peptide, or a combination of these, compared to reference glucose values. Thirteen per cent (13%) of the total group had one or more values greater than or equal to the threshold.

The UK NICE guidelines recommended a diagnosis of GDM for women with a more severe glycaemic disturbance. Their diagnostic criteria suggest a fasting blood glucose of ≥5.6 mmol/L or a 2-hour blood glucose of ≥7.8 mmol/L with a 2-hour 75 g OGTT [2, 3].

Screening for Diabetes in Pregnancy

There is again a lack of international agreement in this area. Some authorities have recommended universal or selective screening, while others advocate screening only women with risk factors for GDM. In North America, screening traditionally has been based on a 50 g 1-hour non-fasting glucose challenge test [4]. In the UK, NICE guidelines recommend screening women with a 75 g OGTT who have any of the following risk factors [4]:

- BMI >30 kg/m²
- Previous baby with macrosomia (birth weight ≥4.5 kg)
- Previous GDM
- First-degree relative with diabetes
- Family origin with high prevalence of diabetes (South Asian, black Caribbean, and Middle Eastern)

Management

Pre-Gestational Diabetes in Pregnancy

Pre-Pregnancy Care

Pre-pregnancy care includes counselling about pregnancy and safe, effective contraception as well as additional care to prepare women for pregnancy. It has been associated with improvements in both pregnancy preparation and pregnancy complications including a reduction in serious adverse outcomes [5]. Despite these data, less than half of women attend specialized pre-pregnancy care clinics. Women with T2D are less likely to receive formal pre-pregnancy care than those with T1D [6].

The education of, and discussion with, women of reproductive age about pregnancy and contraception is an essential component of every diabetes consultation. Ideally, prepregnancy care should begin at least 6 months before stopping contraception and include advice and discussion on the following:

- Continued adherence with safe effective contraception until optimization of glycaemic control
- Individualized glycaemic targets
- Importance of periconception glucose control to pregnancy outcomes including congenital malformations and stillbirth
- The risk of hypoglycaemia and instruction of family members in use of glucagon
- Assessment of microvascular complications with referral and treatment as appropriate
- Review of medications, smoking, alcohol consumption
- Folic acid supplementation (5 mg daily)
- Advice on early referral mechanisms as soon as pregnancy is confirmed

Provision of Pregnancy Care

Specialized interdisciplinary teams operating in a secondary or tertiary care setting is a commonly adopted model for the care of women with diabetes. Members of the team include a diabetologist, obstetrician, a diabetes specialist nurse, dedicated dietitian, and a diabetes-trained midwife. Review is usually fortnightly and women are often seen weekly as term approaches.

Nutrition

A healthy lifestyle consisting of a well-balanced diet and moderate physical activity should be encouraged with the aim of limiting post-meal glucose excursions and preventing hypoglycaemia between meals. Low glycaemic-index foods help to achieve this (5). Individual advice around appropriate carbohydrate intake and insulin adjustment is essential.

Obesity in pregnancies continues to be common in GDM and T2D pregnancies but has also become a substantial concern in T1D with over half of all pregnant women with type 1 diabetes entering pregnancy overweight or obese [7, 8]. Therefore, weight management may be an important part of dietary counselling both

before and during pregnancy. Appropriate weight targets should be based on the woman's pre-pregnancy weight. The following gestational weight gain targets are recommended over pregnancy: BMI <18.5 kg/m² 13–18 kg, BMI 18.5–24.9 kg/m² 11–16 kg, BMI 25–29.9 kg/m² 7–11 kg, >30.0 kg/m² 5–9 kg [9].

Glycaemic Control

In T1D, blood glucose should be measured up to eight times daily (before and after each meal, at bedtime, and, intermittently, overnight). Continuous glucose monitoring (CGM) should be offered to all pregnant women with T1D. Evidence for this is from a landmark international randomized trial which found improvement in not only maternal glycaemic control (increased time spent in-target-glucose-range) but also a halving of the odds ratio for large-for-gestational age, neonatal hypoglycaemia, neonatal intensive care unit admissions and a shorter neonatal length of hospital stay [5]. In T2D, blood glucose should generally be tested at least four times a day but may vary based on treatment strategy.

Treatment targets for women should be individualized and include an assessment of the risk of hypoglycaemia. Women with pre-gestational diabetes should generally target an HbA1c of <6.5% prior to and early in pregnancy. Self-glucose monitoring is essential and women should aim for a fasting glucose of <5.3 mmol/L and a 1 hour postprandial glucose of <7.8 mmol/L or a 2 hour postprandial glucose of <6.4 mmol/L [10]. Any strategy for intensive glycaemic control must constantly be balanced against the risk of maternal hypoglycaemia.

Intensive insulin therapy is the standard of care for women with T1D and many with T2D. This can be in the form of multiple dose injection (MDI) insulin regimen or the insulin pump. MDI usually comprises a short-acting insulin taken before meals and an intermediate- or long-acting insulin taken daily or twice a day. There are no randomized controlled trial data to suggest that insulin pump therapy is superior to MDI for most women, but its selected use in experienced centres with motivated patients may be appropriate. Insulin pump therapy can be combined with CGM (sensor augmented pump therapy) and increasing degrees of automation from low glucose suspend to hybrid closed-loop systems, whereby basal insulin delivery in fully automated but manual pre-meal boluses are still required.

Gestational Diabetes Mellitus

Women with GDM are typically diagnosed during screening or through a diagnostic OGTT around at 24–28 weeks' gestation. Treatment for GDM has been shown to decrease preeclampsia, fetal overgrowth and shoulder dystocia in large randomized controlled trials and meta-analyses [11].

Medical nutritional therapy with regular review of blood glucose results and fetal growth is successful in controlling hyperglycaemia in most women with GDM [10]. For women who are not reaching target glucose with diet alone, pharmacologic therapy should be considered. After a discussion of risks and benefits, metformin can be offered to women in whom insulin therapy may be avoided. Insulin treatment should be offered if metformin therapy is unacceptable, contraindicated, or in women with more severe glycaemic disturbances [5]. While not considered first line, NICE Guidelines suggest that glibenclamide may be considered if women decline insulin therapy and are not achieving glycaemic targets with metformin and/or cannot tolerate metformin [12]. Metformin, unlike glibenclamide, crosses the placenta and caution is necessary until safety in the first trimester has been evaluated more fully. Glibenclamide needs to be administered at least 30–60 minutes before eating for optimal postprandial glucose control which is often impractical.

Diabetic Complications in Women with Pre-Existing Diabetes

When counselling a woman with advanced diabetic complications about pregnancy, the risks both to herself and to the fetus must be considered. The development or progression of retinopathy, nephropathy, or autonomic neuropathy during pregnancy may present major management challenges and require close collaboration between multidisciplinary colleagues. Diabetic ketoacidosis is a serious concern, and every mother should be instructed to monitor ketones and seek urgent advice if needed. Early pregnancy is a high-risk time for severe hypoglycaemia (defined as hypoglycaemia requiring third party assistance) and strategies to avoid and treat hypoglycaemia must be discussed.

Obstetric Surveillance

The goal of obstetric surveillance is to identify fetuses at risk, in order to intervene in a timely and appropriate fashion to reduce perinatal morbidity and mortality. Given the limitations of the available tests and lack of rigorous randomized controlled trials, all protocols used for fetal surveillance are empirical and have limitations. The UK NICE Guideline recommends ultrasound monitoring of fetal growth and amniotic fluid volume every 4 weeks from 28 to 36 weeks, and individualized monitoring of fetal wellbeing for women at risk of intrauterine growth restriction (IUGR) such as women with macrovascular disease or nephropathy [13, 14].

Labour and Delivery

The primary objectives are to avoid stillbirth and the complications of obstructed labour or shoulder dystocia associated with fetal overgrowth. Consequently, Caesarean section rates for women with pre-existing diabetes in most parts of the world are >50% [5]. Iatrogenic prematurity has resulted in high rates of admission to neonatal intensive care particularly following T1D pregnancies (Table 15.10.5.2) [5].

An individualized approach to the timing and mode of delivery is essential. Many factors need to be taken into consideration, including glycaemic control, diabetes complications, past obstetric history, fetal growth, and the availability of healthcare resources in labour.

The management of labour should follow standard practice as for women without diabetes. The treatment of diabetes during labour should follow an established protocol in a dedicated centre with a neonatal care unit equipped to deliver the highest level of care.

Most clinical practice guidelines recommend achieving a maternal blood glucose of 4–7 mmol/L during labour and delivery

Table 15.10.5.2 National pregnancy in diabetes audit outcomes for women with type 1 and type 2 diabetes (England, Wales, and the Isle of Man)

	Type 1 diabetes n = 1563	Type 2 diabetes n = 1386
Congenital anomaly	46.2/1000	4.6/1000
Stillbirth	10.7/1000	10.5/1000
Neonatal death	8.1/1000	11.4/1000
Gestational age at delivery in weeks*	36.4 (SD 2.0)	37.1 (SD 2.0)
Preterm delivery*	39.7%	21.7%
LGA*	46.4%	23.9%

* P <0.05; SD, standard deviation; preterm delivery: defined as delivery <37 weeks' gestation; LGA, large-for-gestational-age, defined as birth weight >90th percentile.

Data derived from Martens PJ, Shafer LA, Dean HJ, Sellers EA, Yamamoto J, Ludwig S, *et al*. Breastfeeding Initiation Associated with Reduced Incidence of Diabetes in Mothers and Offspring. *Obstet Gynecol*. 2016;128(5):1095–104.

to minimize risk of neonatal hypoglycaemia [5]. Hourly capillary glucose measurements are essential for safety and to guide insulin adjustment. For women with T1D, insulin delivery is usually either via intravenous insulin infusion or subcutaneous insulin pump. Some women with insulin-treated T2D and GDM may also require intravenous insulin. For women with diet-controlled GDM, glucose should be monitored every 1–2 hours once labour is established, with the aim of keeping glucose levels <7 mmol/L. If this is not achieved, an insulin/glucose infusion may be required.

Diabetes Management Immediately Postpartum

Because of the dramatic increase in insulin sensitivity following the delivery of the placenta, all women with diabetes in pregnancy will require treatment adjustment postpartum. For women with GDM, insulin is discontinued immediately following delivery. Glucose monitoring should continue for several days to ensure a return of blood glucose values to the normal range. These women should be booked for an assessment of glucose tolerance and review approximately 6–12 weeks after delivery.

Women with pregestational diabetes should be counselled that postpartum glycaemic targets are less stringent (typically 6–10 mmol/L) and that the risk maternal hypoglycaemia during this period is high [3]. Mothers with T2D previously on oral hypoglycaemic agents can typically discontinue insulin. Metformin and glibenclamide are used, often at lower doses, while breastfeeding. However, all other oral hypoglycaemic agents should be avoided. If blood glucose levels remain consistently above target, insulin may be required. For insulin-treated women with pregestational diabetes, a large decrease (typically a 50% reduction) in insulin doses immediately postpartum is required. Dose adjustments should be individualized and based on previous insulin doses and risk of maternal hypoglycaemia.

The benefits of breastfeeding to both mother and infant are well-recognized [15]. In addition to the overall benefits of breastfeeding, women with diabetes may have additional short- and long-term advantages for both mother and offspring including a decreased risk of developing type 2 diabetes following GDM [2].

Contraception

Safe effective contraception should be discussed with all women with diabetes who may become pregnant. Important considerations when choosing contraception include: decision to breastfeed, failure rates, patient preference, and cardiovascular risk. Long-acting reversible contraception methods including progesterone implants and intrauterine contraceptive devices (IUCD) are particularly suited to women who do not wish to become pregnant within the next 1–2 years. Uncomplicated diabetes generally does not limit contraceptive choice [5]. Women with longstanding diabetes, hypertension, microvascular, or cardiovascular complications, and possibly women who smoke cigarettes and/or have a BMI of ≥35 kg/m^2, should consider progesterone-only long-acting reversible contraception methods (injections, implants, or IUCD) although all contraception options may be safer than an unplanned pregnancy in high-risk women.

Postpartum Considerations

All women should be reviewed at 6–7 weeks after delivery, with further counselling regarding contraception and possible pregnancy planning. Women with pre-gestational diabetes are referred back to their pre-pregnancy care providers. Women with GDM are offered a 75 g OGTT after 6–12 weeks.

GDM is a recognized risk factor for the future development of GDM with subsequent pregnancies, T2D, and cardiovascular disease. In addition, risk factors for the development of GDM are similar to those for T2D and metabolic syndrome. The postnatal visit, therefore, provides a unique opportunity to offer specific lifestyle advice, to screen for cardiovascular factors, and remind women of the need for early referral for future pregnancies. Those with normal or impaired glucose tolerance should have annual diabetes screening in the community.

Long-Term Outcomes

There is now increasing recognition that offspring of women with diabetes (whether T1D, T2D, GDM, or maturity-onset diabetes of the young) during pregnancy are at increased future risk of diabetes, obesity, and cardiovascular disease [5]. Since these risk factors develop early in life, they place the offspring of women with diabetes at risk throughout adulthood. The major public health challenge is to break this vicious cycle by the prevention of diabetes until after women have completed their pregnancies and, possibly, also by better control of diabetes during pregnancy.

15.11

Psychiatry and Diabetes

15.11.1 Type 1 Diabetes and Psychiatry

Khalida Ismail, Chris Garrett, and Marietta Stadler

Depression

Epidemiology

Depression is a mental state of pervasive low mood with little to no enjoyment, causing a marked deterioration in function. Early studies using self-rated questionnaires in T1D populations suggested rates of depression of around 15%, and recent studies using standardized clinical interview estimate rates that are twice as frequent as the general population [1–3]. Depressive symptoms have been linked to worse glycaemic control, morbidity, including acute admissions, and premature mortality [4–7].

Assessment and Management

For some clinicians not working in mental health there is sometimes a difficulty in discerning the mental state of a chronic intractable low mood from an existential sadness through the experience of living with T1D. However, from a health resources perspective it is useful that a referring clinician is able to draw the distinction thorough clinical assessment prior to referral for treatment.

For full ICD diagnostic criteria of depression see **Table 15.11.2.1** in Chapter 15.11.2, 'Type 2 Diabetes and Psychiatry'. People with depression feel persistently low with reduced enjoyment of everyday activities. Psychological symptoms emerge from this profound sense of sadness leading to negativity in all aspects of thinking including perception of self, surroundings, and future and some patients will wish to be dead and some will make active plans to end their life.

Physical symptoms of depression include tiredness, decreased concentration and disturbed sleep, an alteration in eating habits either markedly increased or decreased, and loss of sex drive. However, these can be confused with the physical symptoms of T1D and vice versa. For example, prolonged hyperglycaemia can cause dehydration and fatigue and diabetes late complications impair quality of life, which will in turn impact on mood.

One can quickly see how depression could affect a person's ability to self-manage a condition where motivation and consistency is key to achieving glycaemic control—when there has been a marked change in a person's diabetes management, consideration of an underlying depressive illness is appropriate and necessary.

When using standardized psychological tools in screening for depression, an understanding of the co-occurrence of diabetes distress is important and therefore a tool such as the Hospital Anxiety and Depression Scale alongside the Diabetes Distress Scale is appropriate [8, 9].

Treatment of depression alongside type 1 diabetes follows the same pathway as with people without a chronic health condition according to current guidance. In milder presentations a watch, wait, and review policy is employed alongside advice on self-help literature and psychoeducation around the condition, the importance of activity and connectedness to others. Management will generally take place in primary care though a clear plan is necessary for more intensive treatment to be activated if improvement does not occur relatively quickly or diabetes management becomes clearly affected, evidenced by worsening glycaemic control or acute admissions. More intensive treatment is required in moderate to severe presentations with psychological interventions and/or antidepressants in the form of selective serotonin reuptake inhibitors (SSRIs). Where treatment is not provided within the diabetes service, liaison is required between mental health and physical health clinicians, particularly when insulin omission is prominent and where DKA has occurred.

Anxiety Disorders

Epidemiology

Anxiety disorders are a collection of mental health conditions where the most prominent aspect of the presentation is heightened anxiety coupled with physical symptoms of stress response, namely tachycardia, sweating, and increased respiratory rate. Incidence of anxiety disorders in T1D is approximately 7–9%, more than double that in the background population, though caution is again necessary in diagnosis due to the overlapping symptoms of 'diabetes distress' and

Table 15.11.1.1 Outlining the personality disorder diagnoses using ICD-10 Criteria

Personality disorder cluster	Personality disorder diagnosis	ICD-10 Criteria
A	Paranoid	ICD-10 F60.0 • Excessive sensitivity to setbacks • Unforgiving of others • Suspiciousness and jealousy • Combative • Sense of personal rights • May be excessive self-importance, and there is often excessive self-reference
	Schizoid PD	ICD-10 F60.1 • Withdrawal from affectional, social, and other contacts • Preference for fantasy, solitary activities, and introspection • Limited capacity to express feelings and to experience pleasure
B	Dissocial PD	ICD-10 F60.2 • Disregard for social obligations • Callous unconcern for others • Gross disparity between behaviour and the prevailing social norms • Behaviour is not readily modifiable by adverse experience, including punishment • Low frustration tolerance • Low threshold for discharge of aggression, including violence • Tendency to blame others
	Emotionally unstable personality disorder (PD)	ICD-10 F60.3 • Act impulsively without consideration of consequences • Unpredictable mood • Liability to outbursts of emotion and an incapacity to control the behavioural explosions • Quarrelsome • Two subtypes: (1) impulsive type, characterized predominantly by emotional instability and lack of impulse control; (2) borderline type, characterized in addition by disturbances in self-image, aims, and internal preferences, chronic feelings of emptiness, intense and unstable interpersonal relationships, and a tendency to self-destructive behaviour, including suicide gestures and attempts
	Histrionic PD	ICD-10 F60.4 • Shallow and labile affectivity • Self-dramatization and theatricality • Suggestibility • Egocentricity • Lack of consideration for others • Easily hurt feelings • Continuous seeking for appreciation, excitement, and attention
C	Anankastic PD	ICD-10 F60.5 • Feelings of doubt • Perfectionism • Excessive conscientiousness, • Checking and preoccupation with details • Stubbornness, caution, and rigidity
	Anxious	ICD-10 F60.6 • Constant tension and apprehension • Insecurity and inferiority • Continuous yearning to be liked and accepted • Hypersensitivity to rejection and criticism with restricted personal attachments, and a tendency to avoid certain activities by habitual exaggeration of the potential dangers or risks in everyday situations
	Dependent	ICD-10 F60.6 • Passive reliance on other people • Fear of abandonment • Feelings of helplessness and incompetence • Compliance with the wishes of others • Weak response to the demands of daily life

with the majority of studies largely focused on people with type 2 diabetes [10–12].

Assessment and Management

Anxiety disorders divide largely into three categories, those where anxiety is consistently present, those where there are discreet episodes of heightened anxiety without anxiety in between and those where there is background anxiety and overlapping intense episodes. Often these conditions are comorbid with depression and presence of heightened anxiety indicates the need to assess for underlying depression.

Generalized anxiety disorder is a chronic anxiety state characterized by persistent 'free-floating' anxiety, not particularly focused on a specific situation or concern, but pervasive and all-encompassing with inability to feel relaxed or at ease. Physical manifestations can

include unsteadinesss walking, trembling, and light-headedness—symptoms which can be related to T1D or its therapy. Symptomatic anxiety disorder may also be misinterpreted as symptoms of hypoglycaemia or neuropathy (e.g. numbness).

Often this constant worry will lead to avoidance behaviour to prevent anxiety, potentially resulting in functional impairment (e.g. in work, relationships, social life). This may include avoidance of diabetes self-management tasks.

Panic disorder is the experience of intermittent episodes of extremely intense anxiety. Although these episodes may be triggered by specific situations such as getting on a bus or being in a crowded place, or in the diabetes context fear that one is becoming hypoglycaemic, they often emerge 'out of the blue'. During a 'panic attack' the person feels suddenly intensely fearful, about to die, and consequent adrenal activity leads to tachycardia, sweating, and hyperventilation, symptoms also experienced in the adrenergic response to hypoglycaemia, again emphasizing the importance of a detailed history.

Anxiety disorders may impact on type 1 diabetes where many of the health behaviours required could evoke emotion. Specific phobias can occur around finger prick blood tests or self-injection of insulin and can lead to problematic self-management through avoidance. Fear of hypoglycaemia can lead to disproportionate insulin restriction and chronic hyperglycaemia.

Like depression, treatment of anxiety disorders alongside type 1 diabetes depends on severity. Milder presentations, not affecting diabetes management are usually managed by primary care physicians using 'wait and review' alongside psychoeducation and advice on avoidance behaviours and maintaining a social network as well as self-help literature. More intensive treatment is required in moderate to severe presentations with psychological interventions being particularly beneficial in simple diabetes-related phobias including fear of testing or fear of injections. More general cognitive behavioural therapy (CBT) interventions and/or antidepressants are used in more pervasive presentations and liaison is required between mental health and physical health clinicians, particularly when insulin omission is prominent.

Eating Disorders

Epidemiology

Eating disorders (ED) are twice as common in young people with T1D compared with controls without diabetes [13]. Typically, onset is during adolescence either soon after the onset of T1DM or after onset of puberty in established T1D [14]. Poor classification has resulted in broad prevalence estimates from 8% to 36% [15, 16] with a further 9–14% classified as 'subthreshold' ED. Insulin restriction in T1D, which is seen to varying degrees in ED is associated with 3-fold increased mortality compared to those who do not restrict insulin [17]. Mortality is driven by accelerated onset of diabetes late complications secondary to persistent hyperglycaemia [18, 19] and by acute complications due to almost total insulin omission leading to DKA or insulin overdose [17].

Assessment and Management

Diagnostic criteria for common EDs are detailed in Table 15.11.2.2 of Chapter 15.11.2. However, clinical presentations in T1D can vary widely and often do not fit within established ED categories. Some patients restrict by only a few units of insulin per day to keep their weight in check with a normal body mass index (BMI) so that the only clinical indicator is persistent hyperglycaemia. Other patients will restrict by much larger amounts and induce rapid weight loss within a few days (sometimes up to 5 kg) as the severe hyperglycaemia causes a rapid osmotic diuresis [20]. This may present with rDKA. Recently in the media and among diabetes communities, insulin omission for the purpose of losing weight, has been termed 'diabulimia' [21].

Screening questionnaires for ED in the T1D context are problematic due to false positive responses related to overlap between diabetes management and eating disorder behaviours such as a focus on diet, counting carbohydrates, and eating when not hungry to avoid or treat hypoglycaemia. There is only one diabetes-specific questionnaire for ED, the DEPS-R which has been tested in adolescent and adult populations [22].

From a clinical perspective, management of T1D and ED requires a multidisciplinary approach to integrate physical and mental health elements. There are few specialists in this area but treating clinicians should be cognisant of certain concepts. For example, omitting or restricting insulin to control or reduce weight is a harmful behaviour that is only possible in people with type 1 diabetes and occurrence of diabetic ketoacidosis and extent and chronicity of hyperglycaemia are key indicators, while BMI, which is usually used by psychiatrists to make decisions regarding admission in ED is less relevant [23]. In addition, physical and mental health management can be at cross-purposes, with ED therapeutic interventions actively discouraging consideration of calorie content of food, while diabetes clinicians encourage a focus on carbohydrate and fat content in order to calibrate insulin dose.

The main stay of treatment is psychotherapeutic with limited call for psychopharmacological interventions except use of SSRIs as treatment for binge eating. Therapeutic modalities employed include CBT, mentalization based treatment (MBT), and cognitive analytic therapy (CAT) but there is a very limited evidence base for outcomes and treatment generally follows what is available locally. As a general principle, therapy aims to help a person gain greater understanding of their thoughts and emotions connected to the ideas about their body, to help regulate eating patterns and to explore their relationship with diabetes. From a diabetes perspective, clinicians are actively involved in support and monitoring of insulin use as well as monitoring for complications and specialist dietician input.

Personality Disorders

Epidemiology

The personality disorders (PD) are a group of psychiatric conditions made up of enduring, extreme personality characteristics often evident in late childhood or adolescence but generally diagnosed over the age of 18, broadly dividing into three 'clusters' referred to as A (odd, eccentric), B (dramatic) and C (anxious). Table 15.11.1.1 shows ICD-10 criteria for the different PD diagnoses. A recent longitudinal study suggested that PD are twice as common in young adults with T1D, implying that the condition is affecting personality

development *per se*. A recent case-control study indicated association between personality disorder and recurrent DKA [24].

Assessment

Cluster A

The personality disorders that make up cluster A are often referred to as the 'odd' or 'eccentric' group, although an additional key element is ideas or beliefs outside reality. People with paranoid PD have pervasive distrust, struggle to maintain close relationships, bear prolonged grudges towards individuals or organizations and are often litigious. Schizoid personality disorder consists of lack of interest in others, isolation, and lack of close relationships. Typically they are non-plussed about emotions and described as 'cold'. An example in T1D may be a patient with chronic hyperglycaemia who sustains a leg ulcer, yet does not become anxious or change behaviours despite development of a long-term, life-limiting complication.

Cluster B

The cluster B PD diagnoses are described as the 'dramatic' group due to marked fluctuations in emotion regulation and difficulties in impulse control, particularly at times of interpersonal conflict. In the diabetes context, difficulty in emotion regulation is associated with diabetes distress [25]. Often T1D is used as a vehicle for expressing aggression and upset through over- and undertreatment. Such expressions can be external, creating disruptions within families, and internal, inflicting self-harm. Dissocial PD is typified by impulsiveness, recklessness, disregard for others, and externalization of difficulties leading to blaming others. In the diabetes context this can lead to a lack of responsibility for diabetes care and tendency to make others culpable for diabetes treatment and complications. Emotionally unstable PD also classically presents with emotion dysregulation and impulsivity, but recklessness tends to be more self-damaging with interpersonal conflict often acting as a trigger to self-destructive behaviour including undertreatment causing DKA or overtreatment with insulin and subsequent hypoglycaemia.

Cluster C

Cluster C is made up of the 'anxious' PDs and much of the interplay with T1D results in extreme anxiety and panic regarding self-management with subsequent avoidance of self-monitoring and insulin delivery. This may manifest as 'fear of hypoglycaemia' or 'needle phobia' and patients presenting with these common issues should be assessed by their clinician for more pervasive anxiety symptoms. Anxious PD consists of a core feature of profoundly diminished self-esteem and perceived criticism, leading to avoidance of work and social interaction. Dependent PD also has the core feature of negative self-perception. Here, rather than avoidance, feelings of inadequacy may lead to overreliance on others for emotional and physical wellbeing. This group struggle to gain independence and the T1D burden is displaced onto others. Anankastic PD is one of the few psychiatric conditions, which can interact favourably with T1D. The key feature is an obsessive drive for control, mastery over one's environment, and perfectionism, which can lead to focused attention on glycaemic control. This personality type can be associated with profound frustration with the intrinsic unpredictability of blood glucose readings with risk of superimposed depressive disorder or recurrent hypoglycaemia from overtight control.

Management

Unlike depression and anxiety disorders, which are eminently treatable and often transient, PDs are persistent and treatment remains difficult despite advances in the last two decades [26]. Eliciting the disorder early is vital to maximize treatment potential and limit impact on T1D self-management. Moreover, difficulty with relationships is a prime issue in PD and diagnosing the condition can aid understanding and the approach to therapeutic engagement for diabetes clinicians, which should include establishing trust and a consistent approach, with potential redefining of achievable treatment goals. Established psychotherapy interventions for PD focus mainly on the cluster B disorders with MBT, dialectical behaviour therapy and transference-focused psychotherapy all having an established evidence base [26].

Summary and Future Directions

This chapter has summarized the major mental health issues impacting T1D and emphasizes their bidirectional nature: physical symptoms potentiate psychopathology and mental health problems worsen prognosis through impact on self-care. Diabetes clinical care should include an element of mental health management in order to prevent early complications and mortality. Integration of mental healthcare into T1D services is therefore the gold standard. In addition, mental health should be assessed as part of the annual routine screening for diabetes complications and efforts should be made to stratify risk. Embedding mental healthcare into the physical healthcare setting will lower the threshold for accessing early diagnosis and targeted therapies. Such interventions should be delivered by clinicians with experience in managing psychopathology specific to T1D in close partnership with diabetes clinicians.

15.11.2 Type 2 Diabetes and Psychiatry

Marilia Calcia, Clare Whicher, Hermione Price, Khalida Ismail, and Calum Moulton

Depression

Epidemiology

Clinical depression is characterized by pervasive low mood, reduced enjoyment, and/or increased fatigue, accompanied by other biological and cognitive symptoms (Table 15.11.2.1). Approximately 10% of people with type 2 diabetes meet ICD-10 diagnostic criteria for clinical depression and 20–30% have significant depressive symptoms on self-report questionnaires [1, 2]. Depression has a bidirectional relationship with type 2 diabetes: depression increases the risk of incident type 2 diabetes by 60%, while type 2 diabetes increases the risk of incident depression by 15–20% [3]. Diabetes and depression comorbidity are associated with increased incidence of microvascular and macrovascular complications in addition to premature mortality [4]. Notably, depression does not appear to worsen diabetes self-care [5], and growing evidence suggests that shared biological mechanisms, such as inflammation, may link the two conditions [6].

Table 15.11.2.1 Diagnostic criteria for depression according to the International Classification of Diseases (ICD-10)

Diagnosis	Criteria
Depression	At least two of: • Low mood • Anhedonia (loss of interest and enjoyment) • Low energy Plus at least two of: • reduced concentration and attention • reduced self-esteem and self-confidence • ideas of guilt and unworthiness • bleak and pessimistic views of the future • ideas or acts of self-harm or suicide • disturbed sleep • diminished appetite Symptoms must be present for at least 2 weeks (or less if severe and of rapid onset).

Management

Guidelines recommend that clinicians working with people with chronic illnesses, such as type 2 diabetes, should actively screen for concurrent depression [7]. Although brief screening questionnaires may assist, such as the Patient Health Questionnare-9 (PHQ-9) [8], a clinical assessment should confirm the diagnosis of depression. The history should consider previous treatments for depression and social problems that might be perpetuating depression. Patients should specifically be asked about thoughts of self-harm or suicide.

Treatment of depression follows a stepped care model [7]. Patients with mild or subthreshold depressive symptoms may be referred to a group physical activity programme, group-based peer support or low-intensity psychological interventions (e.g. group cognitive-behavioural therapy (CBT)). Patients with moderate and severe depression, or with persistent mild to moderate depression despite lower-intensity treatment, need to have their treatment intensified including antidepressants and/or high-intensity psychological therapies. Selective serotonin reuptake inhibitors (SSRIs), such as sertraline and fluoxetine, are the first-line antidepressants due to their favourable side-effect profile. Prior to starting antidepressants, patients should be advised of the risk of increased agitation, nausea, and suicidal ideation in the first few days of treatment. Regular reviews are indicated, and if an antidepressant is ineffective after 2–4 weeks, the first step is to check the patients' concordance with treatment and for substance misuse. If antidepressants are ineffective or partially effective, a dose increase, or switching to a different medication should be considered.

Antidepressants should be continued for at least 6 months from the point of remission of a depressive episode to prevent early relapse or recurrence [7]. Referral to specialist mental health services is advised for patients with psychotic- or treatment-resistant depression, or those with risk of self-harm, suicide, or severe self-neglect.

Eating Disorders

Epidemiology

Disordered eating affects up to 40% of people with type 2 diabetes [9]. Binge eating disorder (BED), bulimia nervosa (BN) and night eating syndrome (NES) are eating disorders associated with excessive caloric intake and are often comorbid with overweight, obesity and type 2 diabetes [10] (see Table 15.11.2.2 for diagnostic criteria).

Table 15.11.2.2 Diagnostic criteria for eating disorders associated with type 2 diabetes

Diagnosis	Criteria
Bulimia nervosa	ICD-10 F50.2 • Persistent preoccupation with eating, and an irresistible craving for food; episodes in which large amounts of food are consumed in short periods of time • Attempts to counteract the 'fattening' effects of food by one or more of the following: – self-induced vomiting – purgative abuse – alternating periods of starvation – use of drugs such as appetite suppressants, thyroid preparations, or diuretics – neglecting insulin treatment • Morbid dread of fatness and a sharply self-defined weight threshold, well below the premorbid weight that constitutes optimum or healthy weight
Binge eating disorder (BED)	DSM 5 307.51 (American Psychiatric Association, 2013) • Recurrent episodes of binge eating, characterized by eating a large amount of food in a discrete period of time, with lack of control overeating during the episode • Episodes associated with at least 3 of the following: – Eating much more rapidly than normal – Eating until feeling uncomfortably full – Eating large amounts of food when not feeling hungry – Eating alone due to feeling embarrassed by how much one is eating – Feeling disgusted with oneself, depressed, or very guilty after the episode • Marked distress regarding binge eating • Episodes occur at least once a week for 3 months Episodes are not associated with inappropriate compensatory behaviour
Night eating syndrome	DSM 5 307.59 • Recurrent episodes of eating after awakening from sleep, or excessive food consumption after the evening meal • There is awareness and recall of the eating • Episodes are not better explained by changes in the sleep-wake cycle or by local or social norms • Episodes cause significant distress and/or functional impairment The pattern or eating is not better explained by BED, other mental or medical disorder, or the effects of a medication

Cross-sectional studies have found that patients with type 2 diabetes who have frequent episodes of binge eating tend to have higher body mass index, more depressive symptoms, poorer glycaemic control, and more frequent hospital admissions for diabetes complications [11]. Therefore, addressing these conditions is essential in supporting patients in lifestyle interventions to manage type 2 diabetes.

Management

The evidence base for treatment of BED and BN in type 2 diabetes is limited. From evidence in the general population, treatment may include guided self-help and psychological therapies such as CBT. Family therapy may help young people with BN. High-dose SSRI (e.g. fluoxetine up to 60 mg) is effective in combination with psychological therapy or guided self-help for BN [12]. Specialist referral is advised for patients with severe distress or comorbidity with other mental disorders. Those with complications associated with purging or restrictive behaviours or risk of self-harm or suicide may warrant urgent psychiatric assessment. Treatments for NES are not as well established; SSRI may be helpful in treating NES symptoms and promoting weight loss, and pilot studies have indicated that CBT may help reduce the frequency of night eating episodes [13].

Cognitive Impairment and Dementia

Epidemiology

A broad spectrum of cognitive impairment is overrepresented in people with type 2 diabetes. Most severe is dementia: a progressive deterioration in multiple cognitive domains leading to a significant deterioration in functioning [14]. The relative risks for Alzheimer disease and vascular dementia are 1.53 and 2.27, respectively, in people with diabetes, although Alzheimer's disease is more prevalent overall [15]. Mild cognitive impairment (MCI) describes cognitive impairment greater than expected based on age and education but which, unlike dementia, does not interfere with daily activities, and people with diabetes are 1.5–3 times more likely to progress from MCI to dementia [16]. There is also emerging evidence that milder subjective-only cognitive decrements are common in people with diabetes of all ages, although research is at an earlier stage [17].

Risk factors for dementia in diabetes are likely multiple. In the large-scale ACCORD-MIND trial, intensive modification of glycaemic control did not affect cognitive decline in people with type 2 diabetes [18]. By contrast, prior episodes of cardiovascular disease (CVD) and repeated hypoglycaemic episodes are consistent risk factors for dementia in people with type 2 diabetes [19]. Promising novel risk factors for dementia in type 2 diabetes, including inflammation and depression, have not been tested in clinical trials.

Management

Diabetes physicians should be mindful that there may be a bidirectional effect of cognitive impairment and diabetes control. Insight into cognitive impairment is frequently poor and dementia increases the risk of medication errors, hypoglycaemia and CVD [20]. The following steps may support non-specialists encountering suspected cognitive impairment:

1. Obtain collateral history of any cognitive decline, its time-course, and effects on function.
2. Conduct a physical examination and consider blood tests to exclude organic causes of cognitive impairment, such as hypothyroidism and vitamin B_{12} deficiency.
3. Screen for depression (e.g. PHQ-9 score ≥10), as depression can cause cognitive impairment.
4. If time permits, perform a brief supplementary cognitive assessment, such as the 6-item cognitive impairment test or Mini-Cog [14].
5. If MCI or dementia is still suspected, follow local protocols. In the United Kingdom, patients with suspected dementia should be referred to a memory clinic or community old age psychiatry service [14].

Detailed guidance is available on adjusting diabetes management in people with established dementia [20]. In particular, clinicians should be vigilant to hypoglycaemia risk and should consider mitigating this through additional support at mealtimes, relaxation of HbA1c targets to 8.5% (70 mmol/mol), and avoidance of sulphonylurea medication.

Severe Mental Illness

Epidemiology

Individuals with schizophrenia and other severe mental illness (SMI) have a 20-year reduction in life expectancy when compared to the general population, largely due to increased incidence of CVD [21]. Further compounding the risk of CVD is a 2–3-fold increased risk of developing type 2 diabetes [22]. The multiple reasons behind this include genetic susceptibility and environmental factors, such as poor diet, obesity, and lower levels of physical activity. Furthermore, antipsychotic medications, in particular olanzapine and clozapine, are associated with lipid and glucose dysregulation and increased risk of obesity [23]. These medications have sedative and appetite stimulating properties and may also have a direct toxic effect on pancreatic beta-cells [23]. In addition to long-term risks, individuals using antipsychotic medication are also at risk of developing acute complications of diabetes including diabetic ketoacidosis (DKA) [24].

Management

Deaths from acute complications of unrecognized diabetes in individuals with SMI have been reported, indicating a need for all people starting antipsychotic therapy and their carers to be made aware of the risk of developing diabetes and its acute symptoms. Effective strategies for managing obesity and glucose dysregulation in people with SMI using antipsychotic medication are lacking. In patients prescribed clozapine, coprescription of metformin, aripiprazole, or topiramate may help to reduce weight, but this evidence should be balanced against potential side effects [25]. A theory-based, group structured lifestyle education programme was unable to achieve weight loss [26]. Promisingly, glucagon-like peptide-1 receptor agonists have recently been found to achieve reversion to normal glucose tolerance in up to two-thirds of people [27].

Further compounding the challenge of managing diabetes and obesity in people living with SMI is the organization of care systems which often separate physical from mental healthcare. Moreover, innovations for people with type 2 diabetes in the general population

[28] appear to exclude those with SMI, even though these individuals may be in the greatest need.

Future Treatment Directions

In isolation, current treatments for depression are limited by failure rate of around one-third [29], poor concordance rates [30], and inconsistent effects on subsequent diabetes outcomes [31]. Novel strategies may include collaborative interventions to achieve better integration between mental and physical health [31], novel psychological therapies [32], and even the repositioning of current diabetes treatments for mental health [33].

Summary

Psychiatric disorders are overrepresented in patients with type 2 diabetes and predict poor diabetes outcomes. Clinicians in diabetes and primary care should actively screen for these comorbidities and seek to initiate at least first-line management and refer appropriately. Future treatments strategies, such as collaborative care and repositioning of diabetes treatments, may provide novel opportunities to integrate care and improve both psychological and biomedical outcomes.

15.12

Microvascular Complications of Diabetes

15.12.1 Pathogenesis of Microvascular Complications

Angela Shore

Introduction

Diabetes is associated with vascular complications which affect both the large and small blood vessels. The major macrovascular complications include accelerated cardiovascular disease (CVD) and cerebrovascular disease; patients with diabetes have, for example, a 2–3-fold increase risk of myocardial infarction and CVD accounts for more than 50% of the mortality in this patient group [1].

This chapter concentrates on the complications of diabetes which involve the small blood vessels (the microvasculature comprising small arteries, arterioles, capillaries and venules) and their intimate relationship with the organ in which they reside.

By the time **clinically detectable** microvascular complications are present, an individual may have had many years during which the function of the microvasculature has been abnormal and the surrounding tissue has been challenged. Normal microvascular function is important as it maintains the delivery of oxygen, other nutrients and hormones; ensures removal of waste products; maintains the filtration barrier between the blood and tissue; and controls the local tissue blood flow and blood pressure in order to compensate for changes in metabolism, oxygenation, or perfusion pressure.

Microvascular complications are traditionally thought of as those in the eye (see Chapter 15.12.2), kidney (Chapter 15.12.3), and nerves (Chapter 15.12.4) but it is becoming increasingly clear that microvascular complications are not confined to these tissues; they occur in many other tissues, e.g. heart, brain, bone, spinal cord [2–4].

Diabetic complications are the result of the combined effects of the diabetic milieu (hyperglycaemia and altered lipid profiles) and haemodynamic factors on cells, modulated by genetic predisposition and environmental factors. Increasing evidence also suggests that the deleterious effects of hyperglycaemia are exacerbated by an imbalance between factors designed to protect tissues from a variety of toxic effects and the toxic effects of hyperglycaemia *per se*.

These complications of diabetes should not be thought of as arising from the abnormalities of the microcirculation alone but rather they are the result of the disruption of the intimate relationship between the microcirculation and abutting or nearby cells (Figure 15.12.1.1). Recently the American Diabetes Association [5] described *diabetic retinopathy as a highly specific neurovascular complication involving progressive disruption of the interdependence between multiple cell types in the retina.* These cells comprise endothelial cells, pericytes, or vascular smooth muscle cells, retinal glia including Müller cells and astrocytes, neuronal processes, and immune cells both microglia and macrophages [6]. Similarly diabetic neuropathy is due to the interactions of the direct effects of the diabetic milieu on the Schwann cell and the axon as well as the more

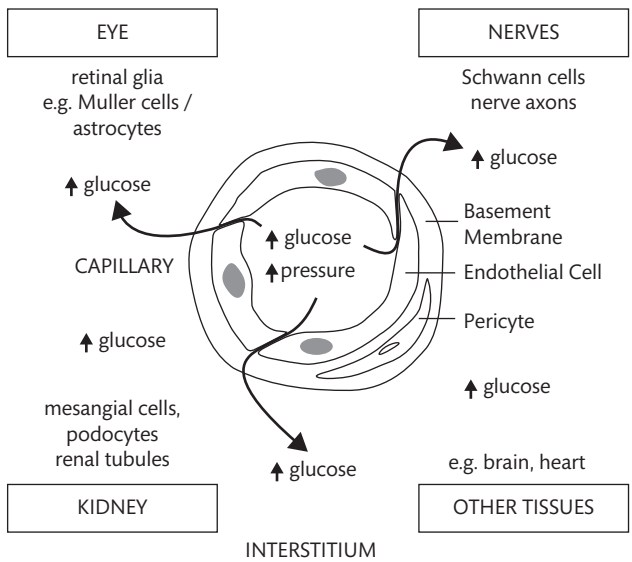

Figure 15.12.1.1 Microvascular complications are the result of disruptions of the intimate relationship between the capillaries and the cells abutting or nearby. These cells also contain the metabolic pathways which are impaired by high glucose and which are responsible for cell dysfunction.

indirect effects on these cells via altered microvascular perfusion [7]; and in the kidney, mesangial cells, podocytes and renal tubules [8] play important roles in diabetic nephropathy in addition to the cells of the vasculature.

Which of these many cell types are the initiators of the complications in diabetes is highly controversial and disputed and is likely to vary according to the tissue examined. One of the main problems in trying to establish which functional abnormality occurs first (e.g. nerve or blood vessel dysfunction) is the intertwined nature of the many components and the fact that the different techniques used to detect these earliest functional abnormalities vary in their ability to detect very small changes. It is however becoming increasingly recognized that many of these 'support' cells, for example Schwann cells or Müller cells contain the metabolic pathways which have been implicated in microvascular complications for many years, and thus they may play direct roles in the development of complications (Figure 15.12.1.1).

It is difficult to give a detailed overview of the pathogenesis of microvascular complications in diabetes as the mechanistic pathway(s) involved varies according to:-

- whether complications are just being initiated, being sustained or in a progressive phase;
- which organ (e.g. kidney, eye, etc.) is being considered and the roles of the vasculature and effects of other cells in the organ;
- whether the patient is receiving treatment which modifies the pathogenic mechanisms.

This chapter thus describes the potential factors involved in the pathogenesis of complications and some of the mechanistic pathways. Further details are available in recent reviews [9]. Subsequent chapters may add specific details about the pathogenesis of an individual complication (e.g. Chapter 15.12.3).

Factors Involved in the Pathogenesis of Microvascular Complications

Metabolic

The Effect of Hyperglycaemia

There is no doubt that the hyperglycaemia associated with diabetes is a major contributing factor but it is not, on its own, sufficient to explain all diabetes complications (see Figure 15.12.1.2). Trial evidence has shown that intensive metabolic control can reduce microvascular complications in both type 1 (DCCT) and type 2 diabetes (UKPDS). The follow-up studies of DCCT and UKPDS show clearly that early intensified glycaemic control can protect against future diabetic complications even when glycaemic control is no longer so intensive—the so-called metabolic memory [10–14].

Higher glycaemic variability, defined as greater pre- and postprandial glucose excursions or more variation of HBA1c over time, predict increased patient risk for cardiovascular complications. Higher glycaemic variability also likely increases the risk of diabetic

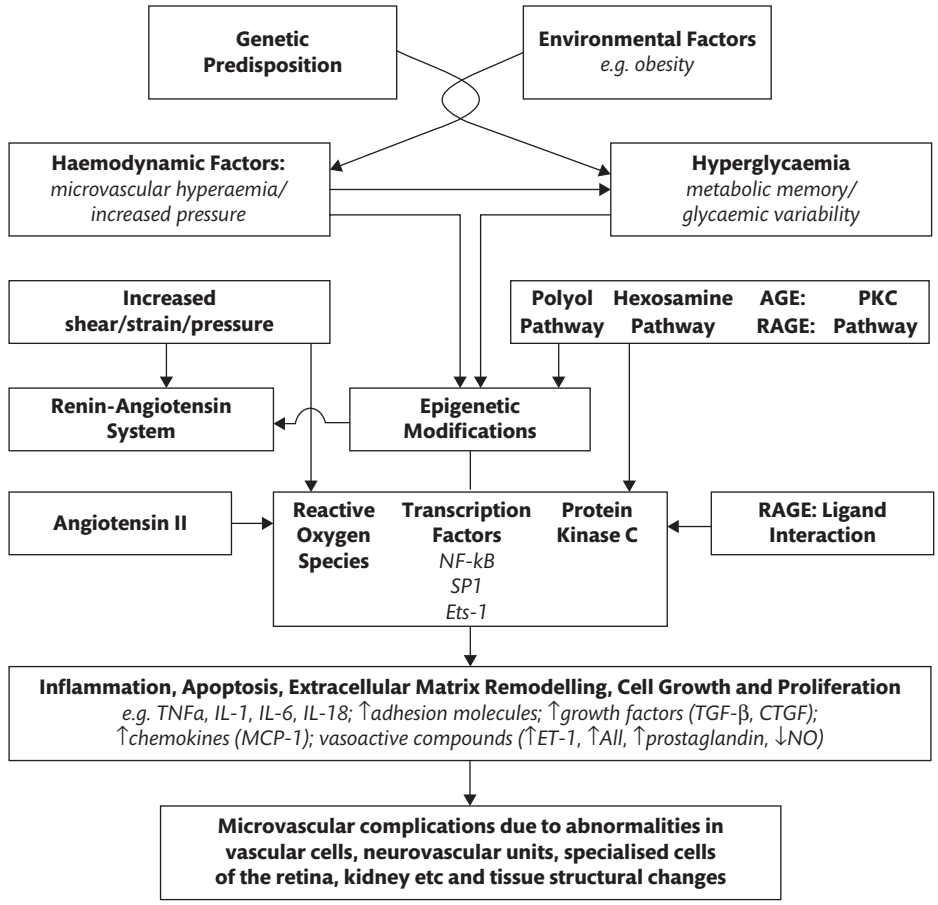

Figure 15.12.1.2 The factors involved in the pathogenesis of microvascular complications.

microvascular complications in patients with diabetes as oxidative stress is increased by acute glucose fluctuations.

Classical pathways [9] implicated in the hyperglycaemic effects include:

- An increased glucose flux through the polyol pathway;
- Increased activity of the protein kinase C (PKC) pathway;
- Increased activity of the hexosamine pathway;
- Accumulation of advanced glycation end-products.

Many of the cells involved in complications respond to an increase in blood glucose by an increase in intracellular glucose. This leads to an increased activity in the glycolysis pathway. Cell glucose is first phosphorylated then converted to fructose 6-phosphate, glyceraldehyde 3-phosphate and dihydroxyacetone phosphate, precursors of diacylglycerol (**DAG**), and at the end of glycolysis, pyruvate is increased and increases activity though the tricarboxylic acid cycle (TCA) cycle in mitochondria.

The high intracellular glucose also results in an increased glucose flux through the polyol pathway which increases the amount of glucose converted to sorbitol and fructose. This leads to a relative depletion of NADPH and activation of NADH oxidase, a reduction in the regeneration of the antioxidant glutathione and increased 3-deoxyglucosone a precursor for advanced glycation end-products (AGE) and histone glycation [15]. Activation of the polyol pathway thus increases oxidative stress and enhances AGE formation. The polyol pathway is present in many cells relevant to diabetic microangiopathy including endothelial cells, Schwann cells, Müller cells, and pericytes.

Increased activity of the PKC pathway which converts glyceraldehyde-3P, by **DAG**, **reactive oxygen species (ROS)** generated from other pathways or by hyperglycaemia causing **transcriptional upregulation of PKC** lead to:-

- Endothelial dysfunction with elevation of the vasoconstrictor endothelin-1 (ET-1), and reduction of the vasodilatory nitric oxide (NO) production, and reduced vasodilatory prostaglandins, and increased permeability via an increase in the vascular endothelial growth factor (VEGF) all important mechanisms in diabetic retinopathy and nephropathy;
- Local inflammation with increases in the transcription factor NF-κB;
- Cell apoptosis, e.g. retinal pericytes, via multiple mechanisms including NF-κB, NADPH oxidase, SHP-1 and MAP kinase;
- Activation of growth factors such as transforming growth factor-β (TGFβ) or connective tissue growth factor (CTGF).

Increased flux through the hexosamine pathway is caused by hyperglycaemia and increases gene expression, for example of plasminogen activator inhibitor-1 (PAI-1) and TGF-β. The pathway converts fructose-6-phosphate to glucosamine-6 phosphate by glutamine-fructose-6 phosphate aminotransferase. Glucosamine-6 phosphate is then converted to uridine diphosphate-N-acetyl glucosamine (UDP-GlcNAc) which, after conversion by 0-GlcNac transferase, activates transcription factors such as Sp1. Insulin vasodilatation and signalling are also impaired by N-acetyl glucosamine [16].

Hyperglycaemia accelerates the formation and **accumulation of AGEs**. AGEs are the products of non-enzymatic glycation and/or oxidation of proteins and lipids [17]. AGEs are slowly metabolized and are postulated to contribute to the metabolic memory of diabetes complications. The receptor for AGE, RAGE, is widely distributed in vascular and inflammatory cells, Müller cells, podocytes, pericytes, neurons, and microglia. RAGE is upregulated in diabetes. The interaction of AGE with their signal–transduction receptor RAGE contributes to many aspects of diabetic microangiopathy particularly inflammation, oxidative stress, and functional effects e.g. in:

- Endothelium—AGE/RAGE upregulates adhesion molecule expression and increases the adherence of leukocytes, increases oxidative stress, increases cytokines and growth factors through activation of NF-κB, increases VEGF, and thus impairs the barrier function of the vessel.
- Nerves—AGE/RAGE impairs perfusion in the vasa nervorum by increasing oxidative stress and prothrombotic signals, causes pro-inflammatory signals in Schwann cells.
- Glomerular—AGE/RAGE increases vascular permeability and proteinuria.
- Macrophages and monocytes—AGE/RAGE stimulates the generation of cytokines and migration.
- Retina—AGE/RAGE causes glial cell dysfunction leading to inflammatory cytokine and chemokine release, oxidative stress, and aberrant growth factor signalling.

AGE-RAGE interaction, via the transcription factors NF-κB and Sp1 for example, increases gene expression of pro-inflammatory cytokines and generates ROS by NADPH oxidase and mitochondrial pathways. Non-AGE ligands for RAGE are also important in diabetic microangiopathy.

Balancing Toxic Effects of Hyperglycaemia and Protective Factors

The consequences of hyperglycaemia for a particular patient depend on the balance of the toxic effects of hyperglycaemia and the patient's natural protective factors [16]. In the Joslin Clinics cohort of 1000 individuals with more than 50 years of insulin requirement [16] 12% have diabetic nephropathy, and 35% have no retinopathy, nephropathy, or neuropathy. Presence or absence of complications was not related to previous glycaemic control. Glomeruli and other cells from these individuals have revealed protective factors several of which have both protective and toxic effects.

Protective factors include:

- Insulin which, via the IRS/PI3Kinase/Akt pathway, upregulates nitric oxide synthase in endothelial cells, upregulates antioxidant activity haeme oxygenase 1 (HO-1), act as an important cell survival factor (e.g. podocytes) and counteracts leukocyte-endothelial cell adhesion;
- Increased endogenous antioxidant enzymes activity, activation of nuclear factor (erythroid derived 2)-like 2 (nrf2) upregulates HO-1 and enzymes in the glutathione pathway;
- Growth factors, e.g. platelet derived growth factor's (PDGF) important cell survival factor function, TGF-β's anti-inflammatory effect, VEGF's role as a survival factor for endothelial cells and podocytes;
- Endothelial and myeloid progenitor cells which can improve angiogenesis and show potential as protective factors.

Metabolic Memory

Metabolic memory refers to the effect of earlier periods of glycaemic control on subsequent development of microvascular complications. DCCT and 30-year follow-up, the Epidemiology of Diabetes Interventions and Complications trial (EDIC) in type 1 diabetes, and the UKPDS and its 10-year follow-up in type 2 diabetes, clearly demonstrated that intensive glycaemic control early in diabetes reduced subsequent microvascular complications compared to the normal control arm, despite the differences in glycaemic control between the treatment arms only being apparent during the trials themselves and not during considerable follow-up periods. See reviews including Cochrane systematic review [10–14].

Animal models show that glycaemic memory is established very early in diabetes causing cellular changes which are not easy to reverse. The mechanisms involved are several. The key biochemical drivers of metabolic memory appear to be oxidative stress and AGE accumulation with various epigenetic marks such as histone methylations and DNA methylation heavily involved [18, 19]. In vascular smooth muscle cells from the db/db mouse model of type 2 diabetes, an epigenetic link to a persistent pro-inflammatory phenotype associated with a reduction in chromatin histone methylation mark, H3K9me3 was reported. This pro-inflammatory phenotype persisted even after culture of the cells in normal glucose levels for several passages [19]. Monocytes of DCCT trial patients from the conventional control group demonstrated evidence of increased acetylation of H3K9 at promoters of genes related to inflammation, apoptosis, NFκB pathway and ROS which increased activation of these pathways. Epigenetic marks may also contribute to the hyperglycaemia associated endothelial dysfunction, changes to histone methylation marks in human microvascular endothelial cells incubated in high glucose, induced upregulation of NFκB p65 expression and an increase in the transcription of numerous inflammatory cytokines. A genome-wide DNA methylation analysis of blood from individuals with type 1 diabetes with or without nephropathy revealed hypermethylation of UNC13B promoter in nephropathy, a region with effects on glomerular apoptosis. DNA methylation has also been associated with glycaemic memory and progression of diabetic retinopathy in a rat model of diabetes. Thus epigenetic modifications likely have a very important effect on the formation and progression of diabetic complications as well as on glycaemic memory. An important role for these biochemical changes on endothelial progenitor cells (EPCs) has also been proposed. Given that EPCs have an extended lifetime and are important for vascular repair and homeostasis, it is likely that the metabolic memory also impairs the vasoreparative capacities of diabetic tissues.

Microvascular Haemodynamic and Structural Factors

Haemodynamic Factors

Both microvascular blood flow and blood pressure contribute to the pathogenesis of microvascular complications (see Figure 15.12.1.2) [20, 21]. Given that microvascular perfusion is not measured or reported clinically, individuals may be classified as remaining free from microvascular complications despite the fact that microvascular perfusion deficits are present. Indeed microvascular dysfunction precedes diabetes. Abnormal microvascular responses are reported in obesity and prediabetes and may contribute to insulin resistance, for example, by impaired insulin mediated vasodilation and reduced capillary recruitment leading to reduced insulin delivery and glucose uptake.

In individuals with type 2 diabetes, reductions in future microvascular complications were achieved by lowering systemic blood pressure from diagnosis in the UKDPS study, irrespective of the therapy used suggesting a beneficial effect of lowering blood pressure *per se* rather than a therapeutic specific effect.

Early in diabetes, tissue hyperperfusion is common, linked to poor glycaemic control followed later by loss of vascular autoregulation and barrier leakage. In type 1 diabetes, abnormalities of the microvascular response to stress are present within the first year of diagnosis, even in prepubertal children. In type 2 diabetes microvascular dysfunction is considerable even at presentation with disease. Endothelial dysfunction becomes increasingly abnormal with longer disease duration and is most marked in those with poor control.

Capillary hypertension, even in the absence of systemic hypertension, is a feature of poorly controlled short duration type 1 diabetes or in those with microalbuminuria. Raised capillary pressure in patients with type 2 diabetes and hypertension is likely due to impaired pressure autoregulation. Whether capillary rarefaction (reduction in number) is a feature of human diabetes is a matter of controversy. Glomerular capillary hypertension in animal models of diabetes precedes the development of glomerulosclerosis and prevention of this glomerular capillary hypertension by treatment with angiotensin converting enzyme inhibitors prevents diabetic nephropathy emphasizing the importance of capillary hypertension in the pathogenesis of diabetic microangiopathy.

Clinical observations link haemodynamic factors with diabetic microangiopathy. Patients with unilateral renal artery stenosis, for example, develop unilateral diabetic nephropathy, the kidney with the stenosed renal artery being protected both from the abnormalities of pressure and diabetic nephropathy. Similar findings are reported for diabetic retinopathy.

Early hyperaemia and elevations in capillary pressure lead to microangiopathy via the effects of pressure, strain, and shear on the vasculature (endothelial cells, vascular smooth muscle cells and pericytes) and supporting cells such as mesangial cells [20].

These haemodynamic forces:

- increase ROS
- activate PKC
- increase NF kappa Beta (NFκB)
- increase Glut 1
- increase adhesion molecules, e.g. ICAM-1, monocyte chemoattractant protein (MCP)
- activate the renin–angiotensin–aldosterone system (RAAS)
- increase growth factors, e.g. CTGF, TGF-β
- stimulate increased secretion of basement membrane components
- change DNA methylation patterns

In addition to these functional changes to the microvasculature, structural changes to the vessels and associated multiple cell types are described.

Structural Changes in the Microcirculation

In a multitude of tissues **thickening of the capillary basement membrane** is the ultrastructural hallmark of diabetic microangiopathy. It

occurs in muscle capillaries, retinal capillaries, glomerulus, and heart capillaries to name a few. The increased thickness is due to increased synthesis of fibronectin, type IV collagen, and laminin by endothelial cells and pericytes which occurs early in diabetes and is not matched by an equivalent increase in the breakdown of these components. Thickening of the basement membrane occurs prior to clinically detectable complications, it increases the rigidity of capillaries, and impairs the barrier function of the vessel wall due to its altered charge and a more open lattice work structure. In the kidney the glomerular basement membrane is twice as thick as other capillary basement membranes as it is synthesized by both the glomerular endothelial cells and the podocytes. Glomerular basement membrane thickness is increased within two years of diagnosis of diabetes at least in part due to podocyte injury, which causes increased synthesis of extracellular matrix components and dysregulation of matrix degradation. In the pathogenesis of diabetic neuropathy not only is the endoneurial capillary basement membrane thickened prior to clinically detectable neuropathy but the Schwann cell basement membrane increases in thickness and changes composition with proposed consequences for neural transmission.

The basement membrane serves as a substratum for cell attachment and regulates cell survival. Thickening of the capillary basement membrane may alter cross talk between the pericytes and endothelial cells in unspecialized capillaries or between the glial cells (Müller cells or astrocytes) and endothelial cells in the retinal neurovascular unit and impair podocyte survival in the glomerulus.

i) Pericytes are perivascular cells embedded in the basement membrane of capillaries and venules which have long processes which interact with one or many endothelial cells. They likely regulate microvascular blood flow. They contain actin, have the ability to contract and are able to respond to vasoconstrictor and vasodilator agents. The interaction between the endothelial cell and pericytes is important in the maintenance and regulation of vessel function and structure, in the control of the vascular barrier function and in the modulation of the immune response.

In diabetes, loss of pericytes from capillaries occurs early in disease. Pericyte deficient capillaries have been reported in many tissues (e.g. skeletal muscle, retina, skin, kidney, and nerves). Pericyte loss contributes to altered endothelial function, impaired barrier function, and neovascularization. Pericyte loss and subsequent weakening of the capillary may result in microaneurysms which, in the retina at least, are normally located adjacent to areas of acellular capillaries and non-perfusion. High glucose induced migration of renal pericytes from the capillary into the interstitial space and subsequent differentiation into collagen producing myofibroblasts has been implicated in tubulointerstitial fibrosis and renal dysfunction [22].

The number of capillary microaneurysms and non-perfused capillaries increases with the severity of the microangiopathy, and together with impaired vascular reactivity of larger vessels, explain the inadequate perfusion of severe microangiopathy.

Diabetic retinopathy histologically is ultimately associated with acellular non-perfused capillaries in the retina due to the death of both endothelial cells and pericytes. These non-perfused capillaries are simply tubes of basement membrane. Delivery of oxygen to such areas is compromised and results in activation of inflammatory cascades.

Diabetic nephropathy is accompanied by several main histological changes;

- extensive mesangial expansion and glomerulosclerosis;
- thickening of the glomerular basement membrane;
- broadening (effacement) of the podocyte foot processes. This reduces filtration slit area between the podocytes and increases macromolecule passage;
- abnormalities of the glycocalyx and glomerular endothelial cells.

The renal structural changes of early diabetes are heterogenous. Abnormalities to the glomerular endothelial cell surface layer (glycocalyx) have recently been reported to contribute to the development of diabetic microalbuminuria [23].

Genetic Susceptibility

Genetic factors contribute to microvascular complications: There is familial clustering of both diabetic nephropathy and severe, vision threatening forms of diabetic retinopathy as reported in the Diabetes Control and Complications Trial. The estimated heritability of albumin excretion rate is ~20–40% and diabetic siblings of patients with diabetic nephropathy have a twofold increased risk of diabetic nephropathy.

Many genetic risk variants for microvascular complications have been reported by candidate gene studies or by genome-wide association studies; however very few have shown robust replication. In the biggest study in type 1 diabetes to date, sets of alleles known to increase body mass index, and those known to increase the risk of type 2 diabetes, were associated with the risk of diabetic nephropathy [24]. Pathway analysis implicated ascorbate and aldarate metabolism, and pentose and glucoronate interconversions. In the largest T2DM study to date, the genetic analysis provided support for the importance of BMI and identified some variants associated with GFR and microalbuminuria in diabetic nephropathy [25]. Further studies are needed, accompanied by more intensive phenotyping of disease in particular using biomarkers which can identify individuals destined to develop the complications prior to any clinical evidence [26]. It is highly likely that epigenetic changes contribute to the formation of both diabetic nephropathy and retinopathy.

Environmental Factors

Environmental and behavioural factors, for example, those influencing BMI and levels of exercise, can modulate many of the pathways through which hyperglycaemia, haemodynamics, and genetic susceptibility lead to microvascular complications of diabetes and thus contribute to the findings of links between the two. Obesity is, for example, accompanied by increases in ROS, dysregulation of mitochondrial biogenesis, mitophagy, and dynamics, downregulation of both the AMP-activated protein kinase (AMPK) and sirtuins and activation of the renin–angiotensin–aldosterone system.

Pathways Involved in the Formation of Microvascular Complications

Reactive Oxygen Species (ROS)

ROS encompasses non-radical species such as hydrogen peroxide and free radical species such as hydroxyl radical and superoxide

anion (see Figure 15.12.1.2). ROS are proposed to act as a common pathway in the pathogenesis of diabetic complications, though the exact species involved has caused dispute over recent years [27]. ROS are produced physiologically in health as normal homeostatic functions. However when the balance between production and removal of ROS is altered, oxidative stress can result. At high concentrations, ROS can cause tissue damage including modifications to proteins, DNA, and lipids. Reactive nitrogen species, e.g. derivatives of NO also cause tissue damage.

In diabetic complications [27], ROS are increased in, for example, endothelial cells, vascular smooth muscle cells, cardiac myocytes, mesangial and tubular epithelial cells, retinal glial cells, Schwann cells by factors including:

- hyperglycaemia
- haemodynamic factors
- inflammatory processes.

There are many pathways which contribute to the generation of ROS in tissues in which diabetic microvascular complications arise.

These include:

- enzymes such as nicotinamide adenine dinucleotide phosphate oxidase (NADPH oxidase complex (NOX)), xanthine oxidase, 12/15 lipoxygenase, myeloperoxidase;
- altered mitochondrial ROS production and clearance due to increased oxidative phosphorylation;
- cytochrome p450;
- uncoupling of nitric oxide synthase so that superoxide anions rather than nitric oxide are produced.

Whether the mitochondrial electron transport chain is involved in diabetic complications has been at the centre of controversy recently but the consensus seems to be that changes in mitochondrial redox status by impaired electron transport are indeed important in the formation of diabetic microangiopathy even if they are subsequently reduced at later stages of the disease [27].

The antioxidant pathways which remove ROS are often also impaired in diabetes such as heme-oxygenase-1 (HO-1), Superoxide dismutase (SOD), glutathione peroxidases (GPx). Nrf2, a transcription factor, controls baseline and induced levels of antioxidants and is thus an important regulator of ROS and a target for future therapies.

The downstream redox sensitive processes which are affected by increases in ROS are numerous and include major metabolic pathways, RAGE/AGE, PKC, renin–angiotensin–aldosterone system (RAAS), cell growth, apoptosis, migration, extracellular matrix modelling, growth factors, vascular function, and permeability. The exact mechanisms and pathways involved in ROS mediated damage differs in retinopathy, nephropathy, neuropathy, and other tissues.

Inflammation

Many mechanisms, mediators and signalling cascades contribute to inflammation in diabetic complications with some variation of pathways and the cells involved in different tissues [28, 29].

Inflammation, recruitment, and activation of immune cells to clear damage to tissue or pathogens, is beneficial in the acute phase; however, chronic inflammation may cause irreversible pathological tissue changes. Pattern recognition receptors such as RAGE are involved as one of the receptors in inflammatory responses. RAGE-ligand interactions both initiate and sustain inflammation, NF-κB is activated and stimulates transcription of pro-inflammatory genes, acute phase proteins, and chemokines such as IL-6, TNF-α, monocyte chemoattractant protein (MCP-1) which all play a major role in the recruitment and activation of monocytes and leukocytes and the subsequent inflammatory response, all are implicated.

Inflammatory mechanisms have been implicated as important early pathogenic factors in retinopathy, neuropathy, and nephropathy. This is strengthened by the finding that modification of inflammation is associated with reduced complications in patients [30]. Circulating markers of inflammation are increased in both type 1 and type 2 diabetes and correlate with albuminuria and risk of progression towards End Stage Renal Disease.

Activation of macrophages, neutrophils, resident immune cells such as microglia or dendritic cells, Schwann cells, endothelial cells, or adipocytes via pattern recognition receptors [28–30] leads to:

- increased NF-κB activity, mitogen-activated protein kinases (MAPKs);
- induction of pro-inflammatory genes;
- release of pro-inflammatory cytokines/chemokines with effects locally and systemically including immune cell recruitment.

Exactly which cytokines are released, in what proportions, and the downstream effects appear to vary according to the stage of disease and the tissue examined. TNFα, IL-1, IL-6, and IL-18 are increased early in diabetic nephropathy; they increase adhesion molecule expression (e.g. ICAM-1), alter glomerular haemodynamics and increase glomerular permeability, increase prostaglandin secretion, induce mesangial cell proliferation, cause apoptosis, generate ROS, and augment the inflammatory response by stimulating transcription factors and other growth factors. Similar cytokines are also increased in retinopathy although VEGF is induced by hypoxia through HIF-1 and contributes to increased vascular permeability [31, 32].

The chemokines such as CCL-2, CCL-4, CXCL-9, and CXCL-10 are elevated in vitreous samples from patients with proliferative diabetic retinopathy as is the MCP-1. All are involved in immune stimulation and recruiting and activating microglia (resident immune cells in retina) and leukocytes. MCP-1 also contributes to fibrosis and angiogenesis [30]. Many of these chemokines are also elevated in patients with diabetic nephropathy.

The Renin–Angiotensin–System (RAS)

RAS is upregulated by both hyperglycaemia and by haemodynamic factors.

RAS is expressed locally in tissues, e.g. in the eye it is present in neuronal (Müller cells, ganglion cells) and vascular cells. The RAS components are produced locally in the tissues rather than being filtered from the circulation. Increased levels of Angiotensin II (Ang II) and other RAS components have been found in the vitreous fluid in patients with proliferative retinopathy compared to controls. Research suggests these locally produced components of RAS especially Ang II are involved in the pathogenesis of complications

and potentially that chymases rather than angiotensin converting enzymes (ACE) are the primary mechanism of intracellular Ang II generation. Chymases convert Ang I to Ang II at a much higher rate than ACE and are not inhibited by ACE inhibitors. In the eye some cells will be exposed to circulating Ang II (e.g. endothelial cells), while cells behind the vascular barrier will be primarily exposed to locally derived Ang II. Kidney Ang II is also locally generated as well as circulating.

Angiotensin II (Ang II) has haemodynamic and non-haemodynamic effects, generating its actions via ROS and stimulation of pro-inflammatory transcription factors such as NF-κB and Ets-1.

Ang II increases:

- glomerular hypertension, by preferentially vasoconstricting the efferent capillary;
- cellular apoptosis which decreases pericyte viability and impairs vascular regulation;
- vascular permeability, by stimulating expression and secretion of VEGF, leukotriene C4, PGE2, and PGE1;
- rolling and sticking leukocytes by upregulating E-selectin VCAM-1 and ICAM-1;
- recruitment of monocytes, T lymphocytes, and neutrophils by stimulating secretion of monocyte chemotactic protein MCP-1, cytokine-inducible neutrophil chemoattractant, keratinocyte-derived chemokine, and macrophage inflammatory protein (MIP)-2.

Ang II also:

- impairs tissue repair;
- mediates fibrosis via TGF-β and CTGF;
- induces apoptosis/proliferation;
- stimulates ECM deposition.

15.12.2 Retinopathy

Peter H. Scanlon

Definition of Diabetic Retinopathy

Diabetic retinopathy refers to the microvascular complication of diabetes with pathology of the capillaries, arterioles and venules in the retina and the subsequent effects of leakage from or occlusion of the small vessels.

The Normal Eye

The eye is an approximate globe consisting of three concentric major layers of tissue. The outermost layer is the white protective sclera except anteriorly where it becomes transparent to allow light to enter through the cornea. The middle layer is the uvea which comprises the iris, ciliary body, and choroid. The innermost layer in the posterior section is the retina which contains the photoreceptor cells. The anterior part of the globe is filled with aqueous humour and the posterior part is filled with the vitreous jelly, both of which are transparent to allow passage of light through to the retina. The majority of the retina, excepting the central foveal region, is provided with oxygen from the retinal vascular circulation. The central foveal region is thinner and has no direct retinal blood supply. Lying between the choroid and the retina are the very thin Bruch's membrane and the retinal pigment epithelium. The supply of oxygen and nutrients is provided through diffusion from the choriocapillaris, which has small gaps (fenestrations) between the cells in the walls of smaller choroidal vessels, and through contact with the retinal pigment epithelium. The blood vessels in the retina exhibit tight junctions between adjacent cells, which prevent leakage of blood components, fluids, chemicals, or drugs through the retinal blood vessel wall maintaining the *blood–retinal barrier*.

Pathology of Diabetic Retinopathy

The histological changes that have been described in diabetic retinopathy are:

1. Thickening of the basement membrane
2. Pericyte loss
3. Loss of epithelial tight junctions
4. Loss of endothelial cells
5. Smooth muscle cell death
6. Capillary weakening
7. Increased capillary permeability
8. Capillary occlusion
9. Microaneurysm formation—this has always been considered one of the earliest lesions in diabetic retinopathy and the hallmark of the condition.

The production of vascular endothelial growth factor (VEGF) during the pathological processes of diabetic retinopathy and the beneficial effects of blocking the effects with VEGF inhibitor drugs have become increasingly apparent.

Modifiable Risk Factors for Progression of DR

a) Systemic hypertension

Although there had been previous descriptions of the effect of hypertension on diabetic retinopathy progression, Joner [1] studied a nationwide cohort of 600 young people with type 1 diabetes in Norway in 1992 and found hypertension to be a significant contributor to the occurrence and progression of diabetic retinopathy in a multiple logistic regression model. Matthews [2] described the UK Prospective Diabetes Study (UKPDS) results

in type 2 diabetes that by 4.5 years after randomization, there was a highly significant difference in microaneurysm count with 23.3% in the tight BP control group and 33.5% in the less tight BP control group having 5 or more microaneurysms (relative risk [RR], 0.70; $P = 0.003$).

More recently the ACCORD [3] and the ADVANCE [4] trials did not show any benefits for retinopathy of more intensive blood pressure lowering, presumably because the blood pressure in the control arms was relatively well controlled compared to the earlier studies.

b) Glucose control.

In type 1 diabetes, the Diabetes Control and Complications Trial (DCCT) [5, 6] demonstrated the beneficial effects of glucose control. After a mean follow-up of 6.5 years in the primary-prevention cohort, intensive therapy reduced the risk for the development of DR by 76% (CI 62–85%), compared with conventional therapy. For the secondary intervention cohort, intensive therapy slowed the progression of DR by 54% (CI 39–66%) and reduced the development of proliferative diabetic retinopathy (PDR) or severe non-proliferative diabetic retinopathy (NPDR) by 47% (CI 14–67%).

In type 2 diabetes, the United Kingdom Prospective Diabetes Study UKPDS [7, 8] demonstrated that there was a 25% (CI 7–40%) risk reduction in the intensive group in development of diabetic retinopathy.

c) Blood lipids.

The role of lipids in the genesis of retinopathy is less clear than that of B/P and glucose control. In 1996 Chew [9] reported an association of elevated serum lipid levels with retinal hard exudates in diabetic patients from the Early Treatment Diabetic Retinopathy Study.

In a recent Health Technology Assessment (HTA) project [10] looking at identifying low risk individuals whose screening risk could be safely extended, the total serum cholesterol (per 1 mmol/L) was a risk factor for progression to screen positive maculopathy but not for progression to pre-proliferative or proliferative DR. The hazard ratio for progression to screen positive maculopathy was 1.14 (95% CI 1.06–1.22).

The FIELD [11] and ACCORD [3] trails suggested that fenofibrate may have beneficial effects on preventing and slowing progression of retinopathy [3, 11], although the mechanism may not be through modification of lipid levels as had previously been thought.

d) Smoking.

In type 1 diabetes Muhlhauser [12] and Karamanos [13] reported smoking to be a risk factor for progression. In type 2 diabetes the evidence is controversial and it may protect against the progression of retinopathy in some patients despite the fact that mortality from cardiovascular disease is increased.

Non-Modifiable Risk Factors for DR

These include:

a) Duration of diabetes:

Numerous studies have reported [14] on the effect of duration of diabetes. Most recently we have reported [15] on the retinopathy levels in 2125 children with diabetes screened for the first time at age 12 or 13. In those diagnosed with diabetes at 2 years of age or less the proportion with retinopathy in one eye or both eyes was 20% and 11%, respectively, decreasing to 8% and 2% in those diagnosed between 2 and 12 years ($P < 0.0001$)

b) Age:

In type 1 diabetes the relationship with age is complex as described [15] earlier in the younger age group where those diagnosed less than 2 years old had disproportionately higher levels of retinopathy at aged 12 years when they were first screened.

However, in type 2 diabetes in the UKPDS [16], in those who already had retinopathy, progression was associated with older age.

c) Genetic predisposition:

Hietala [17] found a familial clustering of proliferative retinopathy in patients with type 1 diabetes. The observation could not be accounted for by conventional risk factors, suggesting a genetic component in the pathogenesis of proliferative retinopathy in type 1 diabetes.

d) Ethnicity:

Simmons [18] compared ethnic differences in Auckland, New Zealand and found that moderate or more severe retinopathy is more common in Polynesians than Europeans and this difference could not be explained by differences in diabetes duration, insulin therapy, the extent of renal disease, blood pressure, or glycaemic control.

Other Common Conditions Affecting the Progression of DR

Pregnancy

Progression of diabetic retinopathy may occur during pregnancy. The known risk factors for progression of diabetic retinopathy in pregnancy are:

a) Pregnancy [19, 20] is independently associated with progression of diabetic retinopathy
b) Baseline severity of retinopathy [21–23]
c) Poor metabolic control at conception [21]
d) Rapid improvement of glycaemic control [20–23]
e) Poor metabolic control during pregnancy or the early postpartum period [19, 20, 23, 24]
f) Duration of diabetes [23, 25, 26]
g) Chronic hypertension and pregnancy-induced hypertension [23]

Renal Failure

Sakata [27] described four patients who exhibited the greatest decline in the estimated glomerular filtration rate (12.3–23.5 ml/min/1.73 m^2/year) had several clinical features in common, including marked retinopathy. It is common in diabetic retinopathy clinics to find deterioration in retinopathy with decline in renal function and there is often (but not always) an improvement once renal dialysis has commenced.

The Early Worsening Phenomenon

In 1998 the DCCT described the effect of early worsening of diabetic retinopathy at the 6- and/or 12-month visit in 13.1% of 711

patients assigned to intensive treatment. Early worsening led to high-risk proliferative retinopathy in two patients in the DCCT who had poorer control on entering the trial. However, the long-term benefits of intensive insulin treatment greatly outweighed the risks of early worsening.

The Early Treatment Diabetic Retinopathy Study (ETDRS)

The ETDRS [29] described the progression of diabetic retinopathy in relation to the development of the specific lesions, the most important of which were:

1. Microaneurysms (Ma)
2. Small retinal haemorrhages or dot haemorrhages
3. HMa (haemorrhage/microaneurysm)
4. Flame haemorrhages
5. Blot haemorrhages
6. Hard exudates—often just referred to as exudates (HE)
7. Cotton wool spots (referred to as soft exudates or SE in the ETDRS but this term is now rarely used)
8. Intraretinal microvascular abnormality (IRMA)
9. Venous beading (VB)
10. New vessels at the disc (NVD)
11. New vessels elsewhere (NVE)
12. Vitreous haemorrhage (VH)
13. Preretinal haemorrhage (PRH)

Table 15.12.2.1 shows the progression to PDR according to the ETDRS severity scale [30] and a comparison to English Screening Programme grades.

Screening for Diabetic Retinopathy

Screening for Diabetic Retinopathy commenced in the Four Nations of England, Scotland, Wales, and Northern Ireland between 2002

Table 15.12.2.1 Diabetic retinopathy classification of progression to proliferative DR

ETDRS final retinopathy severity scale	ETDRS (final) grade	Lesions	Risk of progression to PDR in 1 year (ETDRS interim)	English Screening Programme levels
No apparent retinopathy	10 14, 15	DR absent DR questionable		R0 Currently screen Annually
Mild NPDR	20	Micro aneurysms only		R1 Screen annually **Background** microaneurysm(s) Retinal haemorrhage(s) ± any exudate Venous loop
	35 a b c d e	One or more of the following: Venous loops ≥ definite in 1 field SE, IRMA, or VB questionable Retinal haemorrhages present HE ≥ definite in 1 field SE ≥ definite in 1 field	Level 30 = 6.2%	
Moderate NPDR	43a b	H/Ma moderate in 4–5 fields or severe in 1 field or IRMA definite in 1–3 fields	Level 41 = 11.3%	R2 Refer to ophthalmologist **Pre-proliferative** venous beading venous reduplication intraretinal microvascular abnormality (IRMA) multiple deep, round, or blot haemorrhages
Moderately severe NPDR	47 a b c d	Both level 43 characteristics – H/Ma moderate in 4–5 fields or severe in 1 field and IRMA definite in 1–3 fields **or** any one of the following: IRMA in 4–5 fields HMA severe in 2–3 fields VB definite in 1 field	Level 45 = 20.7%	
Severe NPDR	53 a b c d	One or more of the following: ≥ 2 of the 3 level 47 characteristics H/Ma severe in 4–5 fields IRMA ≥ moderate in 1 field VB ≥ definite in 2–3 fields	Level 51 = 44.2% Level 55 = 54.8%	
Mild PDR	61a b	FPD or FPE present with NVD absent or NVE = definite		**R3** Proliferative DR
Moderate PDR	65a b	1) NVE ≥ moderate in 1 field or definite NVD with VH and PRH absent or questionable or 2) VH or PRH definite and NVE < moderate in 1 field and NVD absent		
High-risk PDR	71 a b c d	Any of the following: 1) VH or PRH ≥ moderate in 1 field 2) NVE ≥ moderate in 1 field and VH or PRH definite in 1 field 3) NVD = 2 and VH or PRH definite in 1 field 4) NVD ≥ moderate		
High-risk PDR	75	NVD ≥ moderate and definite VH or PRH		
Advanced PDR	81	Retina obscured due to VH or PRH		

and 2004 with full population coverage being achieved in England by 2008. All Four Nations use digital photography as their primary screening tool with England and Wales dilating all people with diabetes, Northern Ireland dilating over the age of 50 years and Scotland using a staged approach with dilation if the screener considers the image quality to be poor. In 2014 it was reported [31] that Diabetic Retinopathy was no longer the leading cause of blindness in the working age group in England and Wales and the introduction of the screening programmes was considered to have made a significant contribution to this achievement.

The English Screening Classification for DR Progression

The English Screening Programme takes two 45-degree fields and uses the classification shown in the right-hand column of Table 15.12.2.1 for grading the images. Each eye has a retinopathy R and a maculopathy M grade, and the outcome is dependent on the grade of the worst eye.

R0M0 No Diabetic Retinopathy. No maculopathy
R1M0. Background DR. No maculopathy
R1M1. Background DR. No maculopathy
R1M1 is Background DR. Maculopathy
R2M0. Pre-proliferative DR. No maculopathy
R2M1. Pre-proliferative DR. Maculopathy
R3M0. Proliferative DR. No maculopathy
R3M1. Proliferative DR. Maculopathy
U. Unassessable images

People with diabetes who have unassessable images are referred for slit-lamp biomicroscopy investigation.

Examination Techniques Used to Assess Diabetic Retinopathy

The commonly used examination techniques used are:

1. A carefully taken history.
2. Assessment of visual acuity.
3. Dilation of the pupil with G Tropicamide 1% often with G Phenylephrine 2.5%.
4. Direct ophthalmoscopy has a limited field of view and does not have a good sensitivity and specificity for the detection of sight threatening diabetic retinopathy but is useful for ad hoc detection of diabetic retinopathy.
5. Slit-lamp biomicroscopy is the commonest method used by ophthalmologists to diagnose and monitor retinal disease using an indirect lens such as a 78D lens.
6. Contact lens biomicrosopy is used for more detailed retinal examinations and while conducting laser treatments with a contact lens placed on the eye.
7. Binocular indirect ophthalmoscopy is useful for evaluating the posterior segment and retinal periphery. A larger area can be viewed than with slit-lamp biomicroscopy but this view is less magnified.

Investigations Used to Assess Diabetic Retinopathy

1. Retinal photography—digital colour retinal photography is currently the method of choice for screening for diabetic retinopathy. In the English Screening Programme two 45-degree fields are taken, one centred on the fovea and one centred on the optic disc. In programmes that use non-mydriatic photography such as Scotland, one 45-degree field is used because of the delay in pupil dilation after the flash. All new screening methodologies are tested against a reference standard of seven-field stereophotography. See Figure 15.12.2.1.
2. Scanning laser ophthalmoscopy (SLO)—this method is increasingly being used in the eye clinic environment and they provide an artificial colour image. The SLOs use monochromatic light and provide an artificial colour image by using red, green, and blue lasers sequentially to acquire red, green, and blue reflectance images of the retina and combining these images to produce an artificial colour image. The Optos machine can take a wide 200-degree field although this width of field does limit the central resolution. Other scanning laser ophthalmoscopes such as the Heidelberg Spectralis take a smaller field (e.g. 55 degrees).
3. Scanning confocal ophthalmoscopy (not laser)—some recent machines use the same principle of confocal light but produce a colour image using LED light (e.g. the Eidon by CenterVue and the Zeiss Clarus 500).
4. Fundus fluorescein angiography is a diagnostic procedure in which fluorescein dye (typically 5 ml of 10% sodium fluorescein) is injected in a peripheral vein and a specialized fundus camera or confocal scanning laser ophthalmoscope captures high resolution, rapid sequence photographs, or digital videos to monitor the circulation of the fluorescent dye through the eye. The dye provides a yellow fluorescence with blue light and so the technique involves blue light being transmitted into the eye and yellow filters being inserted for light returning to the camera or SLO. The fluorescein dye can cause side effects in a few individuals such as nausea, vomiting, occasional syncope, skin rashes, and itching. More serious side effects, such as anaphylactic shock, are extremely rare. See Figure 15.12.2.2.
5. Optical coherence tomography (OCT) utilizes time of flight optical interferometry to resolve the different reflective layers of the retina at resolutions typically in the range of 3–8 μm for standard commercial systems. OCT images can be presented as either cross-sectional images or as topographic maps and can be combined with fluorescein angiography. See Figure 15.12.2.3.
6. Optical coherence tomography angiography—advances in OCT technology have seen the development of methods of non-invasive, dye-free angiography. This technique analyses the axial motion associated with blood flow and uses this to generate three-dimensional reconstructions of the vasculature. OCT angiography has a number of advantages over fluorescein angiography—it is non-invasive, does not require the use of fluorescein dye, and is quicker to perform. However, it presents challenges with interpretation because the absence of a vessel may mean that the blood flow is too slow for the technique to detect rather than true absence.
7. See Figure 15.12.2.4.

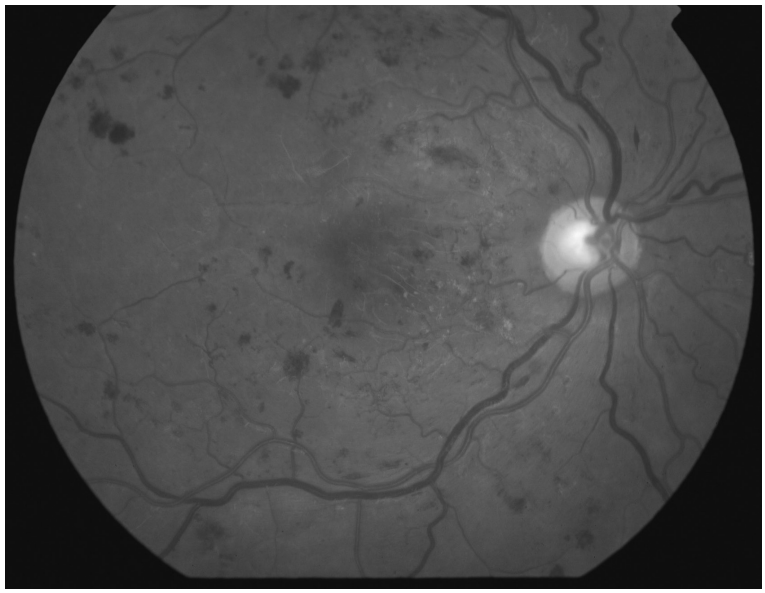

Figure 15.12.2.1 This macular centre digital photograph shows features of R2 preproliferative DR with multiple haemorrhages and IRMA and M1 maculopathy with exudates <1DD from the foveal centre.

8. Ultrasound B scan examination uses high frequency ultrasound typically in the range of 8–15 MHz, to generate images of the eye. Ocular structures are identified by their characteristic reflectivity profiles on the A-scan and B-scans provide cross-sectional images of the eye. This is useful to examine the density and extent of a VH and the presence or absence of a retinal detachment where the retinal view is obscured. This technique is particularly useful in advanced diabetic retinopathy where fibrovascular membranes, tractional retinal detachments, and VHs may coexist and assists in planning vitreoretinal surgery.
9. Visual field perimetry is the systematic measurement of differential light sensitivity in the visual field by the detection of the presence of test targets on a defined background in order to map and quantify the visual field, normally testing each eye independently but binocularly for driving field assessment.

Multidisciplinary Approach

Many patients who have severe diabetic eye disease have suboptimal control of blood glucose, blood pressure, and lipid levels. It

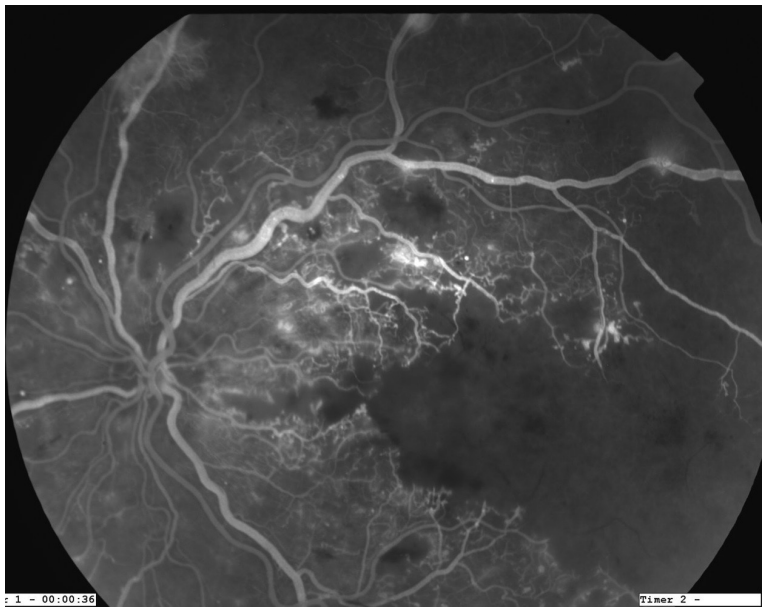

Figure 15.12.2.2 A fluorescein angiogram 36 seconds after injection of dye showing a very ischaemic retina with very poor blood supply to the macular area and leakage of dye from the new vessels elsewhere is starting and will increase over the next few minutes and will be more obvious in the later photos.

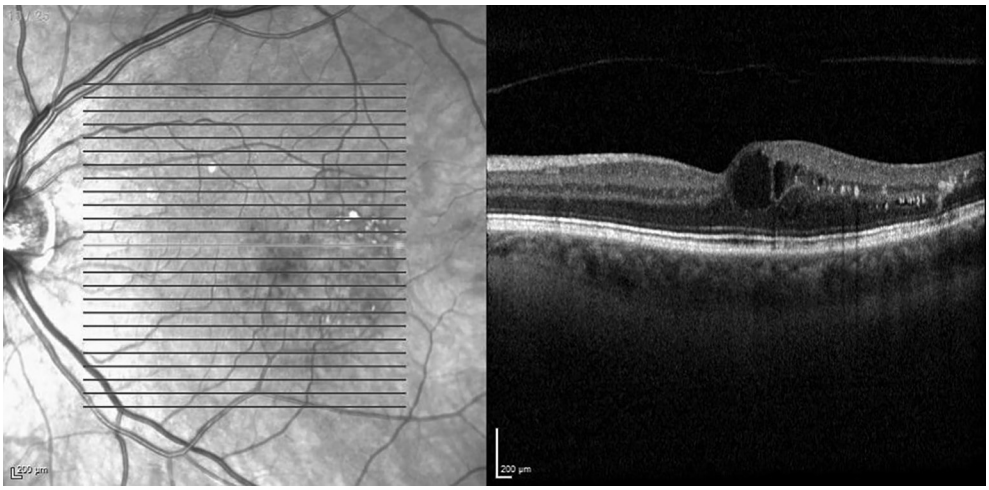

Figure 15.12.2.3 An OCT image of the left macular area showing leaking of fluid into the retinal layers on the temporal side of the macula in a patient with diabetic maculopathy.

is important to have a multidisciplinary approach to these patients so that the eye is not treated in isolation. Hence it is important that proper attention is paid to the management of:

a) Systemic hypertension
b) Glucose control
c) Blood lipids

Treatment of Diabetic Maculopathy

In the past diabetic maculopathy was treated with laser in accordance with the definition of clinically significant macular oedema which was defined by the ETDRS study as:

1. Thickening of the retina at or within 500 microns of the centre of the macula;
2. Hard exudates at or within 500 microns of the centre of the fovea, if associated with thickening of the adjacent retina (not residual hard exudates remaining after disappearance of retinal thickening);
3. A zone or zones of retinal thickening 1 disc area or larger, any part of which is within 1 disc diameter of the centre of the macula.

When treatment was carried out with laser it was recognized that one should not treat within the foveal avascular zone because of the risk of the treated individual noticing a blind spot in their vision and because laser creep over time can affect the central vision at a later date.

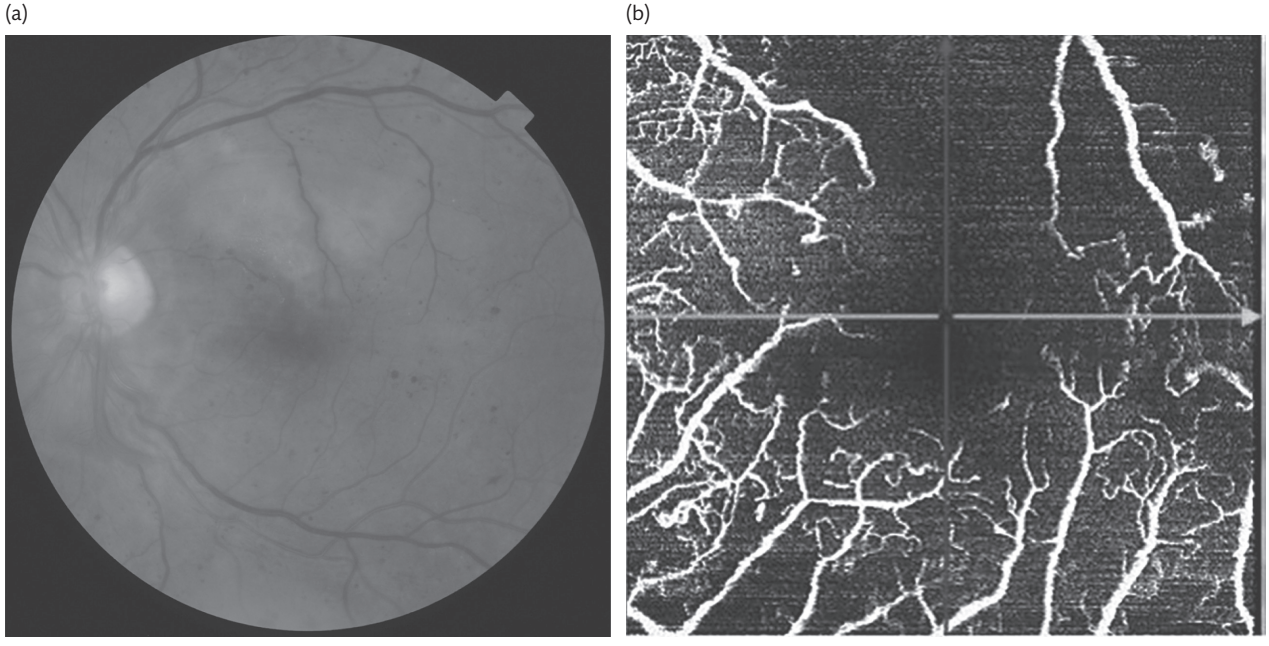

Figure 15.12.2.4 (a) Colour image of the left macula and disc showing NVD at the left disc and a superior branch arterial occlusion above the left macula. (b) An OCT angiogram of the left macular area showing the poor blood supply in the superior left macular area.

VEGF inhibitors—more recently laser has been reserved for thickening that is off centre and those people with diabetes who have diabetic maculopathy and central thickening are offered a course of intravitreal injections of VEGF inhibitors for treatment of their oedema. In England NICE guidelines restrict this treatment to those whose centre thickness are greater than or equal 400 microns.

There have been a number of studies that have shown that this treatment is beneficial in diabetic maculopathy using the two on-label preparations ranibizumab [32], aflibercept [33, 34], and the off-label bevacizumab [35]. One exciting feature of all of these studies was that there was regression of ETDRS levels and there was a significant gain in vision measured by the number of extra letters read. This was of course dependent on the starting level of vision but there was considerably more visual gain with VEGF inhibitors than with laser treatment where stabilization of vision was considered optimal and vision gain was infrequent. One study [36] suggested a higher vision gain could be achieved with aflibercept in patients whose initial vision was worse (less than 69 letters or approximately ≤6/15) than using other VEGF inhibitors. There tends to be a reduction in treatment frequency required over time with an average of 7–9 anti-VEGF injections required in the first year, 2–4 in the second year, 1–3 in the third, and approximately 1 injection per year in years 4 and 5 [37, 38].

Potential side effects of intravitreal VEGF inhibitor therapy are sustained elevation of intraocular pressure [39] (9.5% compared to 3.4% in the control group), endophthalmitis [40] (0.04–0.06/injection) and cardiovascular events [41] which, although a theoretical risk, have not been found to be higher than the control group in a meta-analysis of six randomized controlled studies. Until recently we have had a choice in England of using the on-label preparations of aflibercept and ranibizumab but NICE has recently issued guidance [42] suggesting that they found no significant differences in effectiveness and safety between the different anti-VEGF treatments in age-related macular degeneration following the subsequent statement by the GMC [43] that they would not raise any 'fitness to practice' concerns if doctors prescribed bevacizumab, we may see a wider use of this agent.

Intravitreal corticosteroids—it has been shown [44] that inflammation plays a significant role in the development of macular oedema in some patients with diabetes. Intravitreal triamcinolone acetonide is an off-label treatment that has been extensively studied [45] and has been shown to be beneficial in some patients. Side effects of all intravitreal steroid preparations are elevation of IOP requiring topical treatment or surgery, and cataracts. In addition some patients who were treated with intravitreal triamcinolone developed sterile uveitis/pseudoendophthalmitis (in up to 13% of eyes) that further limited its clinical use [46]. Dexamethasone intravitreal implant (Ozurdex, Allergan, Inc., Irvine, CA) is a sustained-release bio-gradable implant formulation of corticosteroid that has been shown [47] to improve visual acuity in a difficult-to-treat patient population with long-standing refractory DME of macular oedema due to diabetes. Dexamethasone implants only have a duration of action of approximately 3 months. In the UK, it has also been approved by NICE [48] for this indication but only in pseudophakic eyes who have not responded to non-corticosteroid treatment. Fluocinolone acetonide (Illuvien) is an intravitreal implant of fluocinolone acetonide which delivers 36 months of continuous, low-dose corticosteroid. Intravitreal Fluocinolone acetonide was recently granted approval [49] in the UK by NICE but only for treating chronic diabetic macular oedema that is insufficiently responsive to available therapies only if the implant is to be used in an eye with an intraocular (pseudophakic) lens [50].

Treatment of PDR

The Diabetic Retinopathy Study (DRS) [51, 52] provided the first treatment for PDR with panretinal photocoagulation (PRP) in 1976 and recommended prompt treatment in the presence of DRS high-risk characteristics, which reduced the two-year risk of severe visual loss by 50% or more and were defined by:

a) The presence of preretinal or VH;
b) Eyes with NVD equalling or exceeding one-quarter to one-third disc area in extent with no haemorrhage;
c) NVE equalling > one-half disc area with haemorrhage.

See **Figure 15.12.2.5**.

As the side effects of laser have reduced there has been an increasing acceptance that treatment of low risk PDR with PRP should also be undertaken. The modern lasers have reduced the duration of the burn which has reduced discomfort and enabled multiple burn spots to be produced with each depression of the foot pedal, which reduces the time taken for the procedure, although a larger number of burns appears to be required [53] than with traditional lasers.

However, for the first time since 1976 an alternative treatment is being suggested, which are regular injections of VEGF inhibitors. A study [54] by the Diabetic Retinopathy Clinical Research

Figure 15.12.2.5 New vessels are developing at this right disc due to generalized ischaemia. As they are >1/3rd disc area they are considered high risk.

Network assessed the non-inferiority of intravitreal ranibizumab compared with PRP for visual acuity outcomes in patients with PDR. Among eyes with PDR, treatment with ranibizumab resulted in visual acuity that was not worse than PRP treatment at 2 years. A study from the UK [55] found that patients with PDR who were treated with intravitreal aflibercept had an improved outcome at 1 year compared with those treated with PRP standard care. However, the long-term requirements of number of injections required to maintain this benefit and the economic costs are currently unknown and so PRP continues to be standard care for proliferative DR.

Treatment of the Combination of Diabetic Maculopathy and PDR

Before the introduction for VEGF inhibitors, report from the DRS [56] suggested that 'reducing macular oedema by focal photocoagulation before initiating scatter treatment and dividing scatter treatment into multiple sessions with less intense burns may decrease the risk of the visual loss associated with photocoagulation'. However, the introduction of VEGF inhibitors has made VEGF inhibitors the preferred treatment if the centre thickness of the macula is ≥400 microns.

A report from the United Kingdom National Ophthalmology Database Study on diabetic retinopathy showed that of 48 250 eyes of patients with diabetes who had had a structured assessment recorded in the hospital eye service, 5066 eyes had proliferative DR. Of those with proliferative DR there were 14.2% (719 eyes) with centre involving diabetic macular oedema and 7.6% (385 eyes) with non-centre involving diabetic macular oedema. Hence, it is common to see the combination of proliferative DR and diabetic macular oedema.

Treatment of Advanced DR

Advanced DR such as non-clearing VH and tractional retinal detachment involving the macula is treated with pars plana vitrectomy. With frequent follow-up examinations and timely scatter (panretinal) photocoagulation, the 5-year cumulative rate of pars plana vitrectomy in ETDRS patients [57] was 5.3%. Surgical techniques have improved since the early reports and some surgeons [58] are now using preoperative intravitreal VEGF inhibitors to reduce intraoperative bleeding and thereby facilitating the surgery. Iris neovascularization and neovascular glaucoma are usually treated [59] with an intravitreal VEGF inhibitor followed by PRP [60] to control the retinal ischaemia. Before the availability of VEGF inhibitors it was often very difficult to treat these patients because the raised intraocular pressure produced corneal oedema that made it difficult to undertake the PRP because of the poor view. With the advent of the VEGF inhibitors the neovascularization usually responds within 24 hours and the intraocular pressure reduces and this allows a window of approximately 1 month to provide the required PRP. If there is a delay in presentation, the angle may have closed and then other surgical techniques (e.g. cyclodiode laser may be required to control the intraocular pressure).

15.12.3 Diabetic Nephropathy

Luigi Gnudi and Sally M. Marshall

Definition

Classical Diabetic Nephropathy

The evolution of diabetic nephropathy (DN) proceeds through several distinct stages. The stages of DN have been historically depicted as progression through increasing amount of albumin in the urine (normoalbuminuria-A1, microalbuminuria-A2, and macroalbuminuria-A3), as a result of a damaged glomerular filtration barrier [1], until renal failure [2]. DN is defined as presence of albuminuria and progressive decline in glomerular filtration rate (GFR) associated with retinopathy and hypertension. Albuminuria *per se* is inadequate to stage the progression of DN; it has recently been suggested that the parallel use of albuminuria and GFR levels improves the staging of renal disease progression [2].

Non-Classical Diabetic Nephropathy

The presence of albuminuria is not always associated with a commensurate alteration/decline in renal function, especially in the early phase of renal disease in diabetes [3, 4]. GFR progressive decline has been extensively described in the absence of albuminuria [5], a frequent scenario particularly in patients with T2DM [6, 7] observed in many studies (NEFRON [8], UKPDS [9], ADVANCE [10]).

Non-albuminuric renal impairment in T2DM does not associate with poor metabolic control, retinopathy and hypertension but is linked to a higher cardiovascular risk [11]. Vascular disease (macroangiopathy) has been suggested as a potential underlying renal pathology [12].

Up to 40–50% of individuals with T2DM present with some degree of renal function decline in the absence of retinopathy, suggesting atypical renal disease is frequent and should be quickly identified with a kidney biopsy for a conclusive diagnosis [13, 14].

Changing Epidemiology?

Diabetes is the major cause of ESRD (United States Renal Data System, 2016, https://www.usrds.org/2016/view/Default.aspx). The progressive ageing of the population in the western world has contributed to an increased prevalence of T2DM and chronic kidney disease (CKD), the incidence of ESRD in elderly people being higher than in the general population [15]. Similarly, the obesity epidemic, today also observed in young adults, has been linked with an increased risk for diabetic kidney disease (DKD) [16].

The recently observed reduction in cardiovascular events in the T1DM and T2DM population [17] has not been associated with an improvement in CKD [18] which still affects ~50% of patients with T2DM [19].

Of the patients with diabetes who develop CKD, approximately one-third will present with classical DN, one-third with

non-diabetic kidney disease (mostly obesity-related focal segmental glomerulosclerosis in the absence of retinopathy) and one-third with mixed pathologies [20].

Pathology

Classic Diabetic Nephropathy

Histologically, the classical presentation of DN is characterized by specific glomerular and tubulointerstitial lesions [21]:

Glomerulus

The glomerular anatomo-ultrastructural changes comprise thickening of the glomerular basement membrane (GBM), diffuse mesangial sclerosis with accumulation of extracellular matrix and nodular formation (Kimmelstiel-Wilson lesion), as well as hyalinosis, and glomerular capillary microaneurysms [21]. There has been an attempt to classify the glomerular lesions into four classes according to the degree of extracellular matrix accumulation and mesangial expansion [22]. This is paralleled by podocyte loss in the urine [23] and progressive fall in filtration surface and decline in renal function.

Tubular Compartment

Pathological alterations within the tubular compartment occur in the advanced stage of the disease: these are characterized by tubular interstitial fibrosis with significant inflammatory infiltrates and occasionally tubular atrophy. Hyaline arteriosclerosis of renal vessels can be seen as a result of a vascular disease process that occurs from the early stages of DN [24].

Non-Classic Diabetic Nephropathy

There is no structured classification/definition for the 'non-classical' presentation of DN, mostly seen in patients with T2DM; the atypical presentation is characterized mainly by disproportionate tubulointerstitial, glomerulosclerotic, and vascular changes. The aetiology is thought to be related to ageing, atherosclerotic vascular disease in general, and hypertension.

The heterogeneity in renal ultrastructural lesions in T2DM leaves us with many unanswered questions about the natural history of albuminuria or proteinuria in patients with T2DM who may present with minimal or no renal lesions. On the other hand patients with albuminuria/proteinuria can present with mild diabetic glomerular changes but disproportionately severe vasculopathy, tubular atrophy, tubular basement membrane thickening, tubulointerstitial inflammatory infiltrate, and sclerosis.

Especially in patients with T2DM, the renal pathological presentation may have many distinct patterns with variable glomerular, tubular, and vascular involvement [25].

Pathophysiology of Microvascular Damage

Mechanisms of Glomerular Disease

A clear interaction has been proposed between haemodynamic (glomerular hypertension) and metabolic (hyperglycaemia, dyslipidaemia) perturbations as recognized drivers for renal disease in diabetes [26, 27] (see Figure 15.12.3.1 online only).

Hyperglycaemia has been implicated in the dysregulation of afferent and efferent glomerular arteriolae with dysregulation of the local tissue RAAS. Excess angiotensin-2 is a key player in glomerular hypertension [28]. Excess local angiotensin-2 is a major direct stimulus for TGFβ1, one of the main stimuli for glomerular and tubulointerstitial fibrosis [29] and a stimulus for the expression of cytokines such as VEGF-A, monocyte chemoattractant protein-1 (MCP-1), TGFβ1 itself, and connective tissue growth factor (CTGF) [30]. Of note, TGFβ1-mediated facilitative glucose transporter (GLUT)-1 upregulation has been proposed as one of the mediators of metabolic–haemodynamic interaction in diabetic glomerulopathy [27].

Both angiotensin-2 and TGFβ1 stimulate nicotinamide adenine dinucleotide phosphate (NADPH) oxidase leading to excess reactive oxygen species accumulation [31]. Excess cell glucose metabolism /oxidative stress-mediated ER-stress has been proposed as a mechanism of DN [32].

The excess cellular glucose uptake, driven by the ambient elevated circulating glucose levels, and excess oxidative stress also results in activation of different intracellular metabolic pathways such as the polyol and hexosamine pathway, increased production of advanced glycation end-products, activation of protein kinase C (PKC) and p38 mitogen activated protein kinase (MAPK), pathways linked to upregulation of mediators of glomerular damage such as angiotensin-2, VEGF-A, and TGFβ1 [33].

Oxidative stress is an important mediator of inflammation: activation of NFkB, a transcription factor that controls the expression of cytokines involved in inflammation (interleukin (IL)-1, IL-6, IL-18, and tumour necrosis factor), plays an important role in DKD [34].

Recent studies have challenged the role of oxidant species in the pathophysiology of DN, highlighting how oxidant species not only cause oxidative stress if elevated, but also function as important signalling molecules [31], implying that a balanced level of oxidant species must be maintained in physiology [31, 35].

The endothelium plays an important central role in the pathophysiology of diabetic glomerulopathy. Endothelial dysfunction precedes increased vascular permeability and albuminuria. In diabetes, glomerular endothelial cell injury with loss of glycocalyx and cell apoptosis has been proposed as one of the mechanisms of diabetic glomerulopathy [36]. Changes in glycocalyx structure are associated with changes in glomerular permeability [1]. Diabetes affects other glomerular cells, such as podocytes and mesangial cells, resulting in podocyte effacement, foot process fusion and apoptosis with podocyte loss in the urine [23], mesangial expansion, and mesangiolysis.

Diabetes affects the anatomical structure of the cells forming the glomerular filtration barrier and alters the autocrine/paracrine actions of cytokines and vascular growth factors (e.g. TGF-β1, VEGF-A, and angiopoietins) secreted by these cells [37]. Glomerular VEGF-A expression plays a role in the pathophysiology of diabetic glomerulopathy by binding to its receptors expressed in endothelial cells, mesangial cells, and podocytes [37]. Primary VEGF-A overexpression in the podocytes results in proteinuria and disruption of the GBM [38], while inhibition of VEGF-A in animal experimental models of diabetes ameliorates proteinuria and glomerular damage [21, 37].

VEGF-A and nitric oxide (NO) play important roles in endothelial dysfunction [39]. In diabetes, endothelial nitric oxide synthase (eNOS) uncoupling results in decreased NO production and increased reactive oxygen species. The role of eNOS is still debated.

More will be learned from eNOS knockout mice which develop advanced diabetic renal lesions [40]. In addition, lack of eNOS protects from diabetes-mediated hyperfiltration [41].

VEGF-A expression modulates the actions of angiopoietin (Angpt)-1 and -2 on the vasculature [37]. Angpt-1 promotes endothelial cell survival, stabilization of supporting perivascular cells, and inhibition of endothelial permeability, while Angpt-2 is considered to be a natural antagonist of Angpt-1 and its overexpression results in albuminuria [21, 37].

In diabetic glomerulopathy, Angpt-1 and Angpt-2 levels are deregulated (often with Angpt-2 > Angpt-1) and ablation of Angpt-1 in podocytes or mesangial cells results in accelerated diabetes-mediated glomerular damage, while podocyte specific Angpt-1 overexpression in diabetes is protective [37]. VEGF-A has been implicated in maintenance of the endothelial glycocalyx structure and Angpt-1 promotes a healthy endothelial glycocalyx and reduces glomerular capillary permeability [21, 37].

Mechanisms of Tubular Disease and Interstitial Fibrosis

Metabolic perturbations driving inflammation and oxidative stress have been involved in interstitial fibrosis and tubular damage in diabetes [42]; importantly renal function correlates with diabetes-mediated tubulointerstitial changes [43].

Diabetes is characterized by an upregulation of the low-affinity/high-capacity sodium-glucose cotransporter SGLT2 known to represent the major player in glucose reabsorption in the nephron. SGLT2 upregulation is paralleled by activation of the local angiotensin-2 system and prosclerotic cytokines such as CTGF and TGF-β1 which, in turn, will favour tubular cell proliferation and hypertrophy, cell senescence and increased deposition of extracellular matrix [21]. Studies in patients with T1DM have suggested that tubular hypertrophy and excess glucose tubular reabsorption could contribute to hyperfiltration and faster decline in renal function [44]. Hyperfiltration, in turn, results in glomerular proteinuria, and tubulointerstitial inflammation and fibrosis [45].

Clinical Presentation

Early Renal Abnormalities

Hyperfiltration

Whole-kidney hyperfiltration (GFR>120–140 ml/min) is common in newly-diagnosed T1DM and short-duration T2DM. In addition, as kidney disease advances and nephron mass reduces, hyperfiltration occurs in the remaining nephrons [46]. In many individuals, hyperfiltration at diagnosis of diabetes resolves as glucose control improves. In some, hyperfiltration persists and may predispose to later DN. However, this remains controversial [47].

Progression of DKD

At presentation of diabetes, albuminuria A2 or even A3 may be present. As hyperglycaemia resolves, albuminuria returns to normal in almost everyone with T1DM and the majority of those with T2DM. In classical DN, albuminuria then rises gradually through A1 to A2 and A3. Tracking changes in GFR in early disease routinely is extremely difficult because of the insensitivity of serum creatinine and creatinine-based formulae for estimating GFR to small changes in renal function at higher levels. However, it seems that GFR falls in parallel with rising albuminuria, from early persistent hyperfiltration, to normal and then low levels [48]. The fall in GFR is linear but the rate varies widely between individuals [49]. Blood pressure and cardiovascular risk rise in parallel with increasing albuminuria and declining GFR.

In non-classical DN, a substantial number of individuals with T2DM, and approximately 10–20% of those with T1DM, develop ESRD without significant progressive albuminuria. The clinical phenotype of these individuals is different to those with progressive albuminuria [9, 50]. In addition, in T2DM, histological changes are of atherosclerotic vascular disease rather than the glomerulosclerosis of DN [51]. Thus it is likely that classical and non-classical nephropathy are of different aetiology, the non-albuminuric phenotype probably developing from hypertension, atherosclerotic vascular disease, and obesity. The rate of fall of GFR is at least as great as in classical nephropathy. Frank hypertension is usually present throughout and individuals may not have significant retinopathy.

Cardiovascular Disease and the Cardiorenal Syndrome

Cardiovascular risk increases progressively DKD develops [52]. Most individuals with DKD die of cardiovascular disease before developing renal failure. Albuminuria and GFR <60 ml/min/1.73m^2 are both independently and additively associated with increased all-cause and cardiovascular mortality and cardiovascular events [47]. Individuals with both increased albuminuria and decreased GFR have the highest risk.

Non-albuminuric renal impairment is also a strong predictor of mortality, highlighting the prognostic role of renal dysfunction independently of albuminuria [53].

Potential explanations for this increased cardiovascular disease (CVD) risk include shared traditional CVD risk factors, worsening of traditional CVD risk factors as DKD progresses, novel CVD risk factors (e.g. disruption of mineral metabolism) and genetic factors. The term cardiorenal metabolic syndrome has been coined to describe the constellation of central obesity, insulin resistance, hypertension, dyslipidaemia and proteinuria and/or declining GFR [54].

Risk Factors for Disease Onset and Progression

Non-Modifiable

There is a genetic predisposition to classical DN and the associated cardiovascular disease. Different genes may influence disease initiation and progression, and separately affect the development of albuminuria and decline in GFR. Although numerous candidate genes have been suggested, none are currently clinically useful. Epigenetic modification may also play a role. The role of inheritance in the development of non-classical DKD is unknown.

Modifiable

For classical DN, the main modifiable risk factors are burden of glycaemia (increasing duration of diabetes and hyperglycaemia), blood pressure, smoking, dyslipidaemia, and obesity. These factors all probably influence initial development and progression of DN. Other features of the metabolic syndrome, such as insulin resistance, non-alcoholic fatty liver disease, and sleep apnoea are also

associated. All of these risk factors are also likely to influence the development and progression of non-classical DKD, but this is less well studied.

Diagnosis and Monitoring

Despite much work exploring novel biomarkers for DKD [55], only albuminuria and GFR are of clinical use currently. Screening relies on annual measurement of urine albumin excretion and serum creatinine, with calculation of the estimated GFR (eGFR) using the CKD-EPI equation [2] (Figure 15.12.3.2 online only). Urine samples can be spot early morning, spot random, or timed collections. For spot samples, urine creatinine is also measured and the urine albumin:creatinine ratio (ACR) calculated. Timed samples are inconvenient for the individual with diabetes and open to inaccuracies in collection, so generally are not used for screening. Spot early morning samples avoid changes in albuminuria with upright posture so are preferred to random samples.

On screening (Figure 15.12.3.3 online only), if albuminuria is A1 and eGFR>90 ml/min/1.73m^2, the patient does not have DKD and both measurements should be repeated annually. Because of the extremely high intraindividual day-to-day variation in albuminuria, if the first measurement is abnormal, further measurements should be made over 3–6 months. Albuminuria A2 and A3 should only be diagnosed if repeat measurements are abnormal. If present, measurements should be made at each clinic visit, to allow a clear picture of the trajectory of albuminuria over time, and the response to any intervention. If eGFR is 30–60 ml/min/1.73m^2, the test should be repeated 6 monthly, and if <30 ml/min/1.73m^2, every 3 months, so that the rate of change of kidney function can be assessed accurately. As eGFR declines, anaemia and bone chemistry should also be monitored.

Diagnosis of DN is usually made clinically, on the basis of a gradual rise in albuminuria and blood pressure, with GFR falling linearly, in the presence of significant retinopathy and other complications of diabetes. The absence of retinopathy suggests non-diabetic CKD. If there are concerns that other renal disease is present (e.g. sudden occurrence of albuminuria A3 in someone with previously normal ACR), then further investigations might include renal tract ultrasound (symmetrical kidneys of normal size in DN), autoantibodies and immunoglobulins (all normal in DN). If doubt remains, renal biopsy can be performed.

Prevention and Management of Diabetic Kidney Disease

Prevention of DKD is clearly of utmost importance, as once CKD stage 3 develops, its progress can only be slowed, not reversed.

Glycaemic Control

Numerous studies have demonstrated that the better the glucose control (HbA1c), the lower the risk of developing DN. In T1DM, the Diabetes Control and Complications Trial (DCCT) and its open follow-up, the Epidemiology of Diabetes Interventions and Complications Study (DCCT-EDIC) [56] demonstrated highly significant reductions in the number of individuals developing micro- and macroalbuminuria, eGFR <60 ml/min/1.73m^2, and ESRD in those originally assigned to intensive management compared to those initially receiving usual care. The difference in HbA1c during the 6.5 years randomized clinical trial (mean HbA1c 7.2% intensive group, 9.1% conventional group) was lost during open follow-up (mean HbA1c 8.0% in both groups). However, despite the loss of glycaemic separation, DCCT/EDIC showed a durable effect of initial assigned therapies, with risk reductions for new microalbuminuria of 45%, new macroalbuminuria 61% and eGFR<60 ml/min/1.73m^2 44% [56].

In T2DM, several studies have demonstrated reduction in the development of micro- and macro-albuminuria with improved glucose control [57–60], but studies have been too small and too short to demonstrate convincing effects on GFR. The exception to this are the SGLT2 studies, which are discussed later.

Once albuminuria A2 or A3 are present, there is some evidence in both T1DM and T2DM that improving glucose control may reduce albuminuria. In an observational study of T1DM individuals with persistent microalbuminuria at baseline, those who became normoalbuminuric were more likely to have HbA1c less than 8.0%, systolic BP less than 115mmHg and cholesterol less than 5.13 mmol/L [61]. In T2DM, individuals receiving intensive glucose management are less likely to have progressive albuminuria and albuminuria is more likely to regress compared to those receiving usual care [57, 59]. There is no convincing data that rate of fall of GFR is altered by improving glucose control and no head-to-head studies of different classes of oral glucose-lowering agents, so that the choice of therapy should be individualized. Most guidelines recommend a target HbA1c of 6.5–7.2% (48–52 mmol/mol), but this must be individualized. Tight glucose control is inappropriate in individuals with multiple comorbidities and limited life expectancy. In addition, as GFR declines, the risk of hypoglycaemia increases, due to declining kidney gluconeogenesis, reduced clearance of some glucose-lowering agents and declining appetite among others [62].

There is no specific trial data on the effects of improving glucose control in individuals with non-classical DKD.

Inhibition of the Renin Angiotensin Aldosterone System (RAAS)

Inhibitors of the RAAS cause dilatation of the efferent glomerular arteriole and thus reduce intraglomerular pressure and albuminuria. By doing so, we believe they reduce the rate of progression of albuminuric CKD. Experts therefore suggest that diabetic individuals with albuminuria should be prescribed a RAAS inhibitor, regardless of blood pressure, and the dose titrated to the maximum recommended or tolerated. Evidence supporting this rests on a few small studies in T1DM with BP below the definition of hypertension but clearly above that of their normoalbuminuric peers. For historical reasons, the bulk of the evidence favours angiotensin-2 converting enzyme inhibitors (ACEI) in T1DM and angiotensin-2 receptor blockers (ARB) in T2DM, although in reality there is little to choose between the agents. Blockade of RAAS using a single agent is incomplete, so that dual blockade using ACEI plus ARB or aldosterone antagonist has been explored. Dual blockade reduces blood pressure and albuminuria more than single blockade, but

the significantly higher risks of hyperkalaemia and acute kidney injury outweigh any benefit, so that this strategy is currently not recommended.

RAAS blockade does not reduce the risk of developing DN in normoalbuminuric diabetic individuals with BP <140/90 mmHg. We do not know if RAAS inhibitors have any advantages over other classes of antihypertensive medication in individuals with normoalbuminuric DKD.

All patients taking RAAS blockade should be counselled to stop these medications temporarily if they become unwell with vomiting or diarrhoea or cannot maintain a normal fluid intake, and only to restart the drugs when they recover. Women of childbearing age should be advised to stop RAAS blockade if they are considering pregnancy, because of the teratogenic effects. Other agents, including methyldopa, nifedipine, and labetalol should be substituted during the preconception phase.

Blood Pressure

Raised blood pressure is a key initiating and progressing factor in DKD. The higher the blood pressure, the higher the risk of development and progression of DN. Lowering blood pressure reduces albuminuria and slows the rate of decline of GFR and progression to renal failure. Historic data shows that without antihypertensive therapy, GFR declines by 10–12 ml/min/1.73 m^2 per year. With effective blood pressure control, this is slowed to 3–5 ml/min/1.73 m^2 per year. Thus if blood pressure is controlled adequately from early in the disease process, the time to requiring renal replacement therapy can be doubled. There are no specific trials in non-albuminuric DKD, but it seems extremely likely that good blood pressure control is also beneficial.

The target blood pressure for diabetic individuals with CKD is generally 130/80 mmHg. Too tight blood pressure control may actually be harmful, leading to renal hypoperfusion. Thus, as with glucose targets, blood pressure targets should be individualized. In fitter individuals with few comorbidities, lower targets (less than 130 mmHg systolic) can probably be achieved safely. In people with multiple comorbidities, it is probably safer to accept blood pressure in the range 130–140 mmHg. Increasingly, more weight is being put on 24-hour blood pressure monitoring or home measurements by the individual, rather than clinic blood pressure readings. Loss of normal nocturnal blood pressure dipping may occur, even though day-time blood pressure is normal.

The initial antihypertensive agent usually will be either a RAAS inhibitor or calcium-channel blocking agent. Most individuals will need two or more agents to achieve good control. Combinations used in trials include RAAS blocker plus calcium-channel blocker, or RAAS blocker plus a diuretic. There is little evidence to guide choice of a third or fourth agent, but α-blockers, β-blockers, and centrally acting agents are all used routinely. It is vital to reduce the blood pressure to a satisfactory level, using the combination of agents best suited to the individual person.

Dietary Factors

Weight Loss

Obesity may be one of the factors which drives non-albuminuric DKD. Albuminuria decreases significantly after bariatric surgery [63], but we lack robust data on its effects on GFR.

Protein Intake

A low-protein diet reduces progression of CKD [64]. Intake should not be restricted to <0.8 g/kg per day [2]. Vegetable protein may be more beneficial than animal protein.

Salt

The blood pressure lowering effect of RAAS blockade is greater in individuals whose salt intake is lower rather than higher [65]. Thus individuals should be encouraged to moderate their salt intake to <90 mmol sodium /day [2].

Potassium

Hyperkalaemia is common, particularly in those taking RAAS blockade. There is a U-shaped relationship between serum potassium and adverse outcomes [66]. Hyperkalaemia may limit the dose of RAAS inhibitor. Above a level of 5.5 mmol/L, a diet low in potassium should be advised.

Other Cardiovascular Risk Factors

It is important to ensure that cardiovascular risk factors are managed aggressively in individuals with DKD. Smoking cessation is paramount, as is lipid control. Lipid profiles change as DKD progresses, but all individuals should be offered statin therapy. Because of the very high cardiovascular risk, it has been suggested that everyone with DKD should be offered low-dose aspirin therapy as primary prevention, but there is no good evidence to support this. In addition to reducing cardiovascular risk, it is hoped that these therapies will also reduce DKD progression, but there is no trial data to support this.

Multifactorial Intervention

Addressing all renal and cardiovascular risk factors, not just individual factors, is vital, as demonstrated by the Steno-2 multifactorial intervention trial [67]. In this study, T2DM individuals with microalbuminuria were randomized to intensive risk factor management or routine care. Over the 8 years of the intervention trial, and in open follow-up thereafter, the risk of progression to proteinuria and ESRD, need for laser therapy, cardiovascular and all-cause mortality and heart failure were all significantly reduced in the intensively managed group [68, 69]. Thus, intensive management of a wide range of risk factors has tangible long-term benefits encompassing both micro- and macro-vascular complications (see Table 15.12.3.1 **online only**).

Future Treatments

Since the 1990s, blockade of RAAS, along with good metabolic control has been the key therapeutic approach for renal protection in diabetes [21].

The use of aldosterone antagonist on top of conventional RAAS blockade (ACEI or ARB therapy) has demonstrated a reduction in albuminuria and renal disease progression [21, 70], but side effects

such as hyperkalaemia, hypotension and acute kidney injury has dampened the enthusiasm for double RAAS blockade [21].

Other agents such as endothelin antagonists and activator of the antioxidant element NrF2 have failed to show any benefit in renal protection and have often raised important safety concerns [21].

In recent years inhibitors of the SGLT2 glucose transporters, introduced as oral hypoglycaemic agents, have been proposed as new cardiorenal protective treatments; their positive effects seem related to haemodynamic changes [71] and recent studies have confirmed these beneficial effects on renal protection [72].

The incretin pathway has recently been proposed to confer renoprotection; GLP-1 analogues developed as hypoglycaemic agents retain anti-inflammatory and renoprotective properties [21]. Recent human studies have suggested a significant cardiovascular-renal protection of GLP-1 analogues [73, 74]. Further work is needed to confirm and validate these findings.

15.12.4 Diabetic Neuropathy

Solomon Tesfaye and Jing Wu

Introduction

Diabetic neuropathy is a major complication of diabetes and a cause of considerable morbidity and mortality [1]. Diabetic neuropathy is not a single entity but includes several neuropathic syndromes (Figure 15.12.4.1). In clinical practice, the commonest presentation of neuropathy is chronic distal symmetrical polyneuropathy (DSP) also known as diabetic peripheral neuropathy (DPN). The neuropathic syndromes depicted in Figure 15.12.4.1 have varied presentations and pathogenesis. This chapter will cover these syndromes although the main focuses will be: (1) DPN, which is the main initiating factor for foot ulceration and a cause of troublesome painful neuropathic symptoms and (2) autonomic neuropathy.

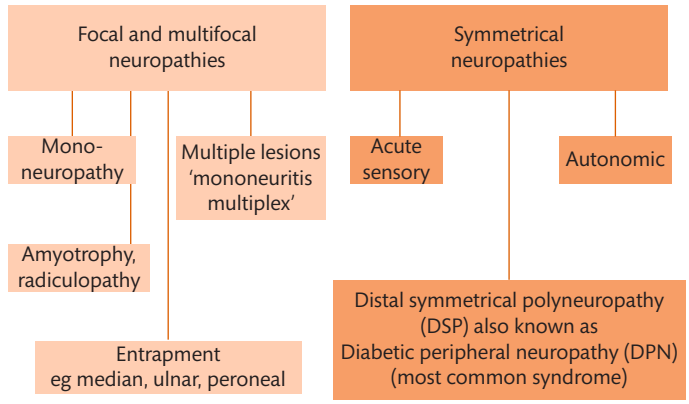

Figure 15.12.4.1 Neuropathic syndromes associated with diabetes mellitus.

Epidemiology

There is much variation in the prevalence of DPN. Where electrophysiology is employed the prevalence rates will be in excess of 50% [2], whereas when clinical parameters or QST (quantitative sensory testing) are employed both clinic- and population-based studies show similar prevalence rates at about 30% [3]. The EURODIAB Prospective Complications Study investigated 3250 type 1 patients, and found a prevalence rate of 28% for DPN [4]. The study also showed that over a 7.3 year period, about one-quarter of type 1 diabetic patients developed DPN [5]. The development of DPN was also associated with modifiable cardiovascular risk factors such as hypertension, hyperlipidaemia, obesity, and cigarette smoking (Figure 15.12.4.2) [5]. Based on recent epidemiological studies, correlates of DPN include age, duration of diabetes, poor glycaemic control, retinopathy, albuminuria, and vascular risk factors [5].

Classification of Diabetic Neuropathy

Classification of the various syndromes of diabetic neuropathy is difficult. The variations and overlap in aetiology, clinical features, natural history, and prognosis have meant that most classifications are necessarily oversimplified. Nevertheless, classification assists in the planning of clinical management.

Figure 15.12.4.1 shows a modified clinical classification of diabetic polyneuropathy [6].

Watkins and Edmonds [7] have suggested a classification for diabetic neuropathy based on the natural history of the various syndromes, which separates them into three distinct groups (Box 15.12.4.1).

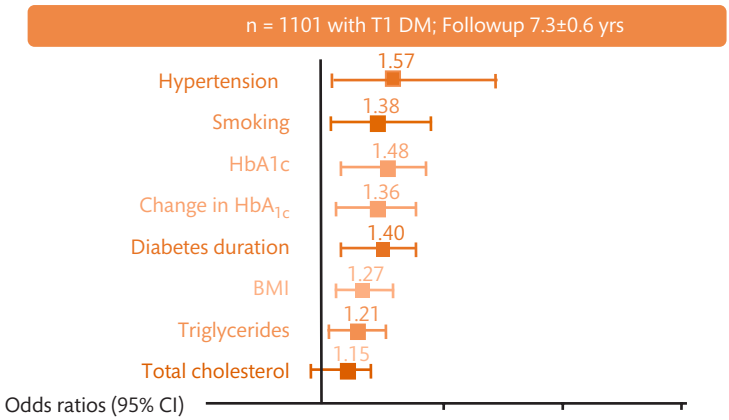

Figure 15.12.4.2 Risk factors for incident DPN in the EURODIAB prospective study.

More recently, the American Diabetes Association Position statement on Diabetic Neuropathy [8] has suggested a classification summarized in Box 15.12.4.2.

Diabetic Peripheral Neuropathy (DPN)

This is the commonest neuropathic syndrome. The Toronto Consensus Panel recently defined DPN as 'a symmetrical, length dependent sensorimotor polyneuropathy attributable to metabolic and microvessel alterations as a result of chronic hyperglycaemia exposure (diabetes) and cardiovascular risk covariates' [9]. There is a 'length-related' pattern of sensory loss, with sensory symptoms starting in the toes and then extending to involve the feet and legs in a stocking distribution. In more severe cases, there is upper limb involvement, with a similar progression proximally. Although the nerve damage can extend over the entire body including the head and face, this is exceptional. Subclinical neuropathy detectable by autonomic function tests is usually present. However, clinical autonomic neuropathy is less common. As the disease advances, overt motor manifestations such as wasting of the small muscles of the hands and limb weakness become apparent. Subclinical motor involvement detected by magnetic resonance imaging appears to be common, and thus motor disturbance is clearly part of the functional impairment caused by DPN [10].

The main clinical presentation of DPN is sensory loss, which the patient may not be aware of or may be described as 'asleep numbness' or 'dead feeling'. However, some may experience a progressive build-up of unpleasant sensory symptoms including tingling (paraesthesiae or 'pins and needles'). Box 15.12.4.3 summarizes the 'positive' and 'negative' symptoms of DPN. There is a large spectrum of severity of these symptoms.

Diabetic neuropathic pain is characteristically more severe at night, and often prevents sleep [11]. Some patients may be in a

Box 15.12.4.1 Classification of diabetic neuropathies by natural history

1. **Progressive neuropathies.** These are associated with increasing duration of diabetes and with other microvascular complications. Sensory disturbance predominates and autonomic involvement is common. The onset is gradual and there is no recovery.
2. **Reversible neuropathies.** These have an acute onset, often occurring at the presentation of diabetes itself, and are not related to the duration of diabetes or other microvascular complications. There is spontaneous recovery of these acute neuropathies.
3. **Pressure palsies.** Although these are not specific to diabetes only, they tend to occur more frequently in diabetic patients than the general population. There is no association with duration of diabetes or other microvascular complications of diabetes.

Box 15.12.4.2 Classification of diabetic neuropathies

Polyneuropathies
- Distal symmetrical polyneuropathy
- Combined large and small-fibre neuropathy
- Predominantly large-fibre neuropathy
- Predominantly small-fibre neuropathy

Autonomic neuropathy
- Cardiovascular
- Resting tachycardia
- Sudden death
- Exercise intolerance
- Orthostatic hypotension
- Foot vein distension and arteriovenous shunting
- Gastrointestinal
- Gastroparesis
- Diarrhoea or constipation
- Bladder hypomotility
- Erectile dysfunction
- Gustatory sweating
- Reduced peripheral sweating

Focal neuropathies
- Mononeuropathies
- Mononeuritis multiplex
- Proximal motor neuropathy (amyotrophy)
- Thoraco-abdominal neuropathy

Box 15.12.4.3 Symptoms of DPN

'Positive' symptoms
- Persistent burning or dull pain
- Paroxysmal electric, shooting, stabbing path
- Dysesthesias (painful parasthesias)
- Evoked pain (hyperalgesia, allodynia)
- Asleep numbness

'Negative' symptoms (deficits)
- Hypoalgesia, analgesia
- Hypoesthesia, anaesthesia

constant state of tiredness because of sleep deprivation [11]. Others are unable to maintain full employment. Severe painful neuropathy can cause marked reduction in exercise threshold so as interfere with daily activities. This is particularly the case when there is an associated disabling, severe postural hypotension due to autonomic involvement. Not surprisingly therefore, mood disorders including anxiety and depressive symptoms are common [12]. It is important to appreciate that many subjects with DPN may not have any of the symptoms shown in Box 15.12.4.3, and their first presentation may be with a foot ulcer [13]. This underpins the need for carefully examining and screening the feet of all diabetic people. The insensate foot is at risk of developing mechanical and thermal injuries, and patients must therefore be warned about these and given appropriate advice with regard to foot care [13]. A curious feature of the neuropathic foot is that both numbness and pain may occur, the so-called 'painful, painless' leg. It is indeed a paradox that the patient with a large foot ulcer may also have severe neuropathic pain. In those with advanced neuropathy, there may be sensory ataxia, unsteadiness on walking, and falls.

DPN is usually easily detected by simple clinical examination (Table 15.12.4.1) [8]. Bare feet should be examined at least annually and more often if neuropathy is present. The most common presenting abnormality is a reduction or absence of vibration sense in the toes. As the disease progresses there is sensory loss in a 'stocking' and sometimes in a 'glove' distribution, involving all modalities. When there is severe sensory loss, proprioception may also be impaired, leading to a positive Romberg's sign. Ankle tendon reflexes are lost (though this may also be lost with old age in non-diabetic people) and with more advanced neuropathy, knee reflexes are often reduced or absent. The recent American Diabetes Association Position Statement made clear recommendations for the screening of DPN (Box 15.12.4.4).

Table 15.12.4.1 Clinical assessment for DPN

History	Signs
• Sensory symptoms	• Inspection (normal or distal wasting, clawing)
• Motor symptoms	• Reflexes (ankle reflex unreliable in the elderly)
• Assessment of disability due to DPN	• Sensory
• Exclude other causes of neuropathy	• Vibration • Temperature • Pinprick (good discriminator in the elderly) • 10 g mono filament
	Assess footwear

In DPN there is ↓ in: reflexes, vibration, pinprick, and pressure sensation.

Box 15.12.4.4 American Diabetes Association recommendations for the screening of DPN

- All patients should be assessed for DPN starting at diagnosis of type 2 diabetes and 5 years after the diagnosis of type 1 diabetes and at least annually thereafter.
- Consider screening patients with prediabetes who have symptoms of peripheral neuropathy.
- Assessment should include a careful history and either temperature or pinprick sensation (small-fibre function) and vibration sensation using a 128-Hz tuning fork (large-fibre function). All patients should have an annual 10-g monofilament testing to assess for feet at risk for ulceration and amputation.
- Electrophysiological testing or referral to a neurologist is rarely needed for screening, except in situations where the clinical features are atypical, the diagnosis is unclear, or a different aetiology is suspected. Atypical features include motor greater than sensory neuropathy, rapid onset, or asymmetrical presentation.

Muscle strength is usually normal early in the course of the disease, although mild weakness may be found in toe extensors. With progressive disease there is significant generalized muscular wasting, particularly in the small muscles of the hand and feet. Wasting of dorsal interossei is usually due to entrapment of the ulnar nerve at the elbow. Clawing of the toes is believed to be due to unopposed pulling of the long extensor and flexor tendons. This scenario results in elevated plantar pressure points at the metatarsal heads that are prone to callus formation and foot ulceration. Deformities such as a bunion can form the focus of ulceration, and with more extreme deformities such as those associated with Charcot arthropathy [14] the risk is further increased. As one of the most common precipitants to foot ulceration is inappropriate footwear, a thorough assessment should also include examination of shoes for poor fit, abnormal wear, and internal pressure areas or foreign bodies.

Autonomic neuropathy affecting the feet can cause a reduction in sweating and consequently dry skin that is likely to crack easily, predisposing the patient to the risk of infection. The 'purely' neuropathic foot is also warm due to arteriovenous shunting. This results in the distension of foot veins that fail to collapse even when the foot is elevated. It is not unusual to observe a gangrenous toe in a foot that has bounding arterial pulses, as there is impairment of the nutritive capillary circulation due to arteriovenous shunting. The oxygen tension of the blood in these veins is typically raised. The increasing blood flow brought about by autonomic neuropathy can sometimes result in neuropathic oedema.

Recent Advances in the Assessment of DPN Using Novel Point-of-Care Devices

Over the past decade there has been an advance in the development of non-invasive, objective, relatively quick and accurate

point-of-care devices (POCDs) that may be able to diagnose DPN early, before overt clinical signs are apparent. These include DPN-Check that can measure sural nerve conduction velocity and amplitude, Sudoscan that can measure sudomotor (small fibre function), Neuropad colour change that can also measure sudomotor function and corneal confocal microscopy that can assess corneal small fibres [15]. A recent study evaluated the use of POCDs in an annual, one-stop diabetes microvascular screening clinic and found that this reduces clinic visits, unmasked new diagnosis of painful DPN in 25% and the at-risk foot [16]. However, the long-term impact of this clinic on hard outcomes such as foot ulcers and amputations has not been evaluated.

Differential Diagnosis of DPN

Before attributing the neuropathy to diabetes other common causes of neuropathy must be excluded. The absence of other complications of diabetes, rapid weight loss, excessive alcohol intake and other atypical features in either the history or clinical examination should direct the physician to search for other causes of neuropathy (Box 15.12.4.5). Some clinicians routinely screen for B_{12} deficiency (particularly as metformin use is linked with B12 deficiency) and hypothyroidism in all diabetic patients.

Confirmed Diagnosis of DPN

The Toronto Consensus Panel on Diabetic Neuropathy [9] defined: *possible DPN* as the presence of typical symptoms or signs; *probable DPN* as one that requires at least two of the symptoms, distal sensory deficits, or decreased/absent ankle jerks; *confirmed DPN* as one abnormal nerve conduction attribute and the presence of symptom(s)/sign (s); *subclinical DPN* is defined as one abnormal nerve conduction attribute or validated measure of small-fibre impairment in the absence of symptom(s)/sign(s). This expert group has also proposed minimal diagnostic criteria for small-fibre neuropathy (SFN) as follows: *possible SFN*: symptoms and/or signs of small-fibre impairment; *probable SFN*: symptoms and signs of small-fibre impairment with normal nerve conduction parameters of the sural nerve; *definite SFN*: symptoms and signs of small-fibre damage, normal nerve conduction parameters of the sural nerve, with reduced intraepidermal nerve fibre density on skin biopsy and/or abnormal thermal perception thresholds.

Box 15.12.4.5 Differential diagnosis of DPN

- Metabolic
  - Diabetes
  - Amyloidosis
  - Uraemia
  - Myxoedema
  - Porphyria

  - Chronic inflammatory demyelinating polyneuropathy (CIDP)
- Polyarteritis nodosa
- Genetic
  - Charcot–Marie–Tooth disease
  - Hereditary sensory neuropathies

Acute Painful Neuropathies

Acute painful neuropathies are transient neuropathic syndromes characterized by an acute onset of pain (over weeks) in the lower limbs. They are relatively rare compared to chronic DPN. There are two distinct syndromes, the first of which occurs within the context of poor glycaemic control, and the second with rapid improvement in glycaemic control.

Acute Painful Neuropathy of Poor Glycaemic Control

This occurs usually in diabetic subjects with poor glycaemic control. There is often an associated severe weight loss. Ellenberg coined the description of this condition as 'neuropathic cachexia' [17]. With improvements in the treatment of diabetes and the achievement of better standards of care, this complication is now rarely seen in developed countries such the UK. Patients typically experience persistent burning pain associated with allodynia (contact pain). The pain is most marked in the feet but often affects the whole of the lower extremities. As in chronic DPN, the pain is typically worse at night and often results in depression.

In acute painful neuropathies sensory loss is usually mild or absent. There are usually no motor signs, although ankle jerks may be absent. Nerve conduction studies are usually normal or mildly abnormal. Temperature discrimination threshold (small fibre function) is affected more commonly than vibration perception threshold (large-fibre function). There is complete resolution of symptoms within 12 months, and weight gain is usual with continued improvement in glycaemic control with the use of insulin.

Acute Painful Neuropathy of Rapid Glycaemic Control (Treatment-Induced Neuropathy of Diabetes–TIND)

Acute painful neuropathy of rapid glycaemic control, also known as treatment-induced neuropathy of diabetes (TIND) and occasionally as 'insulin neuritis' has recently been found to occur in around 10% people with DPN, more common than previously thought [18]. The term 'insulin neuritis' is a misnomer as the condition can follow rapid improvement in glycaemic control with oral hypoglycaemic agents; and is better termed 'acute painful neuropathy of rapid glycaemic control' or TIND [18]. A decrease in the glycosylated haemoglobin A1C of more than 3% in 3 months in individuals with chronic hyperglycaemia increases the risk of developing TIND. The natural history of acute painful neuropathies is an almost guaranteed improvement in contrast to chronic DPN [19]. Presentation is with burning pain, paraesthesiae, allodynia, often with a nocturnal

exacerbation of symptoms; and accompanying depression. There is no associated weight loss, sensory loss is often mild or absent, and there are may be autonomic neuropathy but there are no motor signs [19]. There is little or no abnormality on nerve conduction studies. Prognosis is good with usually complete resolution of symptoms within 12 months [19]. The management of painful neuropathic symptoms is as in chronic painful DPN.

Small-Fibre Neuropathy

The existence of 'small-fibre neuropathy' as a distinct entity has been advocated [20], usually within the context of young type 1 diabetes patients and prediabetes [21]. A dominant feature of this syndrome is neuropathic pain, which may be severe, with relative sparing of large-fibre functions (vibration and proprioception). The pain is sometimes described as burning, deep and aching. The sensation of 'pins and needles' (paraesthesiae) is often experienced. Contact hypersensitivity (allodynia) may be present. Autonomic involvement is common, and severely affected patients may be disabled by postural hypotension and/or gastrointestinal symptoms. The syndrome tends to develop within a few years of diabetes (and indeed in pre-diabetes) as a relatively early complication.

On clinical examination there is little evidence of objective signs of nerve damage, apart from a reduction in pinprick and temperature sensation, which are reduced in a 'stocking' and 'glove' distribution. There is relative sparing of vibration and position sense (due to relative sparing of the large diameter Aβ fibres). Muscle strength and reflexes are usually normal. Autonomic function tests are frequently abnormal and affected male patients usually have erectile dysfunction. Electrophysiological tests are usually normal. Controversy still exists as to whether small-fibre neuropathy is a distinct entity or an earlier manifestation of DPN [20].

Asymmetrical Neuropathies

Asymmetrical (or focal) neuropathies have a relatively rapid onset, and complete recovery is usual. This contrasts with chronic DPN, where there is usually no improvement in symptoms several years after onset. Unlike DPN their presence is not related to the presence of other diabetic complications. Asymmetrical neuropathies predominantly affect middle aged/older patients and are more common in men [22]. A high index of suspicion for a non-diabetic cause is advised.

Diabetic Amyotrophy

Proximal Motor Neuropathy, Lumbo-Sacral Polyradiculopathy

The syndrome of progressive asymmetrical proximal leg weakness and atrophy was first described by Garland [23], who coined the term 'diabetic amyotrophy'. This condition has also been named as 'proximal motor neuropathy' or 'lumbo-sacral polyradiculopathy'. The patient presents with severe pain which is felt deep in the thigh, but can sometimes be of burning quality and extend below the knee. The pain is usually continuous and often causes insomnia and depression. Both type 1 and type 2 patients over the age of 50 are affected [23]. There is an associated weight loss which can be severe, and can raise the possibility of an occult malignancy.

On examination there is profound wasting of the quadriceps with marked weakness in these muscle groups, although hip flexors and hip abductors can also be affected. Thigh adductors, glutei, and hamstring muscles may be involved. The knee jerk is usually reduced or absent. The profound weakness can lead to difficulty from getting out of a low chair or climbing stairs. Sensory loss is unusual, and if present indicates a coexistent DPN.

Other causes of quadriceps wasting such as nerve root and cauda equina lesions and occult malignancy causing proximal myopathy syndromes (e.g. polymyositis) should be excluded. MR imaging of the lumbo-sacral spine is now mandatory in order to exclude focal nerve root entrapment, neoplastic infiltrative lesions, and other pathologies. An erythrocyte sedimentation rate (ESR), an X-ray of the lumbar/sacral spine, a chest X-ray and ultrasound/CT of the abdomen may also be required. Electrophysiological studies may demonstrate increased femoral nerve latency and active denervation of affected muscles. CSF protein is often mildly elevated.

The cause of diabetic proximal motor neuropathy is not known. It tends to occur within the background of DPN. The combination of focal features superimposed on diffuse peripheral neuropathy may suggest vascular damage to the femoral nerve roots, as a cause of this condition. An immune mediated epineurial microvasculitis has been demonstrated in nerve biopsies.

There is scarcity of prospective studies that have looked at the natural history of proximal motor neuropathy. Pain usually starts to settle after about three months, and usually settles by one year, while the knee jerk is restored in 50% of the patients after two years. Recurrence is a rare event. Management is largely symptomatic and supportive. There is still controversy as to whether the use of insulin therapy influences the natural history of this syndrome. Some patients benefit from physiotherapy that including extension exercises to strengthen the quadriceps. The management of pain in diabetic amyotrophy is similar to that of painful DPN (see next).

Cranial Mononeuropathies

The commonest cranial mononeuropathy is the third cranial nerve palsy (Figure 15.12.4.3). The patient presents with pain in the orbit, or sometimes with a frontal headache [24]. There is typically ptosis and ophthalmoplegia, although the pupil is usually spared. Recovery occurs usually over 6 months. It is important to exclude any other cause of third cranial nerve palsy (aneurysm or tumour) by CT or MR scanning, where the diagnosis is in doubt. Fourth, sixth, and seventh cranial nerve palsies have also been described in diabetic subjects, but the association with diabetes is not as strong as that with third cranial nerve palsy.

Thoracoabdominal Neuropathy

Truncal Radiculopathy

Diabetic thoracoabdominal neuropathy (truncal radiculopathy) is characterized by an acute onset pain in a dermatomal

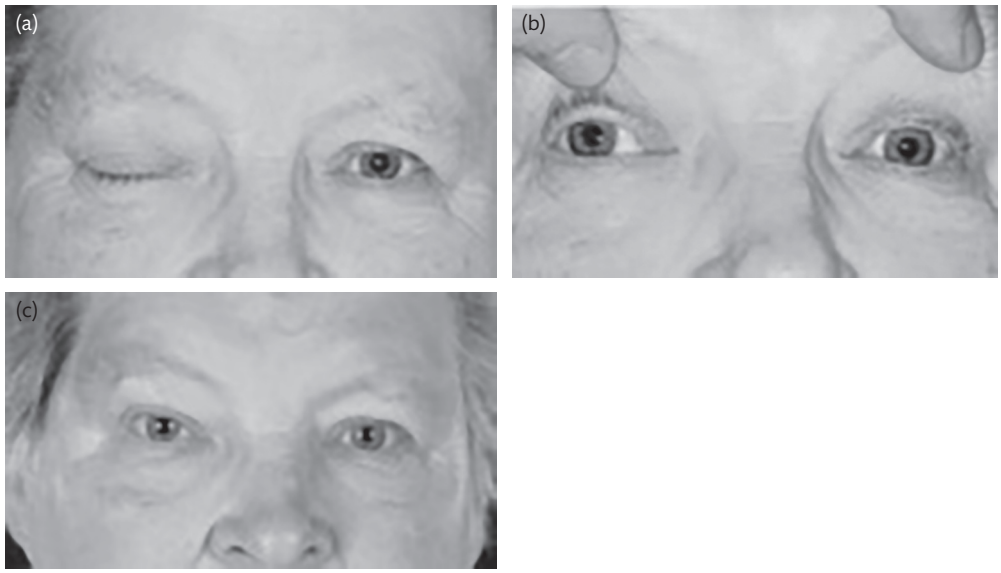

Figure 15.12.4.3 A patient with sudden onset third cranial nerve palsy (3 A) showing ptosis; ophthalmoplegia with mild dilatation of the pupil on manual opening of the eye lid (3B) and complete recovery 4 months later (3C).

distribution over the thorax or the abdomen [25] (Figure 15.12.4.4). The pain is usually asymmetrical, and can cause local bulging of the muscle due to weakness [26]. There may be patchy sensory loss over the affected area and other causes of nerve root compression should be excluded. When the patient presents with focal thoraco/abdominal pain one has to take a careful history and perform a clinical exam of the affected area assessing: pinprick sensation, light touch sensation, and dynamic mechanical allodynia. A clear difference is demonstrated when comparing with the unaffected area. Many patients have ended up with laparotomy or even worse when simple clinical examinations could have avoided this. Recovery is usually the rule within several months, although symptoms can sometimes persist for years.

Pressure Palsies

Carpal Tunnel Syndrome

The patient typically has pain and paraesthesia in the hands, which sometimes radiate to the forearm and are particularly marked at night. In severe cases clinical examination may reveal a reduction in sensation in the median nerve territory in the hands, and wasting of the muscle bulk in the thenar eminence. The clinical diagnosis is confirmed by median nerve conduction studies and treatment involves steroid injection and/or surgical decompression. There is generally a good response to surgery, although painful symptoms may relapse more commonly than in the non-diabetic population.

Ulnar Nerve and Other Isolated Nerve Entrapments

The ulnar nerve is also vulnerable to pressure damage at the elbow resulting in wasting of the dorsal interossei, particularly the first dorsal interosseous. This is confirmed by ulnar electrophysiological studies.

Rarely, the patients may present with wrist drop due to radial nerve palsy after prolonged sitting or while unconscious during hypoglycaemia.

In the lower limbs the common peroneal (lateral popliteal) is the most commonly affected nerve resulting in foot drop. Unfortunately, complete recovery is not usual. The lateral cutaneous nerve of the thigh is occasionally also affected with entrapment neuropathy in diabetes. Phrenic nerve involvement in association with diabetes has been described.

Pathogenesis of DPN

Despite considerable research, the specific mechanisms contributing to DPN are not completely understood [8]. There is experimental evidence for hyperglycaemia, dyslipidaemia, impaired insulin signalling and oxidative-nitrosative stress acting in concert

with other risk factors to activate several biochemical pathways, in addition to vascular factors that contribute to neuronal injury (Figures 15.12.4.5 and 15.12.4.6). These alterations promote the pathological changes of DPN including: (1) segmental demyelination and remyelination without axonal degeneration [27]; (2) a loss of large and small myelinated and unmyelinated nerve fibres [28]; (3) focal areas of demyelination on teased fibre preparations [29]. Nerve regenerative activity may also be seen with the emergence of 'regenerative, clusters' [30], containing groups of myelinated axons and non-myelinated axons sprouts. Until recently, few studies had assessed small fibres, even though these had been shown to have comparable sensitivity/specificity for detecting neuropathy [31] and constitute around 80% of all peripheral nerve fibres. Figure 15.12.4.5 shows the multifactorial pathogenesis of DPN [32].

Metabolic Pathways

Prolonged hyperglycaemia is a key risk factor for DPN and can lead to cellular damage in several ways. Hyperglycaemia induces increased formation of advanced glycation end-products (AGEs) [33]. AGEs cross-link essential proteins, lipids, or nucleic acids, altering their function and causing cellular damage [34]. Extracellular AGEs also bind to the receptor RAGE, initiating inflammatory signalling cascades, activating NADPH oxidases and generating oxidative stress [35]. The polyol pathway is the most studied pathway thought to play an important role in the pathogenesis DPN. Excess glucose is converted to sorbitol by aldose reductase resulting in increase of cellular osmolarity, reduction of NADPH levels and oxidative stress [36]. Increased glycolysis in response to excess glucose can overload the electron transport chain and initiate mitochondrial and cytosolic oxidative stress, which promote neuronal injury [37]. Moreover, the glycolysis intermediate fructose-6-phosphate also enters the hexosamine pathway which is associated with inflammatory injury [38].

Dyslipidaemia has been found to be associated with DPN [5, 39, 40]. Plasma lipoproteins, particularly low-density lipoproteins (LDLs), can be modified by oxidation (oxLDL) and/or glycation,

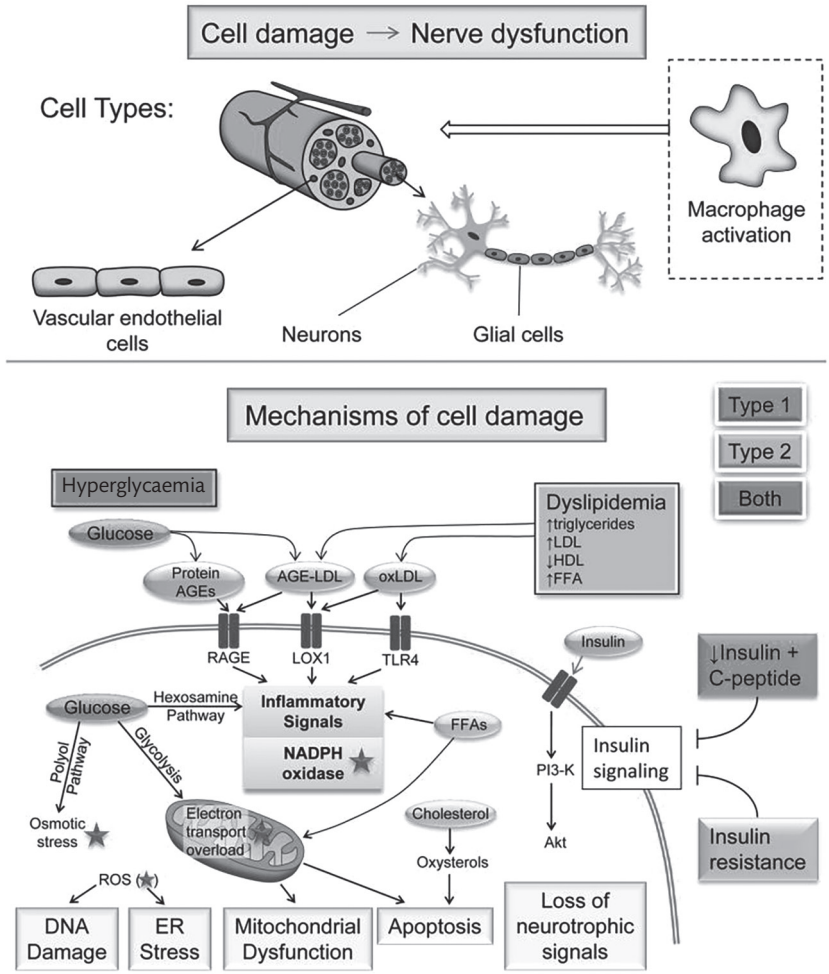

Figure 15.12.4.5 Pathological mechanisms involved in DPN. Factors linked to type 1 diabetes (yellow), type 2 diabetes (blue) and both (green) cause DNA damage, ER stress, mitochondrial dysfunction, apoptosis, and loss of neurotrophic signalling. The relative importance of the pathways in this network will vary with cell type, disease profile, and time. Abbreviations: AGE, advanced glycation end-products; LDL, low-density lipoprotein; HDL, high-density lipoprotein; FFA, free fatty acids; ROS, reactive oxygen species (red star); ER, endoplasmic reticulum; PI3K, phosphatidylinositol 3-kinase. *For a colour version of this figure, please see colour plate section.*

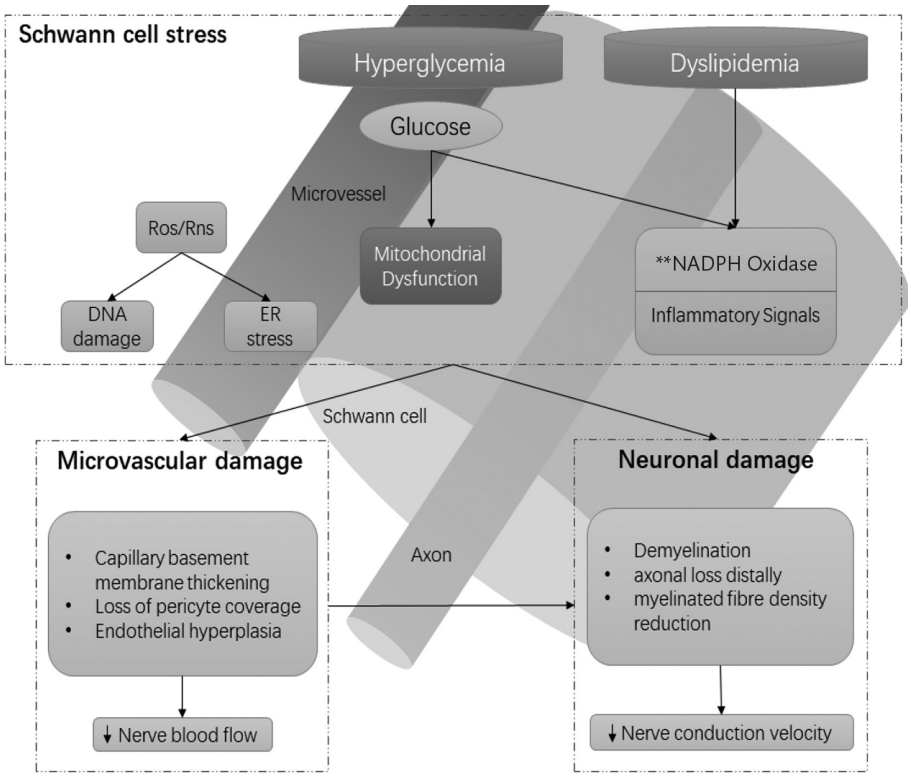

Figure 15.12.4.6 Hyperglycaemia-driven Schwann cells stress and neuronal damage. Hyperglycaemia and dyslipidaemia ultimately lead to reduction of neuronal support from Schwann cells and microvessels. Disruption of neuronal support by Schwann cells and the vascular system contributes to neuropathy, in conjunction with the direct effects of diabetes on neurons themselves.

and these modified LDLs can bind to extracellular receptors (including the oxLDL receptor LOX [41], Toll-like receptor 4 [42], and RAGE [35], triggering signalling cascades that activate NADPH oxidase and subsequent oxidative stress [41]. Free fatty acids (FFAs) result in cellular dysfunction and cell apoptosis that involves activation of inflammatory signalling, mitochondrial dysfunction and an augmented state of cellular oxidative stress [43]. Additionally, cholesterol may be oxidized to oxysterols, which have been suggested to induce neuronal apoptosis [44].

Insulin and insulin signalling dysregulation may also contribute to neuropathic damage. Although insulin does not appear to directly control glucose transport into the PNS, it is a potent neurotrophic factor capable of supporting axonal growth and survival. [45, 46]. Reduced neurotrophic signalling due to insulin deficiency (type 1 diabetes) or insulin resistance (IR; type 2 diabetes) may lead to neuronal injury [47]. In neurons, IR occurs by inhibition of the PI3K/Akt signalling pathway [48]. Disruption of this pathway may result in mitochondrial dysfunction, oxidative stress, and the development of neuropathy [47].

Oxidative Stress, Nitrosative Stress, and Inflammation

Excess glucose overloads the electron transport chain, leading to the production of superoxides and subsequent mitochondrial generation of reactive oxygen species (ROS) [48]. Hyperglycaemia also induces nitrogen generating pathways (nitrosative stress) [49]. These processes impair the capacity of the vascular endothelium to produce biologically active nitric oxide (NO), which adversely affects vascular relaxation. Superoxide combined with NO generated by the endothelial cells then leads to the formation of peroxynitrite, which attacks various biomolecules in the vascular endothelium [50]. Many of these changes trigger inflammatory mechanisms of cell stress and death. Inflammation, a potentially important pathogenic mechanism of DPN, induces activation of nuclear factor kappa B, activator protein 1, mitogen-activated protein kinases and the release of inflammatory cytokines [51]. The increase of inflammatory factors appears to be associated with both the incidence and progression of DPN [52].

Ultimately, the mechanisms outlined earlier result in mitochondrial dysfunction, endoplasmic reticulum (ER) stress and DNA damage, causing neuronal dysfunction and/or apoptosis, and subsequently manifesting as clinical DPN.

Vascular Factors

Microvascular disease of the vara nervorum has long been thought to be important in the pathogenesis of DPN [40, 53, 54]. The promotion of inflammatory cascades and other mechanisms, such as those described earlier, cause endoneurial capillary damage in DPN. This may in turn affect Schwann-cell function by disrupting access to oxygen and glucose (Figure 15.12.4.6). These microvascular changes are particularly severe in endoneurial capillaries, and include capillary basement membrane thickening, loss of pericyte coverage, and endothelial hyperplasia [55]; and the degree of microvascular changes has been correlated with both the extent of peripheral nerve fibre loss and the clinical severity of DPN [55]. Narrowing of individual capillaries might not prevent blood from passing through the endoneurial capillary bed, but the

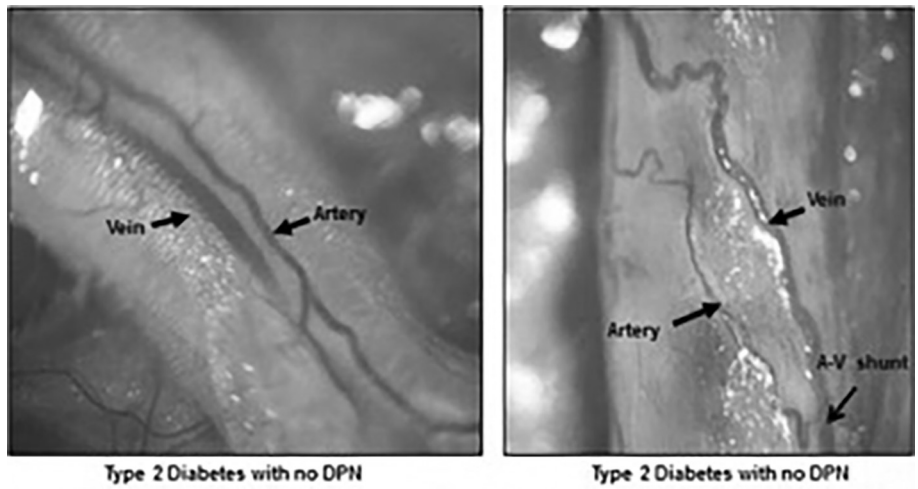

Figure 15.12.4.7 Sural nerve epineurial vessel anatomy in a patient without (left) and with DPN (right).

resulting increase in velocity of blood through endoneurial functional shunts prevents efficient oxygen extraction, causing nerve hypoxia [54, 56].

In vivo studies focused on the sural nerve in human subjects have given evidence of epineural arteriovenous shunting, that seems to cause a 'steal' phenomenon diverting blood from the nutritive endoneurial circulation (Figure 15.12.4.7) [57]. The fall in endoneural oxygen tension demonstrated in DPN [58] appears to be the result of the impairment of nerve blood flow [57].

In addition, there are several other studies providing indirect evidence implicating a vascular aetiology for diabetic neuropathy. In non-neuropathic diabetic subjects, strenuous exercise increases nerve blood flow, increasing nerve conduction velocity by an average of 4 metres/second [59]. But in neuropathic subjects whose nerve microvasculature is severely diseased, this increase in nerve conduction velocity with exercise is diminished [59]. Moreover, the correlation between nerve conduction velocity and lower limb transcutaneous oxygenation measurements in diabetes is strong; macrovascular disease appears to aggravate neuropathy and surgical restoration of perfusion improves nerve conduction velocity [60]. Several studies have also found a strong correlation between DPN and cardiovascular risk factors [5]. A population-based study of patients with type 2 diabetes found that microvascular disease conferred a risk for DPN, equivalent to conventional factors such as smoking, hypertension, and dyslipidaemia [61]. Additionally, the absence of at least one dorsalis pedis or one posterior tibial pulse compared with the presence of all peripheral pulses was associated with diabetic nephropathy and DPN [62].

Impairment of nerve blood flow has also been identified as an early manifestation in rats with streptozotocin diabetes [53]. Several vasodilators have also been demonstrated to improve nerve blood flow and nerve function in diabetic animals [53]. angiotensin-converting-enzyme (ACE) inhibitors have been found to improve nerve function in experimental [53] and human [63] DPN. Subjects with acute painful neuropathy of rapid glycaemic control (insulin neuritis, Treatment-Induced Neuropathy of Diabetes—TIND) have also been found to have severe epineurial microvascular changes and associated new vessel formation similar to that found in proliferative retinopathy, providing perhaps an even stronger evidence for the importance of microvascular factors in the pathogenesis of DPN [19].

Central Nervous System (CNS) Involvement in DPN

Recent work has suggested that DPN may not be as its name suggests and may also involve the CNS [64]. The use of advanced multimodal magnetic resonance imaging (MRI) is now making detailed CNS studies, in carefully phenotyped patients, possible. A detailed review of recent advances in this area is beyond the scope of this chapter but some of the discoveries in brief include:

- A reduction in spinal cord cross-sectional area (shrinkage) in DPN [65].
- Loss of grey matter volume (atrophy) in the primary somatosensory cortex in both painful and painless DPN [66].
- Evidence of neuronal dysfunction in the thalamus, an important gateway for most sensory information to the cerebral cortex, in patients with painless DPN [67].
- Thalamic hyperperfusion in painful DPN whereas there is a sluggish blood flow in those with painless DPN [68].
- Changes in higher brain areas, specifically the 'pain processing matrix' thought to be involved not only in detecting the location and intensity of pain but also the emotional (affective) responses [64, 69].

Autonomic Neuropathy

Abnormalities of autonomic function are very common in subjects with longstanding diabetes; however, clinically significant autonomic dysfunction is uncommon. Several systems are affected (Box 15.12.4.6). Autonomic neuropathy has a gradual onset and is slowly progressive. The prevalence of diabetic autonomic neuropathy depends on the type of population studied, and a number of tests of autonomic function employed. In the EURODIAB study the prevalence of autonomic neuropathy defined as the presence of two abnormal cardiovascular autonomic function tests, was 24%, and the

Box 15.12.4.6 Clinical consequences of autonomic neuropathy

- Cardiac autonomic neuropathy
  - sudden death
  - silent myocardial ischaemia
  - exercise intolerance
  - orthostatic hypotension
  - foot vein distension/AV shunting
- Gastrointestinal autonomic neuropathy
  - gastroparesis
  - diarrhoea or constipation
- Bladder hypomotility
  - urinary incontinence/retention
- Erectile dysfunction
- Gustatory sweating
- Reduced peripheral sweating

prevalence increased with age, duration of diabetes, poor glycaemic control and presence of cardiovascular risk factors [5].

Cardiovascular Autonomic Neuropathy

Cardiovascular autonomic neuropathy (CAN) is a serious complication of long standing diabetes and causes postural hypotension, and may be a cause of sudden death. Although CAN prevalence is very low in newly diagnosed patients with type 1 diabetes, CAN prevalence increases substantially with diabetes duration, and prevalence rates of at least 30% were observed in the DCCT/EDIC cohort after 20 years of diabetes duration [8]. In type 2 diabetes, the prevalence of CAN also increases with diabetes duration and may be present in up to 60% of patients with type 2 diabetes after 15 years. CAN may affect youth, especially young women and those with elevated A1C levels [8]. In addition, CAN is present in patients with pre-diabetes [8].

A timely diagnosis of CAN may have important clinical implications, as CAN is a major risk factor for cardiovascular mortality, arrhythmia, silent ischaemia, and major cardiovascular events.

Postural Hypotension

It is now generally accepted that a fall in systolic blood pressure of >20 mmHg is considered abnormal. Coincidental treatment with tricyclic antidepressants for neuropathic pain, and diuretics may exacerbate postural hypotension. The symptoms of postural hypotension can be disabling for some patients who may not be able to walk for more than a few minutes. Severely affected patients are prone to unsteadiness and falls. The degree of dizziness does not appear to correlate with the postural drop in blood pressure. There is increased mortality in subjects with postural hypotension.

The management of subjects with postural hypotension is challenging. Current treatments include: (1) removing any drugs that may result in orthostatic hypotension such as diuretics, β-blockers, etc.; (2) advising patients to get up from the sitting or lying position slowly, and crossing the legs; (3) increasing sodium intake up to 10 grams (185 mmol) per day and fluid intake of 2–2.5 litres/day (caution in elderly patients with heart failure); (4) the use of custom fitted elastic stockings extending to the waist; (5) treatment with fludrocortisone (starting at 100 μgm per day) while carefully monitoring electrolytes; and (6) in severe cases the alpha-1 adrenal receptor agonist, midodrine, or octreotide may be effective.

Cardiovascular Autonomic Function Tests

Five cardiovascular autonomic function tests are now widely used for the assessment of autonomic function. These tests are non-invasive, and all that is required is an electrocardiogram machine, an aneroid pressure gauge attached to a mouthpiece, a hand grip dynamometer, and sphygmomanometer. See Table 15.12.4.2 [70].

The American Diabetes Association Position Statement on diabetic neuropathy recommends screening for diabetic autonomic neuropathy at diagnosis in type 2 diabetes and 5 years after diagnosis in type 1 diabetes [8]. If negative, it recommends yearly screening subsequently and if, positive or symptomatic, to institute treatment [8].

A correct diagnosis of CAN is based on a combination of symptoms, signs and/or tests of autonomic function. These tests combine reflex responses to parasympathetic and sympathetic testing (Table 15.12.4.2). The recommended tests include the following during a period of electrocardiographic monitoring:

- A demonstration of a resting tachycardia greater than 100 beats per minute. It is useful as a risk stratification tool and a therapeutic target.
- An estimation of the beat–to-beat variation in heart rate under resting conditions while supine. This is best augmented by maximizing vagal activity by breathing at a rate of six breaths per minute. A difference between expiratory and inspiratory heart rates of greater than 15 beats per minute is expected. Less than ten beats is considered abnormal. Between these two figures is borderline. This variation with respiration can be represented as the ratio between the mean heart rates in expiration and inspiration. It is age dependent and varies between the sexes decreasing with advancing age and in females.

Table 15.12.4.2 Reference values for standard cardiovascular function tests

	Normal	Borderline	Abnormal
Heart rate tests Heart rate response to standing up (30:15 ratio)	≥ 1.04	1.01–1.03	≤ 1.00
Heart rate response to deep breathing (maximum minus minimum heart rate)	≥ 15 beats/min	11–14 beats/min	≤ 10 beats/min
Heart rate response to Valsalva manoeuvre (Valsalva ratio)	≥ 1.21	–	≤ 1.20
Blood pressure tests Blood pressure response to standing up (fall in systolic BP)	≤ 10mmHg	11–29 mmHg	≥ 30 mmHg
Blood pressure response to sustained handgrip (increase in diastolic BP)	≥ 16 mmHg	11– 15 mmHg	≤ 10 mmHg

- A measurement of the reflex response to standing which usually involves reflex tachycardia followed by bradycardia. It is usual to express this as the ratio between the R-R interval after 15 beats and at 30 beats. This is more conveniently known as the 30/15 ratio.
- Assessment of the Valsalva manoeuvre. The subject strains at 40 mmHg for 15 seconds during which there is a tachycardia and vasoconstriction. Bradycardia and a rise in blood pressure then occur following relaxation. This expressed as a ratio of the longest to shortest R-R interval. It is regarded as normal when greater than 1.03.
- The presence of postural hypotension measured after being supine for 2 minutes. A drop in systolic blood pressure of up to 10 mmHg is regarded as normal, between 10 and 29 mmHg is borderline and 30 or more is regarded as significant. There is, however, acceptance of postural hypotension as a drop in systolic greater than 20 mmHg and or a diastolic drop greater than 10 mmHg [8].
- ECG determination of corrected QT interval. This is normal below 440 ms and is considered a risk factor for ventricular arrhythmias when prolonged.
- Analysis of spectral heart rate variability (SHRV) expressed in frequency bands. This may manifest as reduced very low frequency, low frequency, and high frequency bands. A ratio of the low frequency to high frequency can be used as a measure of sympathovagal balance. SHRV is considered to provide more information than time domain analysis.

Gastrointestinal Autonomic Neuropathy

Gastroparesis

Autonomic neuropathy can reduce oesophageal motility (dysphagia and heartburn), and cause gastroparesis (reduced gastric emptying, vomiting, swings in blood sugar) [71]. The diagnosis of gastroparesis is often made on clinical grounds by the evaluation of symptoms and sometimes the presence of succussion splash, while barium swallow and follow through, and gastroscopy may reveal a large food residue in the stomach. Gastric motility and emptying studies may aid diagnosis.

Management of diabetic gastroparesis include: optimization of glycaemic control; the use of antiemetics (e.g. metoclopramide) and the use of the cholinergic agent which stimulates oesophageal motility (erythromycin which may enhance the activity of the gut peptide, motilin) [1]. Pyloric Botox injection may provide short-term benefit in some patients. Gastric electrical stimulation (GES) has recently been introduced as a treatment option in patients with drug refractory gastroparesis [1].

Severe gastroparesis causing recurrent vomiting, is associated with dehydration, swings in blood sugar and weight loss, and is an indication for hospital admission. The patient should be adequately hydrated with intravenous fluids and blood sugar should be stabilized, antiemetics could be given intravenously and if the course of the gastroparesis is prolonged, total parenteral nutrition, or feeding through a gastrostomy tube may be required.

Autonomic Diarrhoea

The usual presentation is that of diarrhoea which tends to be worse at night, or alternatively some may present with constipation. Both the diarrhoea and constipation respond to conventional treatment. Diarrhoea associated with bacterial overgrowth may respond to treatment with a broad spectrum antibiotic.

Abnormalities of Bladder Function

Autonomic bladder dysfunction is a rare complication of autonomic neuropathy and may result in hesitancy of micturition, increased frequency of micturition, and in serious cases with urinary retention associated with overflow incontinence. Such a patient is prone to urinary tract infections. Ultrasound scan of the urinary tract and urodynamic studies may be required. Treatments include mechanical methods of bladder emptying by applying suprapubic pressure, or the use of intermittent self-catheterization. Anticholinesterase drugs such as neostigmine or pyridostigmine may be useful.

Gustatory Sweating

Increased sweating usually affecting the face, and often brought about by eating (gustatory sweating) can be embarrassing to patients. Oral anticholinergic agents, including oxybutynin, propantheline, and glycopyrrolate, have improved symptoms; however adverse reactions limit their use. Clonidine has also been used with some success but is also limited by side effects including hypotension and dry mouth. Systemic side effects have led to the investigation of non-systemic approaches. Topical glycopyrrolate, a quaternary ammonium, antimuscarinic compound has been shown to significantly decrease the incidence, severity, and frequency of sweating with eating and is tolerated well [72]. Botulinum toxin has been used for gustatory sweating, though in most literature it is limited to use in unilateral, surgical-related cases.

Management of Painful DPN

Painful DPN can be extremely distressing to many patients but unfortunately, currently available treatment approaches may not completely abolish the pain [73]. An empathic approach is essential. The assessment and treatment of painful DPN should ideally involve a multidisciplinary team (MDT) that may include a diabetologist, a neurologist, the pain clinic team, specialist nurses, podiatrists, psychologists, physiotherapists, occupational therapists, and others. However, in most clinical settings this is not possible and the management falls mainly to the diabetes physician, the primary care physician, or neurologist. When treatment is started, a realistic objective would be to achieve around 50% reduction in pain intensity. However, being 'realistic' shouldn't be interpreted as less aggressive pursuit of maximum pain relief. Secondary objectives should include restoration or improvement in functional measures, quality of life, sleep, and mood.

Glycaemic Control

There is now little doubt that good blood sugar control prevents or delays the onset of DPN in type 1 diabetes [74]. Similar convincing data is lacking in type 2 diabetes and there is currently only Level B evidence [8]. The view that painful neuropathic symptoms may be improved by improving metabolic control, if necessary with the use of insulin in type 2 diabetes is not supported by evidence from controlled trials. Nevertheless, current consensus is that the first step in the management of painful neuropathy is an attempt at improving

glycaemic control where appropriate. Additionally, as cardiovascular disease is common in patients with DPN [5] and vascular risk factors (hypertriglyceridaemia, hypertension, visceral obesity, etc.) appear to be implicated in the pathogenesis of DPN [5], there is a good rationale for management of vascular risk factors beyond glycaemic control.

Pharmacotherapy

International consensus panels [73] including the National Institute for Health and Care Excellence (NICE) [75] broadly recommend that tricyclic compounds such as amitriptyline, serotonin noradrenaline reuptake inhibitors (SNRI) such as duloxetine, and the anticonvulsants, pregabalin and gabapentin as first-line agents for the management of painful DPN. Box 15.12.4.7 shows some of the commonly prescribed medications for painful DPN.

Tricyclic Compounds

Tricyclic compounds are regarded as one of the first-line treatment agents [73]. A number of double-blind clinical trials have confirmed their effectiveness beyond any doubt, although they are not licensed for use in painful DPN. However, there is a good case for their use off label and indeed this is the case. As these drugs do have unwanted side effects such as drowsiness, dry mouth, and postural hypotension, patients should be started on Imipramine or Amitriptyline at a low dose (10–25 mg taken before bed), the dose gradually titrated if necessary up to 100 mg per day. Caution should be taken in elderly patients and in those with cardiovascular disease [73]. The mechanism of action of tricyclic compounds in improving neuropathic pain is not fully understood.

Serotonin Noradrenaline Reuptake Inhibitors (SNRI)

SNRIs such as duloxetine relieve pain by increasing synaptic availability of 5-HT and noradrenaline in the descending pathways that are inhibitory to pain impulses. Duloxetine is licensed for the treatment of painful diabetic neuropathy. The efficacy of duloxetine in painful neuropathy has been investigated in several studies [73] with the 60 mg/day and 120 mg/day doses being effective in relieving painful symptoms. Duloxetine is contraindicated in those with liver disease.

Box 15.12.4.7 Pharmacological treatment of painful DPN

- **Tricyclic antidepressants (TCAs)**
  Amitriptyline 25–150 mg/day;
  Imipramine 25–150 mg/day
- **Serotonin noradrenaline reuptake inhibitors (SNRIs)**
  Duloxetine 60–120 mg/day
- **Anticonvulsants**
  Gabapentin 300–3600 mg/day
  Pregabalin 300–600 mg/day
- **Opiates**
  Tramadol 200–400 mg/day
  Tapentadol slow release 100–500 mg/day
  Oxycodone 20–80 mg/day
  Morphine sulphate SR 20–80 mg/day
- **Capsaicin cream**
  (0.075%) applied sparingly 3–4 times per day)
  8% patch applied under a specialist supervision
- **IV lignocaine**
  5 mg/kg given IV over 30 min with ECG monitoring

Anticonvulsants

Older anticonvulsants, including sodium valproate and carbamazepine, though effective, tend to have more side effects. Gabapentin and pregabalin bind to the α-2-δ subunit of the calcium channel reducing calcium flux, and thus resulting in reduced neurotransmitter release in the hyperexcited neurone. Gabapentin has been used to treat painful neuropathy for over two decades [73]. More recently pregabalin at 300–600 mg/day has been found effective in several clinical trials and is licensed for the treatment of painful DPN. Side effects of include dizziness, somnolence, and peripheral oedema.

Alpha-Lipoic Acid

Infusion of the antioxidant alpha-lipoic acid: at a dose of 600 mg per day orally or intravenously has also been found to be useful in reducing neuropathic pain [73].

Opiates

The opiate derivative tramadol (50–100 mg four times per day) has been found effective in relieving neuropathic pain [73]. Another opioid, oxycodone slow release and tapentadol slow release have also been shown to be effective in the management of neuropathic pain [73]. Because of their marked addiction potential, opioids should only be considered when all other drug combinations have failed.

Topical Capsaicin and Capsaicin Patch

Topical capsaicin works by depleting substance 'P' from nerve terminals, and there may be worsening of neuropathic symptoms for the first 2–4 weeks of application. Topical capsaicin (0.075%) applied sparingly 3–4 times per day to the affected area has also been found to relieve neuropathic pain [73]. In patients with painful DPN, capsaicin 8% patch treatment was found to provide modest pain relief and sleep quality improvements versus a placebo patch, similar in magnitude to other treatments with known efficacy, but without systemic side effects or sensory deterioration [76]. Recently, the European Commission has granted approval for a label extension for QUTENZA (capsaicin 8% patch) to include the treatment of adult diabetic patients with peripheral neuropathic pain, either alone or in combination with other medicinal products for pain. However, this treatment is provided in specialist centres as protective gear has to be worn during the application.

Intravenous Lignocaine

Intravenous lignocaine at a dose of 5 mg per kg body-weight with another 30 minutes with a cardiac monitor in situ, has been found to be effective in relieving neuropathic pain for up to 2–6 weeks [73]. This form of treatment is useful in subjects who are having severe pain which is not responding to these agents, although it does necessitate bringing the patient into hospital for a few hours.

Combination Treatment

Combinations of first-line therapies may be considered if there is pain, despite a change in first-line monotherapy [73]. If pain is still inadequately controlled, opioids such as tramadol and oxycodone may be added in a combination treatment [73]. A number of areas

relating to painful DPN warrant further investigation including population-based prevalence and natural history studies, trials using active comparators rather than placebo [77, 78], assessment of combination therapies in addition to placebo, and longer-term studies of the efficacy and durability of treatments of painful DPN [73].

Management of Disabling Painful Neuropathy Not Responding to Pharmacological Treatment

Neuropathic pain can sometimes be extremely severe. Unfortunately some patients are not helped by conventional pharmacological treatment. Such patients may respond to electrical spinal cord stimulation which relieves both background and peak neuropathic pains [79]. This treatment is provided in specialist centres and a recent two-centre prospective study has confirmed long-term efficacy [80].

15.13

Macrovascular Disease in Diabetes

15.13.1 Mechanisms of Macrovascular Disease in Diabetes

Mark T. Kearney, Peysh A. Patel, and Richard M. Cubbon

Introduction

Type 2 diabetes mellitus represents a growing global public health problem, driven by a demographic shift towards ageing in the population and increased prevalence of obesity. Over 25% of patients presenting to hospital with acute myocardial infarction have comorbid diabetes, and a substantial further proportion have lesser degrees of impaired glycaemic control (pre-diabetes) [1]. Cardiovascular complications remain the most common cause of death in people with diabetes, with major macrovascular events occurring 15 years earlier in those with diabetes than in the general population [2]. Atherogenesis refers to the pathological process wherein fibro-fatty deposits accrue within the arterial wall as a result of chronic injury and inflammation. Diabetes accelerates atherogenesis, resulting in more diffuse and complex lesions, and also impairs coronary vessel repair after percutaneous intervention [3].

Insulin resistance is defined, in principle, as a reduction in the metabolic and/or signalling responses to insulin at cell, tissue, or organismal level. Most commonly it is taken to denote impaired blood glucose lowering action of insulin [4]. Where pancreatic beta-cells are unable to compensate fully for the resulting increased insulin demand, hyperglycaemia ensues, ranging through glucose intolerance to the clinical phenomenon of type 2 diabetes mellitus. This chapter explores the key components of the systemic insulin resistance syndrome that potentially contribute to atherogenesis and atherosclerotic plaque rupture. We also discuss how local perturbation of insulin signalling in the arterial wall may promote atherogenesis, independent of changes in systemic glucose and lipid metabolism, noting that insulin receptors are abundantly expressed in vascular endothelium, vascular smooth muscle cells (VSMCs) and leucocytes. In particular, the notion of cell- and tissue-specific differences in insulin resistance extending beyond classical metabolic tissues, such as liver, adipose tissue, and muscle, is reviewed. Finally, a brief overview is provided of how diabetes impairs endogenous vascular reparative processes which serve to mitigate atherogenesis.

Atherogenesis: From Fatty Streak to Plaque Rupture

The macrovascular risk associated with diabetes mellitus primarily relates to accelerated atherosclerosis in large and medium-sized arteries. Atherogenesis is a multifaceted disease process, perhaps best characterized as an 'inflammatory' disorder of vessel walls associated with progressive accumulation of oxidized lipids in a plaque with a necrotic core. These lesions impinge upon the vascular lumen and are susceptible to rupture [5]. The pathology of atherosclerotic lesions in patients with diabetes is in many regards indistinguishable from that seen in patients without diabetes, although the lesions are generally more advanced and diffusely distributed [6]. A unifying concept thought to explain initiation of atherogenesis is 'endothelial dysfunction', which describes a complex disturbance of endothelial biology, associated with reduced nitric oxide (NO) bioavailability, oxidative stress, and leukocyte adhesion molecule expression. This homeostatic failure initiates the cascade of events that underpin the atherogenic cascade (**Figure 15.13.1.1**).

The earliest discernible vascular lesion is the so-called fatty streak, which is often present in young adults [7]. It occurs as a response to receptor-mediated transcytosis of low-density lipoproteins (LDL) and other apoB-containing lipoproteins across the endothelium, with subsequent trapping in the arterial intima. These are targets for modifications including oxidation, which have pro-inflammatory effects via recruitment of monocytes to the intima, where they terminally differentiate into macrophages. Oxidized LDL can then be internalized by macrophages and stored in cytoplasmic lipid droplets [8]. Progressive failure to clear these modified lipids results in

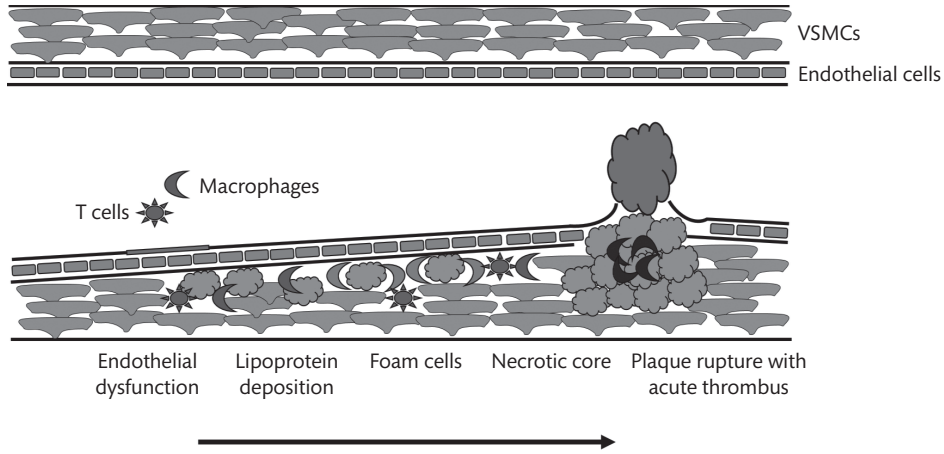

Figure 15.13.1.1 Processes that underpin atherothrombosis. The black arrow indicates time, spanning decades. VSMCs = vascular smooth muscle cells.

the formation of 'foam cells', which characterize lesion progression from early to intermediate stages and, in combination with T lymphocytes, are the histological hallmark of fatty streaks.

Foam cells release chemokines and cytokines, and express adhesion receptors which orchestrate further recruitment of macrophages and T cells, perpetuating the inflammatory process [9]. Supplementary release of growth factors such as platelet derived growth factor (PDGF) and fibroblast growth factor (FGF) results in migration of VSMC into the intima. This provides the major source of extracellular matrix (ECM) in atherosclerotic lesions [10].

Apoptosis of foam cells within the lesions results in formation of a necrotic core, which is essential for the development of the propensity for plaque rupture [11]. This core is moreover impregnated with oxidized lipids and tissue factors, rendering it highly thrombogenic when exposed to circulating blood. The lipid-rich core is covered by a fibrous cap formed by VSMCs and the ECM components that they secrete, which include collagen and proteoglycans. Such advanced lesions may remain stable for years, and be entirely asymptomatic if non-occlusive. However, activated leukocytes within the plaque produce matrix metalloproteinases (MMP), collagenases, and elastases, which collectively act to degrade the fibrous cap. Apoptosis of VSMCs also destabilizes the cap by reducing ECM synthesis. Rupture of the fibrous cap results in exposure of the underlying necrotic core and surrounding extracellular components, such as collagen and von Willebrand factor (vWF), to circulating blood. This results in activation of endogenous haemostatic cascades. Although these processes are crucial in physiological haemostasis, their activation in the context of acute plaque rupture generates thrombus within an already narrowed vascular lumen. If this causes sufficient impairment of blood flow, ischaemic injury occurs downstream, as typified by clinical presentations such as acute coronary syndromes.

The Metabolic Syndrome

Insulin resistance and central obesity are intimately associated with a cluster of cardiovascular risk factors, frequently collectively referred to as the 'metabolic syndrome' [12]. While various diagnostic criteria exist, these generally capture the coexistence of central obesity, dysglycaemia, dyslipidaemia, and hypertension, with broader descriptions also including factors such as inflammation, oxidative stress, and a pro-thrombotic tendency. The incremental value of such wider definitions of the syndrome beyond its constituent parts has been questioned, however there is broad consensus that it captures a unifying driver of multiple pro-atherogenic phenomena. Unpicking the causal relationships involved in these associations with vascular disease, and the mechanisms that underpin them are a major focus of current research.

The Insulin Signalling Cascade

Understanding of insulin resistance and its role both in the complex metabolic perturbation of the metabolic syndrome, and directly in the tissue pathology of the vessel wall, first requires understanding of the cellular pathways whereby insulin exerts its many effects on tissue. These are summarized in Figure 15.13.1.2. The insulin receptor is a transmembrane receptor tyrosine kinase (RTK). Upon ligand binding it undergoes autophosphorylation before recruiting and phosphorylating insulin receptor substrates (IRS) and other adaptor proteins [13]. These then bind to docking proteins containing Src-homology-2 (SH2) domains. In broad terms, proteins bearing SH2 domains can be subdivided into two classes: enzymes such as phosphatidylinositol-4,5-bisphosphate 3-kinase (PI3K), and adaptor proteins such as growth factor receptor-bound protein 2 (Grb2) [14]. Insulin signal transduction is discussed in more detail in Chapter 1.3, 'Molecular Aspects of Hormonal Regulation'.

Class IA PI3K are most strongly implicated in insulin's metabolic actions. Their primary substrate is phosphatidylinositol 4,5-bisphosphate (PtdIns(4,5)P_2), which is phosphorylated to yield PtdIns(3,4,5)P_3 (or PIP_3). This is a membrane-resident lipid second messenger that is able to initiate multiple downstream enzyme cascades by recruiting proteins with Pleckstrin homology (PH) domains specific for PIP_3 [15]. AKT is a serine/threonine kinase of particular relevance, functioning as a critical regulatory node in signalling [16]. Activated AKT has multiple downstream targets which mediate regulation of diverse cellular functions. In skeletal and cardiac muscle AKT action drives translocation of glucose

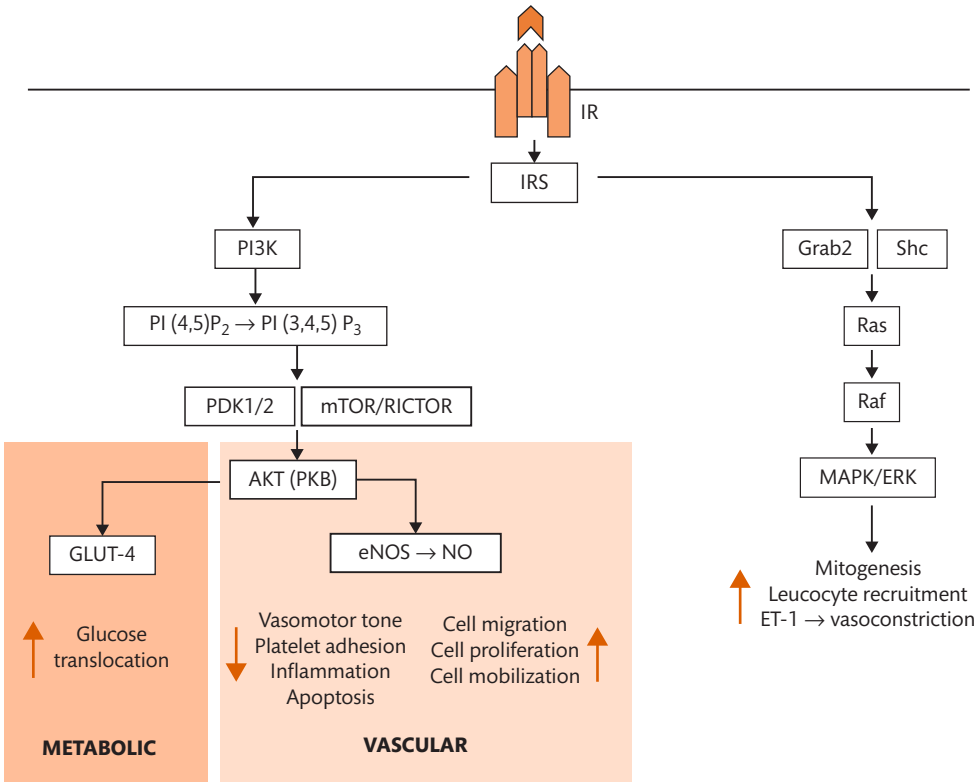

Figure 15.13.1.2 Simplified schematic of key elements of the insulin signalling network implicated in vascular disease. IR, insulin receptor; IRS, insulin receptor substrate; PI3K, phosphoinositide-3-kinase; $PI(4,5)P_2$, phosphatidylinositol 4,5-biphosphate, $PI(3,4,5)P_3$, phosphatidylinositol 3,4,5-triphosphate; PDK, phosphoinositide-dependent kinase; mTOR, mammalian target of rapamycin; RICTOR, rapamycin-insensitive companion on mTOR; GLUT, glucose transporter protein; NOS, nitric oxide synthase; NO, nitric oxide; Grb2, growth-factor-receptor-bound protein 2; ET-1, endothelin-1.

transporter protein 4 (GLUT4)-containing vesicles to the plasma membrane, stimulating cellular glucose uptake. In adipose tissue it plays a similar role, and is also critical in insulin's suppression of triglyceride breakdown to release fatty acids. In liver, insulin's roles include promotion of fatty acid and VLDL synthesis, and suppression of liver glucose output. While much work has focussed on the role of insulin in these 'canonical' insulin responsive tissues, insulin also plays critical roles in other tissues critical for vascular disease. In endothelial cells, for example, AKT activated by insulin phosphorylates endothelial nitric oxide synthase (eNOS) at serine 1177, augmenting catalytic activity and production of NO [17]. NO is considered one of the most important mediators of vascular homeostasis, regulating vascular tone, inflammation, thrombosis, cell growth, and migration.

As well as being important for metabolic regulation, insulin is also a potent growth factor. The Grb2/mitogen-activated protein kinase (MAPK) pathway is essential for insulin's mitogenic effects [18]. Grb2 binds to phosphorylated IRS or Shc, after insulin receptor activation. A phosphorylation cascade eventually results in activation of the kinases ERK-1 and 2. Activated ERK can phosphorylate a range of cellular targets that regulate gene expression, cellular differentiation, and mitogenesis. They also induce surface adhesion molecules on endothelial cells which facilitate leucocyte recruitment. ERK signalling also potentiates release of endothelin-1 (ET-1), which has potent vasoconstrictor and potentially pro-atherogenic effects.

Metabolic Syndrome Components and Atherogenesis

Dyslipidaemia

The dyslipidaemia associated with the metabolic syndrome comprises elevated triglycerides, reduced high-density lipoprotein (HDL) cholesterol and smaller, denser LDL cholesterol particles [19] (see Chapter 15.13.4 'Diabetic Dyslipidaemia'). Triglycerides are a source of free fatty acids (FFA), which in excess can result in cardiovascular lipotoxicity through various mechanisms. FFA-induced mitochondrial dysfunction, uncoupled eNOS (a shift from dimeric to monomeric structure, resulting in generation of superoxide instead of NO) arising from direct enzymatic modification or depleted cofactors, and activation of nicotinamide adenine dinucleotide phosphate (NADPH) oxidases (NOX) results in generation of superoxide (a form of reactive oxygen species, or ROS) and vascular oxidative stress [20]. These phenomena, with the associated pro-inflammatory signalling cascade activation, are directly implicated in insulin resistance, creating a vicious cycle [20]. Ceramide derived from saturated FFA metabolism also directly inhibits insulin-stimulated AKT activation. It impairs glucose uptake in human subjects with obesity and also contributes to oxidized LDL-induced calcification of human VSMCs, a feature of advanced atherosclerosis. Lastly, small, dense LDL cholesterol particles are particularly susceptible to oxidative modification which, as described earlier, is potently atherogenic.

Hyperglycaemia

Hyperglycaemia results in diverse alterations in vascular cell biology which can potentiate atherosclerosis. The formation of advanced glycation end products (AGE) by non-enzymatic glycation driven by high blood glucose levels indirectly promotes ROS production, a pro-inflammatory state, and impaired insulin signal transduction; moreover, by binding to AGE receptors (termed RAGE) on leukocytes, vascular endothelial cells, and VSMCs, AGEs can directly influence cell biology [21]. Higher AGE levels have been found in patients with type II diabetes than in healthy and type I diabetic patients. Moreover, their abundance appears to be increased in patients with diabetes and coronary disease compared to those without coronary disease. Glycated haemoglobin (HbA1c) levels appear to correlate with AGE, and pharmacotherapy with agents that lower blood glucose and AGE is associated with reductions in microvascular sequelae such as nephropathy and retinopathy, though effects on macrovascular complications are less established [22].

Shunting of glucose metabolism through the hexosamine biosynthesis pathway results in modification of proteins such as AKT via O-linked N-acetylglucosamine (O-GlcNAcylation), which is associated with increased vascular calcification in the context of diabetes [23]. Hyperglycaemia activates protein kinase C (PKC), which augments monocyte recruitment, foam cell formation, and promotes switching to a synthetic VSMC phenotype which enables cell migration and proliferation [24]. Consistent with this observation, atherosclerosis-prone mice with genetic deletion of PKC display reduced atherosclerosis. Endothelial expression of the transcriptional coactivator PGC-1α is induced in rodents and humans with hyperglycaemia, and potently inhibits Notch and AKT/eNOS signalling with deleterious effects on endothelial function [25]. Lastly, hyperglycaemia generates oxidative stress and a pro-inflammatory milieu, which is directly implicated in atherogenesis as detailed next.

Hyperinsulinaemia and Insulin Resistance

Insulin resistance is characterized by impaired intracellular insulin signal transduction and compensatory hyperinsulinaemia. A key feature of this complex perturbation is that while signalling via the PI3K/AKT cascade is impaired, the MAPK/ERK pathway remains unaffected [26]. This concept of 'pathway-specific resistance' is relevant because the compensatory hyperinsulinaemia required to sustain glucose homeostasis via PI3K/AKT leads to excessive MAPK/ERK signalling through a 'bystander' effect of high insulin levels acting on relatively unimpaired pathways leading to ERK activation. Since PI3K/AKT signalling promotes eNOS activation, vascular pathway-specific insulin resistance is characterized by reduced NO bioavailability, alongside increased vascular leukocyte adhesion molecule expression and ET-1 mediated vasoconstriction through MAPK signalling. Indeed, people with diabetes have elevated baseline levels of ET-1, and show improved endothelial function when treated with a pharmacological antagonist [27].

Insulin also plays a vital role in regulation of sympathetic nervous system (SNS) activity by acting on the arcuate nucleus of the hypothalamus. In the context of obesity, SNS hyperactivity arises from chronic hyperinsulinaemia. This promotes vasoconstriction and can secondarily activate the renin–angiotensin–aldosterone system (RAAS), contributing to systemic hypertension, which is an independent risk factor for development of atherosclerosis.

Oxidative Stress

Oxidative stress is intimately involved both in development of individual components of the metabolic syndrome, and directly with the pathophysiology of diabetes-associated macrovascular disease. The term refers to disrupted spatiotemporal balance between production of ROS and their scavenging by antioxidant defences, resulting in detrimental modification of lipids, proteins, and nucleic acids [28]. ROS are highly reactive derivatives of oxygen (O_2), loosely categorized into free radicals, such as superoxide (O_2^-) and peroxynitrite ($ONOO^-$), and non-radicals such as hydrogen peroxide (H_2O_2).

At physiological concentrations, ROS are fundamental to cellular homeostasis by acting primarily as a reversible signalling mechanism [29]. Excessive production or inadequate degradation of ROS results in maladaptive oxidative stress. One important mechanism of vascular oxidative stress in animal models of diabetes is increased NADPH oxidase activity [30]. eNOS uncoupling, for example due to oxidation of the enzyme's cofactor tetrahydrobiopterin (BH4), can also paradoxically result in generation of superoxide by eNOS. Dysfunctional mitochondrial lipid metabolism is an additional important source of ROS in the insulin-resistant vasculature [31]. Oxidative stress associated single-strand DNA breakage and poly(ADP-ribose) polymerase (PARP) activation may also subsequently promote diabetic endothelial dysfunction.

Mechanistic insights into the role of vascular ROS have been derived from *in vivo* manipulation of vascular insulin signalling. Mice with endothelium-targeted overexpression of an inhibitory mutant human insulin receptor (ESMIRO), or with loss of one of the two insulin receptor alleles (IRKO), have enhanced vascular superoxide production. This can be suppressed with a pharmacological Nox-2 inhibitor, and is associated with improved endothelium-mediated vasorelaxation [32]. Consistent with this notion, diabetic blood vessels in hamsters demonstrate improved endothelium-dependent relaxation when treated with superoxide dismutase (SOD), an antioxidant. However, conflicting data has arisen from studying mice with endothelium-specific overexpression of the human insulin receptor (hIRECO), a model of *increased* endothelial insulin signalling, which also exhibited reduced NO bioavailability and superoxide-mediated oxidative stress [33]. Similarly, mice with endothelial inactivation of Shc homology 2-containing inositol 5' phosphatase-2 (SHIP2), a negative regulator of insulin signalling, also exhibit oxidative stress and endothelial dysfunction [34]. Overall, these data may provide some explanation for the disappointing results of clinical trials that have sought to improve cardiovascular outcomes with broad-spectrum antioxidants, in addition to intensive insulin regimens.

Pro-Inflammatory Adipocytokines

Chronic inflammation is an important driver of atherosclerosis [35]. It is closely coupled with the glucotoxicity and lipotoxicity of the metabolic syndrome and is aggravated by oxidative stress. Dysfunctional visceral adipose depots are a particularly important driver of systemic inflammation, due to altered adipocytokine (or adipokine) secretion profiles. Adipokines are a diverse group of cytokines derived from adipose tissue, and include interleukin (IL)-1β, IL-6, tumour necrosis factor (TNF)-α, adiponectin, and leptin, among many others [36]. Their impact extends beyond

adipose tissue biology and wider metabolic homeostasis, with direct effects on vascular function also being apparent. However, our understanding of adipokine biology remains limited. For example, adiponectin is generally less abundant in insulin-resistant states, and has been demonstrated to have anti-inflammatory and antiatherosclerotic properties in mouse models of atherosclerosis [37]. While some data suggest its circulating concentration is inversely predictive of coronary plaque calcification and fibrous cap integrity, contradictory observations have also been made. This illustrates a recurring theme in the adipokine literature, probably reflecting our incomplete understanding of their context dependent effects.

Cell-Autonomous Insulin Resistance

Vascular Endothelial Cells

The vascular endothelium is a monolayer composed of approximately 10^{14} cells. It separates the vessel lumen and VSMCs and hence provides a direct mechanical interface between blood and the tissues it supplies. Beyond its role as a structural barrier, it is also metabolically active and has a critical role in regulating physiological homeostasis. Its functions include transport of nutrients and solutes across the endothelium, maintenance of vascular tone, and regulation of the thrombotic environment.

Endothelial dysfunction refers to a subtle alteration in endothelial phenotype that is implicated in early atherosclerosis, and precedes structural changes in the arterial wall. This unfavourable shift is accelerated by systemic contributors including components of the metabolic syndrome and arises through various mechanisms, perhaps most important of which is a reduction in NO bioavailability. NO has many antiatherogenic and antithrombotic properties that are required in normal physiology. In health there is continuous, basal vascular synthesis of NO which is essential for vascular function, for example promoting vasodilation, inhibiting platelet activation, suppressing inflammation and limiting leukocyte adhesion molecule expression [38]. Indeed, eNOS knockout mice are hypertensive, insulin-resistant, and develop accelerated atherosclerosis.

The macrovascular sequelae of endothelium-specific insulin resistance have been explored in various murine models. Importantly, mice with diet-induced obesity exhibit vascular insulin resistance associated with reduced expression of the insulin receptor [39]. In atherosclerosis-prone mice, genetic knockout of endothelial insulin receptors induces expression of the leukocyte adhesion molecule VCAM-1 and increases atherosclerotic lesion area [40]. ESMIRO mice have been shown to develop endothelial dysfunction, and when crossed with atherosclerosis-prone mice, develop accelerated atherosclerosis. This is independent of systemic metabolic perturbations, and associated with reduced NO bioavailability and superoxide-dependent oxidative stress [41]. As outlined earlier, however, murine models of increased endothelial insulin signalling also paradoxically exhibit enhanced superoxide abundance and oxidative stress-induced endothelial dysfunction. Nevertheless these findings, as well as highlighting the complexity in interplay between metabolic and vascular function, prove the principle that perturbated insulin resistance autonomous to vascular tissues may promote atherogenesis.

Macrophages

There is also evidence that myeloid-specific insulin resistance can accelerate atherogenesis. Macrophages from obese mice have reduced insulin receptor expression, alongside increased expression of surface receptors such as scavenger receptor A (SRA) and CD36 [42]; these are implicated in internalization and cytoplasmic storage of oxidized LDL. Similar changes have been observed in insulin receptor-deficient macrophages. Using murine bone marrow transplantation studies, it has been shown that macrophage insulin receptor deficiency increases endoplasmic reticulum (ER) stress-induced apoptosis and necrotic core formation in advanced atherosclerotic lesions [43]. However, conflicting data also exist indicating that myeloid lineage-specific insulin resistance can protect atherosclerosis-prone mice from the development and progression of atherosclerotic lesions [44]. This may relate to insulin receptor-deficient macrophages having impaired capacity to produce pro-inflammatory cytokines, such as IL-1β and IL-6.

Atherothrombosis

The propensity of atherosclerotic plaques to acute rupture is dependent primarily upon plaque constituents, rather than the extent of vessel stenosis [45]. Factors that enhance vulnerability to rupture are also associated with diabetes, and include thinning of the fibrous cap, increased macrophage infiltration, increased size of the necrotic core, and reduced abundance of VSMCs [46]. The extent of plaque vascularization has also been implicated in instability. In the early phases of atherogenesis, plaque neovascularization may have antiapoptotic effects, while facilitating lesion growth. In more advanced lesions, however, release of cytokines secondary to local inflammation can result in dysregulated neointimal proliferation of microvessels which are leaky, fragile, and of poor quality, rendering them susceptible to rupture. Studies in humans have reported higher proportions of neovessel formation in the most advanced atherosclerotic plaques, with increased abundance in those with diabetes. Expression of proteolytic enzymes, such as MMPs, is also increased by hyperglycaemia, and increases propensity for fibrous cap rupture [47].

Platelets initiate plaque thrombosis upon detection of ECM and core constituents, and their aggregation is augmented in the setting of insulin resistance by reduced NO bioavailability, altered calcium regulation, oxidative stress, and increased circulating von Willebrand factor. Notably, atheromatous plaques in people with diabetes have been shown to exhibit increased intracoronary thrombus compared to controls [48]. Normoglycaemic patients with insulin resistance, and those with type II diabetes, have altered circulating components of the coagulation and fibrinolytic pathways, with increased levels of plasminogen activator inhibitor (PAI)-1 particularly implicated in the pro-thrombotic tendency of the metabolic syndrome [49]. PAI-1 binds to tissue plasminogen activator (tPA) to inhibit its conversion of plasminogen to plasmin, an enzyme that is essential to degrade fibrin clots. Indeed, PAI-1 levels have been shown to be lowered in patients with DM by weight reduction and pharmacotherapies, such as metformin and thiazolidinediones. Hyperglycaemia can also directly cause post-translational modification of coagulation proteins, such as fibrinogen. This results in a

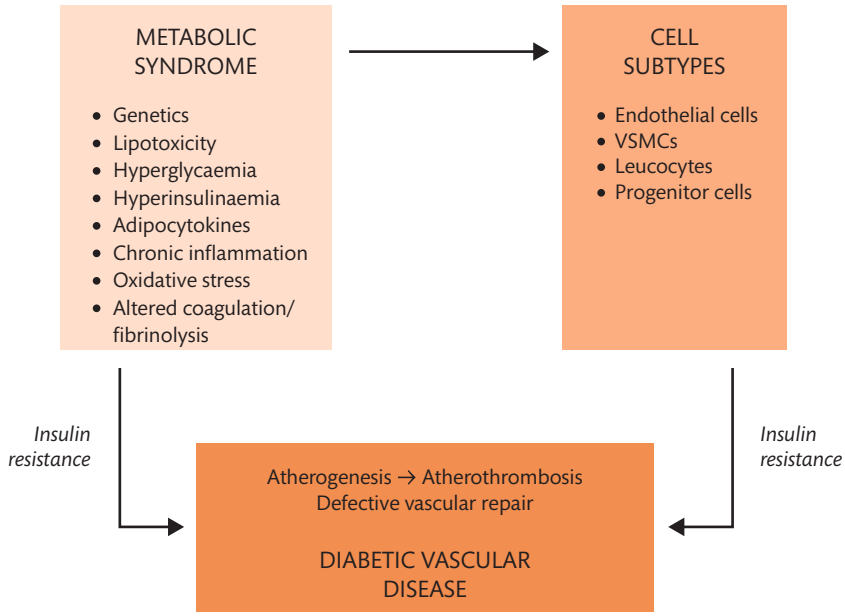

Figure 15.13.1.3 Interplay between systemic and cell-autonomous factors in pathogenesis of diabetic vascular disease.

fibrin clot which is denser, with thinner fibres, and is more resistant to plasmin-mediated lysis [50].

Defects in Vascular Repair

In response to vascular insults, endogenous reparative mechanisms are thought to mitigate injury, and so potentially retard atherogenesis. The term 'vascular repair' is typically used to describe re-endothelialization of existing conduit vessels that have been exposed to injurious insults, and requires complex interaction of local and circulating cells [51] (Figure 15.13.1.3). The endothelium is a critical player in this process, with proliferation and migration of local endothelial cells resulting in restoration of a seamless endothelial monolayer. While bone marrow-derived cells may promote this process via paracrine mechanisms, they do not directly contribute to the neo-endothelium.

There is emerging evidence to support the notion that an insulin-resistant phenotype has adverse effects on indices of endogenous vascular repair. IRKO mice demonstrate broadly preserved metabolic sensitivity to insulin, but markedly impaired re-endothelization of the femoral artery after denudation [52]. *In vivo* models of type 2 diabetes have an exaggerated neointimal response to vascular injury, which is retarded with rosiglitazone, an agent that enhances insulin sensitivity [53]. Myeloid angiogenic cells derived from patients with diabetes have impaired paracrine capacity to promote vascular repair, which correlates with increased superoxide abundance [54]. Outgrowth endothelial cells (OEC) derived from South Asian men, who are insulin resistant and have increased risk of cardiovascular sequelae, also exhibit impaired vascular repair capacity due to impaired AKT signalling [55].

eNOS expression also appears reduced in diabetic vascular progenitors, and this is associated with impaired migration and adhesion capacity [56]. Reduced endothelial NO bioavailability in the context of insulin-resistant states may be pertinent, promoting cell senescence and impairing migration in response to chemotactic stimuli, both factors likely to be relevant in promoting conduit repair [57]. Indeed, NO has more potent inhibitory effects on neointimal hyperplasia after arterial injury in rats with metabolic syndrome and frank diabetes, in comparison to normoglycaemic controls.

Conclusions

Despite contemporary pharmacotherapies and lifestyle modification, the presence of diabetes continues to confer a prognostic disadvantage with regards to atherosclerosis-mediated major cardiovascular events. Significant progress has been made in our understanding of insulin resistance and diabetes-associated vascular disease; however, the complexity of this association means that many mechanistic and translational questions remain. Addressing these uncertainties will be pivotal in the development of therapeutic strategies that safely and effectively promote macrovascular health, survival, and quality of life in patients across the spectrum of dysglycaemia.

15.13.2 Macrovascular Disease in Type 2 Diabetes

Naveed Sattar

Cardiovascular Risk in Type 2 Diabetes

While type 2 diabetes was once considered a coronary heart disease (CHD) risk equivalent, this notion has been superseded. The most comprehensive evidence comes from the emerging risk factor collaboration (ERFC), which produced a collaborative meta-analysis of 102 prospective studies using individual participant data [1]. This showed that prevalent diabetes confers on average a twofold excess risk for a wide range of vascular outcomes, independently of other risk factors (**Figure 15.13.2.1**). This work also showed that diabetes is around a third more strongly related to risk of fatal events than of non-fatal myocardial infarction (MI). Further analyses showed the excess relative risk of vascular events in people with versus without diabetes was greater in women and at younger ages. This fits well with findings in national datasets such as the QRISK2 study from the United Kingdom which reported type 2 diabetes to be associated with CVD risk levels of 2.20 and 2.54 in men and women, respectively, independent of other measured risk factors [2].

Lesser Degrees of Dysglycaemia and Cardiovascular Risk

In those without diabetes, ERFC analyses showed no clear association with CHD risk at fasting blood glucose (FBG) levels between 3.9 and 5.6 mmol/L, but a modest rise in risk thereafter [1]. However, when the hazard ratios for CHD were examined by clinically defined categories, they were only meaningfully elevated with known or undiagnosed diabetes, being modest at FBG levels below 7 mmol/L (**Figure 15.13.2.2**). By contrast, low-density lipoprotein (LDL) cholesterol and blood pressure had stronger and nearly log-linear associations with vascular risk. A subsequent meta-analysis of individual participant data for three different glycaemia measures (HbA1c, random or FBG and post load glucose) from multiple cohorts determined that in those without type 2 diabetes although the HbA1c association with CVD risk was equal to or greater than that seen for fasting, random, or post load glucose levels, no glycaemia measure meaningfully improved CVD risk prediction in this non-diabetic group [3]. Near identical findings were recently reported for a 11.5-year follow-up from the Whitehall II study [4], where CVD risk associations for all glycaemia measures in the pre-diabetes range turned out to be modest. Collectively, these results suggest that, while diabetes is meaningfully and independently related to CVD risk, lesser levels of dysglycaemia are not. In clinical terms, CVD risks in patients with pre-diabetes should be determined using usual CVD risk scores without any multiplication factor.

Factors Associated with Differential CVD Risk in Diabetes

Notably, a doubling of CVD risk represents only the average risk in *all* patients with type 2 diabetes, and wide heterogeneity of risk is seen, driven by several patient characteristics. For example, at the

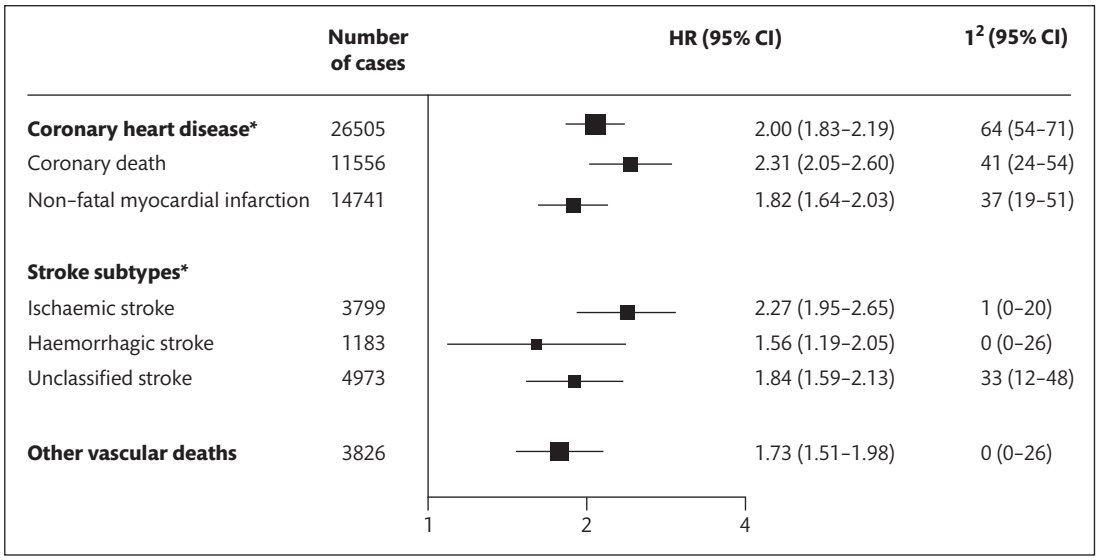

Figure 15.13.2.1 Hazard ratios (HRs) for vascular outcomes in people with versus those without diabetes at baseline. Analyses were based on 530 083 participants. HRs were adjusted for age, smoking status, body mass index, and systolic blood pressure, and, where appropriate, stratified by sex and trial arm. 208 coronary heart disease outcomes that contributed to the grand total could not contribute to the subtotals of coronary death or non-fatal myocardial infarction because there were fewer than 11 cases of these coronary disease subtypes in some studies. *Includes both fatal and non-fatal events.

point of diabetes diagnosis relative risk is well below 2, whereas once a patient has had several years of diabetes or exhibits microvascular complication, such as albuminuria, low glomerular filtration rate (eGFR), or moderate retinopathy, CVD risk levels are elevated many fold. The relevance of these and other risk factors to excess risk of CVD in type 2 diabetes is discussed in more detail next.

Age of Onset

Age of onset of type 2 diabetes is an important determinant of risk of adverse outcomes as well as years lost due to diabetes. Several lines of evidence support this notion. These include the finding from the Swedish diabetes registry of much higher hazard ratios (~2–3 fold) for CVD and total mortality in diabetes patients under 55, whereas hazard ratios (HRs) were around 1–1.2 fold in patients with diabetes above 75 years of age (Figure 15.13.2.3) [5]. Similarly, recent data from the Swedish diabetes registry showed that life-years lost due to type 2 diabetes were more than a decade when it was diagnosed in adolescence, to around 6 years lost when diagnosed in the 40s, and tapering to no loss of life-years when diagnosed above 80 years or so (Figure 15.13.2.4) [6]. More recently, using only two age groups, a Chinese study suggested a near doubling of risk of non-fatal cardiovascular in those with early (<40 years) versus later onset type 2 diabetes [7], while

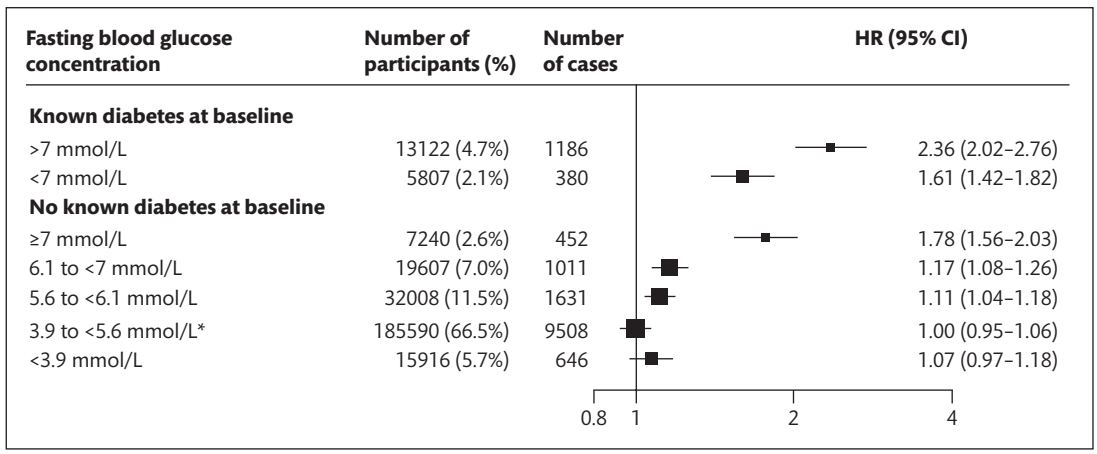

Figure 15.13.2.2 Hazard ratios (HRs) for coronary heart disease by clinically defined categories of baseline fasting blood glucose concentration. Analyses were based on 279 290 participants (14 814 cases). HRs were adjusted as described in Figure 15.13.2.1. HR (95% CI) in people with fasting glucose 5.60–6.99 mmol/L was 1.12 (1.06–1.18). *Reference group.

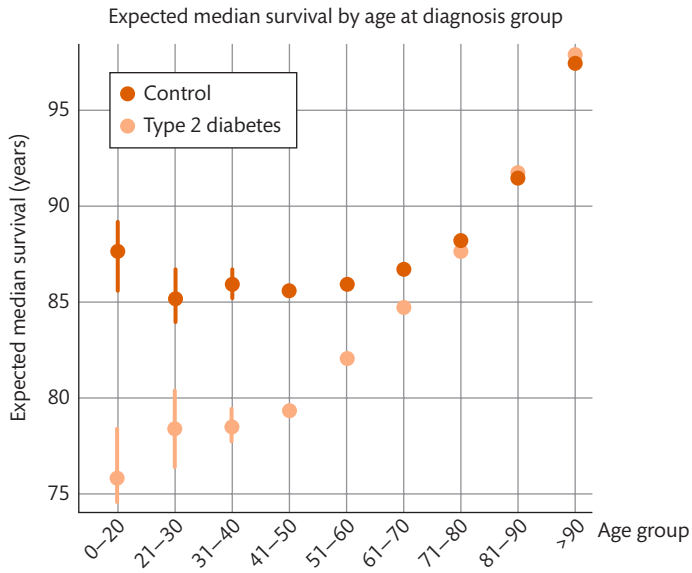

Figure 15.13.2.3 Age at diagnosis of type 2 diabetes mellitus and loss of life-years in persons without previous cardiovascular disease and without any restriction on the duration of type 2 diabetes mellitus.

work from Australia showed higher mortality risk, in particular CVD mortality, in younger onset diabetes patients in a study of just under three-quarters of a million Australians with diabetes [8]. Collectively, these studies support the notion that type 2 diabetes is a more potent driver of CVD risk when it develops at younger ages.

Other research has provided important mechanistic insights into reasons for higher CVD risk at younger age of diabetes onset. In an analysis of just over hundred thousand newly diagnosed patients, individuals with younger onset type 2 diabetes were much more obese and had worse glycaemia and lipid (LDL cholesterol, triglyceride, and high-density lipoprotein (HDL) cholesterol) levels than those developing type 2 diabetes much later in life (Figure 15.13.2.5a–e) [9]. Such differences persisted for several years' post diagnosis and could not be accounted for differential glycaemia or lipid-lowering treatments. There was also evidence from this latter study plus other work from Scotland

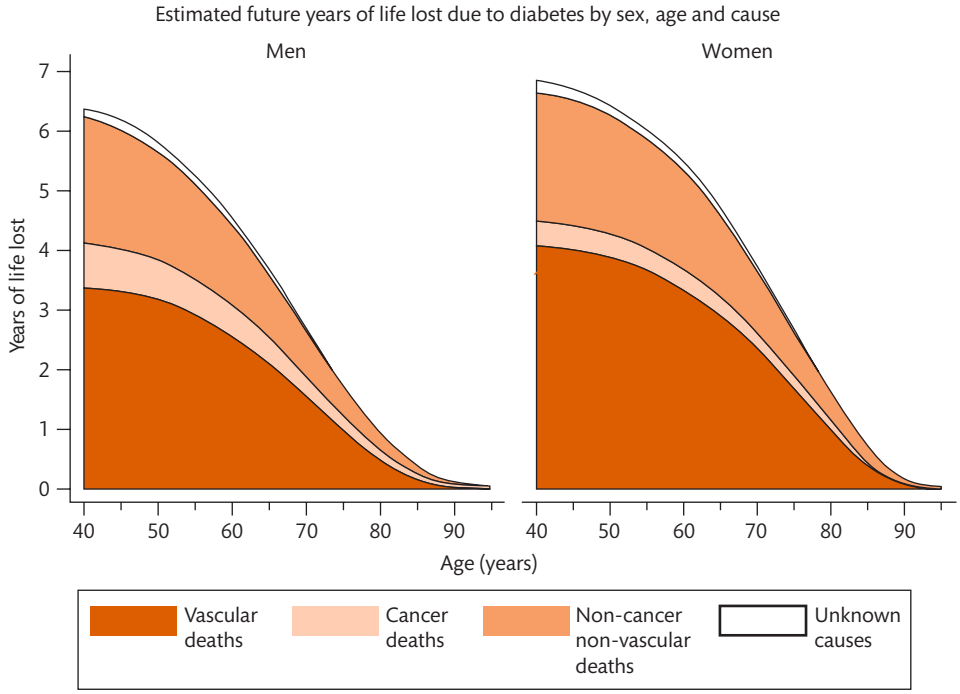

Figure 15.13.2.4 Estimated future years of life lost due to diabetes by sex, age, and cause.

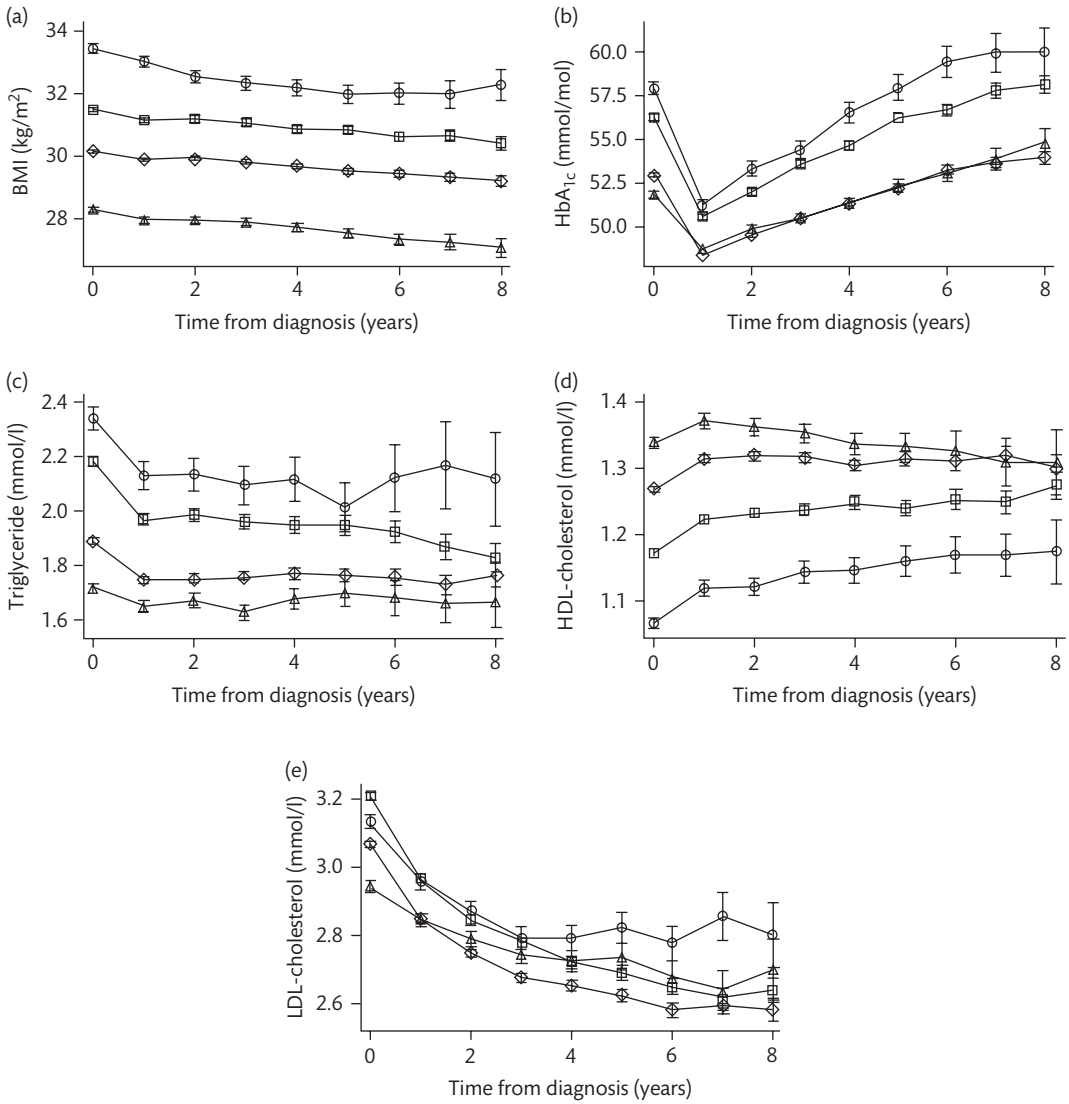

Figure 15.13.2.5 The trajectories of cardiometabolic risk factors over time by age at type 2 diabetes diagnosis. Yearly averages (95% CI) stratified by age group for (a) BMI, (b) HbA1c, (c) triglyceride, (d) HDL cholesterol and (e) LDL cholesterol. White circles, 18–44 years old; plus sign (+), 45–59 years old; crosses (×), 60–74 years old; white triangles, ≥75 years old. All analyses, $p < 0.05$ where 95% CI do not overlap.

for faster glycaemic deterioration in younger type 2 diabetes patients, with HbA1c changes being more modest in those diagnosed with diabetes when older [10]. Indeed, in the latter study, it was noted that 'The rate of deterioration in those diagnosed at over 70 years of age was very low, with 66% having a rate of deterioration of less than 1.1 mmol/mol HbA1c per year, and only 1.5% progressing more rapidly than 4.4 mmol/mol HbA1c per year'. Collectively, these epidemiological findings support age at type 2 diabetes diagnosis as an important stratifier for future CVD and mortality risks. They also suggest that gains from preventative therapies in terms of life-years free from vascular disease will likely be greatest in younger onset type 2 diabetes patients. This is due to the fact that gain in life-years will be greater when treating younger people at elevated risk, than when treating older people who are on average at lower excess risk relative to people without diabetes [11].

Duration

Duration of diabetes is linked to greater CVD risks. In analysis of data from the British Regional Heart Study [12], it was shown that men without prior MI and with diabetes of mean duration 16.7 years had subsequent CHD risks approaching those with prior MI but without diabetes, whereas those with short mean diabetes duration (mean 1.9 years) had much lower risks. One caveat in this type of analysis is that those with longer duration also have earlier onset disease so it is difficult to tease out to what extent duration explains risks with earlier onset disease. Regardless, these findings are understandable if frank hyperglycaemia is causally related to excess CVD risk in a manner consistent with cumulative exposure.

Presence of Microvascular Disease

In a recent report using the UK Clinical Practice Research Datalink [13], it was elegantly demonstrated that the presence of microvascular

complications, whether retinopathy, nephropathy, or neuropathy, signals excess vascular risk perhaps better than differences in usual risk factors (Figure 15.13.2.6). Furthermore, this work demonstrated that if two or three such complications were present then CVD risks were even higher (Figure 15.13.2.6) [13]. This latter observation accords with the notion that small vessel disease begets large vessel disease, perhaps directly by provoking vasculopathy [14]. Of note, several studies have shown that both low eGFR and evidence of proteinuria are very strong prognostic indicators of future CVD risks in diabetes. In a systematic review of event rates from diabetes trials, the presence of proteinuria seemed to be associated with future outcome risks to a similar extent to those with prevalent cardiovascular disease [15].

Of course, microvascular disease is also linked to longer diabetes duration and to cumulative hyperglycaemia exposure as well as other risk factors, in particular hypertension, so that several risk factors can accelerate both small and large vessel disease.

Ethnicity

It is well established that several ethnicities—notably South Asians, Chinese, and Afro-Caribbeans—are at particularly elevated risk for type 2 diabetes even when body mass index (BMI) is taken into account. The reasons for these excess risks are not fully established but could include, among other factors, altered body composition. In terms of cardiovascular risk, historical evidence suggests South Asians with diabetes have even greater risks of premature macrovascular disease, as previously reviewed [16]. More recent evidence suggests such risks may be coming down for immigrant South Asian populations [17], perhaps in part due to earlier diagnosis of diabetes and so earlier and more prolonged exposure to cardiovascular risk factor management. This suggestion remains speculative and more research is needed in this area (see Chapter 15.7.3, 'Type 2 Diabetes in Different Ethnic Groups').

Sex

Plentiful evidence suggests that relative risk of CVD increases more as women transit from non-diabetes to diabetes than as do men, with a recent meta-analysis suggesting that after controlling for major vascular risk factors, diabetes roughly doubles occlusive vascular mortality risk among men while tripling risk among women [18]. However, while relative risks are often greater in women with diabetes, their absolute risks appear similar. In other words, the presence of diabetes appears to narrow or abolish the gap in absolute vascular risks between men and women [18]. Recent work has suggested that the greater excess vascular risk imposed by diabetes in women may be due to women requiring greater weight gain to develop type 2 diabetes than men, since women start from a point of lower risk [19]. This latter observation may explain why risk factor changes (in particular blood pressure) are on average greater in women who develop diabetes than their male counterparts [20]. It also explains why there exists a higher prevalence of diabetes in middle aged men compared to women, a finding which seems true for different ethnicities [21].

Existing Vascular Disease

When diabetes occurs in the context of established vascular disease, then risks for premature mortality are much higher. In an individual participant meta-analysis the presence of diabetes together with premature MI or stroke at the age of 40 years led to a near doubling of life-years lost compared to diabetes alone, whereas when all three conditions coexisted, over 20 years of life were lost (Figure 15.13.2.7) [22]. At older ages, fewer years were lost but even at 65 years of age, having diabetes plus MI or stroke led to loss of nearly 10 years of life compared to 5 years with diabetes alone. These considerations, combined with emerging evidence for significant cardiovascular and total mortality benefits for some newer diabetes drugs [23], mean that it is important to check for occult diabetes in patients with existing vascular disease. Determining HbA1c, which can easily be done at any time of the day or night and is also informative when tested during acute illness, should substantially increase opportunities for diabetes diagnosis in those with existing vascular disease. Relevant guidelines have ratified use of HbA1c in such scenarios [24].

Changes in Cardiovascular and Mortality Risks Over Time in Type 2 Diabetes Relative to the General Population

In high income countries, such as the United States, a pattern of substantially reducing risks for MI and stroke in diabetes patients

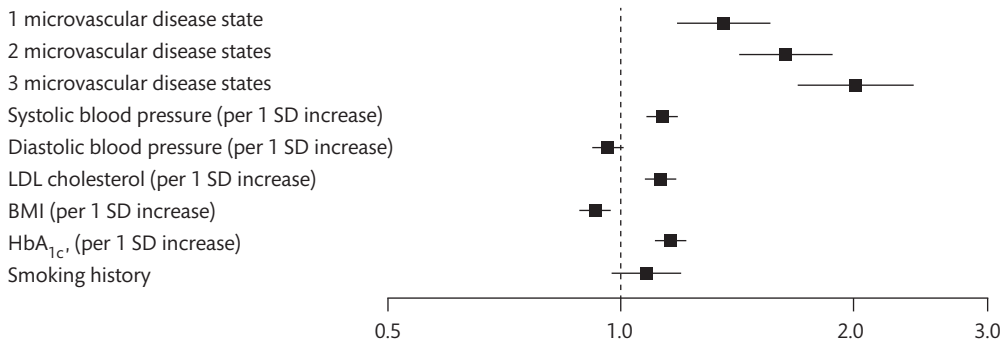

Figure 15.13.2.6 Adjusted hazard ratio for the primary outcome by cumulative burden of microvascular disease and per 1 SD difference in values for established risk factors.* The primary outcome measure was cardiovascular mortality, non-fatal myocardial infarction, or non-fatal ischaemic stroke. 1 SD of each established risk factor is: blood pressure 13.5/8.4 mmHg; LDL cholesterol 0.9 mmol/L; BMI 6.3 kg/m²; HbA1c 1.3% (14.2 mmol/mol).

* Adjusted for age, sex, systolic blood pressure, diastolic blood pressure, LDL cholesterol, HDL cholesterol, HbA1c, BMI, duration of diabetes, smoking status, antiplatelet therapy, lipid-lowering treatment, RAS blockade, other blood pressure treatment, ethnicity, and Index of Multiple Deprivation.

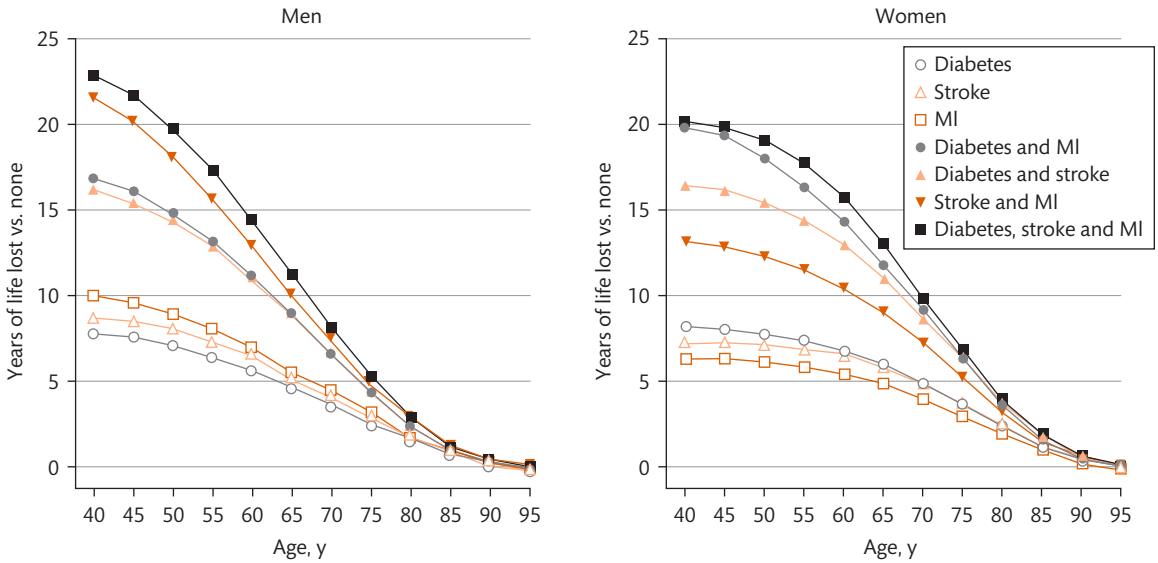

Figure 15.13.2.7 Life-years lost from diabetes, MI, or stroke alone, or in various combinations.

has been noted over the last two or so decades [25], though such risks still remain far in excess of healthy controls (Figure 15.13.2.8a) [26]. Likewise, in recent longitudinal Swedish data covering the period between 1998 and 2013, type 2 diabetes patients experienced greater (44% vs. 29%) relative risk reductions for CVD hospitalizations than did their non-diabetes counterparts (Figure 15.13.2.8b) [27]. However, reduction over time in CVD deaths appeared to be similar so that there was no obvious narrowing in risks in diabetes. Consequently, recent attention has focused more on the excess risk for other 'vascular' outcomes in diabetes such as heart failure and peripheral arterial disease (Figure 15.13.2.9). In a recent analysis of data from the United Kingdom, these latter two outcomes were the most common first 'vascular' outcomes in diabetes patients, with MI and stroke [28] being less frequent. This greater success at preventing non-fatal CVD events in diabetes [27] suggests an incomplete understanding of the causes of excess CVD mortality in type 2 diabetes, an area which requires further research. That noted, as vascular deaths have declined in both individuals with diabetes and in those without known diabetes, the percentage of total deaths in the United States due to vascular causes has declined from around 48% to 34% in diabetes, and 45% to 31% in non-diabetes from 1988 to 2015 [29]. The percentage of deaths due to cancer was stable in both groups so that proportionately more deaths are now due to non-vascular and non-cancer causes [29]. With further dissection of these data by age, it was notable that only people with diabetes of younger onset (<44 years of age) did not experience reductions in mortality, suggesting a need for more particularly assertive risk factor management in this group.

Heart Failure Risks in Type 2 Diabetes

The excess risk for heart failure in diabetes has been known for many years. While this could be due to excess myocardial infarctions, the presence of a specific diabetic cardiomyopathy, linked in part to the altered metabolic milieu in diabetes, has been proposed for many years although its presence remains strongly debated. Recent research has shown that while heart failure risks are elevated in type 2 diabetes at all ages, relative risks are greatest in those with diabetes of earlier onset [30]. Overall, risks for heart failure are around double those in people without diabetes [31]. More recent research suggests a more prominent role for renal disease and obesity in heart failure pathogenesis in diabetes, whereas the usual risk factors—glycaemia, lipids, blood pressure—appear more important for incident myocardial infarction [32]. This finding, together with unexpected results from the EMPAREG outcome trial, where a substantial reduction in mortality and heart failure hospitalizations with treatment with an SGLT2 inhibitor occurred [33], suggests that pathways to heart failure in type 2 diabetes are more complex than previously thought. Perturbation of circulating volume may play a prominent role [34]. Recent thought-provoking reviews [35, 36] have pointed out a need for more attention to be directed at heart failure in future diabetes clinical trials.

Evidence for Better CVD Risk Factor Management in Diabetes

The aforementioned reductions in CVD risk in people with diabetes (greater relative reductions than in general population) and vascular mortality (reductions about the same as in general population) have occurred due to improvements in risk factors. There have been large reductions in cholesterol levels from around the year 2000 in all high income countries as a result of wide prescription of statins, driven by the view enshrined in many guidelines that diabetes confers high CVD risk. For example, Ford and colleagues showed average cholesterol levels in diabetes patients

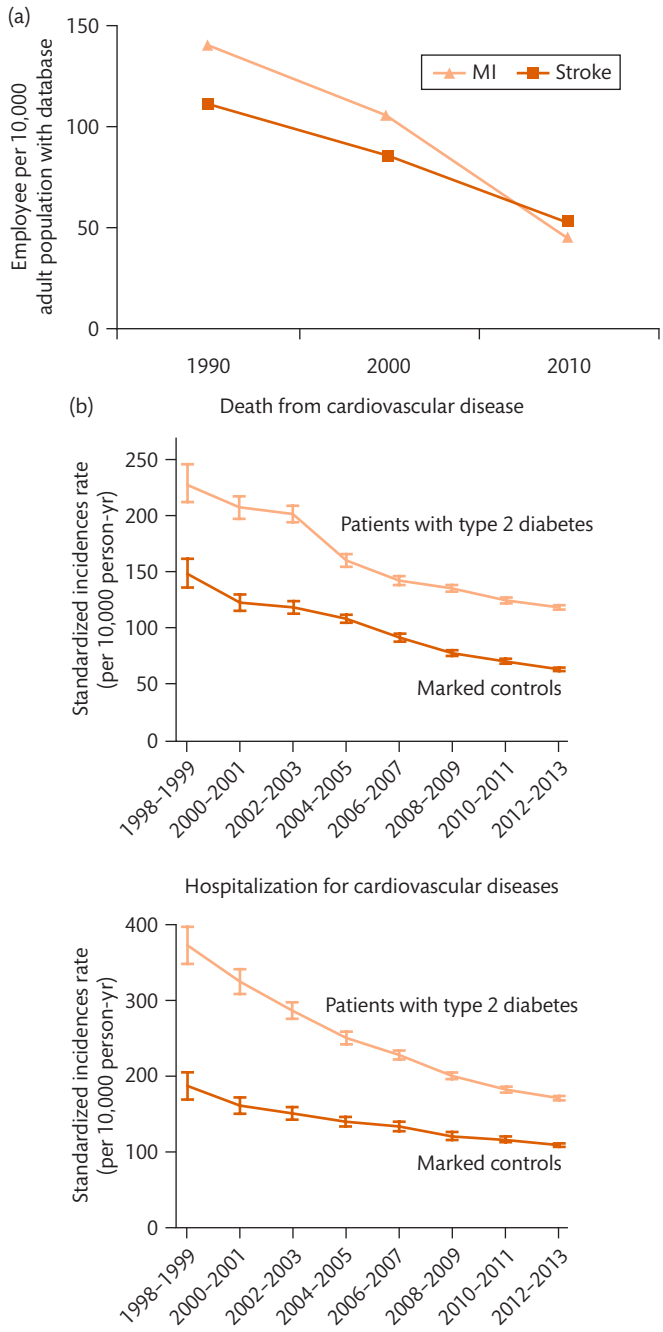

Figure 15.13.2.8 Changes in MI, stroke in United States in diabetes over 1990–2010 and in CVD deaths and CVD hospitalizations in Sweden in diabetes and age and sex-matched controls from 1998 to 2013.

declined from around 5.3 mmol/L in 1999/2000 to 4.6 mmol/L by 2007/8; over the same period smoking rates fell from 20% to 15% and average HbA1c from 7.7% to 7.3% [37]. Large improvements in blood pressure stemmed from 1990s onwards, and the call to even lower targets (to <130 mmHg in many), should continue to push average levels lower whereas glycaemia levels have improved to lesser extents and mostly in the last two decades [26]. Population level reductions in smoking have also contributed to such CVD trends as have earlier diagnosis of diabetes. The relative contribution of such risk factor changes to reductions in CVD outcomes in diabetes have not been formerly calculated but greater short-term outcome benefits have been seen in trials from intensive management of lipids and blood pressure than with intensive glycaemia management [38]. That noted, newer diabetes therapies with proven CVD benefits may start to influence this pattern, even if they may lessen risks partially or largely independent of glucose lowering. Of course, the patterns of risk factor treatments are far from optimal in low and middle income countries where limited resources mean that many patients go without oral antidiabetes drugs, statins, or antihypertensive drugs. This lack of resource explains the persisting very high mortality rates in diabetes in such countries. To reduce CVD risk in diabetes in low- and middle-income countries (LMIC) therefore requires a sustainable supply of cheap statins, antihypertensives and metformin/sulfonylureas. This is by no means an easy task and, as recently reviewed for South Asian countries, many difficult challenges (costs, infrastructure, care processes) need to be overcome/improved to make this happen [39].

Summary

CVD risk in type 2 diabetes has been declining for the last 2–3 decades in high income countries with greater reductions in non-fatal than in fatal outcomes. The main drivers of these improvements are clear: better management of multiple risk factors, including targeting and improvement of glycaemia and LDL cholesterol levels, and blood pressure, as well as a reduction in smoking rates. Better secondary prevention has also played a role. Consequently, patients with type 2 diabetes are living longer than ever, although they continue to suffer an excess (on average double) of cardiovascular risk relative to the general population. Thus, considerable work remains to lower rates further, especially of fatal events. There is also a need to improve prediction and management of other vascular outcomes in diabetes such as heart failure and peripheral arterial disease, which appear now at least as common as incident MI or stroke as vascular outcomes in high income countries. Subgroups of patients have even higher relative risks for CVD outcome dependent on their characteristics such as age of diagnosis (worse in younger), sex (higher relative risks in women, though absolute risks remain lower than in men), ethnicity (most non-whites at higher CVD risks), and presence of coexisting disease. Finally, the greatest future needs for better CVD risk factor management in high income countries is in younger patients, whereas all LMIC patients, require improved and sustainable access to cheap and cost–effective medications across all risk factor domains to lower CVD risks.

15.13.3 Macrovascular Disease in Type 1 Diabetes

John R. Petrie

Introduction

As onset is most common early in life, type 1 diabetes is often thought of as a condition of children and adolescents. However, more than half of those affected are over 40 years of age and the 'typical' person with type 1 diabetes is a middle-aged adult who has had the condition for several decades [1].

'Macrovascular disease' is a collective term for the complications of diabetes as they affect medium or large diameter arteries (>100 μm), predominantly the coronary, cerebral and peripheral (lower limb) arteries. Also known as 'cardiovascular disease', it comprises angina, myocardial infarction, stroke, congestive heart failure, and peripheral artery disease. The glucose-dependent mechanisms and pathways mediating microvascular complications (i.e. retinopathy, nephropathy, and neuropathy) play a key role but additional

inflammatory, lipid, haemodynamic, and other pathways are also implicated.

Pathology and Pathophysiology

By activating enzymes that generate oxidative stress (e.g. by producing superoxide ions), hyperglycaemia initiates several parallel adverse biochemical processes within vascular cells, including activation of the polyol and hexosamine pathways, activation of Protein Kinase C (pro-inflammatory), and formation of advanced glycation end-products (AGEs) [2]. These glucose-mediated mechanisms account for much of the adverse cardiovascular risk in type 1 diabetes [3] but additional immune mechanisms specific to type 1 diabetes may also play a role.

As may also occur in the general population, atherosclerosis in type 1 diabetes is often associated with calcification of the layer of the arterial wall adjacent to the lumen, i.e. the tunica intima. In type 1 diabetes, this may be accompanied by an additional (and independent) process of calcification of the tunica media known as Monckeberg's arteriosclerosis. This is most often seen in the aorta, causing stiffening, elevated systolic BP, and decreased coronary artery perfusion—and in lower limb vessels in association with arterial insufficiency. Its significance is uncertain.

Epidemiology

Since the discovery of insulin a century ago, life expectancy of individuals with type 1 diabetes has dramatically improved, but remains substantially reduced: by 11 years and 13 years for a 20-year-old man and woman, respectively [4]. Metabolic complications (hypoglycaemia, ketoacidosis) and infections (osteomyelitis) are the commonest causes of death in younger individuals, but cardiovascular disease predominates after the age of 40 years [5].

A man in his mid-40s with type 1 diabetes living in Scotland, for example, has an approximately 12% risk of having a cardiovascular event (as defined earlier) over the next ten years, compared with 4% risk in the general population (i.e. a threefold elevation in *relative* risk). For a woman of the same age, the average ten-year risk is 8% compared with 1.6% in the general population (i.e. a fivefold elevation [5]). At younger ages, while the absolute rates are lower, the relative risks are even higher (due to the low risk of the background population). After the menopause, women with type 1 diabetes lose premenopausal protection from cardiovascular disease.

Heart failure is rare in young adults without type 1 diabetes, but recent population-based data from Scotland indicate a fivefold excess risk in men aged 20–29 years (3.6% vs. 0.7% ten-year risk) [6]. There are similar data from Sweden [7–9], where women (but not men) aged 40 years were also shown to have twice the risk of atrial fibrillation compared with the general population [10].

Following a cardiovascular event, outcomes are poorer in type 1 diabetes: for example, in Scotland 30 day mortality in men aged 30–49 years of age after admission to hospital with heart failure is 9.3% compared with 4.4% in the non-diabetic population (i.e. relative risk more than doubled) [6].

Risk Factors and Markers

Glucose: Much of our knowledge about type 1 diabetes comes from the Diabetes Control and Complications Trial (DCCT), a landmark randomized clinical trial initiated in North America in the early 1980s. It compared rates of complications in 1441 children and adolescents with type 1 diabetes on intensive (average HbA1c 7.2%) or conventional (average HbA1c 9.1%) insulin treatment [11]. Follow-up in the study for 6.5 years was insufficient to detect differences in rates of macrovascular complications between groups, but these became evident as participants were followed-up post-randomization in the Epidemiology of Diabetes and its Complications (EDIC study; average HbA1c 8.0% in both groups). In the most recent EDIC study follow-up, 30 years after initial DCCT randomization, there was a 30% reduction in the risk of cardiovascular events in those formerly allocated to intensive insulin therapy: 149 cardiovascular events (in 82 participants) in the intensive arm and 217 cardiovascular events (in 102 participants) in the conventional arm [12].

Other traditional risk factors: In younger individuals with type 1 diabetes the DCCT suggests that blood pressure and cholesterol on average contribute little to overall cardiovascular risk given the dominant effect of blood glucose. However, after the age of 40 years, or 15–20 years from diagnosis for those with earlier onset, blood pressure and cholesterol start to mediate an increasing proportion of the overall risk and require to be targeted directly [13]. In addition, smoking is a powerful risk factor for macrovascular disease in type 1 diabetes, as in the general population, but unfortunately remains prevalent in up to 25% of individuals [5], often receiving insufficient attention.

Microalbuminuria: Much of the excess cardiovascular risk in type 1 diabetes occurs in those who develop renal disease, whether subclinical (microalbuminuria) or clinical (diabetic nephropathy) [13]. Preventing microalbuminuria is an important therapeutic goal, particularly as remission from sustained microalbuminuria to normoalbuminuria in DCCT/EDIC did not lead to a significant improvement in cardiovascular (or renal) outcomes [14].

Novel risk markers: A number of other risk markers are associated with the development of macrovascular complications (e.g. advanced glycation end-products [15], high sensitivity C-reactive protein [16], and haptoglobin genotype [17]). However, these are not routinely measured in clinical practice [18] as risk can be quite accurately predicted by combining traditional risk factors [19].

Assessment

Cardiovascular disease: As in type 2 diabetes and the general population, routine screening for coronary and cerebrovascular disease is not currently undertaken in asymptomatic people with type 1 diabetes, even in those with microalbuminuria [20]. This may seem surprising given a marked elevation of cardiovascular risk. However, while some tests (e.g. measurement of coronary artery calcification by electron beam computed tomography) provide accurate risk stratification, no test has as yet been demonstrated to

have sufficient sensitivity and specificity to guide the planning of cost-effective interventions (i.e. to be suitable for use in widespread screening).

In the absence of screening, presentation with coronary and cerebrovascular disease is thus likely to occur as in the general population, either with the gradual onset of symptoms (angina, breathlessness) or with sudden development of angina, myocardial infarction, congestive heart failure, transient ischaemic attack, or stroke leading to emergency medical assessment. Assessment follows the same pathways as in the general population.

Peripheral vascular disease: In contrast, screening for peripheral arterial disease by palpating the posterior tibial and dorsalis pedis pulses is a routine component of annual foot ulcer risk assessment. Absence of both conveys a significantly higher risk for foot ulceration (and requirement for amputation) in that foot and is associated with a two-year mortality of 14% [21]. There is a further increase in risk if protective sensation (detected by light touch with a 10 g monofilament) is also absent. Individuals with absent foot pulses should be referred to a podiatrist for assessment and ongoing foot care.

Those who also have a history of intermittent claudication and reduced walking distance on direct questioning should be referred to a vascular surgeon for consideration of angiography and/or revascularization. At the time of writing, rates of lower limb amputation vary widely between different areas of the United Kingdom: this is thought to reflect, at least in part, the quality of local foot screening and referral systems [22].

Prevention and Risk Factor Management

Glucose control: Mean glucose concentration (as estimated by HbA1c) is the dominant risk factor for coronary and cerebrovascular disease in type 1 diabetes [3, 13]. Within- and between-day glucose variability predict hypoglycaemia, but do not appear to contribute independently to the risk of long-term complications [23]. For younger individuals, achieving and maintaining target HbA1c while minimizing the risk of hypoglycaemia is therefore the most rational strategy for preventing macrovascular disease.

Doing this in everyday life using multiple daily injections of insulin is challenging, particularly for younger individuals, and HbA1c targets are reached in only a minority [24]. Even in those who do sustain intensive glycaemic control, the cardiovascular benefits can be attenuated or even lost entirely over time by insulin-induced weight gain [25].

Blood pressure and cholesterol: There have been no randomized trials directly addressing management of these risk factors in relation to cardiovascular outcomes specifically in type 1 diabetes. Guidelines therefore draw on epidemiology and studies in type 2 diabetes for selecting therapies, as well as in setting appropriate thresholds and targets for their use (Table 15.13.3.1). In addition, there have been some outcome trials from which people with type 1 diabetes were not excluded (e.g. the Heart Protection Study with simvastatin): this reported a similar point estimate for reduction in risk as in other subgroups, with no evidence of statistical heterogeneity but wide and non-statistically significant confidence intervals for the treatment effect [26].

Smoking: There are few trials from which the benefits of smoking cessation in type 1 diabetes can be directly estimated, or indeed to guide how it can best be achieved and maintained. However, its likely benefits if achieved seem self-evident.

Antiplatelet therapy: Low dose aspirin was widely prescribed for primary prevention of cardiovascular disease for asymptomatic people with types 1 and 2 diabetes until publication of the Prevention Of Progression of Arterial Disease And Diabetes (POPADAD) trial in 2008 [27]. As there was no evidence of benefit over seven years, this practice was removed from guidelines. However, as the trial was not large enough to exclude a small benefit, the larger ASCEND study was undertaken with 12 times the number of participants, 6% of whom had type 1 diabetes. The results, published in 2018, showed a lower absolute rate of cardiovascular events with aspirin than with placebo (8.5% vs. 9.6%, $P = 0.01$) over 7.4 years but this was outweighed by an increased risk of major bleeding (4.1% vs. 3.2%, $P = 0.003$), supporting existing guidelines [28].

Given these uncertainties (Table 15.13.3.1), further clinical trials aimed specifically at optimizing cardiovascular prevention in type 1 diabetes are urgently required.

Treatment

At coronary angiography, people with type 1 diabetes are more likely to have diffuse disease affecting several rather than single arteries: in general, outcomes are better with coronary artery bypass grafting than with stenting individual vessels [29], but technology is developing rapidly and decision-making must be made on an individual basis.

Table 15.13.3.1 Risk factor management in type 1 diabetes: targets for primary prevention in adults

Risk factor	Test	Target	Evidence base	Notes
Glucose	HbA1c	≤7.0% (53 mmol/mol)	High level: DCCT and EDIC [3, 11]	
Lipids	LDL cholesterol	<2.6 mmol/L (<100 mg/dl)	Mainly extrapolation from type 2 diabetes [20]	Lifestyle measures plus statins*
Blood pressure	Semi-automated sphygmomanometer (clinic reading)	<130/ 80 mmHg [20]	Absence of high quality data [34]	Lifestyle measures plus ACE inhibitor or ARB as first line*

* in women at risk of pregnancy ensure adequate contraceptive measures in place.

Abbreviations: HbA1c, glycated haemoglobin; LDL, low density lipoprotein; ACE, angiotensin converting enzyme; ARB, angiotensin receptor blocker.

Future Perspectives

One approach to reducing rates of cardiovascular events in type 1 diabetes is 'adjunct therapy' (i.e. adding in non-insulin treatments that have been shown to be of benefit in type 2 diabetes). The REMOVAL trial recently showed over three years in 428 middle-aged people with type 1 diabetes that metformin decreases weight and LDL cholesterol and may reduce the rate of progression of carotid atherosclerosis [30]. Other candidate agents that require further testing in type 1 diabetes include glucagon-like peptide-1 agonists and sodium glucose transporter-2 inhibitors, ideally using cardiovascular outcomes rather than surrogate endpoints. Wider use of PCSK9 inhibitors in those who do not achieve lipid targets with statins may also be of benefit [31].

Increasing use of technology is another strategy that provides hope for improved cardiovascular outcomes in type 1 diabetes: lower rates of cardiovascular mortality have been observed in association with continuous subcutaneous insulin infusion (CSII, 'insulin pump') use in Sweden [32]. Increasing combination of this method of insulin delivery with continuous glucose monitoring systems, moving towards 'closed-loop' systems ('the artificial pancreas'), is likely to allow more individuals with type 1 diabetes to achieve target glycaemia, while avoiding hypoglycaemia and weight gain.

There have been attempts to design specific therapies to disrupt the downstream intracellular pathways activated by glucose (e.g. alagebrium, an 'AGE-breaker'), but these have so far shown either toxicity or insufficient efficacy, perhaps because glucose can cause vascular damage by multiple biochemical pathways [33].

Conclusion

Macrovascular (cardiovascular) disease decreases life expectancy by more than 10 years on average in type 1 diabetes. Current care focuses on its prevention via glucose control and avoidance of cigarette smoking, combined with controlling blood pressure and cholesterol with longer disease duration. However, this strategy is difficult to implement for many individuals and new approaches are urgently required to reduce macrovascular complications and bring life expectancy in line with the non-diabetic population.

15.13.4 Diabetic Dyslipidaemia

Bruno Vergès

Introduction

Diabetic dyslipidaemia, which encompasses abnormalities in all lipoproteins, is a major contributor to the increased cardiovascular risk associated with type 2 diabetes (T2DM). In this chapter, the pathophysiology of diabetic dyslipidaemia in T2DM, its relationship with cardiovascular disease and its diagnosis and management will be discussed. At the end of this chapter, the main features of the diabetic dyslipidaemia observed in type 1 diabetes (T1DM) will be considered.

Diabetic Dyslipidaemia in T2DM

Pathophysiology of Diabetic Dyslipidaemia

Lipid abnormalities in T2DM are not only quantitative, but also qualitative and kinetic in nature [1]. Increased triglycerides and reduced HDL cholesterol are the main quantitative abnormalities whereas qualitative and kinetic abnormalities are observed for all lipoproteins (Table 15.13.4.1).

Many of the lipid abnormalities observed in patients with T2DM precede the onset of diabetes, and form an important part of the 'insulin resistance' or 'metabolic' syndrome [2]. This emphasizes the important role of insulin resistance in the pathophysiology of diabetic dyslipidaemia. Insulin is a key hormone in the regulation of lipid metabolism, exerting a major influence on several different tissues which collectively regulate lipid metabolism. For example, insulin inhibits hormone-sensitive lipase in adipose tissue, suppressing release and hepatic delivery of free fatty acids, and also inhibits hepatic VLDL production, both directly and indirectly via alteration of substrate flux. It also activates lipoprotein lipase (LPL), responsible for triglyceride catabolism and free fatty acid trapping in tissues, and increases the expression of LDL receptor and LRP (LDL receptor-related protein), responsible for hepatic uptake of chylomicron-remnants. The main lipid abnormalities in T2DM are shown in Figure 15.13.4.1.

Patients with T2DM show postprandial hyperlipidaemia, which is a pro-atherogenic phenomenon. This is due both to increased production and delayed catabolism of chylomicrons. Insulin resistance is likely to be involved in the increased chylomicron production, since the normal acute suppression of postprandial chylomicron secretion by insulin is absent in patients with T2DM [3]. The delayed catabolism of chylomicrons is attributable to decreased activity of LPL, the enzyme responsible for chylomicron hydrolysis, to increased plasma levels of ApoC-III, an inhibitor of

Table 15.13.4.1 Key changes of lipoproteins in type 2 diabetes

Lipoprotein	Quantitative changes in plasma concentration	Qualitative changes	Kinetic/metabolic changes
Chylomicron	Increased	• Very few data (decreased ApoE content in diabetic rabbits)	• Increased production • Decreased catabolism
VLDL	Increased	• Greater proportion of larger particles ($VLDL_1$) • Increased palmitic acid-containing species and diacylglycerol, reduced sphingomyelin • Glycation	• Increased production • Decreased catabolism
LDL	No change or slightly increased	• Greater proportion of small dense particles (triglyceride enrichment) • Increased LDL oxidation • Increased palmitic acid-containing species and diacylglycerol, reduced sphingomyelin • Glycation	• Decreased catabolism
HDL	Decreased	• Triglyceride enrichment • Increased palmitic acid-containing species and diacylglycerol, reduced sphingomyelin • Glycation • ↘ vasorelaxant effect • ↘ antioxidative effect	• Increased catabolism

Apo: apolipoprotein; VLDL: Very Low-Density Lipoprotein; LDL: Low-Density Lipoprotein; HDL: High-Density Lipoprotein.

LPL, and potentially to reduced expression of LRP, the receptor for chylomicron-remnants.

Fasting hypertriglyceridemia in T2DM is largely due to an increased number of VLDLs, particularly large $VLDL_1$ particles [4]. Both increased production and delayed catabolism of VLDL are responsible for the increased VLDL pool. Increased production of $VLDL_1$ has been shown to be correlated with indices of insulin resistance [1]. Several mechanisms are responsible for the increased production of $VLDL_1$. First, insulin resistance is associated with reduced inhibition of the hormone-sensitive lipase by insulin in adipose tissue, leading to increased lipolysis and thus augmented delivery of free fatty acids to the liver, which stimulates synthesis

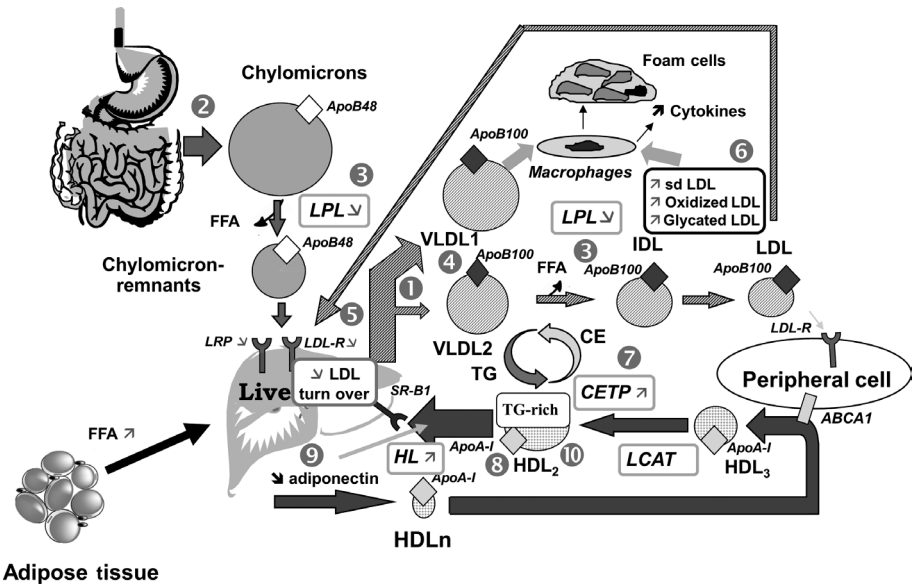

Figure 15.13.4.1 Main lipid abnormalities in type 2 diabetes. Triglycerides (hypertriglyceridemia, qualitative and kinetic abnormalities): ❶ increased VLDL production (mostly $VLDL_1$), ❷ increased chylomicron production, ❸ reduced catabolism of both chylomicrons and VLDLs (diminished LPL activity), ❹ increased production of large VLDL ($VLDL_1$), preferentially taken up by macrophages; **LDL** (qualitative and kinetic abnormalities): ❺ reduced LDL turnover (decreased LDL receptor), ❻ increased number of glycated LDLs, small dense LDLs (TG-rich) and oxidized LDLs, which are preferentially taken up by macrophages; **HDL** (low HDL cholesterol, qualitative and kinetic abnormalities): ❼ increased CETP activity (increased transfer of triglycerides from TG-rich lipoproteins to LDLs and HDLs), ❽ increased TG content of HDLs, promoting HL activity and HDL catabolism, ❾ low plasma adiponectin favouring the increase in HDL catabolism, ❿ Dysfunctional HDLs. Apo: apolipoprotein; FFA: free fatty acid; VLDL: very low-density lipoprotein; IDL: intermediate-density lipoprotein; LDL: low-density lipoprotein; sd LDL: small, dense LDL; HDL: high-density lipoprotein; HDL_n: nascent HDL; TG: triglyceride; CE: cholesterol esters; LDL-R: LDL receptor; LRP: LDL receptor-related protein; ABCA1: ATP-binding cassette A1 transporter; SR-B1: scavenger receptor B1; HSL: hormone-sensitive lipase; LPL: lipoprotein lipase; HL: hepatic lipase; CETP: cholesteryl ester transfer protein; LCAT: lecithin-cholesterol acyl transferase.

of triglycerides in hepatocytes. Second, the normal suppressant effect of insulin on VLDL (and more precisely $VLDL_1$) production is blunted due to hepatic insulin resistance [1]. Third, de novo lipogenesis is increased in individuals with insulin resistance [5]. Delayed catabolism of VLDL in diabetic dyslipidaemia is due to reduced activity of LPL secondary to insulin resistance and/or 'relative' insulin deficiency. Increased plasma levels of ApoC-III could also contribute to the decreased catabolism of VLDL in T2DM patients.

VLDLs from patients with T2DM also show qualitative abnormalities that are potentially atherogenic. Indeed, there is an increase in large $VLDL_1$ particles, enriched with cholesterol esters and phospholipids, which are preferentially taken up by macrophages, leading to the formation of foam cells in vessel walls and the production of pro-inflammatory cytokines. VLDLs from patients with T2DM have increased diacylglycerol content and reduced sphingomyelin, along with increased palmitic acid-containing species. In addition, glycation of apolipoproteins in VLDL (ApoB, ApoCs, ApoE) in poorly controlled diabetes may be detrimental [1].

Although plasma LDL cholesterol is usually normal in patients with T2DM, LDL metabolism is significantly modified, with a substantial reduction of its catabolism observed in parallel with a reduction of its production, secondary to diminution of LDL-receptors. This extends the lifespan of LDL in the plasma and may promote lipid deposition in artery walls. LDLs from patients with T2DM also show important qualitative abnormalities. Small, dense, triglyceride-rich LDL particles are more prevalent in T2DM as a direct consequence of hypertriglyceridemia and increased cholesteryl ester transfer protein (CETP) activity. Furthermore, an increased number of oxidized and glycated LDLs is also observed. Small dense LDLs, oxidized and glycated LDLs are pro-atherogenic since they induce the production of pro-inflammatory cytokines and adhesion molecules. They are preferentially taken up by macrophages, leading to the formation of foam cells. Moreover, LDLs from patients with T2DM have increased diacylglycerol content and reduced sphingomyelin, along with increased palmitic acid-containing species.

The decrease in HDL cholesterol in patients with T2DM is due to increased catabolism of HDLs. Hypertriglyceridemia, or more precisely the increased $VLDL_1$ pool, is an important factor responsible for accelerated HDL catabolism [1, 6]. Indeed, hypertriglyceridemia, observed in T2DM, promotes CETP-mediated triglyceride enrichment of HDL particles and, as a consequence, enhances HDL catabolism, because HDL-rich particles are very good substrates for hepatic lipase, the enzyme responsible for HDL catabolism. The reduction in plasma adiponectin levels often observed in individuals with insulin resistance and T2DM may also be directly involved in the accelerated HDL catabolism [7]. As for other lipoproteins, several qualitative abnormalities of HDL are observed in T2DM, including increased glycation of apoA-I, increased diacylglycerol content and reduced sphingomyelin, and an increased complement of palmitic acid-containing species. HDLs from patients with T2DM are known to be dysfunctional, with reduced capacity to stimulate *ex vivo* cholesterol efflux from cells, and reduced antioxidative and vasorelaxant properties [1].

Diabetic Dyslipidaemia and Cardiovascular Disease

Similarly to what is observed in the general population, elevated LDL cholesterol is a risk factor for cardiovascular disease (CVD) in T2DM, as shown in the United Kingdom Prospective Diabetes Study (UKPDS), the Strong Heart Study or a large Finnish epidemiological study [8–10]. Hypertriglyceridemia has been suggested to be an independent risk factor for CVD in T2DM in the WHO study, the Paris prospective study and the Schwabing study [11–13], while HDL cholesterol has been found to be inversely associated with CVD in patients with T2DM in the UKPDS, and the Strong Heart Study [8, 9]. In the Finnish epidemiological study and the long-term follow-up of the Strong Heart Study, coupling of hypertriglyceridemia and low HDL cholesterol was an independent risk factor for CVD [10, 14]. Collectively these findings suggest that hypertriglyceridemia and low HDL cholesterol, the main quantitative lipid abnormalities in T2DM, are likely to be *bona fide* risk factors for CVD (Table 15.13.4.2).

Many *in vitro* and *ex vivo* data argue that the qualitative lipoprotein abnormalities of diabetic dyslipidaemia are likely to be atherogenic, as just discussed. However, the direct association between these abnormalities and CVD has not been extensively studied. Although some epidemiological studies have shown that high concentrations of small dense LDL particles are an independent factor for CVD in large unselected populations, the question of a direct role of small dense LDL particles in development of CVD among patients with T2DM remains to be answered. Similarly, the direct role of other qualitative abnormalities such as increased levels of oxidized LDL, glycation of apolipoproteins or dysfunctional HDLs in the increased CVD risk in T2DM remains to be fully assessed.

Diagnosis of Diabetic Dyslipidaemia

Diagnosis of diabetic dyslipidaemia is based on quantitative lipid abnormalities, being made based on the presence of triglycerides ≥150 mg/dl (1.7 mmol/L) and/or HDL cholesterol <40 mg/dl (1.03 mmol/L) in men or <50 mg/dl (1.29 mmol/L) in women. However, vigilance is required, as not all lipid disorders observed in

Table 15.13.4.2 Independent association between plasma lipids and CVD risk in patients with type 2 diabetes. Data from epidemiological studies. CVD, cardiovascular disease.

LDL cholesterol	**Positive** independent association with CVD risk: • UKPDS [16] • Strong Heart Study [17] • Finnish epidemiological study [18]
HDL cholesterol	**Negative** independent association with CVD risk: • UKPDS [16] • Strong Heart Study [17] • Finnish epidemiological study [18], in association with triglycerides • Long-term follow-up of the Strong Heart Study [19], in association with triglycerides
Triglycerides	**Positive** independent association with CVD risk: • WHO study [20] • Paris Prospective study [21] • Schwabing study [22] • Finnish epidemiological study [18], in association with low HDL cholesterol • Long-term follow-up of the Strong Heart Study [19] in association with low HDL cholesterol

patients with T2DM are related to diabetic dyslipidaemia. Indeed, in situations with very high triglycerides (>500 mg/dl or 5.6 mmol/L), lipodystrophy or a primary hypertriglyceridemia associated with diabetes should be considered. If a significant elevation of plasma LDL-cholesterol is observed in a patient with T2DM, then a diagnosis of coincidental familial hypercholesterolemia must be considered.

Management of Diabetic Dyslipidaemia

Lifestyle modification focusing on weight loss (if indicated), dietary alterations including reduction of saturated fat and transfat, and increase of n-3 fatty acids and viscous fibre, and increased physical activity are recommended to improve the lipid profile in patients with diabetes. Improvement of glycaemic control is likely to reduce hypertriglyceridemia but will not, alone, normalize the lipid profile.

The clear cardiovascular benefit of LDL cholesterol reduction with statins in patients with diabetes has been shown in several prospective controlled trials [15]. In the Heart Protection Study (HPS), in the subgroup of 5963 patients with diabetes (mainly type 2), treatment with simvastatin reduced by 22% the risk for major CV events (P <0.0001) and by 26% the risk for major coronary events (P <0.0001). There was also a highly significant 33% reduction of major CV events (P <0.0001) among the 2912 diabetic patients without history of CVD. The primary prevention Collaborative Atorvastatin Diabetes Study (CARDS), which was undertaken in 2838 patients with T2DM, showed that treatment with atorvastatin 10 mg daily for 3.9 years induced a 37% reduction of major CV events (P = 0.001). In the Treating to New Targets (TNT) study, which compared the efficacy of atorvastatin 80 mg daily versus 10 mg daily, a significant 25% reduction of major CV events (P = 0.026) was observed with the highest atorvastatin dose in the subgroup of 1501 diabetic patients.

Data from all clinical trials indicate that the CV benefit obtained by LDL cholesterol reduction with a statin is similar in patients with diabetes and in non-diabetic individuals. The clear CV benefit of statin treatment in patients with diabetes has been confirmed in several meta-analyses. Indeed, data from a meta-analysis of 12 randomized prospective studies indicate that, in patients with diabetes, a significant 21% reduction of major CV event and a 19% reduction of CV mortality is observed for each 1 mmol/L (39 mg/dl) decrease in LDL cholesterol [8]. The Cholesterol Treatment Trialists' Collaborators meta-analysis, performed from 14 randomized prospective studies, which includes 17 220 patients with T2DM, shows a significant 21% reduction of major CV event for each 1 mmol/L (39 mg/dl) decrease in LDL cholesterol [9].

Because of the clear cardiovascular benefit of LDL cholesterol reduction in patients with T2DM, the use of statins is widely recommended in guidelines. In the 2016 European Guidelines on CVD prevention, lipid lowering agents (principally statins) are recommended in all patients with diabetes above the age of 40 years, since most diabetic patients are at high risk [10]. In diabetic patients with high-risk, LDL cholesterol target <2.6 mmol/L (<100 mg/dl) or a reduction of at least 50% if the baseline LDL cholesterol is between 2.6 and 5.1 mmol/L (100 and 200 mg/dl) is recommended. In diabetic patients at very high-risk (secondary prevention, target organ damage, severe kidney disease with GFR<30 ml/min or a calculated SCORE ≥10%), an LDL cholesterol target <1.8 mmol/L (<70 mg/dl), or a reduction of at least 50% if the baseline LDL cholesterol is between 1.8 and 3.5 mmol/L (70 and 135 mg/dl), is recommended [10]. American Diabetes Association (ADA) standards of care recommend moderate-intensity statins for all T2DM patients over the age of 40 years and in patients less than 40 years with additional CV risk factors [11]. For patients of all ages with diabetes and CVD, high-intensity statin therapy is recommended by the ADA [11]. If the LDL-target is not obtained with the optimal dose of statin, additional treatment with ezetimibe or PCSK9 inhibitor may be needed.

Post-hoc analyses of the FIELD and ACCORD-Lipid trials have shown a significant reduction of major cardiovascular events with fenofibrate in individuals with elevated triglycerides and low HDL cholesterol. This was confirmed in a meta-analysis demonstrating a 35% reduction for the risk of major cardiovascular events with fibrates in this specific population [12]. This is the reason why some recent guidelines suggest considering adding fenofibrate to a statin in high CV risk patients featuring fasting triglyceride levels ≥2.26 mmol/L (200 mg/dl) and low HDL cholesterol levels [13]. For patients with fasting triglycerides above 5.7 mmol/L (500 mg/dl), it is recommended to look for secondary or primary hypertriglyceridemia and to consider fibrate treatment to reduce the risk of pancreatitis [11, 13].

Diabetic Dyslipidaemia in T1DM

Type 1 diabetic patients with good glycaemic control and without nephropathy do not show quantitative lipid disorders. Plasma triglyceride and LDL cholesterol levels are normal or slightly reduced and HDL cholesterol level is normal or slightly increased. However, several qualitative and potentially atherogenic abnormalities of lipoproteins are observed in patients with T1DM, even in those with good metabolic control. These include increased cholesterol/triglyceride ratio within VLDLs, increased triglyceride content of LDLs and HDLs, augmented oxidation of LDLs, increased small dense LDL particles and reduced ceramides and sphingosine-1-phosphate in HDLs [14]. In the context of hyperglycaemia, glycation of apolipoproteins may occur. All these qualitative changes of lipoproteins are likely to impair their function. HDLs from type 1 diabetic patients show reduced antioxidative and vasorelaxant properties. The reasons for these qualitative abnormalities are not clear. However, some are due to increased CETP activity promoted by peripheral hyperinsulinemia secondary to the subcutaneous route of insulin administration [14].

The cardiovascular benefit of LDL cholesterol reduction with statins is similar in T1DM and T2DM (10). ADA standards of care recommend statin therapy for all T1DM patients over the age of 40 years and in those less than 40 years with additional CV risk factors [11].

For the Future: Questions and Perspectives

Many questions about diabetic dyslipidaemia remain unanswered. These relate to the pathophysiology and the cardiovascular consequences of the qualitative lipid abnormalities, the mechanisms and signalling pathways linking insulin resistance to lipid abnormalities, and the role played by adipose tissue dysfunction and adipocytokines. Additional studies focusing on these areas will be

required to improve our understanding of lipid disorders associated with type 2 diabetes, and these should lead to new specific therapeutic targets.

In the clinical trial arena, the important question of the ability of fibrate to reduce CVD in high-risk diabetic patients with triglycerides ≥2.26 mmol/L (200 mg/dl) and HDL cholesterol ≤1.03 mmol/L (40 mg/dl) will be assessed by the ongoing PROMINENT trial, which is assessing pemafibrate in addition to high-dose statins.

15.13.5 Hypertension in Diabetes Mellitus

Bryan Williams

Epidemiology and Pathophysiology of Hypertension in Diabetes

Hypertension is very common in people with diabetes. There is moreover an association between hypertension and diabetes that tracks through life, while the blood glucose concentration of young non-diabetic individuals has been shown to predict risk of future

hypertension. Conversely, people with hypertension are twice as likely to develop type 2 diabetes over their lifetime.

In younger people with type 1 diabetes, the excess prevalence of hypertension compared to the non-diabetic population is closely associated with the development of albuminuria. Blood pressure rises by about 2–4 mmHg per year following the onset of microalbuminuria, tracking the increase in urinary albumin excretion. Thus, by the time overt proteinuria is established, hypertension is nearly inevitable.

The situation is different in people with type 2 diabetes, who tend to be older. Hypertension—defined by blood pressures above the arbitrary cut-off of 140/90 mmHg for clinic/office measurements—is at least twice as common as in the age-matched non-diabetic population, affecting approximately 80% of people with type 2 diabetes. It is also important to note that the pathophysiology and characteristics of hypertension are different in people with type 2 diabetes. Although the development of microalbuminuria also heralds the onset of hypertension, by far the commonest cause is an acceleration of the vascular and renal ageing process. Mechanisms include stiffening of large conduit arteries, such as the aorta, principally due to advanced glycation of vascular wall collagen and a reduction in endothelium-dependent vasorelaxation. This reduction in vascular compliance results in a widening of pulse pressure and acceleration of the age-related rise in systolic blood pressure, accompanied by a corresponding fall in diastolic blood pressure. This means that many people with type 2 diabetes develop systolic hypertension at least 10 years earlier than the general population.

Arterial stiffening is important because it renders the systolic blood pressure more resistant to treatment. The vascular changes are compounded by accelerated loss of glomerular filtration rate (GFR) and a shift in the pressure—natriuresis curve to the right. That is, higher pressures are required to generate any given level of natriuresis. Alongside these changes, there is often inappropriate activity of the renin–angiotensin system (RAS) and enhanced renal sympathetic tone, which promote sodium retention. Moreover, the insulin resistance that characterizes type 2 diabetes (and common in people with hypertension) does not extend to insulin's action on the renal tubule, so hyperinsulinaemia promotes further sodium retention. Together, these mechanisms conspire to produce an exquisitely salt-sensitive state. A vicious circle is created whereby volume expansion is poorly accommodated by the reduced vascular compliance, culminating in hypertension (Figure 15.13.5.1). Although separated for the purposes of this discussion, younger people with type 1 diabetes, even if they do not develop nephropathy, ultimately develop the same high risk of hypertension with ageing due to the mechanisms discussed for type 2 diabetes.

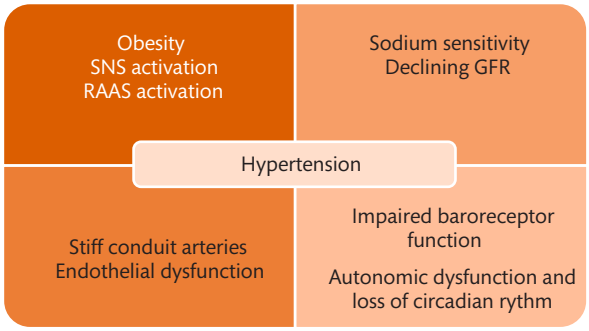

Figure 15.13.5.1 Mechanisms contributing to the pathogenesis of hypertension in people with diabetes. SNS, sympathetic nervous system; RAAS, renin–angiotensin–aldosterone system.

Vulnerability to Hypertensive Complications in Diabetes

Not only is hypertension remarkably common in people with diabetes, but there is also enhanced vulnerability to its cardiovascular and microcirculatory system sequelae [1]. There are two important reasons why people with diabetes are especially vulnerable to pressure-mediated macrovascular and microvascular damage:

1. Soon after onset of diabetes, subtle autonomic dysfunction develops in the majority of people with diabetes, disturbing the circadian rhythm of blood pressure regulation. In particular, there is a blunting of the usual nocturnal dip in blood pressure during sleep. This means that, for any given level of clinic blood pressure, people with type diabetes invariably have an increase in their 24-h blood pressure 'load'. Importantly, this means that 24-h blood pressure load is a more accurate predictor of structural damage to the heart and circulation than measurements in clinic. This explains why the magnitude of left ventricular mass and carotid intima-media thickness often appear disproportionate to clinic blood pressure levels.
2. To compound matters, blood flow autoregulation is impaired in people with diabetes. This means that any increase in circulatory pressure is more readily transferred to the delicate microcirculation, thereby explaining in large part the development of sometimes devastating microvascular disease (Figure 15.13.5.2).

This vulnerability is captured by the European Systematic COronary Risk Evaluation (SCORE) system which classifies the large majority of patients with diabetes and hypertension as being at very high (evidence of organ damage) or high risk of

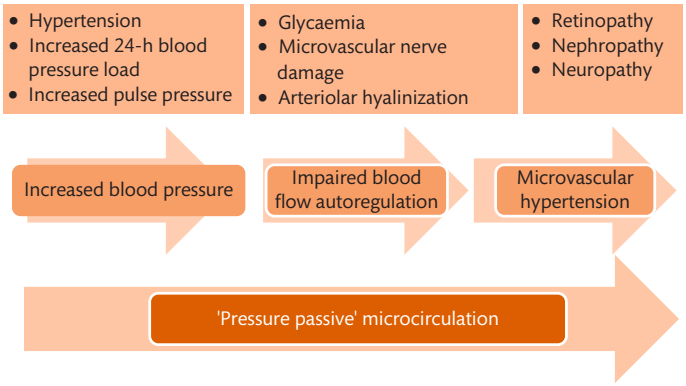

Figure 15.13.5.2 The special vulnerability of the microcirculation to hypertensive injury in people with diabetes. This arises from impairment of blood flow autoregulation, leading to increased pressure transmission to the microcirculation. This results in higher microvascular pressures than would otherwise be encountered for the level of systemic blood pressure, culminating in microvascular injury. Glycaemia is a major factor associated with blunting of autoregulation, compounded by microvascular denervation and poor responsiveness of hyalinized arterioles.

a fatal atherosclerotic event over 10 years [2]. Younger patients with diabetes, or those with no other risk factors may be at moderate risk only. Detection and treatment of hypertension in people with diabetes is thus critical in protection of both the macro- and microvasculature. The combination of increased blood pressure load and impaired microcirculatory defences have also provided the rational for advocating more aggressive blood pressure lowering.

Benefits of Blood Pressure Lowering in People with Diabetes

In patients with type 2 diabetes, there is a continuous relationship between systolic blood pressure and the risk of cardiac, microvascular, and all diabetes-related endpoints (Figure 15.13.5.3). The Framingham cohort study established that the presence of diabetes at least doubles the risk of all cardiovascular events relative to the non-diabetic population with the same levels of blood pressure [3], while the lower cardiovascular risk experienced by premenopausal women appeared to be eliminated by the presence of diabetes.

Since this link between cardiovascular risk and diabetes has been established, numerous randomized clinical trials and meta-analyses have demonstrated that blood pressure lowering reduces the risk of cardiovascular disease, microvascular disease, and premature mortality in people with diabetes. The United Kingdom Prospective Diabetes Study (UKPDS) first illustrated the magnitude of benefit associated with 'more' versus 'less' blood pressure control [4]. A difference in blood pressure achieved in that study of approximately 10/5 mmHg was associated with a reduction in diabetes-related endpoints by a quarter, reductions in death related to diabetes by almost a third, a reduction in stroke by almost half and in heart failure by more than half. Moreover, microvascular disease was reduced by about a third (mainly accounted for by delayed progression of retinopathy). The 'number needed to treat' to prevent one major complication over 10 years was only 6 patients, and to prevent a diabetes-related death was only 15 patients. Subsequent studies have confirmed the impact of blood pressure lowering on major clinical outcomes.

A feature of clinical outcome trials of blood pressure-lowering therapy in people with diabetes is that the treatment benefit is usually greater than anticipated from the epidemiological association between blood pressure and risk. This perhaps reflects the aforementioned enhanced vulnerability of patients with diabetes to pressure-mediated cardiovascular and microvascular disease.

The potency of blood pressure lowering as a strategy to reduce the cardiovascular risk of people with diabetes highlights the importance of early intervention to prevent the evolution of disease. The importance of primary prevention of cardiovascular disease in people with diabetes is underscored by the observation that when people with type 2 diabetes develop coronary heart disease, heart failure, or stroke, their prognosis was worse than that of the non-diabetic population.

Evaluation of Hypertension in People with Diabetes

The aims of evaluation of any patient with hypertension are:

- to establish whether blood pressure is elevated, and, if so, to determine the magnitude of the elevation;
- to determine the presence of any associated target organ damage. This may be manifest as established cardiovascular complications (e.g. ischaemic heart disease, cerebrovascular disease, cardiac

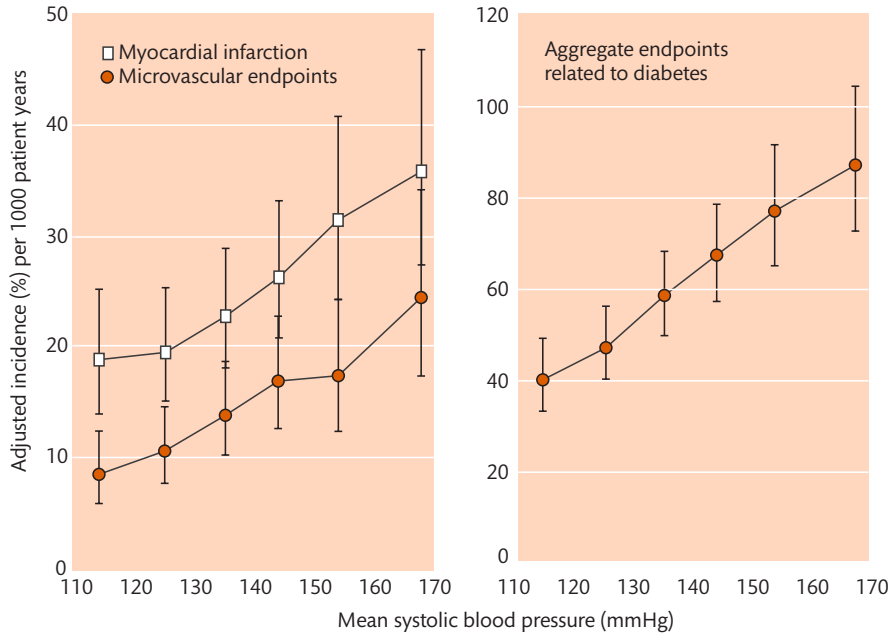

Figure 15.13.5.3 Incidence rates (95% CI) of various endpoints by category of updated mean systolic blood pressure adjusted for age, gender, ethnicity, smoking history, lipid levels, and albuminuria, expressed for white men aged 50–54 at diagnosis of diabetes and a mean duration of diabetes of 10 years in the UKPDS.

failure, peripheral vascular disease) or be subclinical and ascertained by investigation (e.g. retinopathy, renal dysfunction, left ventricular hypertrophy);

- to seek underlying causes of hypertension (e.g. Conn's adenoma, renovascular disease, chronic kidney disease unrelated to diabetes, phaeochromocytoma, Cushing's disease). Although diabetes is commonly associated with hypertension, secondary causes of hypertension must be considered, especially where the blood pressure is refractory to treatment and where there are specific suggestive signs or symptoms. Presentation and investigation of 'secondary' hypertension is beyond the scope of this chapter;
- to assess lifestyle (especially salt intake) or pharmacological (e.g. non-steroidal anti-inflammatory drugs) contributors to blood pressure elevation
- to document concomitant conditions (e.g. asthma, heart failure, ischaemic heart disease) relevant to selection of drug therapy.

Basic Investigations

These include measurement of renal function and electrolyte concentrations, a 12-lead ECG, urinalysis for albumin, urine albumin:creatine ratio (ACR) and blood lipid profile, as well as assessment of glycaemic control.

Blood Pressure Measurement

The method for estimating blood pressure assumes particular importance in people with diabetes. Traditional seated clinic blood pressure measurement has remained the standard approach, however recognition that people with diabetes often have an elevated 24-h blood pressure load and nocturnal hypertension has prompted increased use of 24-h ambulatory blood pressure recording; 24-h ambulatory recording is underused in characterizing the blood pressure elevation at diagnosis and in establishing the quality of blood pressure control on treatment for people with diabetes. Such 24-h ambulatory monitoring can also identify those patients who have either high clinic blood pressure measurements but normal blood pressure outside this environment ('white coat' hypertension) and those with normal clinic blood pressure measurements but high 24-h blood pressure levels ('masked' hypertension). Both variants of hypertension confer increased cardiovascular risk, with masked hypertension increasing risk of cardiovascular and renal events in diabetes especially where blood pressure is elevated nocturnally [5].

Home blood pressure monitoring (HBPM) is increasingly being validated as another useful clinical tool in assessment of blood pressure. It should be performed using a semiautomated, validated monitor, for 3–7 days prior to a clinic visit, and be undertaken morning and evening in a quiet room after 5 minutes of rest. It has shown more reproducible measurements than clinic blood pressure determinations, and these show a stronger relationship to hypertension-mediated end organ disease [6] and perhaps cardiovascular morbidity and mortality [7].

It should be noted that the normal ranges for 24-h ambulatory daytime and night-time averages, and for home blood pressure recordings, are substantially lower than those measured in clinic. That said, the normal ranges for 24-h ambulatory blood pressure have not been formally defined for people with diabetes and it is recommended that the ranges identified for the general population should be used for people with diabetes (Table 15.13.5.1).

Table 15.13.5.1 Definitions of hypertension according to the method of measurement (mmHg); similar values should apply to people with diabetes

	Systolic blood pressure	Diastolic blood pressure
Office or clinic	≥ 140 AND/OR	≥ 90
24-h average	≥ 130 AND/OR	≥ 80
Day	≥ 135 AND/OR	≥ 85
Night	≥ 120 AND/OR	≥ 70
Home	≥ 135 AND/OR	≥ 85

24 h, day, and night refer to the averages for these time periods as measured by ambulatory blood pressure monitoring. The home average refers to an average of readings, usually twice daily, over 7 days. If a lower blood pressure threshold for intervention and/or target for treatment is adopted, then the values for 24-h and home blood pressure averages will be lower, in proportion to the threshold/target adjustment.

Two additional caveats are important when measuring blood pressure in people with diabetes: (1) lying and standing blood pressure should be recorded at diagnosis and to assess the impact of treatment because of the potential of autonomic dysfunction to induce significant postural hypotension and supine hypertension; and (2) the correct cuff size must be used to measure blood pressure, either in the clinic, at home, or when using ambulatory devices. The use of blood pressure cuffs that are too small for the arm circumference (e.g. in people with obesity) leads to overestimation of blood pressure readings. Comprehensive information on blood pressure measurement, validated monitors and appropriate cuff sizes is available at British Hypertension Society website (https://www.bhsoc.org).

Treatment Thresholds for Hypertension in Diabetes

Blood pressure is a continuous variable and has a continuous relationship with cardiovascular disease risk, so 'cut offs' are arbitrary, although pragmatic and important in guiding practice. A 'normal' blood pressure is commonly taken to be less than 120/80 mmHg, but cardiovascular risk begins to rise when systolic blood pressure increases to greater than 115 mmHg. Treatment guidelines are based on data from clinical intervention trials, however, and, for the most part, these have not enrolled patients with blood pressure values less than 140/90 mmHg. Thus, the definition of hypertension and the threshold for intervention with blood pressure-lowering drugs for people with diabetes has been defined as a blood pressure of 140/90 mmHg or higher. This value is based on clinic blood pressure and lower thresholds apply for 24-h ambulatory blood pressure averages (Table 15.13.5.1).

Some guidelines over the past decade have recommended intervention with blood pressure-lowering medications at a lower threshold (i.e. 130–139/85–90 mmHg). For those with microalbuminuria or evidence of target organ damage and/or microvascular or macrovascular disease it could be argued that lower blood pressure thresholds for intervention with blood pressure-lowering drugs are justified because such patients already exhibit evidence of pressure-mediated damage. This illustrates the conflict between generalized evidence-based guidance and individualized patient care. Evidence supporting lower blood pressure intervention thresholds for those with manifest blood pressure-related disease is sparse, however

the approach is supported by a strong pathophysiological rational. Further clinical trials are required to conclusively demonstrate the benefits of initiating blood pressure-lowering therapy in those at high risk with blood pressure in the high normal range (i.e. 130–139/80–89 mmHg). It is thus suggested that this approach be considered in recent guidelines [8].

Blood Pressure Treatment Targets

Most available evidence on cardiovascular endpoints in people with diabetes relates to type 2 diabetes. Blood pressure targets for those with diabetes and treated hypertension have been contentious, with previous recommendations often ahead of the evidence from clinical trials. Important uncertainty remains, but the evidence guiding practice has solidified somewhat in recent years, in the form of randomized controlled trials, meta-analyses, and post-hoc subgroup analyses of controlled trials [8, 9].

There is a broad evidence base for a blood pressure target of less than 140/85 mmHg for all people with treated hypertension and diabetes. International guidance previously suggested that blood pressure targets for people with diabetes should be lower than those advocated for the treatment of hypertension in general, with an optimal treatment target of less than 130/80 mmHg recommended, especially for patients with manifest cardiovascular disease and/or nephropathy. However, no major trial of blood pressure lowering in diabetes had achieved such low levels of blood pressure (Figure 15.13.5.4). A preponderance of more recent evidence from trials, meta-analyses and post-hoc analyses of trials now suggests that targeting systolic blood pressures towards the lower end of the 130–130 mmHg is beneficial, and this is now enshrined in most guidelines (e.g. [8]).

Whether systolic blood pressure targets lower than 130 mmHg are appropriate is a matter of much greater debate [9]. There is no outcome evidence that lowering systolic blood pressure below 120 mmHg is beneficial, and indeed the ACCORD study suggested this may increase risk [10], and so this should be avoided. The evidence for cardiovascular benefits of targets between 120 and 130 is mixed, however. There is no conclusive evidence that lowering blood pressure to these levels improves general cardiovascular risk, especially where glycaemia is optimally controlled, however consistent evidence has emerged from several trials and meta-analyses that risk of stroke is reduced [9]. Targets in this range may thus be considered where risk of stroke is considered particularly high. Regarding diastolic blood pressure, current evidence suggests that a target of 80 mmHg, is safe, with little evidence on which to base a judgement about lower levels.

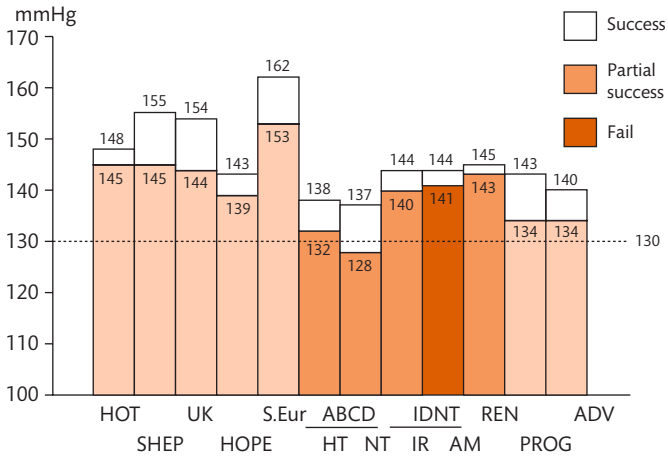

Figure 15.13.5.4 Clinical outcomes in blood pressure-lowering studies of people with diabetes; 130 refers to the recommended blood pressure target (mmHg) in most guidelines. Success refers to a positive clinical outcome in the study; partial success refers to positive outcomes in some endpoints, but not all; fail refers to no evidence of benefit. The various trials are annotated on the axis.

Blood Pressure Treatment Strategies

The ultimate objective of treating blood pressure is not only to lower the blood pressure but also to safely minimize cardiovascular and microvascular risk. This is best achieved through a combination of lifestyle intervention, blood pressure-lowering medication, and concomitant use of other medications to reduce cardiovascular risk, notably statins.

Lifestyle Interventions

These are important and should be implemented early. Lifestyle intervention can lower blood pressure and also reduce cardiovascular risk. Recommended lifestyle interventions for people with diabetes and hypertension are shown in Box 15.13.5.1. With regard to blood pressure reduction, one of the most effective lifestyle interventions for people with diabetes is restriction of dietary sodium intake. This is important because the pathophysiology of hypertension in people with diabetes points to a 'salt-sensitive state'. Moreover, most people with diabetes and treated hypertension will receive medication to inhibit the activity of the RAS, and sodium restriction increases the effectiveness of these medications with regard to blood pressure-lowering and the reduction of albuminuria. Other lifestyle interventions such as increasing intake of fresh fruit and vegetables, reduction in saturated fat intake, increased regular exercise, weight reduction, and moderation of alcohol intake, can all contribute to blood pressure lowering, as well as improving cardiovascular health.

Box 15.13.5.1 Lifestyle measures suggested for people with diabetes and high blood pressure

Lifestyle measures that lower blood pressure:
- Weight reduction
- Reduced salt intake
- Limitation of alcohol consumption
- Increased physical activity
- Increased fruit and vegetable consumption
- Reduced total fat and saturated fat intake

Measures to reduce cardiovascular disease risk
- Cessation of smoking
- Reduced total fat and saturated fat intake
- Replacement of saturated fats with monounsaturated fats
- Increased oily fish consumption

Blood Pressure-Lowering Medication

Medication is invariably required to lower blood pressure in most patients. Patients with diabetes often develop systolic hypertension and this can be particularly resistant to treatment. There has been much debate about the relative merits of specific medications with regard to cardiovascular and renal protection in people with hypertension and diabetes. What is beyond dispute is that the most important driver of benefit is the magnitude of blood pressure lowering. This must be the first objective.

Data from clinical trials have suggested that blockade of the RAS 'adds value' over and above the blood pressure lowering they produce in preventing cardiovascular and renal events in people with diabetes, although this has not been confirmed by all studies. There appears to be a clear advantage of RAS blockade in people with diabetes on key renal endpoints (albuminuria and progression of renal disease), however, which has prompted international guidelines to conclude that RAS blockade should be part of the cocktail of treatments used to lower blood pressure in people with diabetes.

It is emphasized that most people with diabetes will need two or more medications to control their blood pressure. Thus, modern treatment strategies would usually include RAS blockade along with a calcium channel blocker (CCB) and/or a thiazide-type diuretic, or all three, ideally in a single pill [8]. This is based on the higher cardiovascular risk conferred by hypertension in the context of diabetes, and the challenges in controlling hypertension in diabetes. Recent trials have suggested that sodium glucose cotransporter 2 inhibitors, used primarily for their hyperglycaemic effect, also lower clinic and ambulatory blood pressure by several mmHg, even in those concomitantly treated with antihypertensive drugs [11, 12]. This may help improve blood pressure control in people with diabetes, which is often challenging. Of note, ACE inhibitors and angiotensin receptor antagonists should not be combined, as was once suggested, due to trial evidence that this confers unacceptable excess risk of renal side effects without outcome benefit [13].

Concerns About Some Blood Pressure-Lowering Medications in Diabetes

In the 1990s, there was concern that CCBs, especially the dihydropyridines (e.g. nifedipine, amlodipine), might be less effective at protecting against cardiovascular and renal events when compared to alternative treatments. This is worthy of comment because such concern still lingers. This concern was surprising because the CCBs are arguably the most effective blood pressure-lowering agents in people with diabetes. It arose from post-hoc analyses of trials and case–control studies and was ill-founded. However, subsequent large-scale, prospective trials have conclusively demonstrated the effectiveness, safety, and importance of CCBs for the management of hypertension in people with diabetes.

There has also been longer standing concern about the use of thiazide-type diuretics for people with diabetes because of their potential to adversely impact on glucose homoeostasis. This in part reflects the glucocentric perspective of the clinical management of diabetes. Once again, data from large-scale trials have demonstrated that thiazide-type diuretics are very effective at reducing blood pressure and cardiovascular events in people with diabetes. Moreover, as sodium retention plays such a fundamental part in the pathogenesis of hypertension in diabetes, thiazide-type diuretics are often essential to control blood pressure in people with diabetes.

Finally, β-blockers have slipped down the hierarchy of prescribing for hypertension because they appear less effective at reducing cardiovascular events, especially stroke, when compared to aforementioned blood pressure-lowering medications. However, β-blockers would still be used where there is a specific indication for their use, i.e. symptomatic angina, post myocardial infarction, and in people with chronic heart failure.

An Algorithm for Use of Blood Pressure Lowering Medications in Diabetes

As indicated earlier, most guidelines, including prominent recent revisions [8] recommend the inclusion of RAS blockade (i.e. an ACE-inhibitor or angiotensin receptor blocker) as part of the treatment strategy for people with hypertension and diabetes. For many, RAS blockade alone will not be sufficient to control blood pressure and the addition of a CCB or thiazide-type diuretic will be required to improve blood pressure control [8]. The fact that two or more medications is almost inevitable to control blood pressure for most people with diabetes, has led to strengthening of the view that initial therapy for hypertension in people with diabetes should be with a combination of two medications, ideally combined in a single pill to reduce medication burden and increase compliance.

Which combination of blood pressure-lowering medications is preferred remains unclear, despite a growing number of randomized trials, summarized in recent guidelines [8]. The ACCOMPLISH study from the United States, for example, compared the combination of an ACE-inhibitor with either a CCB or thiazide-type diuretic in a hypertensive population in which a high proportion had diabetes [14]. This study suggested that despite similar blood pressure control, those treated with the ACE + CCB combination experienced fewer cardiovascular events than those treated with the ACE + thiazide combination. In reality, however, there is no single combination that is preferred or tolerated by all patients and thus choice is needed. The initial preferred choice is; RAS blockade + CCB, or RAS blockade + thiazide. For those not controlled with two drugs, RAS blockade + CCB + thiazide would be the most logical next step (Figure 15.13.5.5).

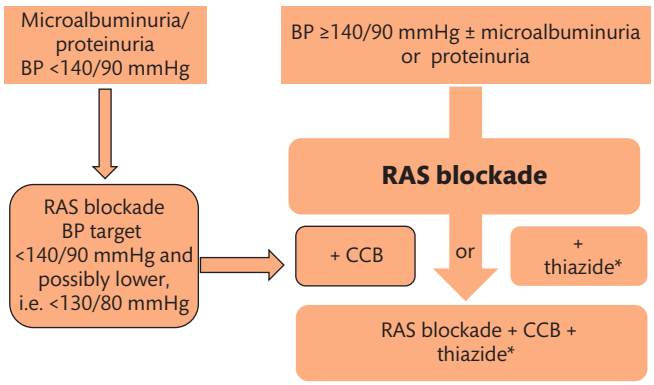

Figure 15.13.5.5 A suggested treatment algorithm for hypertension in people with diabetes. Guidelines concur that RAS blockade would usually be the foundation for treatment with a common requirement for additional therapy, i.e. a dihydropyridine CCB, or a thiazide-type diuretic, or all three in those with more resistant hypertension.

Resistant Hypertension

The blood pressure of some patients remains uncontrolled despite treatment with optimal doses of three medications. This is described as resistant hypertension [15]. This is more common in people with people with diabetes, in whom systolic blood pressure is often the most difficult to control. Specific causes of secondary resistant hypertension to be considered in diabetes include progressive nephropathy, obstructive sleep apnoea, atherosclerotic renovascular disease, certain medications or, more rarely, Cushing's syndrome or phaeochromocytoma, which also both often cause diabetes.

Treatment options for resistant hypertension have been poorly evaluated. Sodium restriction is a valuable adjunct to pharmacotherapy. Pharmacological options include further increasing the potency or dose of thiazide-type diuretic, or use of an additional diuretic such as low-dose spironolactone, or a loop diuretic at low eGFR. Careful monitoring of potassium and sodium are required. Other options are β-blockade or α-blockade and selective endothelin receptor antagonism. Referral to a specialist hypertension centre should be considered in patients in whom a secondary cause of hypertension is considered likely and for patients in whom blood pressure is resistant to treatment.

Treating Blood Pressure and Wider Cardiovascular Risk in Diabetes

People with diabetes and hypertension are at especially high risk of premature cardiovascular disease. It therefore seems illogical not to optimize their risk reduction by considering the use of statin therapy alongside blood pressure-lowering medications. The Anglo-Scandinavian Cardiac Outcomes Trial (ASCOT) used a factorial design to demonstrate that the addition of statin therapy to people with hypertension (many with diabetes) resulted in a reduction of ischaemic heart disease related events by over a third and stroke events by almost a quarter [16]. This was in addition to the benefits already accrued by blood pressure lowering. Moreover, the relative risk reduction was consistent irrespective of baseline cholesterol levels. This and other similar observations from the Heart Protection Study and CARDS supports the philosophy that if a decision has been taken to reduce blood pressure with medication, then the addition of statin therapy should be the rule rather than the exception for people with diabetes.

The Diabetic Foot

15.14.1 Modern Management of Diabetes-Related Foot Disease

Frank Lee Bowling and Andrew J.M. Boulton

Introduction

Diabetic foot problems are preventable but still account for a high number of hospital admissions in developed countries. In 2005, The International Diabetes Federation (IDF) focused on the diabetic foot. The 'Put Feet First' campaign highlighted the high prevalence of amputations within the diabetic population worldwide. Parallel to this World Diabetes Day launch, *The Lancet* dedicated a large proportion of its issue to the diabetic foot: a first for any major non-specialist journal focusing on this global challenge [1].

The economic burden both nationally and internationally can be extremely high. UK data suggest an annual cost of over $749 million for diabetic foot complications [2]. The financial constraints are influenced by ulcer type as illustrated in the Eurodiale study [3] which reported an average spend of $13 000 for treating non-infected foot ulcers increasing to $18 000 for infected ulcers with concurrent peripheral arterial disease. A grossly infected lesion can be predicted to incur higher costs. Calculations that incorporate failed antibiotic regimens, inpatient admissions for intravenous antibiotics, limb salvage and/or major amputations with associated aftercare generated sums in excesses of $188 645 [4].

In many Western countries, neuroischaemic lesions account for the greatest majority and represent a major challenge both medically and surgically. Routine podiatric diabetic foot care in high-risk patients was emphasized by a recent observational study from Arizona where the state cut podiatric care as a cost-saving measure. This led to an annual saving of $351 000 but the cost of this action measured by increased hospitalization, length of stay, and amputations was $16.7 million per annum [5].

Armstrong *et al.* concluded that 34% of people with diabetes will develop a foot ulcer during the course of their life [6]; thus the overall treatment and healthcare management of diabetic foot complications can be sustained and time-consuming requiring the involvement of a multidisciplinary team (MDT) dedicated to foot health. It has recently been suggested that those with a previous foot ulcer history should be described as being in 'remission' rather than 'healed', emphasizing the seriousness of a foot ulcer history [7]. A non-healing lesion complicated by gross infection is estimated to precede 85% of all major lower limb amputations [8].

Epidemiology of Diabetic Foot Problems

In the United Kingdom, the annual incidence and prevalence of foot ulceration in patients with diabetes was calculated at 2.2% and 1.7%, respectively, in 2002 [9]. Later, a European multicentre study on Diabetes and the Lower Extremity (Eurodiale) [3] followed 1232 diabetes patients with a foot ulcer for 12 months, and found that 5% of these underwent a major amputation (above or below knee) during the follow-up period. Krishnan *et al.* [10] reported

an amputation rate of 16.5 per 10 000 people with diabetes in the United Kingdom. Data extracted from the General Physicians databases in Scotland identified that 2.5% of the diagnosed diabetes population had an active foot ulcer at the beginning of December 2010 [11]. Diabetic foot disease is associated with a risk of amputation 23 times that of a person without diabetes [12].

There are few databases that capture diabetic foot ulceration as a distinct entity but Diabetes UK used data from the Public Health Observatory and National Diabetes In-patient Audit [13], to estimate the cost of inpatient care for complicated diabetic foot ulcers (DFUs). For the period 2010 to 2011 expenditure was UK £219 million ($285 million) [14].

Prevalence of Major Amputations

The overall rate of major amputation in England in the general adult population from studies published over the last 15 years was approximately 5/100 000. The rate was approximately eight times higher in those with diabetes than those without while the rate for males was three times higher than for females [15]. In the absence of diabetes, amputation rates were higher in the black British versus white-British population; however, black British people with diabetes had a 50% lower rate of amputation compared with their white-British counterparts.

Vamos *et al.* [16] published two studies describing the prevalence of major amputation in England. The first described rates in 1996 and 2005 based on hospital data and found the overall rate in England to have decreased from 7.0 to 4.9/100 000. A subsequent study using similar methodology describing major amputation rates from 2004 to 2008 found the overall rate to have decreased from 7.7 in 2004 to 6.9/100 000 in 2008 [17]. Moxey *et al.* [18] described the major amputation rate in England between 2003–2008 using the same data and found it to be 5.1/100 000.

Prevalence of Major Amputation by Diabetic Status

Rayman *et al.* [19] compared the rates for major amputations in patients with and without diabetes between 1997 and 2000 in the south-east of England. At the end of the study period those with diabetes had an amputation rate of 108/100 000 compared to 3.0/100 000 for those without. McCaslin *et al.* [20], however, described the age-specific major amputation rate by diabetes status across the whole of England in 2004. Surprisingly, the rate was much lower for diabetes where the rates, per 100 000, for the age ranges 45–64, 65–74, and 75–84 were 1.9 (11.5), 5.0 (30.9), and 6.5 (51.5).

Canavan *et al.* [21] described a 5-year reduction of amputation by diabetes status between 1995 and 2000 in the north-east of England. At the end of the study period the rate was 75.8 for people with diabetes compared to 15.3/100 000 for those without diabetes.

Vamos *et al.* described the amputation rate by diabetes status in 1996 and 2005 using national data [16]. During the 9 year intervening period, the rate of amputation in type 1 diabetes reduced from 1.3 to 0.7/100 000 in contrast to the increased rate of amputation observed for type 2 diabetes rising from 2.0 to 2.7/100 000. Again the rate in the general population was similar to McCaslin *et al.* (i.e. higher in the non-diabetic population but decreased over the same period from 7.0 to 4.9/100 000). A further study by Vamos *et al.* reported amputation rates for the period 2004 to 2008 in adults over 17 years of age across England [17]. The rate for diabetes in 2008 was over ten times higher than the rate for people without diabetes at 102 versus 6.9/100 000, respectively.

Abbott *et al.* [22] reported rates for lower extremity amputation based on diabetes patients attending a specialist clinic in Manchester. Rates were 1.3%, 0.6%, and 1.4% for white-British, south Asian, and black British attendees, respectively.

Diabetic Peripheral Neuropathy (DPN)

The late sequelae of diabetic neuropathy (DPN) include foot ulceration, Charcot neuroarthropathy (CN), and amputation: likewise, peripheral vascular disease (PVD) is a major aetiological factor in diabetic foot disease. DPN increases the risk of foot ulceration through the loss of protective sensation by a sevenfold increase when comparing to the non-diabetic population [23]. The resultant soft tissue trauma results in the development of a diabetic foot lesion; in many cases the patient is unaware and continues to mobilize in some cases for days or even weeks. DPN is also inextricably linked to an increased risk of falls by a marked alteration in gait and foot architecture [24].

Distal Symmetrical Sensorimotor Peripheral Neuropathy

Sensorimotor peripheral neuropathy can be divided into painful and painless via the symptoms, although both may occur simultaneously. Symptoms include reduced or absent sensation, burning, tingling, stabbing sensation, pain, paraesthesia, and patients can also report the sensation of walking on marbles. In contrast, numbness, heaviness or in some cases asymptomatic, profound sensory loss renders the foot 'at risk'. Up to 50% may not experience any type of symptomatology at all [25]; thus careful examination of both feet is paramount.

Peripheral Sympathetic Autonomic Neuropathy

In some cases, autonomic dysfunction can manifest as anhidrosis predisposing the foot to callus and fissure formation beneath weight-bearing structures [26]. Sympathetic vasoconstrictor tone resulting in arteriovenous shunting and a warm well-perfused foot result in 'auto-sympathectomy'. Distended dorsal foot veins remain distended on elevation. Thus it is the warm, insensate, and painless foot that is the 'at-risk foot'.

Other Long-Term Risk Factors for Foot Ulceration

Diabetic foot lesions remain a major cause of morbidity in patients with renal failure and even in the early stages of renal disease microalbuminuria is a strong predictor of foot ulceration [27]. Patients who undergo simultaneous pancreas and kidney transplants (SPK) may have normoglycemia with near normal renal output but are still at high risk of ulceration and must be monitored long term. As their overall health status improves and activity levels

increase, reports of foot ulcers and even acute CN some years after the SPK have been reported [28].

Structural changes within the foot/ankle render the foot vulnerable to areas of high pressures, associated digital flexion deformities along with migration of the plantar fat pad distally increases the risk of tissue breakdown.

A number of studies have examined the role of psychosocial factors in the pathway to foot ulceration. They have demonstrated that patients' behaviour is not driven by the abstract designation of being 'at risk': it is more that the patients' perception of their risk [29]. A recent prospective study confirmed that depression predicts first, although not recurrent, DFUs [30].

Peripheral Vascular Disease

Critical Limb Ischaemia–Risk Factors and Epidemiology

Critical limb ischaemia (CLI) is a late complication of PVD with a European prevalence of 500–1000 per million [31]. It is defined as stage 3 in the Rutherford Classification [32]. The progression from intermittent claudication to CLI is related to diabetes (fourfold risk), smoking (threefold risk) and hypercholesterolaemia (twofold risk) [33]. Approximately half of all patients with CLI have some form of revascularization with 40% of those with no reconstructable disease undergoing amputation within 6 months and 20% dying within the same period [34].

The influence of different risk factors on the progression of PAD into CLI was described by Dormandy *et al.* [35] and is illustrated in Figure 15.14.1.1.

Identification of the High-Risk Foot

An annual foot examination by a clinician should occur in tandem with patient engagement (i.e. patients should be actively engaged through regular monitoring of their own feet). The foot should always be an integral part of the annual review. The clinician should never rely on symptoms alone to identify high-risk patients; 50% of patients with insensitive feet have no previous history of neuropathic symptoms, and claudication [36].

Assessment

Up to 50% of older, type 2 diabetic patients have signs of DPN [37]. The American Diabetes Association (ADA) document on the 'Comprehensive Diabetic Foot Examination (CDFE)' [37] provides a robust assessment tool.

Examination is the 'key' component of foot screening but needs to be placed in context via a thorough history that identifies specific risk factors.

History

- Past or present neuropathic symptoms
- Vascular (intermittent claudication/rest pain/past history of bypass surgery or angioplasty)
- History of ulcer or minor/major amputation
- Social factors (living alone, smoking)
- Visual impairment or end-stage renal failure (dialysis or post-transplant)

Clinical Examination

- Skin colour, callus, fissures, reduced sweating
- Bacterial/fungal infection
- Ulceration?
- Architecture/structural alterations, claw toes, prominent metatarsal heads
- Anhidrosis
- Skin temperature; a unilateral, warm, insensate foot should be considered to be acute CN until proven otherwise
- Footwear suitability

Neurological Assessment

The 10 g monofilament (Bailey Instruments Ltd, Manchester, UK) is widely used in clinical practice and designed to buckle when a 10 g force is applied. Testing at the first, third and fifth metatarsal heads along with plantar surface of hallux (a simple yes or no if a stimulus has been detected) is a reliable and highly accurate predictor of foot ulceration [38].

The Ipswich Touch Test requires a light touch via the index finger onto the 1st, 3rd, and 5th digits. A loss of sensation, neuropathy, is identified when detection fails at two or more sites (out of the total

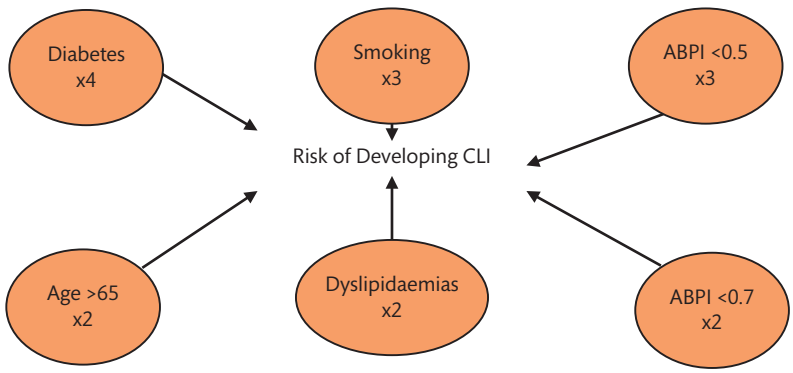

Figure 15.14.1.1 The influence of different risk factors on the risk of developing critical limb ischaemia.

six). This highly simplistic test demonstrates strong agreement with other validated tests such as the monofilament [39].

The Vibratip™, (McCallan Medical, Nottingham, UK) is a small, battery operated, disposable vibrating stylus that assesses vibration sensation. Levels of agreement with other, similar tests are highly positive [40].

The Vibration Perception Testing (VPT) is a hand-held device that generates a vibratory stimulus when applied to the hallux. VPT has demonstrated excellent sensitivity and specificity for neuropathy.

A 128 Hz tuning fork is a traditional method of assessing vibration perception when placed over the apices of the hallux bilaterally. The cold metal can also provide additional stimuli in the form of temperature.

A pin-prick test is a simple test sensation over the apex of the halluces. Ankle reflex testing is a standard component of neurological testing whereby the absence of ankle reflexes bilaterally is an abnormal response [41].

Vascular Assessment

Classification of Peripheral Arterial Disease

Peripheral arterial disease (PAD) is characterized by progressive arterial occlusive disease of the lower extremities. The worldwide prevalence has been estimated at 3–10% increasing to 15–20% in individuals over 70 [42]. The ratio of symptomatic to asymptomatic disease is up to one in three with as many as 50% never consulting a clinician. Those with PAD have a threefold increase in risk of mortality from major cardiovascular events (heart attack and stroke) compared to those without PAD [43].

It can be diagnosed based on symptoms—classically intermittent claudication (cramping pain in legs on walking) and signs such as absent peripheral pulses, ulcers, gangrene, and amputation. Non-invasive diagnosis can also be made using the ankle-brachial pressure index. This is a ratio of the blood pressure taken at the arm and the leg (at the level of the malleoli). A ratio of <0.9 is 95% sensitive and 100% specific for detecting angiogram positive disease [44].

PAD is classified by the Fontaine and Rutherford classification system [32] and ranges from asymptomatic, through to claudication and finally tissue loss and gangrene.

Screening for vascular disease can be difficult. Palpation for posterior tibial and dorsalis pedis pulses is important but detection can be influenced by the skill and room temperature. A femoral bruit can also be a strong indicator of PVD. Doppler ultrasound can be useful to assess flow signal waveforms although vessel wall calcification can lead to a falsely elevated reading of the ankle-brachial index (ABI).

The High-Risk Patient

If anomalies identified and/or relevant clinical history place the foot 'at risk', strategies aimed at-risk management must be implemented. Education promotes self-monitoring and foot hygiene; however, this needs to be supported by regular clinical reviews by the multidisciplinary team.

Wound Classification

A number of classification systems are currently in existence but all follow a similar theme: size, depth, appearance, and location. These provide the clinician with a good reference point for wound surveillance (Box 15.14.1.1). In this system, grades refer to the depth of the wound, and each grade has four stages, depending on the presence or absence of infection and/or ischaemia.

Box 15.14.1.1 Wound classification

The 'University of Texas Diabetic Wound Classification' is regularly used for staging diabetic foot ulcers. This classification grades and stages ulcers by their depth and the presence of any infection or ischaemia.

- Staging
  - **A:** No infection or ischaemia
  - **B:** Infection present
  - **C:** Ischaemia present
  - **D:** Infection and ischaemia present
- Grading
  - **0:** Epithelialized wound
  - **1:** Superficial wound
  - **2:** Wound penetrates to tendon or capsule
  - **3:** Wound penetrates to bone or joint

Grade 0

A UT grade 0 foot has no open lesions, but is at risk. The patient may have a history of foot ulcers or pre-ulcer lesions.

Grade 1

Superficial full-thickness loss: these lesions tend to be predominantly neuropathic with (UT 1B) or without (UT 1A) infection. Lesions commonly occur under points of high-pressure areas (e.g. the metatarsal heads, toes). The presence of ischaemia should be confirmed examination.

Grade 2

Deeper seated lesions that penetrate into the subcutaneous tissue, exposing tendon and/or capsule but without bony involvement.

Grade 3

Lesions penetrating to bone and/or joints. The ability to probe to bone has been shown to be sensitive for identifying osteomyelitis.

Evidence shows that UT grade 3B lesions may respond to antibiotic treatment without the need for surgical intervention. A recent randomized comparative trial (RCT) of antibiotics versus surgery for localized bone infection yielded similar outcomes in both groups [45]. A recent interim analysis of a large multicentre UK RCT of Oral Versus Intravenous Antibiotics (OVIVA) over a 6-week period for localized joint and bone infection showed oral to be inferior to IV antibiotics. It should be emphasized that only 16% of the study population had a diagnosis of diabetes mellitus [46].

Management of Diabetic Foot Ulceration

Neuropathic Ulcers

The mainstay of management of uncomplicated lesions consists of debridement of non-viable tissues along with an appropriate wound dressing; very little evidence exists for any one type of wound dressing over others and the decision in clinical practice has generally been dictated by the clinician's personal experience.

The EXPLORER trial is the first clinical study to indicate the efficacy of a dressing in the treatment of diabetic foot lesions [47]. The

double-blind RCT involved teams in 43 hospitals with specialized diabetic foot clinics in France, Spain, Italy, Germany, and the UK. The aim was to assess the effect of a sucrose octasulfate dressing versus a control dressing on wound closure in patients with neuroischaemic lesions. Ulcers were deemed neuroischaemic if peripheral neuropathy/PAD were both present. Over a period of three years, 240 individuals took part in the trial. Of these, 126 were treated with the sucrose octasulfate dressing under investigation and 114 with a control dressing of a type usually used to dress this type of wound.

After 20 weeks, 18% more wound closures were recorded in the sucrose octasulfate dressing group, compared to the control dressing group and there was an observed 30% improvement in healing. The expected time to wound closure for all participants—as determined by Kaplan–Meier analysis—was 180 days in the control group and only 120 days in the sucrose octasulfate dressing group. The results suggest a significant improvement in wound healing resulting from treatment with the sucrose octasulfate dressing. This is the first study to demonstrate proven efficacy of a dressing in wound healing.

Debridement

The formation of hyperkeratotic tissue (Callus) results from sheer pressure and removal reduces abnormally high plantar pressures. Lesions that show extensive bone and soft tissue involvement require aggressive debridement providing drainage of purulent discharge. Surgical removal/excision has been shown to significantly reduce time to healing when compared to conservative management [48].

Offloading

This is the key to healing plantar foot lesions, and outcomes are positive when offloading devices are used. Total contact casts (TCC) are the gold standard based on evidence of a 90% success rate for ulcer healing, supported by several RCTs [49–51]. Other devices, removable cast walkers, or adapted footwear, to date have not been successful in demonstrating similar results. Armstrong *et al.* [49] recorded the activity levels of patients prescribed removable cast walkers as treatment for neuropathic foot ulcers. Findings demonstrated that patients only wore the offloading device for 28% of their total daily activity. Further randomized controlled trials were carried out in Miami and Tucson. In Miami, patients with non-infected neuropathic plantar ulcers were randomized either to a total contact cast, or a removable cast walker, rendered irremovable by wrapping with a sheet of cast material. Not surprisingly, there were no differences in healing rates which were generally rapid [50]. By contrast, in the Tucson study, where patients were randomized either to a total contact cast or a removable cast walker, healing rates were much more rapid in the total contact cast group as the removable walkers were not used for much of the time [51, 52].

Neuroischaemic Ulcers

Conservative debridement in the case of neuroischaemic lesions may be necessary using minimal sharp techniques, using instead debriding agents. Conflicting advice exists with regards to casting neuroischaemic with or without osseous involvement and to date little evidence exists but offloading remains an essential part of the management plan for these patients [53]. However, some degree of vascular intervention may need to be considered in order to increase the potential for healing. Initial investigations should comprise a non-invasive assessment using Doppler ultrasound techniques. Prior to any vascular surgical intervention, arteriography is usually indicated. Care should be taken with the use of certain contrast media as many patients with foot ulceration have renal dysfunction. All patients with PVD should be seen by a vascular surgeon or interventional radiologist who would normally be a member of the MDT.

Infection

DFUs serve as a portal for pathogens and approximately 60% of DFUs are already infected on initial presentation. Gram-positive cocci, especially *Staphylococcus aureus,* streptococcus species, and coagulase-negative staphylococci have all been isolated from DFUs [54, 55]. The prevalence of Gram-negative bacteria, pseudomonas, and *Enterobacteriaceae* species is lower, but increases in chronic wounds previously treated with antibiotics. Anaerobic bacteria must also be considered, especially in neuroischaemic ulcers.

Antibiotic-resistant organisms have become an increasing problem in the management of DFUs over recent decades with the rise of methicillin-resistant *Staphylococcus aureus* (MRSA). Multidrug resistant (MDR) Gram-negative strains such as highly resistant pseudomonas, extended-spectrum β-lactamase (ESBL) and carbapenemase-producing Gram-negative bacilli are also being isolated from diabetic foot wounds [56].

The clinical signs, pain, warmth, erythema, raised temperature, and inflammatory markers can be reduced or absent in patients with neuropathy and or ischaemia with approximately 50% remaining asymptomatic. Characteristics such as onset of tenderness, prolonged healing, and wound malodour may be the only indicators of infection. Others include discharge, poor granulation tissue, and hyperglycaemia [54]. Tissue samples are the gold standard for culture and sensitivity to inform the choice of antibiotic regimen as superficial cultures are contaminated by colonizing bacteria.

Non-infected wounds do not require antibiotics; superficial wound swabs are inaccurate and misleading, only yielding contaminants; deep tissue specimens via a curettage or after aggressive debridement are the gold standard for microbiological testing. Initial antibiotic therapy should be empirical consisting of activity against *Staphylococcus aureus* and aerobic *streptococci*. Consider that agents against Gram-negative organisms may be required for patients with severe infections.

Tailor antibiotic regimen once culture and sensitivity results are available; a more specific regimen should be initiated being mindful of local resistance patterns. Intravenous antibiotic administration should only be indicated in severe infections; for mild to moderate infections oral antibiotics with a high bioavailability will suffice. 'It's not what you put on the ulcer, it's what you take off'. Antibiotics will be of little benefit if sharp debridement, drainage of purulent discharge, and appropriate offloading are not adhered to. Both the International Working Group on the Diabetic Foot [57] and the Infectious Disease

Society of North America [54] have provided useful guidelines to assist in the antibiotic treatment of infected DFUs.

Wound Dressings

Selection of the ideal wound dressing will depend upon specific characteristics of the lesion. Unfortunately, there is currently little evidence concerning wound dressings, such that selection relies more on clinical experience rather than evidence. Wound healing can be challenging and is further complicated by neuropathy and/or ischaemia. The wound environment is paramount in maintaining a moist protective occlusive layer at the wound interface. The basic make-up of wound dressings requires absorption of exudate, thermal insulation, gas permeability, and being impenetrable to microorganisms. Adherent products should not contact the wound bed, thus preventing removal of newly granulated tissue. As the wound progresses, a variety of different dressings can come into play (i.e. sloughy wounds require debridement agents, clean moist wounds absorbency properties). Products are divided into three broad categories; debriding, antiseptic-based, and moisture control, and are listed in Table 15.14.1.1.

Negative Pressure Wound Therapy

The application of Negative Pressure Wound Therapy (NPWT) is believed to accelerate healing through reducing oedema, removal of exudate, increased perfusion, self-proliferation, and the formation of granulation tissue [58]. Studies have demonstrated that wounds achieve faster closure over conventional dressing regimes [59]. Increased perfusion and promotion of granulation tissue have been reported via increasing cell mitosis. RCTs have suggested efficacy in rates of wound healing and reduced amputations in post-surgical wounds [60].

Hyperbaric Oxygen Therapy

Hyperbaric oxygen therapy (HBO) enhances the body's natural healing process by inhalation of 100% oxygen in a total body chamber, where atmospheric pressure is increased and controlled. HBO has been promoted as an effective treatment in diabetic foot wounds over many years. Unfortunately, early RCTs consisted of small patient numbers and methodological flaws. A well designed Swedish RCT suggested there was a benefit from HBO in neuroischaemic infected lesions without the possibility of revascularization [61]. Two large multicentre RCTs, one carried out in the Netherlands [62] and a further undertaken in Canada [63], showed no benefits of HBO of the patient groups. To date there is no definite clinical indication for the use of HBO in diabetic foot lesions and few data to support its efficacy.

Growth Factors and Skin Substitutes

Becaplermin is a recombinant platelet-derived growth factor (PDGF) ointment which has shown some slight benefit in wounds with delayed healing. Granulocyte colony stimulating factor (GCS-F) has been reported to improve resolution of infection and is claimed to reduce amputation rates [64]. Bioengineered skin (Apligraf) and human dermis (Dermagraft) are types of biologically active implants and contain human fibroblasts that deliver growth factors to the wound. The evidence base is weak for these expensive

Table 15.14.1.1 Wound management products

Dressing	Description	Contraindications	Example
Hydrocolloid	Facilitate re-hydration & autolytic debridement. Dry, sloughy, necrotic wounds. Promote granulation.	Infected wounds. Twice weekly change.	Aquacel: ConvaTec Deeside, Wales, UK. Comfeel: Coloplast Peterborough, UK.
Hydrogels	Donates liquid to dry wounds & absorbs exudates. Dry, sloughy wounds. Autyolitic debridement.	Hydrogel sheets avoided in infected wounds.	Intrasite gel: Smith & Nephew wound management, Hull, UK. Iodosorb: Smith & Nephew wound mgt, UK.
Silver	Antimicrobial. Colonization.	Sensitivity to silver.	Acticoat: Smith & Nephew wound mgt, USA.
Vapour-permeable	Provide a moist healing environment. Mild exude.	Heavily exudating wound.	Tegaderm: 3M, Reading, UK.
Foam dressing	Primary or secondary cover. Light & Heavy exudates.	Remove if strike through occurs.	Allevyn: Smith & Nephew wound mgt, Europe. Lyofoam: Molnlyck,. Oldham, UK.
Odour absorbent	Absorbs odour. Malodorous.	Silver (sensitivity).	Actisorb: Johnson & Johnson Medical Skipton, UK
Larval therapy	Debridement, promote granulation. Heavily sloughy necrotic wounds.	Increase in pain.	Maggots: BioMond Bridgend, Wales, UK.
Alginate	Haemostat. Heavy exudates.	Blockage. Loose fibres.	Kaltostate: ConvaTec, UK.
Skin substitutes	Living skin. Obstinate wounds.	Colonized. Infected wound.	Dermagraft: Smith & Nephew medical, Europe.
Iodine	Antibacterial. Exudating wounds.	Iodine (sensitivity) Renal/thyroid conditions.	Iodosorb: Smith & Nephew medical, Europe.
Honey	Antimicrobial. Sloughy necrotic wounds. Autolytic debridement.	Medical grade only.	L-Mesitran: Aspen medical Europe Ltd Ashby de la Zouch, Europe.

therapies and large-scale randomized controlled trials (RCTS) are needed. A recent systematic review concluded that there is little published evidence to justify the use of any of these therapies [65].

Charcot Neuroarthropathy

CN is non-infective arthropathy in a well-perfused, insensitive foot. CN is inextricably linked with distal symmetrical somatic and autonomic neuropathy although the exact pathogenetic mechanisms are unknown.

Advances into the pathogenesis of osteopenia and osteoporosis, and the role of the receptor activator of nuclear factor κB/osteoprotegerin (RANKL/OPG) signalling system have led to the theory that acute CN might be triggered in a susceptible individual by an event that leads to localized inflammation in the affected foot, resulting in an increasing cycle of osteoblastic/clastic activity.

Its main characteristics are osseous and joint destruction leading to a gross alteration in foot structure (Figure 15.14.1.2). Abnormalities may occur in the forefoot, mid-foot, peri-talar, or ankle regions with avulsion fractures affecting the posterior tuberosity of the calcaneus. Mobilization due to a lack of sensory awareness compounds further destruction. In the later stages complete mid-foot collapse can be recognized by a rocker bottom deformity [66] (Figure 15.14.1.3). The patient with acute CN continues to walk and more minor trauma occurs. Any patient with neuropathy who complains of swelling or discomfort, with or without a history of injury, should be assessed.

Figure 15.14.1.2 Chronic Charcot neuroarthropathy involving the mid-foot (cuneiform-metatarsal bone area). There was extensive deformity with a large plantar ulcerative lesion under the bony prominence.

Figure 15.14.1.3 Chronic neuropathic foot problems with Charcot deformity and previous amputations of four toes.

Treatment in the initial stages of acute CN is offloading with a cast walker. Unfortunately, there are currently no proven medical or pharmacological approaches other than immobilization. Controversy exists over the timing of surgical intervention in the acute or later phase due to a lack of evidence. Simple exostectomies and tendon transfers can offer therapeutic benefit thereby reducing the risk of ulcerative lesions (Figure 15.14.1.4). Little evidence exists to show a surgically corrected Charcot deformity functions any better than a non-surgically corrected deformity [67].

Patient Education

Successful self-management requires motivation and compliance from the patient to accept a degree of responsibility for their own care. However, foot inspection can be problematic for obese individuals and those with visual impairment. Difficulty understanding the nature and relevance of neuropathy to the individual with diabetes has also been suggested as a barrier to engaging in the education process [68].

Some success with patient engagement in foot care has been demonstrated utilizing self-monitoring tools such as temperature monitoring [69], the Neuropad™ (an indicator of autonomic neuropathy

Figure 15.14.1.4 (a) Radiograph of a chronic Charcot foot demonstrating previous amputation of three digits, vascular calcification, and gross disruption in the cuneiform-metatarsal joints of the mid-foot. (b) Radiograph showing chronic Charcot neuroarthopathic changes in the mid-foot with peritalar destruction.

[70]), and a simple foot pressure mat for monitoring pressure changes under the foot [71]. Inappropriate footwear, either incorrect size or inadequate cushioning, has been observed to contribute to the development of ulcers. Tightly fitting shoes commonly lead to ulceration at dorsal deformities such as bunions or between the spaces of toes which have been crushed together. Loose shoes can also be problematic, leading to ulceration from frictional forces.

Additionally, patients should be advised about other associated risk factors such as controlling high blood pressure, cholesterol, smoking cessation, and obesity. Not only will these measures reduce patients' risk of ulcers, they will also lower their macrovascular complication risk.

Multidisciplinary Team Input

Successful management of diabetic foot complications depends upon achieving stability in all aspects of diabetes care. Patients requiring a total package of care from a specialist diabetes foot care team need a structured management plan in order to contend with the multiple comorbidities and complications associated with diabetes. Varying levels of care currently exist in different countries. At a minimum, a multidisciplinary foot-care team should consist of a diabetologist, surgeon (podiatric, vascular, or orthopaedist), diabetes specialist nurse and podiatrists (or in some countries the older title of chiropodist).

Improved outcomes, including reduced incidence of amputations, have been shown in a number of studies where there is a clear MDT involvement [10]. One study directly compared outcomes associated with care delivered by an established MDT comparing with another hospital lacking an MDT. Major amputations performed on patients treated by the MDT were lower (4.7%) vs. 21.7% without MDT input (P <0.0001). Mortality during hospitalization was also significantly different between the two groups at 2.5% for the MDT group and 9.4% for the controls (P <0.001) [72].

Conclusion

The Foot in Remission

Recurrence rates after ulcer healing may be as high as 40% after 1 year and 65% after 5. CN patients have up to 50% chance of developing the same scenario in the contralateral foot. Thus the concept of 'remission' may be preferable to referring to 'healed' [73, 74].

The Future

Diabetic foot complications involve multiple factors coming into play driven primarily by prolonged hyperglycaemia. The tools for reducing foot complications are already available to the MDT in the form of consensus and evidence based guidelines. Lack of patient engagement and self-empowerment represent the most significant barrier to future success in diabetic related foot complications.

The aetiopathogenesis and management of diabetic foot disease over the last three decades, in the mainstay comes from what we have learned from clinical practice still lacking evidence base. Most important of all however in the management of patients with diabetic foot disorders, is to remember that the patient has frequently

lost the 'gift of pain' that protects most of us from developing significant foot problems but, when absent, can lead to devastating consequences.

Delivery of Diabetes Care

15.15.1 Diabetes Service Organization

Jonathan Valabhji

This section was written in June 2018. Several programmes which are discussed to offer context are described as they were at this time, namely:

- The Healthier You: NHS Diabetes Prevention Programme
- The NHS England Digital Diabetes Programme
- The NHS England Diabetes Treatment and Care Programme.

Introduction

The World Health Organization has estimated that globally, 422 million adults were living with diabetes in 2014, compared to 108 million in 1980. This represents an almost doubling of the age-standardized global prevalence of diabetes since 1980, rising from 4.7% to 8.5% in the adult population over this period [1]. Separate global estimates of diabetes prevalence for type 1 and type 2 do not exist. However, the majority of people with diabetes have type 2 diabetes.

Overweight and obesity is the major modifiable risk factor for type 2 diabetes, and the global increase in prevalence of type 2 diabetes has tracked the global increase in prevalence of overweight and obesity. The World Health Organization has estimated that worldwide, obesity has nearly tripled since 1975; that in 2016, more than 1.9 billion adults were overweight, and of these over 650 million were obese; and that in 2016, 39% of adults were overweight and 13% were obese [2].

In England, with a population of approximately 55 million, 3.8 million people aged over 16 had diabetes in 2015, around 9% of the adult population. Approximately 90% had type 2 diabetes, and the model estimated that 940 000 of those with type 2 diabetes were as yet undiagnosed [3].

The direct health costs for type 1 and type 2 diabetes in the United Kingdom were estimated to be £9.8billion in financial year 2010/11, approximately 10% of the total health resource expenditure. The majority of the direct costs, 80%, related to the management of the complications of diabetes [4]. The National Audit Office estimated in 2012 that National Health Service (NHS) spending on diabetes services in England in 2009/10 was at least £3.9 billion [5], and in 2015 estimated that the cost of diabetes to the NHS in England in 2010/11 was £5.6 billion [6]. The differences in estimates reflect different assumptions made, and reflect the difficulties in accurately assessing health costs related to diabetes.

Increasing Prevalence Has Required Evolution of Healthcare Delivery Systems

Although different healthcare systems have different means of funding, increasing prevalence of diabetes has required evolution of healthcare delivery systems irrespective of funding methods. While the lens of the current article is the NHS in England, a taxpayer funded system that provides universal care free at the point of delivery, the challenges posed by increasing diabetes prevalence, and the potential solutions, will to some extent be common to most healthcare systems. Whereas in the 1980s, diabetes care delivery was often the preserve of hospital-based specialist diabetes services, increasing patient numbers now require the majority of diabetes care to be delivered by generalist healthcare professionals outside of hospital settings, with more complex care, and care related to the complications of diabetes usually delivered by hospital-based specialists, with an integrated interface between generalist and specialist services. The nature of the interface, and the differing relative care distributions between generalist and specialist teams, vary across local healthcare systems and local health economies in England. Type 1 diabetes and rarer forms of diabetes are usually cared for by specialist teams even in the absence of complications.

In some low and middle income countries, there may be additional and distinct problems, such as access to medicines, including insulin,

that will not be covered specifically in this chapter. Where both resources and diabetes expertise are in short supply, care delivery is often centralized. However, although approaches may be quite different, the principles of providing the best possible services within a specific and sometimes limited resource envelope remain the same.

Sustainability of Healthcare Systems

With health inflation at around 7% per annum and ageing populations, sustainability is a concern for most healthcare systems internationally. In England, a strategy document called the Five Year Forward View was published in 2014 that suggested a direction of travel for healthcare, with an important emphasis on long-term sustainability of the NHS in England [7]. Areas of focus relevant to diabetes care prioritized either within that document or subsequently are:

- To establish a national evidence-based type 2 diabetes prevention programme for those already identified to be at high risk, in order to reduce the current national trajectory of type 2 diabetes incidence.
- To invest in diabetes treatment and care in order to reduce future complication burden, and so potentially realize long-term return on investment as well as improvements in care and outcomes.
- To empower individuals with diabetes to better self-manage their condition, through better access to information, support, and structured education.
- To harness digital technologies for healthcare provision and to support individuals to better self-manage their condition through digital health platforms.
- To better integrate services, across primary care and hospital interfaces, across physical and mental healthcare interfaces, and across health and social care interfaces.

The Healthier You: NHS Diabetes Prevention Programme

Based on best evidence [8], an intervention was developed to prevent or delay onset of type 2 diabetes in those already identified to be at high risk. The intervention encourages behavioural change focussing on weight loss, increased physical activity, and better quality nutrition. The intervention is for those with non-diabetic hyperglycaemia (also referred to as pre-diabetes) and involves at least 13 group-based face-to-face sessions, across at least a 9 month period, constituting at least 16 hours of contact time. During the first year of national roll-out (financial year 2016/17), the programme was implemented across approximately 50% of England. Referral numbers and percentage uptake were found to be in excess of prior modelled values, suggesting that general practices and people at high risk of type 2 diabetes value the prevention opportunities provided. Attendance rates for men, Asian, Afro-Caribbean, mixed, and other ethnic groups and participants from areas in the most deprived quintile suggest that, in its early stages, the programme is reaching both those who are at greater risk of developing type 2 diabetes and those who typically access healthcare less effectively [9]. During the second year of national roll-out (financial year 2017/18), implementation reached 75% of England, with early data demonstrating encouraging weight loss seen in participants that have so far completed the intervention, as well as demonstrating encouraging completion rates, with over 50% of those that initiated an intervention attending at least eight of the tailored support sessions. By summer 2018, implementation reached 100% of England. At full roll-out, the programme is planned to deliver to 100 000 people each year, although more recent policy decisions (announced 30 November 2018), based on the initial encouraging results, suggest that this will be extended to 200 000 people each year. The National Institute of Health Research has supported an independent evaluation of the programme, scheduled to report in 2021, that will assess programme impact on the current national trajectory of type 2 diabetes incidence.

Interventions for individuals at high risk of type 2 diabetes will be complemented by population level interventions, outlined in the UK Government's Childhood Obesity Plan [10], such as a levy on sugar-sweetened beverages, and plans to encourage product reformulation to reduce sugar and total calorie content.

An overview of systematic reviews and meta-analysis has recently evaluated the efficacy of population-wide obesity and diabetes prevention programmes. Increased price of sugar-sweetened beverages and decreased price of fruit and vegetables, menu labelling, grocery-store interventions and multicomponent interventions were associated with small reductions in body mass index (BMI) or weight. While the reach of such interventions was many times greater than interventions for those at high risk, the effect size was smaller by a similar factor [11]. So a combination of both approaches is desirable.

The NHS England Digital Diabetes Programme

The two promises of digital health interventions are greater reach and lower unit cost, and these may be another route to deliver behaviour change services with large reach. However, while evidence of effectiveness of digital interventions in the prevention of type 2 diabetes is currently emerging, this has not yet reached a consensus position. For this reason, NHS England is currently piloting a Digital Diabetes Prevention programme, trialling five digital products in those at high risk of type 2 diabetes in the real world setting, with a formal evaluation to assess clinical effectiveness and reach [12].

Digital health interventions also offer opportunities for delivery of behaviour change services around diabetes self-management [13], and this is a further area of investment and development in England.

The NHS England Diabetes Treatment and Care Programme

The focus here is to reduce the future diabetes complication burden, with up-front investment. Cases for potential return on investment, by way of improvements in care and outcomes that evidence indicated should result in reinvestable savings, were made in the following areas:

- Achievement of treatment targets for HbA1c, blood pressure, and cholesterol and tackling variation around that achievement in order to reduce the risk of onset of complications.
- Attendance at structured education to empower individuals with diabetes to better self-manage their condition and so support improved glycaemic control and psychosocial well-being.

- Multidisciplinary diabetic foot care, and more specifically the existence of and sufficient capacity within a multidisciplinary foot service. Multidisciplinary diabetic foot care has been shown to reduce amputations by up to 50% [14] and a strong economic case has been made [15].
- Inpatient care, and more specifically the existence of and sufficient capacity within a diabetes inpatient specialist nurse service which has been shown to support reduction in lengths of inpatient stay. One in six of all hospital beds in England are now occupied by someone with diabetes.

A Model of Service Provision That Promotes Integrated Care Delivery

In the latter part of 2014, NHS England, in collaboration with stakeholders, produced a sample service specification for diabetes services [16]. The principals involved are broadly applicable—the model outlines the provision of high quality care for all those with diabetes, and differentiates the care needs of those with type 1 from those with type 2 diabetes where those care needs differ. It details the entire care pathway for people with diabetes, including those with the long-term complications of diabetes. The model divides the care pathway into two broad elements:

- Generalist care and
- Specialist care.

In the example (see Figure 15.15.1.1), a community based multidisciplinary team (MDT) that interfaces between general practice-based and specialist services is also included.

In the model described, the generalist practice-based service will have primary responsibility for the person with diabetes. Specialist services and the community based MDT will have responsibility for the episodes of care provided in those settings. However, accountability for the incidence of onset of complications and incidence of hard clinical endpoints such as amputation and blindness across the

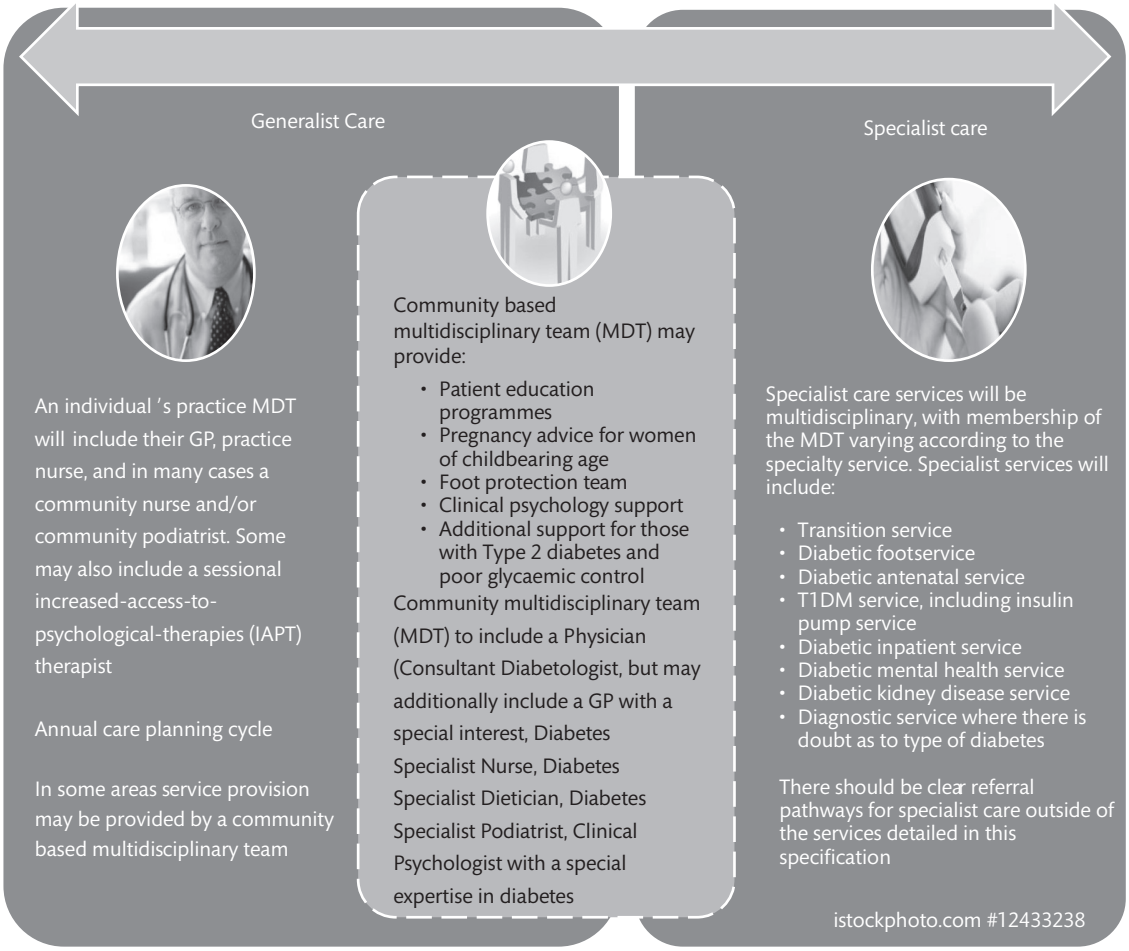

Figure 15.15.1.1 An exemplar care pathway. Care delivery is based on a multidisciplinary approach whether the care setting is the GP practice, a community centre, or a hospital. The example illustrates a community based multidisciplinary team (MDT) at the interface between generalist practice-based care and specialist care. The community based multidisciplinary team can support delivery of parts of the pathway that could not be delivered in every GP practice—an example could be delivery of structured education. Such teams should be innovatively exploring ways of generalists and specialists working together in the community using information technology and new technologies to ensure patient care is delivered in an appropriate setting local to the patient when possible. They need to have strong networking links and channels of communication with generalist and specialist colleagues working in the hospital and community.

health economy should be shared by all providers of diabetes care. Therefore both generalist and specialist services will be jointly accountable for clinical outcomes.

A community based MDT may act as the link between generalist clinicians and hospital-based specialists by representing both. Hospital-based specialists should spend a proportion of their time in the community advising and facilitating the work of the community based MDT. The presence of specialists in the MDT will facilitate fast-tracking of complications once diagnosed up to appropriate specialist settings and allow the team to provide more routine aspects of specialist care closer to the patient's home. Examples of services that may be delivered by the community based MDT include:

1. Structured education for those with type 2 diabetes, for people whose GP practice does not provide this in-house.
2. Structured education for those with type 1 diabetes.
3. Type 2 diabetes with poor glycaemic control despite best efforts in primary care.
4. Pregnancy advice for women of childbearing age.
5. Foot protection—assessing and advising those identified to be at high risk of diabetic foot disease (e.g. those already identified to have peripheral neuropathy or/and peripheral vascular disease).
6. Type 1 diabetes care when the MDT includes a consultant diabetologist.
7. Clinical psychology support within the MDT environment for those with depression and anxiety that is related to their diabetes.

All people with T1DM should have access to specialist services if they so choose, given the relative rarity of type 1 diabetes and the associated specific care needs. People with other forms of diabetes, such as monogenic diabetes (e.g. maturity-onset diabetes of the young (MODY), mitochondrial diabetes), diabetes due to chronic pancreatitis or total pancreatectomy, should also have access to specialist services given their specific care needs.

For the purposes of this model the providers of specialist care have the following designated responsibilities:

1. Provision of a transition diabetes service (ages 13–25 years).
2. Provision of a diabetic foot service.
3. Provision of a diabetic antenatal service.
4. Provision of a diabetic kidney service, prior to renal replacement therapy.
5. Provision of a T1DM service, including an insulin pump service.
6. Provision of a diabetic inpatient service.
7. Provision of a diabetic mental health service.
8. Provision of a diagnostic service where there is doubt as to the type of diabetes—if there is difficulty differentiating type 1 from type 2 diabetes, or if a rarer form of diabetes, such as MODY or mitochondrial diabetes, is suspected.

There may be additional services provided by the specialist provider, depending on local requirement that are not covered here. There will also be additional services that contribute to comprehensive diabetes care, that are dealt with through broader population based services, such as ophthalmology/medical retinal services and retinal screening services. Where this is the case, it is however important that such services are still integrated within the diabetes care pathways—for example, that the recognition of significant diabetic retinopathy is associated with greater input and efforts to improve glycaemic and blood pressure control by diabetes care pathway generalists and/or specialists as appropriate. It is also important to ensure that the number screening positive with retinal screening is matched by appropriate capacity in ophthalmology/medical retinal services, even if such services are not included within the diabetes service specification.

This model of care is reliant on the seamless integration of generalist and specialist services. To achieve this it is essential that patient records are integrated—and wherever possible shared or owned by the person with diabetes—and the two elements have good communication mechanisms to allow for continuity of care. Integration can be further supported by formal arrangements for specialists to support generalists through:

- Email advice (e.g. a specified one working day turn-around for email advice);
- Telephone contact support (e.g. a dedicated daily time window for taking calls for advice).

For older people, many of whom will have complications of diabetes and hence will have multiple comorbidities and may also suffer frailty, there will need to be coordination of health and social care.

Competency of Healthcare Professionals and Continuous Professional Development

It is important to ensure that all staff involved in designing and delivering the service are trained in line with any national/professional recommendations and curricula to achieve key competencies that have been identified in their job role to deliver appropriate diabetes care. Time should be made available in job plans to support relevant initial, and then continuous professional development for all staff contributing to the diabetes clinical pathway. This provides an opportunity to foster further interaction between generalists and specialists. Diabetes specialist physicians, nurses, dieticians, podiatrist, and psychologist members of the MDT should provide continuing diabetes-specific education to members of the generalist teams. These specialist members of the MDT can also provide support, advice, and mentorship in diabetes management to members of the generalist teams.

Other Models of Service Provision

While the broad principles are similar, other models of diabetes care provision have been described and implemented in the NHS in England. All share the principles of patient-centred care, and integration of diabetes services [17].

The NHS RightCare Diabetes Pathway

NHS RightCare is a national NHS England supported programme committed to delivering the best care to patients, making the funding available go as far as possible and improving patient outcomes [18]. NHS RightCare advises local health economies to:

- Make the best use of their resources—by tackling overuse and underuse of resources.
- Understand their performance—by identifying variation between demographically similar populations so they can adopt and implement optimal care pathways more efficiently and effectively.

- Talk together about the same things—about population healthcare rather than organizations and encouraging joint decision-making.
- Focus on areas of greatest opportunity by identifying priority programmes which offer the best opportunities to improve healthcare for people and ensuring taxpayer money goes as far as possible.
- Use tried and tested evidence-based processes to make sustainable improvement to reduce unwarranted variation.

The RightCare diabetes pathway defines the core components of an optimal diabetes service, leaning heavily on the principles already outlined in the model of service delivery here, for people with type 1 and type 2 diabetes or those at risk of developing type 2 diabetes that delivers better value in terms of outcomes and cost. The pathway shows the core components of an optimal diabetes service, evidence of the opportunity to reduce variation and improve outcomes and the key evidence-based interventions which the system should focus on for greatest improvement, supported by practice examples from across the NHS [19]. The pathway allows local health economies to think about their existing diabetes service and compare it with an optimal diabetes service. It provides guidance for commissioners about the scale of improvements that could be delivered through optimization of local pathways.

Conclusions

Increasing diabetes prevalence has required evolution of healthcare delivery systems, with a view to long-term sustainability. With a focus on patient-centredness, much of the care now provided is by generalist healthcare professionals, necessitating effective integration of generalist and specialist services.

15.15.2 Health Economics of Diabetes Care and Prevention

Philip Clarke and Thomas Lung

Introduction

It has been estimated that the cost of diagnosed diabetes in 2017 was $327 billion accounting for 1 in 4 healthcare dollars [1]. A recent review of studies globally indicates an even greater relative cost in low- and middle-income countries [2]. For the majority of countries, overall healthcare expenditure has been increasing over time. Estimates from the Organisation for Economic Co-operation and Development (OECD) indicate that in 2019 the United States had the highest health expenditure amongst the developed nations of the world, at 17.0% of GDP. This has increased from 12.5% in the year 2000. Over the same period, health expenditure in the United Kingdom was 9.8% of GDP in 2019, up from 7.3% in 2000.

Like other types of healthcare, costs associated with diabetes has been rising over time. In the United States, the population diagnosed with diabetes has grown by approximately 700 000 people annually between 2012 and 2017 (24.7 million people in 2017) and medical costs associated with diabetes has increased by 26% (from $188 billion to $237.3 billion) during that same period [3]. 36.3% of these medical costs are attributed to insulin and prescription medications.

Sustainability

Studies examining key drivers of changes in health expenditure over time attribute the rise in many countries to population ageing, increasing demand for more and better healthcare, rising incomes as well as technological change. If real expenditure (i.e. spending adjusted for inflation) is rising faster than allocated expenditure (i.e. receipts from taxation), the increase in health expenditure must be offset by either increasing the allocated expenditure through raising the level of taxation, or reducing expenditure on other government programmes (e.g. education, defence). It is also important to efficiently allocate resources to ensure spending on healthcare represents value for money. Health economics is an important feature of healthcare decision-making to ensure sustainability of the health system.

Variations in Drug Prices and Its Impact on Sustainability

The changing demand for insulins in the United States is an example of how increasing health expenditure is impacted by technological change [4]. The introduction of newer medications has resulted in many individuals substituting analogue for human insulin, which is costlier. Figure 15.15.2.1 shows the cost of antihyperglycemic medications in the United States based on data from the Medicare Expenditure Panel Survey (MEPS) over time. The estimated cost of insulin per patient has increased from $231 in 2002 to $722 in 2012 (after adjusting for inflation), while the price of older oral therapies has decreased to $111 in 2012 (Figure 15.15.2.1). Given the substantial variation and increasing discrepancies in costs over time between these therapies, it is important to assess whether the more expensive therapies provide additional benefits to justify the additional costs (i.e. provide value for money).

Technological Change—An Ongoing Challenge for Health Systems

New technologies for the treatment of diabetes such as analogue insulin can provide additional benefits to patients but are often more expensive than the medical care they replace. The substantial costs in research and development incurred when developing new pharmaceuticals and medical devices means that higher prices are charged, particularly when patents protect new products.

Government budgetary constraints mean that expenditure on new drugs need to be assessed to determine if it represents value for money relative to existing expenditure and the communities' willingness to pay for more healthcare relative to other types of goods.

Economic evaluation is a tool that involves quantifying the healthcare costs and health outcomes of the new drug relative to a comparator drug. Normally, the comparator refers to the drug that is currently in use and will be replaced by the new drug. What matters most in an evaluation is the **incremental** (or **additional**) outcomes and costs between the new drug and its comparator, which is relevant for use in an economic evaluation [5].

The drug being evaluated and its comparator may incur positive and negative impacts on both outcomes and costs, highlighted in Table 15.15.2.1.

Positive outcomes associated with a new drug are reductions in the risk of morbidity (such as diabetes-related complications) and mortality and therefore an increase in patient's life expectancy, as well as their quality of life. Negative side effects can potentially increase the risk of adverse events, worsen quality of life, and elevate mortality risk.

When quantifying costs it is important to take account of the full cost of the intervention, so if a pharmaceutical drug was being evaluated, not only is it important to cost the drug itself, but also the cost of administration (e.g. the time taken by a practice nurse or diabetes educator when patients start insulin therapy). The use of

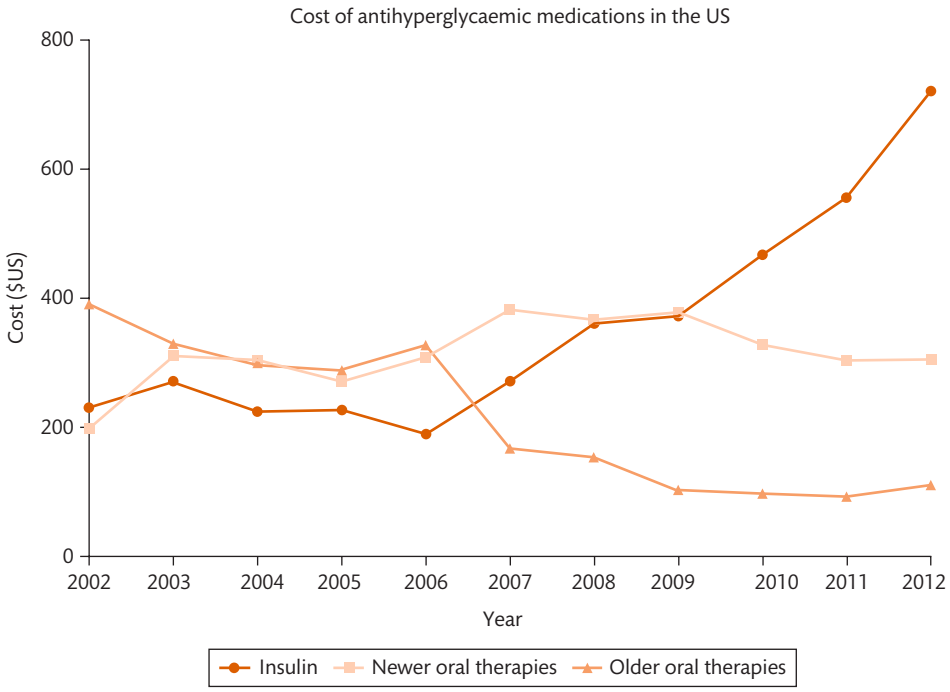

Figure 15.15.2.1 Cost of antihyperglycemic medications in the United States, 2002–2012.

Insulin = human and analogue. Newer oral therapies = thiazolidinediones, dipeptidyl peptidase-4 inhibitors, and combinations. Older oral therapies = metformin, sulfonylureas, α-galactosidase inhibitors, and non-sulfonylurea secretagogues.

some types of healthcare may have an impact on downstream costs. For example, drugs that prevent diabetes complications may reduce rates of hospitalizations and other medical services. Reductions in healthcare costs are known as **cost savings** and represents a monetary gain to society.

Economic evaluation essentially compares the costs and benefits of the intervention in question (new or existing) to an alternative intervention; it is dependent on the availability of information on the costs and effectiveness associated with an intervention.

Economic evaluation involves the calculation of a ratio of incremental costs to incremental outcomes, known as the **incremental cost-effectiveness ratio** (ICER) using the formula:

$$\text{Incremental cost} - \text{effectiveness ratio} = \frac{\text{Cost of intervention A} - \text{Cost of intervention B}}{\text{Outcomes of intervention A} - \text{Outcomes of intervention B}}$$

Table 15.15.2.1 Outcomes and costs to be considered when assessing a new diabetes intervention

Costs • Drug price and duration of use; • Cost of administration/prescription (e.g. visits to doctor) • Cost of healthcare utilization (hospitalizations, medical services, use of other drugs)	**Positive outcomes (Benefits)** • Increases in life expectancy • Improvements in quality of life • Reduced hospitalization events
Savings • Reduced healthcare utilization due to the drug	**Negative outcomes (Side effects)** • Adverse events including elevated risk of mortality • Adverse impacts on patient reported outcomes including quality of life

The ICER is a measure of the additional cost per additional unit of health outcome produced by an intervention compared with another.

There are three main types of economic evaluation: **cost-benefit analysis**, **cost-effectiveness analysis, and cost-utility analysis**. These differ only in the metric used to qualify outcomes. Cost-benefit analysis values outcomes in monetary terms, which is often challenging due to the subjectivity of putting a dollar value on the health of individuals. Cost-effectiveness analysis values outcomes in the same unit of health gain. Examples of health outcomes are life expectancy, cardiovascular disease event prevented, and hospital admission averted or life-years gained. A limitation of cost-effectiveness analysis is its reliance on a single, specific measure of outcome. Cost-utility analysis enables comparison of interventions of different health outcomes of interest because it accounts for both length and quality of life using an outcome known as **quality-adjusted life-years** (QALYs).

QALYs are a measure of health outcomes in which life expectancy, in terms of life-years, is weighted by an index of quality of life and measured on a scale in which 1 represents full health and zero represents health states equivalent to death. For example, if an intervention that results in a 10-year gain in life expectancy but the quality of life for each of those years was valued at 0.5, then the gain over a 10-year period is calculated to be 5 QALYs.

Health Technology Assessments

Economic evaluation is a tool used in health technology assessment (HTA) to help inform decision-making and is one of the criteria for allocating public funds. In many countries, HTA research is undertaken to evaluate any intervention used in the treatment,

prevention, or diagnosis of disease that has the potential to directly benefit patients. Normally, some evidence of efficacy already exists for an intervention. However evidence of cost-effectiveness has yet to be determined. There are a wide range of interventions for diabetes management, from treatment-specific interventions (pharmaceutical and medical devices) that lower blood glucose, improve metabolic control, to prevention, health promotion, and broader community interventions.

Economic evaluations of early intensive blood glucose-lowering trials, notably the DCCT and UKPDS, suggested that such policies are cost-effective. For example, an analysis of UKPDS intensive blood glucose control based on policies of using insulin and sulphonylureas reported an ICER of around £6000 per QALY, while blood glucose control with metformin was cost-saving [6]. Similarly, large clinical trials of better control of blood pressure [7] and lipid lowering [8] show that these strategies are also cost-effective and (in some cases) cost-saving. Lifestyle management interventions such as the Diabetes Prevention Program (DPP) have also been found to be cost-effective (discussed later) [9].

It is important to note that the cost-effectiveness of interventions may vary over time or across different healthcare settings, particularly if the cost of therapies change (see Figure 15.15.2.1). In such an environment, decision makers need to consider whether different strategies for prevention and treatment of diabetes are considered value for money and hence should be funded. Economists use the calculated ICER to implicitly place a value on extending and improving the quality of life. This is done by identifying a benchmark or threshold to determine whether an intervention is worth funding relative to outcomes.

What threshold should be used in the US? While there is no universally accepted amount, many studies often quote around $US50 000 per QALY. The origins of this threshold come from an American study in the 1970s that estimated the funding of dialysis patients with end-stage renal disease, the argument being that if there was public funding provided for dialysis then public funding should also be provided for interventions that had lower cost-effectiveness ratios [10]. In the United Kingdom, the National Institute for Health and Clinical Excellence (NICE) has an explicit threshold of £30 000 per QALY [11] although some have recently questioned this level as analyses of actual funding decisions indicates lower levels are currently being spent on care in the United Kingdom.

Use of Simulation Modelling

While there are now many randomized controlled trials of therapies for people with diabetes, economic evaluations just based on the evidence from such studies do not capture all the costs and benefits associated with these interventions due to the limited timeframe of the trial. Figure 15.15.2.2 illustrates the lifetime outcomes (measured in QALYs) of intensive blood glucose therapy based on evidence from the UKPDS [6, 12]. Although the UKPDS was a study of comparatively long duration having a median follow-up of over 10 years, the majority of the incremental outcomes (and costs) of intensive therapy over conventional therapy occurred after completion of the trial.

Quality-Adjusted Life Year in the US

Simulation modelling can be used to extrapolate beyond the results of a clinical trial to capture the costs and health outcomes accumulated over a lifetime associated with an intervention. Models such as

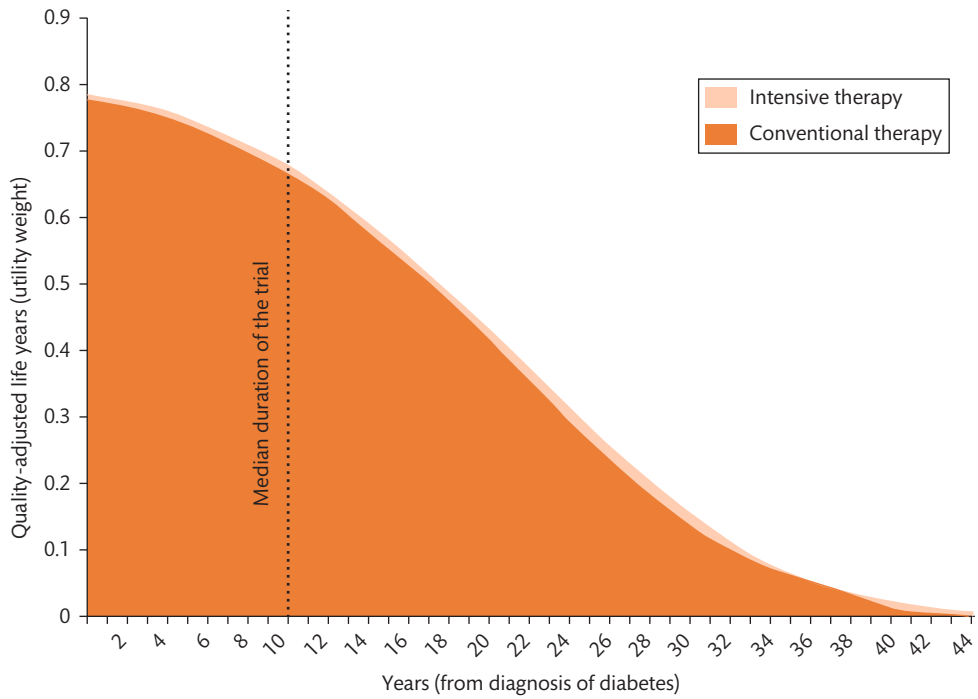

Figure 15.15.2.2 Average quality-adjusted life year estimates per year following the diagnosis of diabetes for individuals randomized to the intensive blood glucose and conventional therapy group of the United Kingdom Prospective Diabetes Study (UKPDS).

the UKPDS Outcomes model have been used in type 2 diabetes to explore head-to-head comparisons of new interventions to an existing treatment, developed using survival analysis techniques on data from the trial to estimate lifetime health outcomes and costs for type 2 diabetes patients [13, 14]. This has been used worldwide to investigate the cost-effectiveness of interventions that could potentially lower the risk and healthcare costs associated with diabetes-related complications, as well as prevent premature mortality.

Case Study—Economic Evaluation Comparing a Lifestyle Intervention Versus Metformin for the Prevention of Diabetes

People with impaired glucose tolerance (IGT) are at high risk of progressing to type 2 diabetes. The DPP was a large randomized controlled clinical trial that tested whether either lifestyle (diet, exercise, and behaviour modification) changes or metformin could prevent or delay the onset of type 2 diabetes in over 3000 people with IGT [15]. Over a 3-year period, individuals reduced their risk of developing diabetes by 58% in the lifestyle intervention group and 31% in the metformin group when compared to the placebo group. DPP participants were followed up for an additional 7 years to assess the long-term effects of the interventions on health and healthcare utilization.

An economic evaluation was conducted comparing the lifestyle and metformin interventions with the placebo group. Both intervention groups experienced savings due to lower medical care costs, with less doctor and hospital visits, and other types of medications compared to the placebo group. Over a 10-year period the average cost per person was calculated to be an additional $928 in the lifestyle group compared to placebo, while metformin was cheaper than the placebo group ($321 per person).

Outcomes were assessed in terms of the cumulative number of QALYs over a 10-year period. The total increase in QALYs was approximately 0.14 and 0.02 for the lifestyle and metformin groups, respectively. It is important to remember that both outcomes and costs in economic evaluation are represented as the average or mean change, and may vary considerably between individual patients. For example, blood-pressure medication may have a large impact on an individuals' survival if it prevents them having a stroke, but may be of no benefit on survival for other patients.

Using the information provided on the costs and outcomes of both interventions (see Table 15.15.2.2):

Then, using the formula to calculate an ICER for the lifestyle intervention group compared to the placebo group:

$$\textit{Incremental cost} - \textit{effectiveness ratio} = \frac{\$928}{0.14} = \$6629.$$

Table 15.15.2.2 Incremental costs and incremental QALYs of the lifestyle and metformin interventions, when compared to the placebo group over a 10-year period

	Incremental Costs	Incremental QALYs
Lifestyle intervention	$928	0.14
Metformin intervention	-$321	0.02

Note that no incremental cost-effectiveness ratio was calculated for the metformin group. That is because the metformin intervention is both **cheaper** and **more effective** compared to placebo, which is a cost-saving scenario and an easy decision to fund for policymakers. This is known as a **dominant** intervention.

This means it costs on average around $6600 for each additional QALY gained through the use of a lifestyle intervention. Is it worth society spending the extra money to ensure access to the lifestyle intervention for diabetes prevention in adults with IGT?
