Chromosomal disorders: In these disorders the number of chromosomes in an individual (their **karyotype**), or their DNA structure, is altered producing excessive or deficient genetic material. Normally every individual has 22 pairs of autosomes and one pair of sex chromosomes (XX in females and XY in males). In chromosomal disorders the number of chromosomes may be different (e.g. in Down's syndrome there are three copies of chromosome 21), or large segments of chromosomes may be deleted or exchanged with other chromosomes causing a variety of different disorders and syndromes. One of the most important of these changes is termed copy number variants (CNVs), and they consist of deletions or duplications of DNA segments with a size of 1000 bases to several million bases.

Mendelian disorders: These disorders are caused by a mutation in a single gene. They display specific patterns of inheritance that can be classified as **dominant** (inheritance of one mutant gene, from either parent, will cause disease), **recessive** (only inheritance of both mutant genes, one from each parent will cause disease), or X-linked (see next).

Complex diseases: These disorders are caused by interactions between multiple genes. These interactions may presumably be deficient or excessive or unusual and involve most of the common diseases we know so well including autoimmune thyroid disease. How multiple gene involvement may produce such similar clinical phenotypes is not well understood.

Epigenetics and disease: One explanation to help understand complex genetics has been our increased understanding of epigenetic and environmental factors. Gene expression and suppression is not only controlled by mRNA and its cofactors but by how DNAs folds thus opening and closing genes to the polymerases. Such acetylation and methylation events on the surface of the DNA (epigenetics) may also be influenced by the environment and contribute to the activity of multiple genes impacting the clinical phenotype.

Inheritance of Mendelian Disorders

Dominant Mendelian disorders: These disorders manifest in heterozygotes (i.e. when one mutant allele is present but the second allele of the same gene is normal then the mutant is expressed). The mutant gene in this case is on one of the 22 autosomes. Examples of dominant Mendelian disorders include thyroid hormone resistance syndrome, and MEN 2.

Recessive Mendelian disorders: These disorders are clinically apparent only in homozygotes (i.e. when both alleles at a particular genetic locus are mutated so there is no normal gene at all). The mutation in these disorders is also on one of the 22 autosomes. Examples of recessive Mendelian disorders include familial non-autoimmune hypothyroidism and Pendred's syndrome.

X-linked Mendelian disorders: These disorders occur when the mutant gene is on the X chromosome. Most X-linked Mendelian disorders are recessive rather than dominant. Therefore, females can be affected only if they inherit two mutant genes on both of their X chromosomes, while males are affected if they inherit only one mutant gene on their X chromosome. An endocrine example of an X-linked Mendelian disorder is familial thyroxine binding globulin (TBG) deficiency.

Inheritance of Complex Diseases

As we discussed earlier, the inheritance of complex diseases, such as GD and Hashimoto's thyroiditis (HT), does not follow a simple Mendelian pattern. These diseases are caused, in part, by multiple genes with additive and negative effects. Moreover, the penetrance of complex diseases tends to be low (i.e. not all the individuals inheriting the mutations or polymorphisms will actually develop the clinical phenotype). This causes a non-Mendelian pattern of transmission of the disease in pedigrees and makes mapping their susceptibility genes much more challenging than mapping Mendelian disorder genes. But, of course, all individual genes are inherited in a Mendelian pattern.

Chromosomal and Mendelian Disorders Affecting the Thyroid

Chromosomal Disorders Associated with Thyroid Dysfunction

Several chromosomal disorders are known to be associated with an increased incidence of thyroid disease (Table 3.2.1.1). The association between Down's syndrome and autoimmune thyroid diseases (AITD) is especially intriguing because of the possibility that a gene conferring susceptibility to autoimmune thyroid diseases is located on chromosome 21. Although this has been investigated extensively there is still no evidence of an AITD susceptibility gene on chromosome 21 (see next). Interestingly, on chromosome 21 is the autoimmune regulator (AIRE) gene and, when it is mutated it causes autoimmune polyglandular syndrome type I.

Mendelian Disorders Involving the Thyroid

Many Mendelian disorders of thyroid hormonogenesis and regulation have been described and many of the mutations causing these disorders have been revealed. Table 3.2.1.2 summarizes the major Mendelian disorders affecting the thyroid, their pathophysiology,

Table 3.2.1.2 Mendelian disorders of the thyroid*

Gene	Locus/Chr	Disease	MOI	Gene mutation and pathogenesis	Clinical signs
TRH	3	Isolated TRH deficiency	AR	TRH deficiency leads to low TSH that increases with TRH administration	Central hypothyroidism
TSH-β chain	1p22	Isolated TSH deficiency	AR	Mutations in the TSHβ gene that lead to a mutated TSHβ protein that cannot associate with the α-subunit to produce a functional TSH heterodimer	Central hypothyroidism
Pit-1	3p11	Combined pituitary GH, PRL, TSH deficiency	AD/AR	Mutations in the transcription activating factor Pit-1 that regulates expression of GH, PRL, TSH, and the development of somatotrophs, lactotrophs, and thyrotrophs	Central hypothyroidism and GH and PRL deficiencies
TSH Receptor	14q31	Familial hypothyroidism/ TSH Resistance	AR	Inactivating mutations in the extracellular or transmembrane domains of the TSHR making it unresponsive to TSH	Congenital hypothyroidism, hypoplastic thyroid, or euthyroidism with high TSH
		Familial non-autoimmune hyperthyroidism	AD	Activating mutations in the transmembrane domain of the TSHR leading to constitutive activation of the TSHR	Hyperthyroidism, goitre, no signs of autoimmunity
		Familial gestational hyperthyroidism	AD	Mutation in the extracellular domain of the TSHR leading to hypersensitivity of the TSHR to chorionic gonadotropin	Gestational hyperthyroidism and hyperemesis gravidarum
TTF1	14q12-13	Congenital hypothyroidism	AD	Mutations (missense, nonsense) cause an alteration of the DNA-binding domain resulting in loss of functional activity and reduction in the production of TTF1 levels in heterozygotes (haploinsufficiency). The mechanism responsible for elevated TSH with normal thyroid gland, in several cases, is still unclear	Elevated TSH, normal or low T_4, neurological abnormalities, respiratory distress
TTF-2	9q22	Congenital hypothyroidism	AR	Missense mutations of TTF-2 lead to a protein with impaired DNA binding and total (homozygotes) or partial (heterozygotes) loss of transcriptional function	Congenital hypothyroidism with thyroid agenesis, cleft palate, spiky hair
PAX-8	2q12-q14	Congenital hypothyroidism	AD	Mutations cause a marked reduced DNA binding capacity with loss of transcriptional activation function	Congenital hypothyroidism, hypoplastic, and sometimes ectopic thyroid, renal abnormalities
Na/I Symporter	19p12	Congenital hypothyroidism	AR	Inactivating mutations of the Na/I symporter leading to defective or absent iodine uptake by thyroid cells	Congenital hypothyroidism, goitre, defective iodine uptake in the thyroid
TPO	2p25	Congenital hypothyroidism	AR	Inactivating mutations leading to inactive TPO, or to disturbed integration of TPO in the membrane thus causing defective or absent organification of iodide	Congenital hypothyroidism, goitre, abnormal perchlorate discharge test, sometimes intellectual disability
Pendrin	7q22	Pendred's syndrome	AR	Inactivating mutations in the Pendrin gene, which is a sulphate transporter, cause disruption of iodide transport from thyroid follicular cells to the follicular lumen	Goitre, congenital sensorineural deafness
Tg	8q24	Congenital Tg deficiency	AR	Quantitative abnormalities in Tg, mutations in the Tg gene, defects in glycosylation, or transport of Tg cause impaired coupling of iodotyrosines	Goitre, hypothyroidism, or euthyroidism, low or absent serum Tg, no colloid in the thyroid gland
DUOX2 (THOX2)	15q15.3	Congenital hypothyroidism	AD	Mutations (nonsense, missense) in the *DUOX2* gene result in insufficient or absent production of hydrogen peroxide, needed for TPO action	Permanent/transient congenital hypothyroidism, complete/partial iodide organification defect
DUOXA2	15q15.1	Congenital hypothyroidism	AR	Nonsense mutation of *DUOXA2* result in complete loss of function of the protein. Since *DUOXA2* is essential for DUOX2 activity, it leads to a secondary deficit of *DUOX2* (see above)	Congenital hypothyroidism, goitre, abnormal perchlorate discharge test

(*continued*)

Table 3.2.1.2 *Continued*

Gene	Locus/Chr	Disease	MOI	Gene mutation and pathogenesis	Clinical signs
DEHAL1	6q25	Goitrous hypothyroidism	AR	Missense mutations or deletion in *DEHAL1* lead to a protein with reduced capacity to deiodinate monoiodotyrosine and diiodotyrosine	Hypothyroidism in infanthood or childhood, goitre, elevated serum diiodotyrosine. Mental and psychomotor retardation develop if hypothyroidism is not treated
SECISBP2	9q22.2	Reduced deiodinase activity	AR	Mutations in SECISBP2 gene affect the synthesis of selenoproteins and lead to a reduction in deiodinase 2 activity	Short stature and delayed bone age. High T_4, low T_3, high rT_3, slightly elevated TSH
TBG	Xq23	Congenital TBG deficiency	X-linked	Inactivating (deletions, missense, non-sense) mutations in the TBG gene leading to partial or complete deficiency of TBG	Decreased total T_4, normal free T_4, euthyroidism
		Inherited TBG excess	?	Excess TBG of unknown cause results in elevated levels of TBG and total T_4	Increased total T_4, normal free T_4, euthyroidism
Transthyretin	18	Familial euthyroid hyperthyroxinaemia due to TTR abnormalities	AD	Point mutations in the *TTR* gene cause increased affinity for T_4 and T_3	High total T_4, normal free T_4, euthyroidism, Familial amyloidotic polyneuropathy
Albumin	4q11	Familial dysalbuminaemic hyperthyroxinaemia	AD	Point mutations in the albumin gene lead to increased affinity for T_4 and T_3	High total T_4, normal free T_4, euthyroidism
MCT-8	Xq13.2	Allan–Herndon–Dudley syndrome	X-linked	Mutations (truncating, in-frame deletion, missense) in the *MCT-8* gene alter the intracellular availability of thyroid hormones	Affected males present abnormal thyroid function tests (increased T_3 and decreased T_4 and rT_3) and severe psychomotor and developmental delay. Females carriers have only mild thyroid functions test abnormalities
TRβ	3	Resistance to thyroid hormone	AD	Mutations in the TRβ gene lead to a thyroid hormone receptor with reduced affinity for T_3 or abnormal interaction with a cofactor necessary for T_3 action	Goitre, tachycardia, hyperactivity, developmental delay. Elevated serum T_3 and T_4 with non-suppressed TSH. Serum Tg is often elevated

* Abbreviations used in the table: AD, autosomal dominant; AR, autosomal recessive; Chr, chromosome; DEHAL1, iodotyrosine deiodinase; DUOX2, dual oxidase 2; DUOXA2, dual oxidase maturation factor 2;GH, growth hormone; MOI, mode of inheritance; MCT-8, monocarboxylate transporter 8; Na/I symporter, sodium iodide symporter; PAX-8, paired box 8;PRL, prolactin; SECISBP2, selenocysteine insertion sequence-binding protein 2; TBG, thyroxine binding globulin; Tg, thyroglobulin; THOX2, thyroid oxidase 2; TPO, thyroid peroxidase; TRβ, thyroid hormone receptor β;TRH, thyrotropin releasing hormone; TTF-1, thyroid transcription factor-1; TTF2, thyroid transcription factor-2; TTR, transthyretin; TSH, thyroid stimulating hormone (thyrotropin).

clinical characteristics, and their mode of inheritance. These disorders are described in more detail elsewhere in this book.

Genetic Susceptibility to Autoimmune Thyroid Disease (AITD)

The AITDs are examples of complex genetic diseases affecting the thyroid. Classically, the AITDs encompass a spectrum of related disorders varying from hyperthyroid Graves' disease (GD) to hypothyroid Hashimoto's thyroiditis (HT) and which are characterized by abnormal autoimmune responses to thyroid antigens. Additional variants of AITD include postpartum thyroiditis (reviewed in [1]), drug induced thyroiditis, such as interferon induced thyroiditis (IIT) [2], thyroiditis associated with polyglandular autoimmune syndromes (reviewed in [3]) and just the presence of thyroid antibodies (TAb) with no apparent clinical disease [4] but which simply indicates the presence of an intrathyroidal infiltrate but retention of normal thyroid function. The AITD are among the commonest human autoimmune disorders affecting more than 5% of the general population [5, 6]. The AITD, including Graves' and Hashimoto's diseases, are categorized as complex diseases because they are believed to be caused by an interaction between several genes and a variety of environmental factors. In recent years, sound epidemiologic evidence for a genetic susceptibility to AITD has been established. Box 3.2.1.1 summarizes these main epidemiological data pointing to a genetic susceptibility to AITD.

Geographic and Longitudinal Trends in the Incidence of the AITD

The annual incidence of GD in populations of different geographic locations, excluding extremes of iodine intake, is similar and ranges from 0.22 to 0.27 per 1000 [5, 6]. A similar pattern has been observed for HT. In the UK Whickham survey the prevalence of spontaneous hypothyroidism was 15/1000 in females compared with less than 1/1000 in males [6]. The mean annual incidence of spontaneous hypothyroidism in women was 3.5/1000 and in men was 0.6/1000 [7]. Similar prevalence and incidence data of spontaneous hypothyroidism have been reported by others in the United States, Finland, Japan, and Sweden. The comparable prevalence and incidence of the AITD in geographically different populations has suggested that the genetic contribution to the development of the AITD is more important than the environmental contribution because these populations are exposed to different environmental factors.

A longitudinal study from the Mayo clinic (1935–1967) showed no significant change in the incidence of GD over the 33 years of the study [8]. The stable incidence of GD with time once again points to strong genetic effects because the genetic makeup of a population did not appear to change over several decades, but environmental factors most probably did. The Mayo clinic observations were supported by a more recent study from Sweden [9]. However, the Swedish study found an increased incidence of GD in a subset of the population, demonstrating that environmental effects may still play a crucial role in the aetiology of GD. In the Mayo survey (1935–1967) there was a significant increase in the incidence of HT over the 33 years of the survey [8]. This could reflect a stronger environmental influence on the development of HT rather than GD or more likely a change in the diagnostic criteria over time [10].

Box 3.2.1.1 Epidemiological evidence for a genetic susceptibility to Graves' disease and Hashimoto's thyroiditis (see text)

- I Secular trends in the incidence of AITD:
  - 1) The incidence of GD/HT is similar in different ethnic populations
  - 2) The incidence of GD has not changed over time in the past several decades
- II Variations in the incidence of AITD with age:
  - 1) The incidence of GD/HT peaks in the fifth decade of life
  - 2) After peaking the incidence of GD/HT declines to zero (suggesting that all genetically susceptible individuals have developed the disease)
- III Familial clustering of AITD:
  - 1) AITD develops in 20–30% of siblings of patients with AITD
  - 2) The sibling risk ratio (8_s) for AITD is 16.9
  - 3) Thyroid antibodies are found in up to 50% of siblings of patients with AITD
- IV Twin studies:
  - 1) Concordance rate in MZ twins for GD is 30–35% and in DZ twins it is 3–5%
  - 2) Concordance rate in MZ twins for GD is 55% and in DZ twins it is 0%

Familial Clustering

The familial occurrence of the AITD has been recognized by investigators for many years. More than 50 years ago it was recognized that a familial predisposition can be found in approximately 50% of cases with GD. Later studies have shown a high frequency of thyroid abnormalities in relatives of patients with AITD [11], most commonly the presence of thyroid autoantibodies which were reported in up to 50% of the siblings of patients with GD [12]; 36% of GD patients with ophthalmopathy had a family history of AITD while 32% had a first-degree relative with AITD [13]. Moreover, a study from Holland in which 790 healthy female relatives of AITD patients were followed for up to 5 years, showed that 7.5% of them developed overt hypothyroidism or hyperthyroidism [14].

Such familial clustering of a disease can be due to non-genetic factors including the shared environmental exposures (e.g. infections, diet). Therefore, methods have been developed to determine whether familial clustering of a disease is the result of genetic susceptibility or non-genetic factors. One method is to calculate the sibling risk ratio (λs) which expresses the increased risk of developing the disease in an individual who has a sibling with the disease compared to the risk in the general population, and has been claimed as a quantitative measure of the genetic contribution to the disease. A λs of > 5 has been used to indicate a significant genetic contribution to the pathogenesis of a disease [15]. We calculated the λs in AITD in a cohort of 155 AITD patients. The λs was 16.9 for AITD, 11.6 for GD, and 28.0 for HT. These high λs values indicate a strong familial influence on the development of AITD.

Twins Studies

Twin studies can provide information concerning the inheritance of a disease and may yield certain quantitative evaluations on the role of heredity in relation to exogenous factors. Twin analysis is based upon comparison of the concordance (simultaneous occurrence) of a disease among monozygotic (MZ) twins vs. dizygotic (DZ)

twins. MZ twins have similar genetic makeup, whereas DZ twins share an average of 50% of their genes (like siblings). Therefore, if concordance is higher in the MZ twins when compared to the DZ twins it suggests that the disease has an inherited component. Any discordance among the MZ twin pairs is usually interpreted to mean that the gene or genes concerned show reduced penetrance (i.e. certain epigenetic or environmental factors must be present before the disease becomes manifest). However, this logic has its limits for autoimmune diseases. This is because MZ twins are not immunologically identical. Since the T-cell receptor and immunoglobulin V genes undergo random recombination, twins have different immune repertoires although they may be sculpted by the same environment.

Nevertheless, the concordance rate in MZ twins is taken as an estimate of the penetrance of the disease but this is only up to the age they are examined. For example, if the concordance rate among the MZ twins is 50%, this is taken to mean that the penetrance of the disease genes is approximately 50%. As discussed, however, it must be emphasized again that MZ twins are not identical and their individual immune experiences will influence their immune repertoire. Therefore, part of the observed discordance between MZ twins may also be due to the discordance in their immune repertoire.

The concordance rate for GD in MZ twins was found to be approximately 30–35% while the concordance rate in DZ twins was reported to be about 3–5% [16–18]. These data indicated that there is a substantial inherited susceptibility to Graves' disease, presumably related to both immune and non-immune genes. For HT the concordance rates were 55% and 0% for MZ and DZ twins, respectively [19], again pointing to a strong genetic component in the aetiology of the disease. Finally, for thyroid antibodies, MZ twins had 80% concordance and DZ twins had 40% concordance [19]. Thus, the twin data support a substantial inherited susceptibility to AITD. Indeed, a recent study estimated that 80% of the liability to develop GD was due to genetic factors [17]. A similar strong genetic contribution was estimated for the production of thyroid antibodies.

Thyroid Autoantibodies

Autoantibodies to thyroglobulin (Tg) and thyroid peroxidase ([TPO] the microsomal antigen) have been widely used to show the population at most risk for the development of AITD. An increased prevalence of thyroid autoantibodies has been reported in relatives of patients with AITD [20–30]. Antithyroid autoantibodies (antithyroglobulin and antithyroid peroxidase) have been found in up to 50% of the siblings of patients with the AITD [12], in contrast to a prevalence of 7–20% in the general population [6]. These findings are true in different populations such as the Japanese [20] and British populations [11]. In one study, it was found that thyroid antibodies were almost always present in one of the parents of an affected individual with AITD [11]. These data suggested an inherited influence on the production of antithyroid antibodies compatible with dominant inheritance. Indeed, segregation analyses in a panel of families with thyroid antibodies also suggested a Mendelian dominant pattern of inheritance for the tendency to develop antithyroid antibodies [21]. In keeping with these observations, it was reported that recognition of particular thyroid peroxidase (TPO) epitopes within the autoantibody immunodominant region may be transmitted within families [22].

Graves' Orbitopathy

Depending on the definition of Graves' ophthalmopathy (GO), it would appear to affect about 90% of patients with GD and so is an intrinsic part of the disorder although rarely it may be found without thyroid involvement and also is seen regularly in patients with HT who may or may not have experienced GD. However, the severe form of ophthalmopathy occurs in less than 10% of GD patients. Severe GO manifests by proptosis, conjunctival injection, eye muscle weakness to paralysis, and sometimes optic nerve damage. GO is considered pathognomonic of GD even when the individual is not thyrotoxic. It was speculated that the genetic influence on the development of Graves ophthalmopathy could be more pronounced because GO represents the most severe form of the disease. We, therefore performed a segregation analysis in patients selected for severe GO by studying the first-degree relatives of individuals with severe GO. If the disease is hereditary the first-degree relatives would be expected to be affected by the disease more often than individuals randomly selected from the general population. Our segregation analysis showed that GO did not have a major genetic component [13]. Although a genetic contribution to the susceptibility to develop GO has been claimed [23] such a non-specific gene association could simply enhance susceptibility to more severe GD.

Tools to Map Complex Disease Genes

Based on the abundant epidemiologic evidence for a strong genetic effect on the development of AITD, many searches for the susceptibility genes have been performed. The basic strategies used for finding complex disease genes include association and linkage studies of candidate genes, and whole genome screening. These tools have proven successful in the mapping of many novel complex disease genes such as rheumatoid arthritis but often find genes which provide very small contributions to susceptibility.

Association and Linkage

Association analyses: Association analyses are sensitive tests which can locate even minor susceptibility genes. Population-based association tests compare **marker allele** frequencies (such as an HLA haplotype) in unrelated patients to a set of unrelated, carefully matched, controls. Identification of a significant difference between patients and controls suggests that a genetic locus at, or near, the marker locus influences disease predisposition due to linkage disequilibrium. Linkage disequilibrium exists when chromosomes with the mutant allele at the disease locus carry certain marker alleles more often than expected by random chance. It cannot be emphasized enough that the control population must be appropriate since everything hinges on simple comparisons. Furthermore, the larger the control group the less chance of getting this matching wrong.

Association analysis is very sensitive and may detect genes contributing less than 5% of the total genetic contribution to a disease. Classically, association studies were used for studying candidate genes, and for fine mapping linked loci. However, association studies are also utilized to screen the entire human genome (see next).

As discussed earlier, one of the weaknesses of population-based methods is that they can produce spurious associations if the patients and controls are not accurately matched (so-called **population**

stratification). Therefore, family-based association tests have been developed which use an internal control group from within each family, thus avoiding the necessity to match patients and controls for ethnicity. The most widely used family-based association test is the **transmission disequilibrium test** (TDT). The TDT is based on the comparison of the parental marker alleles which ***are*** transmitted and those which are ***not*** transmitted to affected children (Figure 3.2.1.2). Assuming two heterozygote parents for a certain tested marker, each parent has two sets of chromosomes so there are four parental alleles in each family. These are categorized into two groups: those transmitted to a child with the disease (T alleles), and those not transmitted to any affected child (N alleles). The same allele may belong to the T group or the N group in different families. The frequency of the T alleles versus the N alleles is then compared by a Π^2 test. An association between a certain allele and the disease exists if there is an excess occurrence of this allele in the T group compared to the N group.

Linkage: Genetic linkage techniques are powerful tools for analysing complex disease-related genes because they detect only genes that theoretically have a major effect (>5%) on the aetiology of a disease. The consequence is that linkage studies are less sensitive than association studies since they do not detect minor contributing genes. The principle of linkage analysis is based on the fact that if two genes are close together on a chromosome they will segregate together because the likelihood that a recombination will occur between them is low. Therefore, if a tested marker is close to a disease susceptibility gene, its alleles will cosegregate with the disease in families (Figure 3.2.1.3). The LOD (logarithm of odds) score is the statistical measure of the likelihood of linkage between a disease and a genetic marker. The LOD score is the base-10 logarithm of the odds ratio in favour of linkage. Arbitrarily, a LOD score of greater than 3 (i.e. odds ratio greater than 1000) is considered strong evidence for linkage and a LOD score greater than 2 is suggestive of linkage.

Linkage at a certain locus is established when at least two or more independent datasets give strong evidence for linkage at the same locus. Conversely, a LOD score lower than –2 can be used to exclude linkage. The classical linkage tests are model based (i.e. a mode of inheritance and penetrance have to be assumed when calculating the likelihood of linkage). However, in complex diseases the mode of inheritance is often unknown and, therefore, model-independent methods are sometimes used. One such method, which became very popular, is sib-pair analysis (Figure 3.2.1.4). Here siblings, which are both affected by the disease being studied, are tested for sharing of alleles at a marker locus. By random chance alone the sibs would be expected to share one allele of the marker 50% of the time. If affected sib-pairs share a significantly higher than expected proportion of alleles at the marker locus, this suggests that the marker locus is in linkage disequilibrium with the disease gene. This observed to expected allele sharing can be converted to a LOD score equivalent.

Candidate Gene Analysis

Candidate genes are genes of known sequence and location that by virtue of their known functions may be involved in disease pathogenesis. For example, one can hypothesize that the TSH receptor may be a candidate gene for GD because the hallmark of the disease is the presence of TSH receptor antibodies. If a candidate locus is indeed the cause of a disease, then markers in that locus should segregate with the disease within families giving high LOD scores. Since the basic abnormality in AITD is an immune response against thyroid antigens, possible candidate genes for AITD include genes that control immune responses (e.g. the major histocompatibility complex [MHC or HLA] genes, and costimulatory molecule genes), and genes encoding the target autoantigens in AITD (thyroglobulin, thyroid peroxidase, iodide transporter, TSH receptor). Many of these genes have now been studied for their possible role in the genetic susceptibility to the AITD (see next).

Whole Genome Screening

Another approach is to screen the whole human genome without any assumptions on disease pathogenesis. This method is called whole genome screening. Whole genome scans can be performed using linkage as well as association methods.

Linkage-based genome scans: The two requirements for performing a linkage-based whole genome screen in a complex disease are:

1. The availability of a sizeable and well validated data set of multiplex families (large families with more than one individual affected).
2. The availability of a map of highly polymorphic markers covering the whole genome.

Microsatellite markers: The first useful polymorphic markers for whole genome screening were discovered in 1989 and were called microsatellites. Microsatellites are regions in the genome that are composed of short sequence repeats, most commonly two-base CA-repeats (Figure 3.2.1.5). Microsatellite loci are highly polymorphic (i.e. have many alleles) because the number of repeats in each individual is variable. Moreover, they are extremely abundant and uniformly distributed throughout the genome at distances of less than 1 million base pairs. Therefore, microsatellites serve as excellent markers in whole genome linkage studies.

Single nucleotide polymorphisms (SNPs): SNPs are single base pair positions in genomic DNA at which different sequence alternatives (alleles) exist in normal individuals. In humans most SNPs have only two alleles. SNPs are very abundant with a frequency of about one SNP per <500 bp. Since SNPs have only two alleles they are less informative than microsatellites, and a larger number of SNPs is required to screen the human genome by linkage. However, since SNP's are much more abundant and closely spaced than microsatellites, they are ideal for fine mapping genes, in linked regions, using association studies and for association-based genome scans (see next). The importance of SNPs stems from the fact that many have the potential to change the amino acid sequence of a gene product, or other regulatory sequences (e.g. promoter) and be directly involved in the susceptibility to complex diseases because they cause changes in gene function. Thus, if a SNP allele inside a gene is found to be significantly associated with a disease it may be the actual causative allele, increasing susceptibility to the disease.

Using microsatellites or SNPs many linkage-based whole genome screens have been now completed for several complex diseases including the AITD (see next).

Genome-wide association studies: Genome-wide association studies have two major requirements:

1. The availability of a sizeable data set of affected individuals and a sizeable ethnically matched control group.
2. The availability of closely spaced polymorphic markers covering the whole genome.

For genome-wide screening by association analysis one would need to employ more than 300 000 closely spaced markers. The completion of the HapMap project made whole genome scanning by association studies feasible. The HapMap project genotyped more than one million SNPs spanning the entire human genome in four ethnically distinct human populations and tested these SNPs for linkage disequilibrium (LD). This project discovered that the human genome is highly organized into discrete **linkage disequilibrium blocks** (LD blocks) which are flanked by **recombination hot spots**, or areas at which recombinations most often occur. This enabled the utilization of tagged SNPs (each SNP representing an entire LD block) to test the entire human genome for association with disease without having to employ all SNPs in the genome. Moreover, microarray-based genotyping technology enabled the typing of up to 500 000 SNPs in a single experiment. Thus, it became possible to scan the entire human genome by association analysis using selected SNPs on a chip.

Next Generation Sequencing for Rare Variants

Association studies detect common variants with small effect size as shown by numerous GWAS studies. In contrast, linkage studies, which test cosegregation of variants with disease in families, are robust for detecting variants with large effect size as shown by our linkage studies in AITD [24]. However, variants with large effect size may be rare and can only be identified by sequencing. Rare variants are defined as having minor allele frequency of less than 1%. The recent developments in next generation sequencing have made it possible to identify rare variants either by sequencing linked loci which are usually 5–30 Mb in size or by sequencing the entire human genome. Sequencing the entire human genome is usually limited to exons (exome sequencing) but can also be performed for the entire genome including coding and non-coding sequences.

Genetics of Autoimmune Thyroid Disease

The Primary Role of HLA Genes

The MHC region, encoding the HLA glycoproteins, consists of a complex of genes located on chromosome 6p21 (Figure 3.2.1.6). The MHC region also encodes various additional proteins, most of which are associated with immune responsiveness. Since this gene region is highly polymorphic and contains many immune response genes it was the first candidate genetic region to be studied for association and linkage with AITD.

Association of HLA with GD: GD was initially found to be associated with HLA-B8 in Caucasians. This finding was then confirmed in a wide number of studies, mostly examining populations of Caucasian origin (Table 3.2.1.3). In these early studies HLA-B8 was associated with relative risks for GD ranging from 1.5 to 3.5. Subsequently, it was found that GD was more strongly associated with HLA-DR3, which is in LD with HLA-B8. The frequency of DR3 in GD patients was 40–55% and in the general population 20–30% giving a relative risk for people with HLA-DR3 of 2–3. Even though the frequency of HLA-DR3 was increased in Caucasians with GD, there were also HLA-DR3 negative associations with GD, and in addition, the HLA associations were found to be different in other ethnic groups (Table 3.2.1.4). In the Japanese population GD was associated with HLA-B35, and in the Chinese population

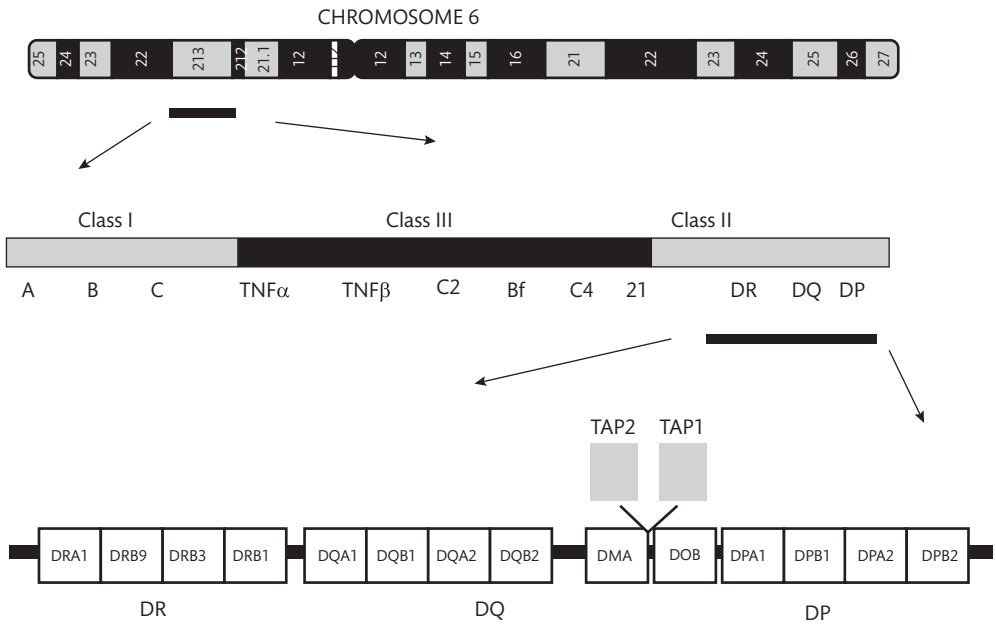

Figure 3.2.1.6 The HLA region is located on chromosome 6p21. It is a complex genetic region which consists of several loci, all of which code for proteins which influence the different arms of the immune system. Depicted are the major loci.

Table 3.2.1.3 Some of the important HLA association studies in Graves' disease performed in Caucasians

Country	Ethnic group	No. of patients	HLA allele	RR
Canada	Caucasians	175	B8 DR3	3.1 5.7
Belgium	Caucasians	101	DRB1*0301 DQA1*0501	
UK	Caucasians	127	B8 DR3	2.8 2.1

[1]In this study the TDT also showed an association to the extended haplotype DRB1*0304-DQB1*02-DQA1*0501.

an increased frequency of HLA-Bw46 was reported. In African Americans, no overall susceptibility could be associated with any DR allele, although subdivision of the patients revealed that DRw6 was associated with thyroid antibody formation. Among Caucasians, HLA-DQA1*0501 has also been associated with Graves' disease (Table 3.2.1.3), but it appears that the most common susceptibility allele in GD is indeed HLA-DR3 (HLA-DRB1*03) [25].

The exact amino-acid sequence in the DRβ1 chain conferring susceptibility to GD was determined by sequencing the HLA-DRB1 locus in a population of GD patients and controls. These studies identified arginine at position 74 of the HLA-DRβ1 chain (DRβ-Arg74) as the most critical DR amino acid conferring susceptibility to GD [25]. Further analysis showed that the presence of glutamine at position 74 was protective for GD. This suggests that position 74 of the DRβ1 chain is critical for GD development in certain patients but not in others. Recent work suggests that certain TSHR and Tg peptides, in particular, have higher affinity for these HLA-DR pocket sequences.

Not only has the association with 'disease' been explored but the role of HLA polymorphisms may be critical for the clinical expression of the different GD phenotypes. Some groups reported an association between the likelihood of relapse of GD with HLA-DR3 while others were unable to confirm this. Studies of HLA associations in GO have also produced conflicting results with some workers reporting increased frequency of HLA-DR3 in patients with GO, and others reporting no difference in the distribution of HLA-DR alleles between GD patients with and without ophthalmopathy. Likewise, no difference in the DR3 frequency was found in GD patients with and without pretibial myxoedema. It appears, therefore, that HLA provides a broad degree of susceptibility rather than for any particular phenotype.

Association of HLA with Hashimoto's thyroiditis: Data on HLA haplotypes in HT have been much less definitive than in GD (see Table 3.2.1.5). Early studies suggested an association of goitrous HT with HLA-DR5 (RR = 3.1) and of atrophic HT with DR3 (RR = 5.1) in Caucasians. Later studies in Caucasians reported weak associations of HT with HLA-DR3 and HLA-DR4. Associations of HT with other HLA haplotypes have also been reported in different ethnic populations (e.g. HLA-DRw53 in Japanese, and HLA-DR9 in Chinese). An HLA-DR pocket amino acid signature was found to confer a strong risk for HT resulting in an odds ratio of 3.7 [26] from a unique pocket structure that could influence the binding of pathogenic peptides to the HLA-DR pocket and their presentation to T cells. In addition, studies suggest that certain Tg peptides, in particular, have affinity for these specific HLA-DR pocket sequences [27].

[1] RR, relative risk; [2]NR, not reported.

Non-HLA Genes in AITD

HLA genes most likely account for only part of the genetic susceptibility to AITD. At least five additional non-HLA genes have been found to confer risk for AITD although each confers much less risk than HLA. Three immunoregulatory genes (*CTLA-4, CD40*, and *PTPN22*) and two thyroid-specific genes (thyroglobulin, and the *TSHR*) have been reproducibly associated with these diseases. There are multiple other reports in the literature but many of these involve low risks and lack confirmation in different study populations. Such reproducibility is the hallmark of significance.

Cytotoxic T-lymphocyte antigen-4 (*CTLA-4*): *CTLA-4* is a costimulatory molecule that participates in the interaction between T cells and antigen presenting cells (APCs). APC's activate T cells by presenting to the T-cell receptor an antigenic peptide bound to an HLA class II protein on the cell surface. For this activation to work, a second signal is required and these **costimulatory signals** are provided by a variety of proteins which are expressed on APCs (e.g. B7-1, B7-2, B7h, CD-40) and interact with receptors (*CD28, CTLA-4*, and *CD-40L*) on the surface of CD 4+ T-lymphocytes during antigen presentation. Whereas, the binding of B7 to CD28 on T cells costimulates T-cell activation, the presence of *CTLA-4*, which has a higher affinity for B7, downregulates T-cell activation by competing for the binding of B7 to CD28. The suppressive effects of *CTLA-4* on T-cell activation may be altered by polymorphisms reducing *CTLA-4* expression and/or function resulting in exaggerated T-cell activation which may lead to the development of autoimmunity in susceptible individuals. Indeed, *CTLA-4* polymorphisms have been consistently shown to be associated with many different autoimmune conditions [28] including both GD and HT [29, 30] and this association has been consistent across populations of different ethnic backgrounds.

Several *CTLA-4* variants have been reported as associated with AITD but three have shown the most consistent association including an (AT)n microsatellite within the 3'UTR region of the *CTLA-4* gene [29], a SNP at position 49 in the *CTLA-4* leader peptide (designated A/G49), resulting in an alanine/threonine substitution [13, 31], and a SNP (designated CT60) located near the 3'UTR of the *CTLA-4* gene [30]. Interestingly the *CTLA-4* gene also appears to confer susceptibility to the production of thyroid antibodies (TAbs) without clinically significant disease [32, 33], thus substantiating its role as a general autoimmunity gene.

CD40: *CD40* is a member of the tumour necrosis factor receptor (TNFR) family of molecules and is expressed primarily on B cells and other APCs including thyroid cells. *CD40* plays a fundamental role in B-cell activation, inducing B-cell proliferation, immunoglobulin class switching, and antibody secretion.

Recently, using a combination of linkage and association studies, *CD40* has been identified as a novel susceptibility gene for GD [34]. A C/T SNP at the 5'UTR of *CD40* was associated with GD, with the CC genotype conferring the risk [35] an observation replicated in several studies [36, 37].

The protein tyrosine phosphatase-22 (*PTPN22*) gene: The lymphoid tyrosine phosphatase (LYP), encoded by the protein tyrosine phosphatase-22 (*PTPN22*) gene, is a 110 kDa protein tyrosine phosphatase that, like *CTLA-4*, is a powerful inhibitor of T-cell activation. A tryptophan/arginine substitution at codon 620 (R620W) of *PTPN22* was found to be associated with AITD mostly with GD [38], as well as with other autoimmune diseases.

Thyroglobulin: Thyroglobulin represents one of the major targets of the immune response in AITD. The Tg gene has been shown consistently to also be an important AITD susceptibility gene [39, 40] with four Tg SNPs significantly associated with AITD [41]. Moreover, three of the associated Tg SNPs were non-synonymous (i.e. they caused amino acid changes in the Tg protein). The association between Tg and AITD has been well replicated [42, 43] although the associated Tg polymorphism has not been consistent in different populations [43, 44].

The thyrotropin receptor (TSHR): The presence of stimulating TSHR autoantibodies is the hallmark of GD indicating that the TSHR is a primary antigen. It is not surprising, therefore, that the *TSHR* gene is also reproducibly associated with GD [45] and the most consistent studies have identified non-coding SNPs in intron 1 of the *TSHR* [46–48].

Whole Genome Screening in AITD

Several early microsatellite and **linkage-based whole genome screens** were performed in AITD with considerable success. In a data set of 102 multiplex Caucasian families (540 individuals) [40] whole genome screening revealed 7 loci that showed evidence for linkage to AITD. Three loci, on chromosomes 6 (named AITD-1 and appearing distinct from the HLA region), chromosome 8 (identified as the thyroglobulin locus), and chromosome 10, showed evidence for linkage with both GD and HT. In contrast, one locus, on chromosome 12 (called HT-2), showed evidence for linkage to HT only while three loci showed evidence for linkage with GD: GD-1 on chromosome 14 (identified as the TSHR locus), GD-2 on chromosome 20 (identified as the *CD40* locus), and a locus on 7q. Another whole genome screen from Japan identified the same AITD locus on 8q (the thyroglobulin gene), as well as a 5q locus [39]. The same 5q locus was also identified in a genome scan performed in the Old Order Amish population in the United States [49]. A large whole genome scan in 1119 European sib-pairs identified three different loci on chromosomes 18p11, 2q36 (distinct from *CTLA-4*), and 11p15 [50]. These studies confirmed that the genetic contribution to the development of AITD involves multiple genes with mostly low-level effects.

More recent **whole genome association studies** (GWAS) using large numbers of SNPs have dominated recent genetic thinking but have added very little to our understanding of AITD genetics. The data have shown primarily HLA as the major contributor to genetic susceptibility and have confirmed the sites previously identified by earlier techniques. Online Table 3.2.1.6 lists the current state of associated sites, not all of which have been replicated but continues the idea that multiple genes contribute small genetic effects.

A Note on Graves' Orbitopathy (GO) and the Importance of Phenotype

Although sensational reports of specific genetic associations with GO have appeared, they have not been replicated, and there remains no conclusive evidence that any of the known AITD susceptibility genes are specific for GO [51]. It appears that the GO phenotype is simply a more severe form of GD rather than a distinct entity and that other factors (such as the environment) may also be important in the development of the more malignant GO pathology.

Mechanisms of Disease Induction by Susceptibility Genes

Mapping susceptibility genes for complex diseases can better our understanding of their pathogenesis. However, even when a

complex disease gene is mapped, unravelling the mechanisms underlying its association with disease is not straightforward. In contrast to classical monogenic diseases where a genetic mutation usually inactivates a gene or causes unchecked activation of a gene, in complex diseases such as AITD the associated genetic variants may cause subtle changes in the function of one or more genes. Therefore, even when a gene associated with a complex disease is mapped it can be challenging to prove that a certain variant changes the function of the gene in a way that will promote the development of the disease. However, considerable progress has been made in dissecting some of the mechanisms by which AITD associated genes predispose to disease.

HLA

The mechanisms by which HLA associations confer disease susceptibility in many autoimmune diseases are now well understood. For T cells to recognize and respond to an antigen they require interaction with a molecular complex consisting pf an antigenic peptide and an HLA class II molecule. It is thought that different HLA alleles have different affinities for peptides derived from the processing of autoantigens (e.g. such as Tg and the TSHR) and which are then recognized by T-cell receptors. Thus, certain alleles may have a preferential affinity for a particular autoantigen because the peptide is able to fit in the antigen binding groove inside the HLA molecule allowing it to be recognized by the T-cell receptor while other HLA molecules may not have the same binding pocket structure. This would determine if an autoimmune response to that antigen peptide will develop.

Studies have demonstrated that DRβ-Arg74 is a critical HLA-DR pocket amino acid associated with GD [52]. Position 74 of the DRβ chain is located in pocket 4 (P4) of the DR peptide-binding cleft. Structural modelling analysis demonstrated that the change at position 74, from the common neutral amino acids (Ala or Gln) to a positively charged hydrophilic amino acid (Arg), significantly modified the three dimensional structure of the P4 peptide-binding pocket [52] thus altering the peptide-binding properties of the pocket and favouring peptides able to induce GD [52, 53]. A similar pocket HLA-DR amino acid signature has been strongly associated with HT [26].

For thyroid autoantigens to be presented by HLA molecules to T cells, a mechanism of autoantigen presentation must exist within the target tissue. One potential mechanism not utilizing professional APCs may be through aberrant expression of HLA class II molecules on the target tissue cells. Indeed, thyroid epithelial cells from patients with AITD have been shown to express HLA class II antigen molecules which are normally expressed only on APCs such as macrophages and dendritic cells [54]. This aberrant expression of HLA molecules on thyroid cells, could initiate thyroid autoimmunity via direct thyroid autoantigen presentation [54, 55].

CTLA-4

CTLA-4 is a negative regulator of T cells and a polymorphism that decreases *CTLA-4* function and/or cell surface expression would cause enhanced T-cell activation potentially contributing to the development of an autoimmune condition [45] as seen when treating patients with anti-*CTLA-4*. Several *CTLA-4* variants have been analysed in detail for their effect on *CTLA-4* function and/or expression and a comprehensive analysis of the *CTLA-4* gene locus reported that the CT60 SNP of *CTLA-4* (rs3087243) showed the strongest association with GD, suggesting that it might be the causative SNP [30].

CD40

CD40 is an important costimulator of T-cell activation associated with a number of autoimmune diseases. The CC genotype of a *CD40* 5'UTR SNP was shown to be associated with GD. This *CD40* SNP resides in a region which can influence the initiation of translation and, therefore, the expression of *CD40*. Indeed, the C-allele of the 5'UTR SNP was shown to increase the translation of *CD40* mRNA transcripts, by 20–30% compared to the T-allele [56, 57]. At least two potential mechanisms can explain how the C-allele of the *CD40* 5'UTR SNP increases the risk for GD: (1) The C-allele may increase *CD40* expression and function on B cells, thereby potentially lowering the threshold of activation of thyroid autoreactive B cells; and/or (2) The C-allele may increase the expression of *CD40* in the thyroid gland itself [58, 59]. *CD40* signalling in thyrocytes can result in cytokine secretion (e.g. IL-6) [58]. Thus, overexpression of *CD40* on thyroid cells may, under certain conditions (e.g. infection), result in increased secretion of cytokines by thyroid cells causing local inflammation and activation of autoreactive T cells that were dormant or suppressed by peripheral regulatory mechanisms. This mechanism is known as a bystander mechanism of induction of autoimmunity and is seen in experimental thyroiditis [60]. Studies with transgenic mice overexpressing thyroid *CD40* indicate that the development of GD after TSHR immunization was more profound confirming the potential role of this costimulator [61].

PTPN22

The lymphoid tyrosine phosphatase (LYP) encoded by the *PTPN22* gene belongs to a family of protein tyrosine phosphatases that are expressed in both immature and mature B- and T-lymphocytes. LYP is a powerful inhibitor of the T-cell antigen receptor signalling pathway. LYP binds to the C terminal of the protein kinase, Csk, restricting the response to antigens by disrupting protein tyrosine phosphorylation events that control cell activation and differentiation. This negative control mechanism prevents spontaneous T-cell activation [62].

The exact mechanism by which the associated R620W variant of the *PTPN22* gene predisposes to autoimmunity is not known. The substitution of arginine with tryptophan at this position interferes with the interaction of LYP with Csk. *In vitro* experiments show that only LYP with arginine at position 620 forms a complex with Csk whereas LYP with tryptophan at this position binds less efficiently [63]. One study suggested that the tryptophan variant is a gain-of-function change that makes the protein an even stronger inhibitor of T cells [64]. Thus, the disease-associated tryptophan variant would be expected to suppress T-cell activation and proliferation. Reduced T-cell receptor signalling could lead to a tendency for self-reactive T cells to escape thymic deletion and thus remain in the periphery.

Thyroglobulin

Thyroglobulin (Tg) is a 660 kDA homodimeric protein that serves as a precursor and storehouse for thyroid hormones. Tg is one of the main targets of the immune response in both HT and GD and by immunization is able to induce experimental autoimmune thyroiditis (EAT) in a variety of animal models, most notably the mouse [65]. EAT, like HT is characterized by a diffuse cellular infiltrate of the thyroid with anti-Tg T-cell responses as well as high titres of Tg autoantibodies. This indicates that Tg is a critical thyroid-specific antigen involved in the aetiology of AITD.

It is not surprising, therefore, that the Tg gene is an AITD susceptibility gene [42, 45]. Three amino acid substitutions in Tg were first reported to be significantly associated with AITD [40] and several mechanisms have been postulated to explain the association. Clearly the presentation of a Tg peptide by APCs to T cells must be involved and since peptide antigens are presented within HLA class II molecules, as discussed earlier, this mechanism would imply that there exist a more potent interaction between certain Tg variant peptides related to the associated SNPs and certain HLA-DR variants in susceptible patients predisposing them to AITD. This was shown for one such peptide which had a strong statistical interaction with the Arg74 polymorphism of HLA-DR, resulting in a high odds ratio of 15 for susceptibility to GD [66]. Supporting this hypothesis was a study which identified specific HLA-DR bound Tg peptides within the thyroid glands from Graves' patients [67]. Moreover, studies in 'humanized' mice expressing HLA-DR3 have shown that certain Tg peptides can induce EAT in these mice [68]. Another variant in the Tg promoter (-1623A/G) was also found to be associated with AITD. Functional analysis showed that the nucleotide substitution introduced by this Tg promoter SNP created a binding site for interferon regulatory factor-1 (IRF-1), causing up-regulating Tg promoter activity upon IRF-1 binding [69]. These data suggest an attractive mechanism for environmental–genetic interaction whereby during viral infections local production of interferon alpha can lead to upregulation of Tg transcription via IRF-1 in individuals carrying the risk (G) allele of the Tg promoter SNP but not in individuals carrying the protective (A) allele.

TSH Receptor (TSHR)

All the TSHR SNPs which are consistently associated with GD are intronic [46–48]. Therefore, the mechanism by which they predispose to GD is more challenging to dissect. It has been postulated that these intronic SNPs may influence the expression of the TSHR through regulatory elements. For example, intrathymic TSHR expression was decreased in individuals homozygous for a particular associated SNP (rs12101261) compared with carriers of the disease-protective allele. Furthermore, such repression was enhanced by interferon alpha acting through an epigenetic mechanism [70]. Alternatively, SNPs may be associated with changes in the alternative splicing of the TSHR although how this alters the immune response is uncertain [71] but changes in thymic expression may be involved [72].

The X Chromosome

There are a number of possible mechanisms whereby the X chromosome could influence the development of AITD. One mechanism is probabilistic. Females have two X chromosomes (one paternal and one maternal) while males have only one X chromosome (maternal). Therefore, females are twice as likely to inherit an X chromosome AITD susceptibility gene as males. Several immune regulatory genes are located on the X chromosome including the *FOXP3* gene which was associated with AITD in Caucasians [73]. FOXP3 is the master regulator gene of T regulatory cell differentiation hinting at a mechanism for the female preponderance of AITD.

Another possible mechanism involves X-inactivation. X-inactivation in females results in the production of two classes of cells that differ in the transcription of X-chromosome encoded genes including genes coding for self-antigens. If these two cell classes extend to the thymic cells responsible for tolerizing T cells in embryonic life, some lymphocytes may not be tolerized to one of the two self-antigens encoded by the X chromosome. Such lymphocytes would be autoreactive to that antigen and could induce an autoimmune response. Supporting this hypothesis are data showing skewing of X-inactivation in females with AITD [74–76].

Conclusions

Genetic susceptibility plays an important role in the development of AITD. While significant progress has been made in identifying AITD susceptibility genes and understanding the mechanisms by which they confer risk for disease, their contribution to the genetic susceptibility is far from overwhelming suggesting other important genetic mechanisms must be involved. Intriguingly, the AITD susceptibility genes identified participate in the immunological synapse and/or the signalling pathways activated by the immunological synapse. The immunological synapse is the interface between antigen presenting cell and T-cell formed during antigen presentation. This finding, alone, suggests that the genetic factors predisposing to AITD may lead to breakdown of tolerance by altering the immunological synapse.

Some of the AITD susceptibility genes identified so far are unique for GD or HT, while other are common to both conditions [40] and even type 1 diabetes [77] (**Figure 3.2.1.7**). Mechanistically, the AITD susceptibility genes can be divided into immune modulating genes (*HLA-DR, CD40, CTLA-4*, and *PTPN22*), and thyroid-specific genes (Tg and TSHR). Interactions between these genes may significantly increase the assigned risk [3], for example with Tg and *HLA-DR* [66]. In addition, some genes, while exerting small effects in all patients, have a much stronger effect in subsets of patients [78]. Most importantly, identifying the AITD susceptibility genes and understanding the mechanisms by which they predispose to disease gives us a better understanding of the molecular mechanisms causing thyroid autoimmunity.

3.2.2 Environmental Factors

Josef Köhrle

Introduction

The hypothalamus–, pituitary–, thyroid–periphery (HPTP) axis has been known as a vulnerable target for environmental factors and nutritional agents since centuries. Goitrogenesis, hypo-, hyperthyroidism, tumorigenesis and autoimmune diseases of this gland have been linked to single or combined deficiencies of several essential trace elements. Normal thyroid function depends on adequate and balanced availability of the essential trace elements iodine, selenium, iron, and the mineral zinc in the daily diet. Evolution of humankind has been suggested to closely follow coast lines and regions with high availability of iodine, the key element required for thyroid hormone (TH) synthesis [1–4]. Involuntary or voluntary environmental or nutritive exposure to adverse factors and agents impairing TH synthesis, secretion, binding, transport, metabolism, and action ('goitrogens') contributes to development and persistence of thyroid disorders [5]. Especially conditions of iodine deficiency, still prevalent in many regions of our world, but also iodine excess [6], both of which might occur already during embryonal and fetal development, in newborns, adolescents, and adults provide the vulnerable platform for action of adverse agents, which might be well tolerated by a normally functioning, 'quiescent' thyroid gland with adequate iodine supply (see Chapters 3.2.3 and 3.2.4). Compounds adversely affecting the HPTP axis belong to several chemical classes of food ingredients and environmental contaminants, but might also represent pharmaceutical drugs acting either directly on biomolecules comprising the HPTP axis or after modification by phase I and/or II drug metabolism (see Table 3.2.2.1). Apart from ingestion several agents reach their targets after inhalation (e.g. occupational exposure or smoking) or by dermal application (e.g. UV sunscreens).

Environmental factors such as temperature, light, altitude, and latitude of living as well as physical, emotional, and acute mental stress, diseases and adverse life events impinge on normal HPTP function (Box 3.2.2.1) [7]. Very recently, it has been suggested that the worldwide pandemic of diseases associated with changes in industrialized and developing countries, such as obesity, diabetes, and metabolic syndrome, is linked to inadequate iodine supply and altered TH homeostasis during development by epigenetic mechanisms [6–13]. Current conditions in industrialized westernized countries are characterized by the permanent availability and overconsumption of energy-rich, fibre-poor, semi-processed, industrialized, enhanced, fortified, or even 'novel food', sedentary lifestyle, lack of sufficient mobility and physical activity, all of which impinge on hormonal homeostasis that is mainly integrated at the hypothalamic level involving thyrotropin-releasing-hormone producing neurons. It is becoming apparent that not only starvation, fasting, and protein-calorie malnutrition in developing countries but also overfeeding with hypercaloric, energy-dense food and obesity in Western-style regions can lead to inadequate intake of micronutrients (minerals, vitamins, and secondary metabolites of plants), so-called hidden hunger. In addition, active and passive smoking, wellness-, neuroenhancement-, lifestyle-, fashion-, and psychodrugs and narcotics have strong impact on TH synthesis, secretion, and action.

Impaired thyroid function has also been observed after consumption of protein-restricted diets, as recommended for patients with phenylketonuria or milder hyperphenylalaninaemias, where adequate iodide supply is essential to compensate for possible adverse effects on TH synthesis and metabolism [14]. Various staple foods, if inadequately processed or preserved, contain efficient goitrogens (e.g. linamarin, goitrin), which release (iso-)thiocyanate, potent inhibitors of NIS-mediated iodide uptake by thyrocytes and—at higher concentrations—also act as effective blockers of thyroperoxidase (TPO), if iodide supply is inadequate.

This chapter will summarize established data for humans, discuss recent findings and possible risk factors identified from exposure data of human subgroups, epidemiology, and selected findings in experimental animal models accepted as relevant for human risk analysis. Figure 3.2.2.1 illustrates currently identified targets of the HPTP axes for environmental agents. Issues of iodine deficiency and excess, pharmaceutical drugs, and radioactive isotopes interfering with the thyroid axis will be discussed elsewhere in this volume. It is quite obvious that adverse effects of nutritional and environmental agents on the human TH axis can only be deduced and extrapolated from occupational exposure data, epidemiological observations, mainly retrospective analysis, but not from interventional studies or very rarely from prospective or blinded trials. However, for many of these observational and epidemiological observations solid interventional studies have been made from appropriate validated animal experimental studies, which clearly provide mechanistic insight and allow conclusions on cause–effect relationships also for adverse human health effects.

Various mechanisms for interference of environment with the HPTP axis have been identified, such as:

- Reversible or irreversible competition with ligand binding sites of the TH axis
- Interference with or alterations of the feedback setpoints, which can already occur in the pre- and early postnatal phase
- Classic 'goitrogenesis' by impaired hormone synthesis
- Disturbance of serum hormone binding, tissue distribution, cellular uptake, metabolism, and action

Many of these disturbances may be initially compensated by the complex regulatory network of the axis, which is characterized by multiply redundant and fail-safe feedback mechanisms and a high degree of plasticity and adaptation to the environment. However,

Table 3.2.2.1 Agents and compounds interfering with the HPTP axis

Compounds	Source and occurrence	Mechanism of action	Effects	Reference(s)
Environmental				
Perchlorate	Solid rocket and missile fuel; air bags	Inhibition of NIS	Goitrogenic	[16–27]
Phthalate esters	Daily life and medical products	?	?	[59, 73, 74]
Polychlorinated (PCB) and polybrominated (PBB) biphenyls	Chemicals; daily life products; flame retardants; fracking	TH transport, uptake, metabolism; T_3 receptor binding		[7, 48, 49, 51–58, 72, 109]
Dioxins (TCDD) and furans	Unintentionally produced by-products, pyrolysis	TH transport, uptake, metabolism		[46, 47, 54–58]
Polycyclic aromatic hydrocarbons PAH)	Chemicals			[104, 109]
(Poly-)Phenols, bisphenol A (BPA)	Plasticizer in daily life products	Multiple actions		[63–71]
Nitrate; nitrite	Fertilizers; food preserver	NIS inhibitors	Goitrogenic	[22, 25, 28, 29]
UV screens (4-MBC, BP2–4)	Sunscreens in cosmetics, daily life products	NIS expression TPO inhibitors	Goitrogenic	[5, 29]
Tobacco and cigar smoke	Goitrogens	Inhibition of TH synthesis, metabolism, and action	Goitrogenic, Strongest risk factor for Graves' disease; might prevent Hashimoto's thyroiditis? Altered maternal and fetal thyroid function	[34–39]
Nutritive				
Various goitrogens	Staple food, vegetables, inappropriately processed food	TPO inhibitor	Goitrogenic	[31, 32]
Linamarin, goitrin, various glycosides	Staple food (Cassava), vegetables (*Cruciferae*)	TPO inhibitor	Goitrogenic	[31]
Flavonoids (polyphenols), silychristin		TPO inhibitors TTR competitors, MCT8 inhibitors	Goitrogenic	[5, 105]
Polyhydroxyphenols and phenol derivatives				[59]
Sulphurated organics, (Iso-)thiocyanate, cyanide, thio-oxazolidone (goitrin)	Nutritive goitrogen Tobacco smoke	NIS inhibitor TPO inhibitor at higher concentration	Goitrogenic	[17, 22, 31, 34, 42]
aliphatic disulphides	Onions, garlic; Water contaminated from coal mining	TPO inhibitors	Goitrogenic	[31]
Humic acids	Ground and drinking water	Interference with TH synthesis	Goitrogenic	[44, 45]
Deficiencies in trace elements and minerals				
Selenium deficiency	Seafood and red meat	Essential trace element for TH synthesis and metabolism	Goitrogenic	[94–96]
Iron deficiency	Protein malnutrition Genetic predisposition	Essential trace element for TH biosynthesis, inadequate function of the haemoprotein TPO for TH biosynthesis		[96, 106]
Zn deficiency				[107]
Pharmaceuticals				
Lithium	Antidepressant	Inhibition of TH secretion	Goitrogenic	[108]
Iodinated agents	Oral bile duct X-ray contrast agents (e.g. iopanoate); antiarrhythmic drug amiodarone	TR antagonist	Hypothyroidism	[80–82]

Box 3.2.2.1 Environmental agents and factors interfering with hypothalamus–pituitary–thyroid–periphery axis

- Light, day–night rhythm (shift workers)
- Latitude of living
- Ambient temperature
- Drinking water, food, nutritional components (voluntarily or involuntarily exposure)
- Inappropriately processed food: goitrogens
- Diets (vegetarian, vegan, or macrobiotics with inadequate iodide, selenium, iron, zinc and retinol content)
- Diet containing constituents with goitrogenic effects under conditions of inadequate iodide intake
- Environmental emissions and exposure: inhalation of aerosol, 'particulate matter' and nanoparticles
- Industrial contaminants
- Agricultural environmental agents
- UV filters and UV screens

long-term exposure to low dose or acute challenge by adverse agents may overstrain the HPTP axis especially under conditions of inadequate iodine supply or during vulnerable phases of the individual's life (development, pregnancy, and lactation, non-thyroidal disease) and thus create harm or disease. There are clear 'windows of susceptibility' to irreversible disruption of the HPTP axis and its setpoints (e.g. during early intrauterine development, adolescence, puberty, and adult life) [13, 15].

Adverse Effects of Various Agents on HPTP Axis

Perchlorate

Perchlorate, similar to pertechnetate, perrhenate, astatine and (iso-)thiocyanate, is a voluminous anion and relevant substrate for the sodium-iodide symporter (NIS) [16], which is located in the basolateral membrane of thyrocytes but also in the lactating mammary gland, salivary gland and several internal epithelial structures (gastric mucosa, lung epithelium, etc.). These anions effectively compete for the essential iodide uptake (Table 3.2.2.2) but are not organified in thyroglobulin (Tg) by the haemoprotein thyroperoxidase (TPO). Thus, perchlorate has been even used as efficient pharmaceutical to treat hyperthyroidism and to block unwanted (radio-)iodide uptake into the gland or for the diagnostic perchlorate discharge test, performed to identify iodide organification defects. Hypothyroidism can be obtained by regular administration of doses of 0.4 mg/kg body weight per day, while reference doses, where no appreciable risk can be observed for human populations, are in the range of 0.7 µg/kg/day. Thiocyanate or nitrate are less potent by a factor of 15 or 240, respectively [17]. Recently, reports have been emerging on increasing contamination of surface land and water by potassium or ammonium perchlorate around areas close to civil or military plants as well as installations producing and handling rockets, missiles, ammunitions, and fireworks. Potassium and ammonium perchlorate are increasingly used and widely distributed over our planet as rocket and missile fuel waste and are extremely stable and poorly degraded in environment. Other perchlorate salts are used as oxidizers, electrolytes and in various technical processes [18]. Concerns have been raised and published whether this increasing contamination of surface soil and drinking water might negatively impact on thyroid function of exposed populations, especially babies, children and adolescents [19–22], who still have limited capacity and reserve to synthesize and store iodinated thyroglobulin. In contrast, adults, whose follicular colloid thyroglobulin stores might last for up to 3 months, if adequately supplied with iodide before interference, might be less vulnerable except during pregnancy or lactation, where iodine demands are increased. This controversial issue is subject of several ongoing surveys by environmental and regulatory authorities, but for the moment no clear evidence for risk assessment is available. However, perchlorate concentrations in drinking water of exposed areas have been determined which are in the range or even exceed recommendations by regulatory authorities. Observations in workers regularly exposed to airborne perchlorate provided no evidence for adverse effects, but individuals with inadequate iodide intake, exposed to other environmental NIS inhibitors or belonging to other susceptible risk groups might experience negative consequences of long-term perchlorate exposure by drinking water with perchlorate concentrations in the range of the discussed US reference doses (US Environmental Protection Agency reference dose 0.7 µg/kg body weight per day) [17, 20].

Perchlorate exposure leads to increased urinary iodine excretion due to the blocking of thyroidal uptake [23] and perchlorate has been found in mothers' and cows' milk, generating a risk for babies and children with inadequate iodide supply. A longitudinal study in pregnant women exposed to different perchlorate concentrations in drinking water during pregnancy and lactation revealed no changes in thyroid status and function or adverse effects in mothers and newborns [24], but several recent studies report on changes in maternal thyroid status and effects on their offspring [19–22, 25].

Exposure of tadpoles and adult African clawed frog Xenopus laevis to perchlorate impairs amphibian metamorphosis and thyroid function of these model organisms, which might serve as a

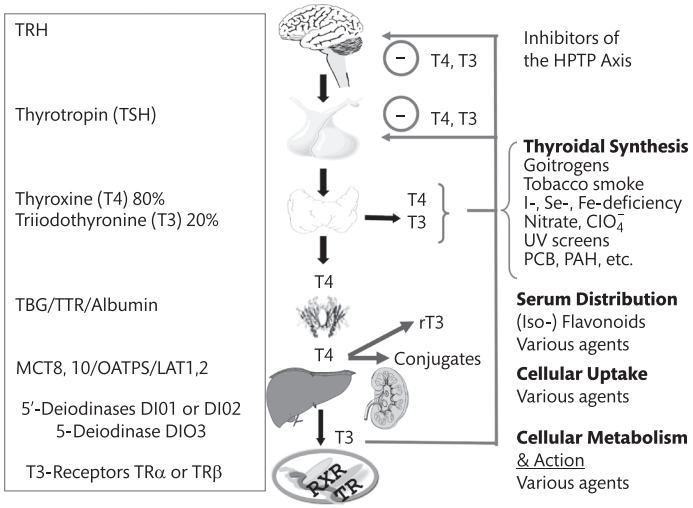

Figure 3.2.2.1 Hypothalamus–pituitary–thyroid–periphery (HPTP) axis, hormonal feedback regulation, and interference by inhibitors.

PAH, polycyclic aromatic hydrocarbons; PCB, polychlorinated biphenyls; RXR, retinoid X receptor.

Table 3.2.2.2 Synthesis of thyroid hormones by follicular thyrocyte epithelial cells, storage of iodinated thyroglobulin in colloidal space and secretion of thyroid hormones is affected by environmental and nutritive agents

Reaction contributing to thyroid hormone biosynthesis	Interfering compound
Basolateral iodide uptake by NIS	Perchlorate, (iso-) thiocyanate; 4-MBC
Apical export by pendrin (PDS)	?
Synthesis and apical secretion of Tg	?
Synthesis and apical insertion of TPO and DUOX	Iron, ?
NADPH-dependent production of H_2O_2 by DUOX	?
Iodide oxidation, iodination of Tg-tyrosyl residues	Goitrogens, goitrin
Coupling of Tg iodotyrosine residues to iodothyronines is catalyzed by TPO using H_2O_2 as cosubstrate	BP-2–4
Polymerization and deposition of iodinated Tg in colloid	?
Micropinocytosis, reduction, and proteolysis of Tg in secondary lysosomes	?
Release of thyroid hormones T_4 and T_3 into the blood by the transporter MCT8	Silychristin
Dehalogenation of DIT and MIT and re-utilization of iodide for thyroid hormone biosynthesis	3-nitro-L-tyrosine (MNT)
Secretion of pGPx (GPx-3) into the colloidal space for degradation of excess H_2O_2	Selenium, ?

DIT, diiodotyrosine; DUOX, dual oxidase; MIT, monoiodotyrosine; NIS, sodium-iodide symporter; PDS, pendrin; Tg, thyroglobulin; TPO, thyroid peroxidase.

very sensitive biomarker for monitoring purposes of several compensatory and also adverse effects caused by environmental exposure to goitrogens such as perchlorate and others; interspecies differences for adverse effects in amphibians, rodents and humans have not been ruled out [26]. These studies indicate that aquatic life forms might already be affected by environmental agents, while humans and terrestrial animals might still be able to compensate or adapt to some extent as long as the concentrations of goitrogens are not excessive. Issues related to extrapolations of rodent studies with perchlorate for human iodide and TH kinetics and possible risk assessments have been extensively studied and discussed [27].

Nitrate

A continuously increased world population requires enhanced efforts for production of sufficient food and this is achieved by enhanced use of nitrogen containing fertilizers in agricultural production. Nitrate and nitrite contamination of ground, surface, and drinking water as well as many food products, especially vegetables, is the downside of this development. Nitrite and nitrate are also widely used as preservatives for fish and meat. Nitrate efficiently interferes with NIS catalysed iodide uptake and represents a relevant goitrogen especially in children exposed to drinking water containing 100 mg/L or more nitrate [28]. In highly contaminated or nutritionally exposed areas, the goitrogenic effects of nitrate/nitrite cannot be neglected, but adequate iodide supply might prevent such an adverse effect and subchronic exposure (15 µg/kg body weight for 28 d in volunteers) appears to be tolerable in humans with respect to thyroid function [29]. Whether nitrate also directly interferes with TPO or thyroid oxidase (DUOX) is unclear.

Nitric oxide (NO, identified as prostacyclin and endothelium-derived hyperpolarizing factor) is a powerful signalling molecule activating guanylate cyclase and cGMP production in the vascular system and thyrocytes and acts as a potent inhibitor of TH synthesis and function [30]. Whether pharmaceuticals generating NO, which is also endogenously produced in the thyroid by NO synthase isoenzymes, have adverse or therapeutic effects on thyroid function in hyperthyroidism remains to be analysed [30]. Adverse nitrate effects on maternal thyroid function during pregnancy as well as on size of newborns has been reported in studies, which included relatively limited numbers of pregnant women (week 12, n = 284) [22] or mother–child pairs (n = 107) exposed to several agents [25].

Goitrin, Thiocyanate, and Smoking

This voluminous anion and its related structural isomer isothiocyanate are both potent iodide competitors for NIS, at higher concentrations thiocyanate also inhibits TPO by acting as pseudosubstrate. Both agents are formed by metabolic pathways from cyanogenic glucosides or thioglucosides from plant origin, respectively. Plant and (bacterial) glucosidases in the gut cleave these glucosides, and release cyanide, which is converted to thiocyanate, or isothiocyanate. 'Goitrin' (L-5-vinyl-2-thio-oxazolidone), isolated from yellow turnips and from *Brassica* seeds, is a potent antithyroid compound and thiocyanate is also endogenously released from linamarin, a cyanogenic glucoside present particularly in the tuberous roots of the staple food cassava [31]. Goitrin, a goitrogen as potent as propylthiouracil (PTU), is not degraded like thioglycosides. Relevant sources for such goitrogens are the *Brassicacea* (e.g. cabbage, broccoli, cauliflower, Brussels sprouts), *Cruciferaceae, Compositae*, and *Umbelliferae*, but food content of these adverse metabolites strongly depends on adequate processing by cooking, hydrolysis, and preservation. Exposure to these goitrogens, monitored by urinary excretion of (iso-) thiocyanate, is a major problem in developing countries, where inadequate economic and social life conditions or energy resources prevent correct processing of these staple foods such as cassava, sweet potatoes, lima beans, sorghum, pearl millet, and corn representing the main source for carbohydrates. Especially, concomitant iodide deficiency

and protein malnutrition leading to inadequate iron supply can exaggerate this problem for risk groups such as pregnant and lactating women, infants, children, and adolescents. In the thyroid thiocyanate is metabolized to sulphate and thus does not accumulate. Probably, thiocyanate and goitrin in plant derived nutrients may play a minor role in impairing thyroid function in societies with adequate iodine intake [32], but overzealous unbalanced human vegetarian diets might cause adverse effects well known also from life stock production.

Thiocyanate and isothiocyanate exposure is also of relevance in western countries as recently documented [33] for nutritional sources but especially also for tobacco smokers, which inhale significant amounts of these goitrogens together with other adverse agents. Up to fourfold increased thiocyanate concentrations were determined in breast milk of breast feeding mothers who smoked and this was associated with up to two fold decreases in iodide content, the combination of which amplified the goitrogenic risk for the baby [34]. Further adverse constellations might be observed if nutritional and environmental exposures to combinations several of these goitrogens add to or amplify the risk and potential damage to the TH homeostasis. Altered maternal and fetal thyroid function has been reported for mothers who smoke [35] and smoking is one of the strongest risk factors for progress and severity of Graves' disease. Conversely smoking reduces anti-TPO and antithyroglobulin antibody titres and might reduce incidence of Hashimoto's thyroiditis by mechanisms not understood so far [36, 37]. Smoking is also a risk factor for goitrogenesis, even under improved iodide supply [36–39].

Tolerable exposure limits recommended by environmental and health authorities and goitrogen contents of nutrients and foods strongly vary even by orders of magnitude in different regions, countries, and continents of our globe. As several of these environmental or nutritive exposures cannot be modified by exposed individuals it is more than necessary to warrant adequate iodide intake for the whole population, and especially for risk groups [17, 19, 22, 32, 40–42].

Gaitan *et al.* have reported on the occurrence of small aliphatic disulphides (R-S-S-R; R = methyl-, ethyl-, *n*-propyl, phenyl-), which are goitrogens inhibiting iodide organification catalysed by TPO. These compounds occur in some vegetables (onion and garlic), well water, sedimentary rocks and as water contaminants in aqueous effluents from coal-conversion processes [43]. Humic acids, another coal or plant origin contaminant of well and drinking water, have also been identified as goitrogens, but again their effect is only observed when there is inadequate iodide supply, at least in animal experimental models [44]. Iodine may be bound to such humic substances in drinking water from natural wells but seems to be bioavailable [45].

Environmental Chemicals

The remarkable progress of worldwide industrialization, expanded and intensified agricultural and (semi-)industrial production of nutrients and food, and the tremendous increase in quality of life associated with longevity had and continues to have a major impact on our environment, which raises several concerns. Especially the synthesis, use, and dissemination of ten-thousands of new chemicals and compounds, some of which are produced at high tonnage worldwide and are persistent chemicals, have introduced new agents into our environment some of which interfere with the hormone system, including the thyroid. Several candidate agents with relevance to the HPTP axis have been identified from effects in wildlife including aquatic life forms and for some compounds adverse effects on thyroid morphology, structure, function, and TH status have already been described. Among those are polychlorinated (polychlorinated biphenyls (PCBs), hexachlorobenzene (HCB), organochlorines) and polybrominated (polybrominated diphenyl ethers (PBDE)) aromatic and phenolic (resorcinol, bisphenol A (BPA)) compounds, chlorinated furans such as dioxin derivatives, polyphenolic hydrocarbons, phthalates, pyridines, and others (see **Table 3.2.2.3** for selected compounds and their main characteristics).

The Seveso accident in 1976 releasing highly persistent 2,3,7,8-tetrachloro-dibenzo-p-dioxin (TCDD) created a first caesura, shortly followed by Bhopal, India in 1984, Basel 1986, and several other accidents, which raised awareness of the issue of endocrine disrupting compounds (EDC) which have not only immediate toxic effects but might act in a transgenerational way including epigenetic mechanisms of action (**Box 3.2.2.2**).

Maternal exposure to TCDD and related compounds in the Seveso area has been linked to markedly elevated neonatal thyroid-stimulating hormone (TSH) blood levels in the inner versus the marginally affected and the control area [46] in the affected offspring after the accident. This still controversial data, although correlated with current plasma concentrations of TCDD and coplanar dioxin-like compounds, suggests long-lasting impact of such contamination both for the immediately exposed population and for the subsequent generation. A follow-up analysis of women in premenarche at the accident later on observed an inverse association between serum tetrachlorodibenzo-p-dioxin (TCCD) and total T_4 concentrations measured shortly after the accident but not the other TH parameters analysed in 2008 [47]. Elevated neonatal TSH is a well-accepted biomarker for fetal hypothyroidism and used in the worldwide highly successful screening programmes for congenital hypothyroidism. Increased thyroid volume, elevated prevalence of antibodies against TPO and the TSH receptor associated with impaired fasting glucose, was also reported for the young adult offspring of mothers exposed and living in a highly polluted area in eastern Slovakia, where a mix of organochlorines (PCBs, dichlorodiphenyldichloroethylene (DDE), HCB) can still be detected in the exposed inhabitants, albeit at lower levels in the young adults compared to their parents, but still higher than in a control region [48, 49]. Again, these data were discussed in the context of a transgenerational adverse effect on the HPTP and other endocrine feedback circuits, and convincing evidence for an altered HPTP axis seems obvious for the total exposed population of that region.

A major human biomonitoring programme was initiated in 2002 in a heavily industrialized and populated area in Flanders, Belgium. Results from this carefully conceived analysis, including internal exposure to various EDC and agents, revealed among other alterations of hormonal parameters, effects on the serum TH levels (e.g. lowered TSH, and elevated free triiodothyronine) [50]. TH serum profiles were also found to be altered in adolescent

Table 3.2.2.3 Representative examples of nutritive and environmental agents interfering with the hypothalamus–pituitary–thyroid-periphery axis (HPTP axis)

Chemical structure	Compound name	IUPAC	MW	Typical use
	Goitrin, DL-goitrin	5-ethenyl-1,3-oxazolidine-2-thione	129	Contained in food, goitrogen
	Arochlor 1254	1,2,3-trichloro-4-(2,3-dichlorophenyl)benzene	326	Antithyroid agent, pesticide
	Tetradioxin; dioxin	2,3,7,8-tetrachlorooxanthrene	322	Insecticide, teratogen
	Minocycline	(2Z,4S,4aS,5aR,12aS)-2-[amino(hydroxy)methylidene]-4,7-bis(dimethylamino)-10,11,12a-trihydroxy-4a,5,5a,6-tetrahydro-4H-tetracene-1,3,12-trione	457	Antibacterial agent
	Bisphenol A; diphenylolpropane	4-[2-(4-hydroxyphenyl)propan-2-yl]phenol	228	'Free radical scavenger'
	Dibutyl phthalate	dibutyl benzene-1,2-dicarboxylate	278	Plasticizer
	Benzophenone-2; Uvinul D-50	bis(2,4-dihydroxyphenyl) methanone	246	UV screen
	Enzacamene; Neo Heliopan MBC; Eusolex 63	(3E)-1,7,7-trimethyl-3-[(4-methylphenyl)methylidene]bicyclo[2.2.1]heptan-2	254	UV screen

from the Akwesasne Mohawk Nation living in a PCB exposed area [12]. Different relationships were observed for different PCB congeners, HCB, and DDE versus TSH and free thyroxine (T_4) levels, with breast milk feeding modulating these interactions. Although only a small group of adolescents had been analysed, the authors interpret their findings as evidence for prenatal impact of exposure to these EDC on long-lasting alterations of the setpoints of the HPTP axis, in agreement with several other recent studies in exposed regions. Apparently small amounts of selected persisting EDC present during fetal, postnatal, and pubertal development might lead to adverse effects on the HPTP axis via epigenetic mechanisms. Whether these mechanisms manifest only in certain subpopulations, susceptible or genetically predisposed subgroups or individuals remain to be studied in more detail. Nevertheless, even subtle alterations of the HPTP axis will have major impact on brain development, IQ, long-term metabolic and age-related disease risks during life-course due to the pleiotropic nature of TH action and feedback regulation (Box 3.2.2.3) [51–53].

Recently, first results from the large Hokkaido Birth Cohort Study on Environment and Children's Health revealed complex associations of prenatal exposure to PCDD/PCDFs and PCBs with maternal and infant TH concentrations in multiple regression analysis with some hints towards elevated neonatal free T_4 in boys [54] but no information on developmental outcome is yet available. Several of these agents are known to activate aryl hydrocarbon receptor-mediated gene expression (e.g. of various cytochrome P450 enzymes).

As there are trends for direct relationships between blood, tissue, adipose tissue, whole body or breast milk contents for TCDD,

Box 3.2.2.2 Mechanisms of adverse action of environmental and nutritive agents interfering with hypothalamus–pituitary–thyroid–periphery axis

Thyroid hormone synthesis, secretion, distribution, transport, uptake, metabolism, action

Known targets:

Thyroid: TSHr, NIS, TPO, DUOX, dehalogenase

Serum: transthyretin, albumin, TBG, lipoproteins

Target cells: transmembrane transporters, deiodinases, conjugating enzymes, T3 receptors

Possible targets: TRH, TRH receptor, TRH degrading ectoenzyme, TSH, dehalogenase, cathepsins, cellular uptake systems: MCT8, MCT10, OATP14, LAT2

Known mechanisms: direct competition (reversible, irreversible) for TH protein binding sites, inactivation of essential protein components of the HPTP axis (e.g. heavy metals, toxins)

Probable mechanisms: epigenetic effects

Age- and life phase-dependent actions: developmental, teratogenic, *in utero*, pregnancy, lactation,

Box 3.2.2.3 Current research concepts and paradigms for analysis of endocrine disruptor-like effects of hypothalamus–pituitary–thyroid–periphery axis

- Convergence of EDC effects on neural and endocrine targets in hypothalamus
- Neuroendocrine regulation and organizational units of hypothalamus
- Timing of EDC exposure is key to its ultimate effects, windows of susceptibility, life-course specific effects
- Transgenerational effects of EDC: both personal and parental exposure is relevant
- Analysis of subpopulations with high accidental or occupational exposure or (genetically) predisposed vulnerability
- Epidemiological analysis of consumer and occupationally exposed groups
- Impact of subtle thyroid axis alterations on pre- and postnatal development and long-term ageing-associated risks

polychlorinated dibenzofurans (PCDF), PCB congeners, and other related EDC to impaired thyroid function especially in babies, children and young adults [54–58], there is not only need for monitoring and further research of potential long-term damage, but again the urgent necessity to warrant adequate iodide intake in these areas. This precaution might reduce the risk for the HPTP axis by EDC exposure and contamination. Even under such conditions breast feeding should be considered, provided the mother adapts her iodine intake not only to pregnancy and lactation but also to her elevated EDC contamination, transferred into milk.

PCBs are environmental persistent, some of their more than 200 congeners show bioaccumulation in adipose tissue and exhibit high structural similarity to TH. This is reflected by their strong competition of TH binding to serum transthyretin but also significant competition for T_3 binding to T_3 receptors as demonstrated by *in vitro*, cellular, and intact animal experimental models. Whether these mechanistically plausible effects, which are however associated with divergent findings on serum TH status of affected humans, will also have impact on functionally relevant readouts and biomarkers, remains to be analysed in long-term studies in larger cohorts.

Recently several highly sensitive, powerful, and sophisticated high-throughput *in vitro* screening systems have been established, validated, and are currently used in research. They are also applied for biomonitoring by environmental authorities and allow for detailed analysis of terrestrial and aquatic environment, food components, nutrition, and occupational exposure with respect to endpoints of interference of EDC with TH synthesis, metabolism and action [26, 51, 59–62].

The 'xenoestrogen' BPA, recently receiving much scientific and public attention among the most controversial compounds, is a relevant antagonistic ligand for T_3 receptor and might affect modulation of T_3-responsive genes. BPA, an agent used as plasticizer in daily life articles from polycarbonate baby bottles, food can inner linings, to cosmetic and dental products, is currently intensively analysed as a potent EDC not only for the thyroid but also the hypothalamus–pituitary–gonadal (HPG) axis [13, 63–65]. Some companies stopped already using the compound in baby products. Animal experimental studies suggest immediate and also transgenerational BPA effects including interference with sex differentiation. As long as only few accepted data exist on critical BPA leakage and human exposure levels during various life phases caution should be taken in further expanding the use of this compound in human daily life. BPA has clear adverse effects on several components of the HPTP axis in experimental *in vitro* and *in vivo* models and is a powerful EDC inhibiting several T_3-regulated pathways in vertebrate development as analysed in the excellent premetamorphic *Xenopus laevis* model [66]. These observations add complexity to the analysis of adverse effects and necessary risk assessment because BPA in the scientific and public discussion was mainly considered to be a 'xenoestrogenic' compound with impact on development, differentiation, and function of the HPG axis. Findings like this and related observations of EDC affecting more than one endocrine axis with rather distinct developmental windows of susceptibility to even very low doses of the compounds led to new initiatives, motions and approaches how to analyse such EDC effects that will probably rarely be detected with classical approaches of toxicology focusing on serum parameters, morphology, linear dose-response relationships and toxicological endpoints [63]. It should not be forgotten that relevant species differences for the HPG axis require careful analysis of potential human impact of findings in non-human *in vitro* and animal experimental models. BPA at human relevant concentrations interferes with TH metabolism in pregnant ewes, which represent a valuable model for interference of EDC with maternal–fetal TH communication and more detailed analysis of mechanism involved [67]. Associations between BPA exposure and altered TH parameters or tissue structure have been reported for Chinese school children [68], adult or pregnant women [69–71] and their offspring in studies analysing EDC exposure at single or repeated time points, but mainly single agents such as BPA and not complex EDC mixtures have been analysed.

Similar considerations apply for the various phthalates in use which have already created a worldwide significant exposure level in humans. Here only very few data have been collected for their interference with the HPTP axis, but most studies indicate relevant interference with TH levels in children, pregnant women, and adult individuals [13, 71–74]. The detailed mode of action remains unclear so far as the wide number of phthalate congeners and their metabolites poses major analytical problems for clear cause–effect analysis.

Also, for another group of persistent organohalogen pollutants, the perfluorinated compounds, which are markedly enriched in aquatic food chain, interference with the HPTP axis has been shown in environmental, nutritional, and occupational exposure analysis. Perfluorinated compounds are structurally related to free fatty acids and thus bind to albumin in the blood, thereby competing with TH and interfering with TH bioavailability to target tissues. While at high occupational exposures altered TH serum parameters were reported so far no clinical evidence for disturbed TH status in humans is evident [53, 75–77]. However, as exposure to perfluorinated agents increases globally this issue will remain on the agenda.

Pharmaceuticals and Drugs

Thyroid is a Sensitive Target of Side Effects of Various Drugs

Many drugs are known to interact with the thyroid gland or with components involved in the function and regulation of the HPTP axis. In toxicology departments of pharmaceutical industries, the thyroid gland is a well-known problematic target for adverse or toxic side effects of new pharmaceuticals. It is estimated that up to one-third of

newly developed compounds, especially aromatic and polycyclic compounds, fail the acute or chronic toxicity screening test batteries due to their side effects leading to alterations of thyroid morphology, goitrogenesis, development of thyroid tumours or merely to changes of serum TSH and/or TH concentrations. The reason for this is not completely understood, but the permanent, lifelong H_2O_2 production by thyroid follicles catalysed by the NADPH-dependent DUOX, as well as peroxide consumption by TPO for iodide oxidation, organification, and TH synthesis on the thyroglobulin scaffold might be the major cause. Compounds accumulating in the thyroid and its luminal colloid might be exposed to H_2O_2, be chemically modified by oxidative processes, and be deposited there or damage the follicles. One illustrative example might be the incidentally rare observation of 'black thyroid' syndrome, which is a tetracycline (especially minocycline)-induced asymptomatic discolouration of the thyroid gland probably related to TPO-induced oxidation of the tetracycline [78].

Benzofurans

The powerful benzofuran drugs amiodarone and dronedarone are widely used for treating resistant tachyarrhythmia. Apart from their target molecules in the heart, these drugs, the active metabolite desethylamiodarone and other derivatives are potent antagonistic ligands for the T_3 receptor and inhibitors for the Dio enzymes (Figure 3.2.2.2). However, dibutyl-dronedarone acts as a selective T_3 receptor α1 antagonist (see Chapter 3.3.12). Therefore, chronic administration leads to impaired thyroid function with a clear cumulative dose associated increase in risk. The drugs are substantially accumulated in the thyroid, which in addition to the high iodine content of amiodarone (between 3 and 20 mg iodide are released per day into the blood) explains their prominent disturbance of thyroid function [79, 80]. Not only the iodide contamination associated with the administration of the drug but also the thyroid accumulation of the drug might lead to the severe structural defects of the gland and follicles seen in some patients treated with amiodarone [80, 81]. Therefore, the new iodine-free alternative dronedarone raises high interest as no comparable thyroid-related effects are reported such as inhibition of deiodinase, binding to T_3 receptor, or thyroid accumulation. The adverse effects with respect to iodide contamination of other iodinated drugs such as the iodinated oral bile X-ray contrast agents iopanoate and its congeners [82], will be discussed elsewhere in this volume.

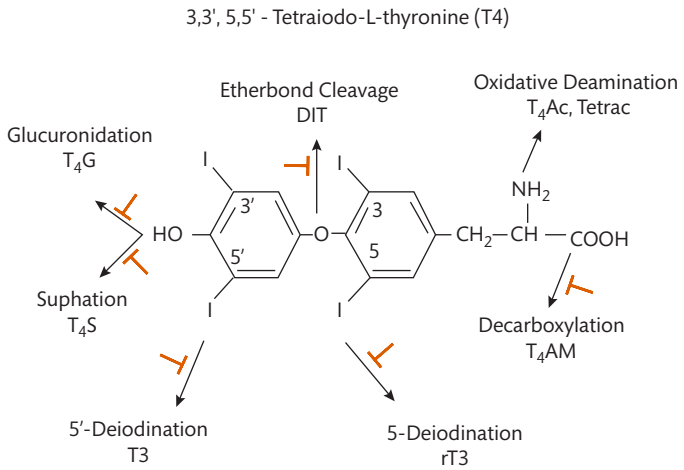

Figure 3.2.2.2 Pathways of thyroxine (T4) metabolism known to be affected by nutritional or environmental agents ⊣.

UV Screens in Cosmetics and Daily Life Products

A further representative example of a group of EDC with relevance for the HPTP axis are widely used UV screens, filters, or absorbers. These are ubiquitous components of various plastic materials of our daily life which have to be protected from UV damage; they are also contained in sunscreens and various cosmetics such as lip sticks or body lotions. Octyl methoxycinnamate (OMC) is one of the most commonly used filters. UV screens may contain up to 10 % (w/w) of typical compounds such as 4-methylbenzylidene camphor (4-MBC) and benzophenones 1–4 and related products. Typical administration of the UV filters leads to measurable serum concentrations in the submicromolar to micromolar range [83]. At these concentrations clear adverse effects have been observed in thyroid-related *in vitro* and *in vivo* animal models, such as rapid and dose-dependent goitrogenesis in rats after 4-MBC administration or efficient inhibition of TPO by benzophenone 2 [5]. Some of these effects might be prevented or at least attenuated by adequate iodide supply which still is not warranted globally. Considering the increased application of these UV screens not only for product protection but also for prevention of human skin cancer due to higher exposure to UV irradiation associated with ozone loss in the atmosphere, some of these UV filters might impose marked risks for the adequate function of the HPTP axis. This might apply especially for babies and children, whose skin is more sensitive to UV light, less protected by endogenous melanocytes and therefore more frequently treated with these dermal UV lotions. Also, these products might be even more easily absorbed by young skin. So far no clear evidence for a goitrogenic action of UV filter ingredients has been described in humans. Therefore, the advice might be to guarantee and adequate iodide supply, and to protect skin from UV irradiation by avoiding too much sun and applying UV screens that have less risk for interference with the HPTP axis especially in babies, children, and individuals with sensitive skin. However, human biomonitoring assessment values, recently updated for such compounds [84] and used as references for safety considerations and risk assessment, remain controversial [85, 86].

Heavy Metals and Thyroid

Environmental contamination by heavy metals and their ions has raised public concern based on their direct effects on several tissues and organs. Both accidentally and occupationally exposed subgroups are affected, and significant adverse effects might result in the central nervous system (CNS) during development and with respect to the pathogenesis of neurodegenerative, ageing-associated diseases. Whether the TH system, known to have major impact on proper brain development and function in children and adults, is directly involved in these processes remains unclear. As thyrocytes exhibit a highly active redox-regulated cellular metabolism [87], impairment of reactive redox centres of enzymes and other thyrocyte proteins such as metallothioneins by heavy metals will create problems for TH synthesis and secretion. Therefore, environmental or occupational exposure to high mercury, lead, and cadmium concentrations has been associated with altered thyroid homeostasis. For example, a gender-specific effect on increased serum TSH, correlated with increased hair and blood mercury concentrations in males, has been reported in lakeside communities of Quebec and is associated with consumption of contaminated lake fish from

exposed environment [88]. Divergent reports have been published on the relationship between cadmium exposure and TSH, positively associated in several studies, but inversely related in a pilot study in cord blood of Japanese newborns [89]. Animal experimental data clearly suggest adverse effects of cadmium exposure, which interferes with both TH synthesis and peripheral Dio1 activity.

Adverse effects of lead on the thyroid axis have been reported. Previous environmental lead sources were lead-enhanced gasoline and lead-based paints, but both of these sources are of decreasing relevance due to bans that have been enforced in most countries, while contaminations by cadmium, mercury, and, recently, platinum leaking into environment from car exhaust catalytic converters are tending to further increase. The evidence that manganese, essential constituent of several redox-relevant enzymes such as manganese-superoxide dismutase, may directly or indirectly affect thyroid function by injuring the thyroid gland or dysregulating dopaminergic modulation of TH synthesis and thus contributing to altered TH homeostasis and neurodegenerative diseases has recently been reviewed [90].

On the other hand, adequate selenium supply can efficiently counteract the adverse effects of several heavy metal cations such as cadmium, mercury, lead, and vanadium and thus avoid their age-related neurotoxicity [91, 92]. It may be plausible that many adverse effects claimed to be caused by heavy metal exposure might be only occurring indirectly because most heavy metal ions very efficiently inactivate selenocysteine-containing proteins, which are pivotal in cellular and systemic redox regulation [93] as well as in TH synthesis and metabolism. Apparently Se leads to their accumulation or deposit in a presumably non-toxic complex in the brain, kidney, and several other tissues.

Many nutritional or environmental contaminants exhibit their goitrogenic potential only under conditions of inadequate maternal, fetal or neonatal iodide (selenium, and iron) supply [94–96]. Therefore, comprehensive nutritional iodide supplementation is one of the most efficient preventive measures to avoid impaired and delayed development of humans and other higher life forms.

Environmental Temperature

Temperature, light, circadian and circannual rhythms, altitude, latitude, and extreme environmental life conditions are well known to influence TH, energy, thermoregulatory and metabolic homeostasis in free living animals (homeotherms, hibernators or aestivators such as bears) but also in humans and livestock adapted to modern housing conditions. Nevertheless, there exist clear circadian and circannual rhythms for TSH and, delayed in phase, for free T_3 in human serum, while T_4, tightly bound to its four serum distributor proteins (thyroxine-binding globulin (TBG), transthyretin, albumin, and lipoproteins) shows no significant circadian or circannual variation [97–99].

Lowest TSH values are observed in spring and summer and increases by 25% are seen in autumn not reflected by T_4 variations and not related to iodine intake. It has to be kept in mind that the TSH response curve is exponentially related to linear changes in TH serum concentration. Whether alterations in food intake, enhanced sympathetic tone, and adrenergic stimulation of thermogenesis, altered contribution of thermogenesis by uncoupling protein(s) activation in skeletal muscles mediated by fatty acids and bile acid metabolites or neuroendocrine hypothalamic adaptations are contributing to these changes remains to be studied. During prolonged stay in arctic environments enhanced TH secretion by the thyroid has been documented, indicated by increased serum thyroglobulin and elevated T_3 production and turnover, reflected by decreased total and free T_3, but accompanied by unchanged total and free T_4 and TBG. This constellation has been termed 'polar T3 syndrome' and related constellations can be found under extreme physical exercise, endurance training, etc. Some of the changes might be prevented by increased calorie intake, sleep adaptation or TH treatment [100].

Increased environmental temperature during summertime but also elevated body temperature during febrile conditions are associated with lower TSH and serum T_3 levels [101, 102].

Various short- and long-term adaptations of TH secretion, turnover, serum levels and feedback set points have been observed in studies examining the HPTP axis in people at high altitude, but results were controversial and might be confounded by other altered factors such as nutritional profiles, physical activity, light, sleep rhythm, and altered time zone adaptations. Animal experimental simulations could dissociate between distinct effects of high altitude and hypoxia and suggest powerful adaptations of the TH axis, characterized by decreased TH synthesis and secretion but elevated serum free TH [7]. Recently, the role of deiodinase 2, locally generating T3 and activating brown adipose tissue or browning 'beige' fat in humans, has attracted major interest in the context of regulation of body weight by stimulation of expression of uncoupling protein(s), thermogenesis and fatty acid oxidation [103].

3.2.3 Iodine Deficiency Disorders

Michael B. Zimmermann

Dietary Sources and Metabolism

Iodine (atomic weight 126.9 g/atom) is an essential component of the hormones produced by the thyroid gland. Thyroid hormones, and therefore iodine, are essential for mammalian life [1]. The native iodine content of most foods and beverages is low, and most commonly consumed foods provide 3–80 µg per serving [1]. Major dietary sources of iodine in the US and Europe are bread and milk [2]. Boiling, baking, and canning of foods containing iodized salt cause only small losses (≤10%) of iodine content. Iodine content in foods is also influenced by iodine-containing compounds used in irrigation, fertilizers, livestock feed, dairy industry disinfectants, and bakery dough conditioners. Recommendations for iodine intake by age and population group [3] are shown in Table 3.2.3.1.

Table 3.2.3.1 Recommendations for iodine intake (μg/day) by age or population group

Age or population group[a]	U.S. Institute of Medicine [4]	Age or population group[c]	World Health Organization [3]
Infants 0–12 months[b]	110–130	Children 0–5 years	90
Children 1–8 years	90	Children 6–12 years	120
Children 9–13 years	120		
Adults ≥14 years	150	Adults >12 years	150
Pregnancy	220	Pregnancy	250
Lactation	290	Lactation	250

[a] Recommended daily allowance. [b] Adequate intake. [c] Recommended nutrient intake.

Iodide is rapidly and nearly completely absorbed (>90%) in the stomach and duodenum [4]. Iodate, widely used in salt iodization, is reduced in the gut and absorbed as iodide. Thyroid clearance of circulating iodine varies with iodine intake: in conditions of adequate iodine supply, ≤10% of absorbed iodine is taken up by the thyroid. In chronic iodine deficiency, this fraction can exceed 80% [1]. Under normal circumstances, plasma iodine has a half-life of ≈10 hours, but this is reduced in iodine deficiency. During lactation, the mammary gland concentrates iodine and secretes it into breast milk to provide for the newborn. The body of a healthy adult contains 15–20 mg of iodine, of which 70–80% is in the thyroid. In chronic iodine deficiency, the iodine content of the thyroid may fall to less than 20 μg. In iodine-sufficient areas, the adult thyroid traps ≈60 μg of iodine/day to balance losses and maintain thyroid hormone synthesis; the sodium/iodide symporter (NIS), transfers iodide into the thyroid at a concentration gradient 20–50 times that of plasma [5]. Iodine comprises 65% and 59% of the weights of thyroxine (T_4) and triiodothyronine (T_3), respectively. Turnover is relatively slow: the half-life of T_4 is ≈5 days and for T_3, 1.5–3 days. The released iodine enters the plasma iodine pool and can be taken up again by the thyroid or excreted by the kidney. More than 90% of ingested iodine is ultimately excreted in the urine.

Historical Perspective

In 1811, Courtois noted a violet vapour arising from burning seaweed ash, and Gay-Lussac subsequently identified the vapour as iodine, a new element. The Swiss physician Coindet, in 1813, hypothesized the traditional treatment of goitre with seaweed was effective because of its iodine content, and successfully treated goitrous patients with iodine [6]. Two decades later, the French chemist Boussingault, working in the Andes Mountains, was the first to advocate prophylaxis with iodine-rich salt to prevent goitre. The French chemist Chatin was the first to publish, in 1851, the hypothesis that iodine deficiency was the cause of goitre. In 1883, Semon suggested myxoedema was due to thyroid insufficiency, and the link between goitre, myxoedema and iodine was established when, in 1896, Baumann and Roos discovered iodine in the thyroid. In the first two decades of the twentieth century, pioneering studies by Swiss and American physicians demonstrated the efficacy of iodine prophylaxis in the prevention of goitre and cretinism [6].

Epidemiology

Only a few countries, including Switzerland, some of the Scandinavian countries, Australia, the United States, and Canada, were completely iodine sufficient before 1990 [3]. Since then, globally, the number of households using iodized salt has risen from <20% to >80%, dramatically reducing iodine deficiency. The Iodine Global Network (IGN) Global Scorecard currently tracks global and national progress towards iodine sufficiency [7]. In 2020, based on recent national or subnational data, only 24 countries remain iodine deficient, 115 have optimal iodine intake, and 14 have excessive iodine intake [7]. This remarkable progress has been spurred by a coalition of international organizations, including the Iodine Global Network (formerly ICCIDD), WHO, and UNICEF, working closely with national iodine deficiency disorders (IDD) control committees and the salt industry; this informal partnership was established after the World Summit for Children in 1990.

In the US and the UK, iodine intakes have fallen over the past 2–3 decades, likely because of decreased iodine intake from dairy products. Pregnant women in the US are now mildly iodine deficient [8]. Other countries, because of over-iodized salt or high iodine in groundwater (e.g. Somalia), have excessive iodine intakes [8]. Vietnam, a country in Southeast Asia with a previously effective iodized salt programme, has experienced backsliding, and has relapsed to iodine deficiency [7]. These changes emphasize the importance of regular and systematic monitoring of iodine status in countries, to detect both low and excessive intakes of iodine.

Pathogenesis and Pathology

Iodine deficiency has multiple adverse effects on growth and development in animals and humans. These are collectively termed the IDD (Table 3.2.3.2) and result from inadequate thyroid hormone production due to lack of sufficient iodine [1].

Goitre

Thyroid enlargement (goitre) is the classic sign of iodine deficiency, and can occur at any age, even in the newborn. It is a physiologic adaptation to chronic iodine deficiency. As iodine intake falls, secretion of thyroid-stimulating hormone (TSH) increases in an effort to maximize uptake of available iodine, and TSH stimulates thyroid hypertrophy and hyperplasia. Initially, goitres are characterized by diffuse, homogeneous enlargement, but over time, nodules often

Table 3.2.3.2 The iodine deficiency disorders, by age group

Physiological groups [1]	Health consequences of iodine deficiency
All ages	Goitre, including toxic nodular goitre
	Increased occurrence of hypothyroidism in moderate-to-severe iodine deficiency; decreased occurrence of hypothyroidism in mild-to-moderate iodine deficiency
	Increased susceptibility of the thyroid gland to nuclear radiation
Fetus	Abortion
	Stillbirth
	Congenital anomalies
	Perinatal mortality
Neonate	Infant mortality
	Endemic cretinism
Child and adolescent	Impaired mental function
	Delayed physical development
Adults	Impaired mental function
	Iodine-induced hyperthyroidism
	Overall, moderate-to-severe iodine deficiency causes subtle but widespread adverse effects in a population secondary to hypothyroidism, including decreased educability, apathy, and reduced work productivity, resulting in impaired social and economic development

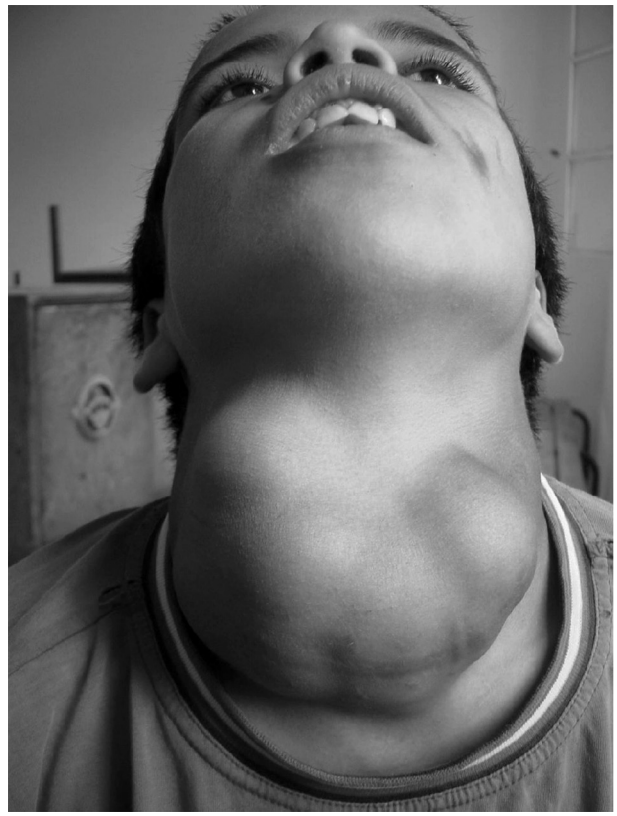

Figure 3.2.3.1 Large nodular goitre in a 14-year-old boy photographed in 2004 in an area of severe IDD in northern Morocco, with tracheal and oesophageal compression and hoarseness, likely due to damage to the recurrent laryngeal nerves.

develop (Figure 3.2.3.1). Many thyroid nodules derive from a somatic mutation and are of monoclonal origin; the mutations appear to be more likely to result in nodules under the influence of a growth promoter, such as iodine deficiency. Iodine deficiency is associated with a high occurrence of multinodular toxic goitre, mainly seen in women older than 50 years. Large goitres may be cosmetically unattractive, can obstruct the trachea and oesophagus, and may damage the recurrent laryngeal nerves and cause hoarseness. Surgery to reduce goitre has significant risks, including bleeding and nerve damage, and hypothyroidism may develop after removal of thyroid tissue.

Severe Iodine Deficiency in Pregnancy: Cretinism and Increased Fetal and Perinatal Mortality

The most serious adverse effect of iodine deficiency is damage to the fetus. Maternal thyroxine crosses the placenta before onset of fetal thyroid function at 10–12 weeks and represents up to 20–40% of T_4 measured in cord blood at birth. Normal levels of thyroid hormones are required for neuronal migration and myelination of the fetal brain, and lack of iodine irreversibly impairs brain development [9]. Severe iodine deficiency during pregnancy increases risk for stillbirths, abortions, and congenital abnormalities [1]. Iodine treatment of pregnant women in areas of severe deficiency reduces fetal and perinatal mortality and improves motor and cognitive performance of the offspring [10]. Severe iodine deficiency *in utero* causes a condition characterized by gross intellectual disability along with varying degrees of short stature, deaf mutism, and spasticity that is termed cretinism [1]. Two distinct types—neurological and myxedematous— have been described, but it may also present as a mixed form (Figure 3.2.3.2). The more common type, neurologic cretinism, has specific neurologic deficits that include spastic quadriplegia with sparing of the distal extremities. The myxedematous form is seen most frequently in central Africa, and has the predominant finding of profound hypothyroidism, with thyroid atrophy and fibrosis. In areas of severe iodine deficiency, cretinism can affect 5–15% of the population. Iodine prophylaxis has completely eliminated the appearance of new cases of cretinism in previously iodine-deficient Switzerland and many other countries; however, new cases have been recently reported from Papua New Guinea.

Mild-to-Moderate Deficiency in Pregnancy

The potential adverse effects of mild-to-moderate iodine deficiency during pregnancy are unclear. Maternal subclinical hypothyroidism (an increased TSH in the second trimester) and maternal hypothyroxinaemia (a free T_4 concentration <10 percentile at 12-week gestation) are associated with impaired mental and psychomotor development of the offspring [11]. However, in these studies, the maternal thyroid abnormalities were unlikely due to iodine deficiency. Observational studies have found that mild-to-moderate iodine deficiency during pregnancy is associated with impaired cognitive development in the offspring [12]. However, observational studies are often confounded by other factors that affect child development. In Europe, several randomized controlled trials of iodine

Figure 3.2.3.2 (a) Neurological cretinism. This 2007 photograph of a 9-year-old girl from Western China demonstrates the three characteristic features: severe mental deficiency together with squint, deaf mutism, and motor spasticity of the arms and legs. The thyroid is present, and frequency of goitre and thyroid dysfunction is similar to that observed in the general population. (b) Myxedematous cretinism. This 2007 photograph of a 5-year-old boy from Western China demonstrates the characteristic findings: profound hypothyroidism, severe growth retardation, incomplete maturation of the features including the naso-orbital configuration, atrophy of the mandible, puffy features, umbilical hernia, myxedematous, thickened, dry skin, and dry hair, eyelashes, and eyebrows. The thyroid typically shows atrophic fibrosis.

supplementation in mild-to-moderately iodine-deficient pregnant women have been done [13]. Iodine reduced maternal and newborn thyroid size, and, in some, decreased maternal TSH. However, none of the trials showed an effect on maternal and newborn total or free thyroid hormone concentrations, the most important outcome, and none measured long-term clinical outcomes, such as maternal goitre, thyroid autoimmunity, or child development [13]. A recent randomized multicentre intervention trial in Thailand and India that provided mildly iodine-deficient pregnant women 200 µg iodine supplements or placebo from the first trimester to delivery did not find benefits on maternal thyroid function, or offspring development at age 5–6 years [14].

Growth and Cognition in Childhood

Although iodine deficiency *in utero* impairs fetal growth and brain development, its postnatal effects on growth and cognition are less clear. Cross-sectional studies of moderate-to-severely iodine-deficient children have generally reported impaired intellectual function and fine motor skills; meta-analyses suggest populations with chronic iodine deficiency experience a reduction in IQ of 12.5–13.5 points [15]. Two randomized controlled trials in mild-to-moderately deficient school-aged children have shown clear benefits of iodine on cognitive and motor function [16, 17]. Moderately iodine-deficient 10–12-year-old children (n = 310) in Albania were randomized to receive either 400 mg of iodine as oral iodized oil or placebo [16]. Compared to placebo, iodine treatment significantly improved performance on tests of information processing, fine motor skills, and visual problem solving. The second placebo-controlled, double-blind trial was conducted in mildly iodine-deficient New Zealand children (n = 184) randomly assigned to receive 150 µg I daily or placebo for 28 weeks [17]. The overall cognitive score of the iodine-supplemented group was 0.19 SDs higher than that of the placebo group ($P = 0.011$) [17]. Thus, in children born and raised in areas of iodine deficiency, cognitive impairment is at least partially reversible by iodine repletion.

Data from cross-sectional studies on iodine intake and child growth are mixed, with most studies finding modest positive correlations. In iodine-deficient children, impaired thyroid function and goitre were inversely correlated with IGF-1 and IGFBP-3 concentrations. Iodine repletion in school-age children increased insulin-like growth factor (IGF)-1 and insulin-like growth factor binding protein (IGFBP)-3 and improved somatic growth [18]. However, other controlled intervention studies of iodized oil alone and iodine given with other micronutrients have generally not found effects on child growth. In a recent systematic review [19], iodine supplementation of severely iodine-deficient pregnant women increased mean birthweight (mean difference: 200 g; 95% CI: 183, 217 g) compared to controls, but iodine repletion in infants and children showed no effects on somatic growth.

A recent systematic review by WHO summarized the efficacy of iodized salt for preventing IDD [20]. Comparisons were made between the consumption of iodized salt and a placebo, non-iodized salt, or no intervention. The participants included members of the general population of any age and sex. The results of this review showed that iodized salt has substantial benefits on cognition including reducing the risk of: cretinism (odds ratio [OR] = 0.13

(95% CI, 0.08–0.20)), and low IQ (RR = 0.28 (95% CI, 0.21–0.36) [20]. The International Child Development Steering Group identified iodine deficiency as one of four key global risk factors for impaired child development where the need for intervention is urgent [21].

Assessment and Diagnosis

Four methods are generally recommended for assessment of iodine nutrition: urinary iodine concentration (UI), the goitre rate, serum TSH, and serum thyroglobulin (Tg) [3, 22]. These indicators are complementary, in that UI is a sensitive indicator of recent iodine intake (days), Tg shows an intermediate response (weeks to months), while changes in the goitre rate reflect long-term iodine nutrition (months to years).

Thyroid Size

Two methods are available for measuring goitre: neck inspection and palpation, and thyroid ultrasonography. By palpation, a thyroid is considered goitrous when each lateral lobe has a volume greater than the terminal phalanx of the thumbs of the subject being examined [3]. However, palpation of goitre in mild iodine deficiency has poor sensitivity and specificity and measurement of thyroid volume (Tvol) by ultrasound is preferable [22]. Thyroid ultrasound is non-invasive, quickly done (2–3 minutes per subject) and feasible even in remote areas using portable equipment. However, interpretation of Tvol data requires valid reference criteria, and age- and gender-specific references are available for 6–12-year-old children [3], but there are no established reference values for adults. Goitre can be classified by thyroid ultrasonography only if Tvol is determined by a standard method. Thyroid ultrasound is subjective; differences in technique can produce interobserver errors in Tvol as high as 26% [22].

Urinary Iodine Concentration

Because more than 90% of ingested iodine is excreted in the urine, UI is an excellent indicator of recent iodine intake. UI can be expressed as a concentration (μg/L), in relationship to creatinine excretion (μg iodine/g creatinine), or as 24-hour excretion (μg/day). For populations, because it is impractical to collect 24-hour samples in field studies, UI can be measured in spot urine specimens from a representative sample of the target group, and expressed as the median, in μg/L (3) (Table 3.2.3.3). However, the median UI is often misinterpreted. Individual iodine intakes, and, therefore, spot UI concentrations are highly variable from day-to-day and a common mistake is to assume that all subjects with a spot UI <100 μg/L are iodine deficient. To estimate iodine intakes in individuals, 24-hour collections are preferable, but difficult to obtain. An alternative is to use the age-and sex-adjusted iodine:creatinine ratio in adults, but this also has limitations [22]. Creatinine may be unreliable for estimating daily iodine excretion from spot samples, especially in malnourished subjects where creatinine concentration is low. Daily iodine intake in adults can be extrapolated from the median UI in populations using estimates of mean 24-hour urine volume and assuming an average iodine bioavailability of 92% using the

Table 3.2.3.3 Epidemiological criteria for assessing iodine nutrition in a population based on median and/or range of urinary iodine concentrations

Median urinary iodine (μg/L) [3]	Iodine intake	Iodine nutrition
School-aged children		
<20	Insufficient	Severe iodine deficiency
20–49	Insufficient	Moderate iodine deficiency
50–99	Insufficient	Mild iodine deficiency
100–199	Adequate	Optimal
200–299	More than adequate	Risk of iodine-induced hyperthyroidism in susceptible groups
>300	Excessive	Risk of adverse health consequences (iodine-induced hyperthyroidism, autoimmune thyroid disease)
Pregnant women		
<150	Insufficient	
150–249	Adequate	
250–499	More than adequate	
≥500	Excessive[a]	
Lactating women[b]		
<100	Insufficient	
≥100	Adequate	
Children less than 2 years old		
<100	Insufficient	
≥100	Adequate	

[a] The term 'excessive' means in excess of the amount required to prevent and control iodine deficiency.

[b] In lactating women, the figures for median urinary iodine are lower than the iodine requirements because of the iodine excreted in breast milk.

formula: Urinary iodine (μg/L) × 0.0235 × body weight (kg) = daily iodine intake [4]. Using this formula, a median UI of 100 μg/L in adults corresponds roughly to an average daily intake of 150 μg.

Thyroid-Stimulating Hormone

Because serum TSH is determined mainly by the level of circulating thyroid hormone, which in turn reflects iodine intake, TSH can be used as an indicator of iodine nutrition. However, in older children and adults, although serum TSH may be slightly increased by iodine deficiency, values often remain within the normal range. TSH is therefore a relatively insensitive indicator of iodine nutrition in adults [3]. In contrast, TSH is a sensitive indicator of iodine status in the newborn period. Compared to the adult, the newborn thyroid contains less iodine but has higher rates of iodine turnover. Particularly when iodine supply is low, maintaining high iodine turnover requires increased TSH stimulation. Serum TSH concentrations are therefore increased in iodine-deficient infants for the first few weeks of life, a condition termed transient newborn hypothyroidism. In areas of iodine deficiency, an increase in transient newborn hypothyroidism, indicated by more than 3% of newborn TSH values above the threshold of 5 mU/L whole blood collected 3 to 4 days after birth, suggests iodine deficiency in the population [3]. Newborn TSH is an important measure because it reflects iodine status during a period when the developing brain is particularly sensitive to iodine deficiency.

Thyroglobulin

Thyroglobulin (Tg) is synthesized only in the thyroid, and is the most abundant intrathyroidal protein. In iodine sufficiency, small amounts of Tg are secreted into the circulation, and serum Tg is normally less than 10 μg/L [22]. In iodine deficiency, serum Tg increases due to greater thyroid cell mass and TSH stimulation. Serum Tg is well correlated with the severity of iodine deficiency as measured by UI. Tg falls rapidly with iodine repletion, and Tg is a more sensitive indicator of iodine repletion than TSH or T_4 [22].

New assays for Tg have been developed for dried blood spots taken by a finger prick, simplifying collection and transport [23]. In prospective studies, dried blood spot Tg has been shown to be a sensitive measure of iodine status and reflects improved thyroid function within several months after iodine repletion [23]. International reference ranges for DBS Tg have been proposed for school-age children [3, 23] and pregnant women [24].

Thyroid Hormone Concentrations

Thyroid hormone concentrations (T_4 and T_3) are poor indicators of iodine intake. In iodine-deficient individuals, serum T_3 increases or remains unchanged, and serum T_4 usually decreases. However, these changes are often within the normal range, and make thyroid hormone levels an insensitive measure of iodine nutrition [3].

Prevention and Treatment

Salt Fortification with Iodine

In nearly all regions affected by iodine deficiency, the most effective way to control iodine deficiency is through salt iodization [3]. Universal salt iodization (USI) is a term used to describe the iodization of all salt for human (food industry and household) and livestock consumption. Although the ideal, even in countries with successful salt iodization programmes, USI is rarely achieved, as food industries are often reluctant to use iodized salt, and many countries do not iodize salt for livestock.

WHO/UNICEF/ICCIDD recommends that iodine is added at a level of 20–40 mg iodine/kg salt, depending on local salt intake [3]. Iodine can be added to salt in the form of potassium iodide (KI) or potassium iodate (KIO_3). Because KIO_3 has higher stability than KI in the presence of salt impurities, humidity, and porous packaging, it is the recommended form in tropical countries and those with low-grade salt. Iodine is usually added after the salt has been dried. Two techniques are used: (1) the wet method, where a solution of KIO_3 is dripped or sprayed at a regular rate on to salt passing by on a conveyor belt; (2) the dry method, where KI or KIO_3 powder is sprinkled over the dry salt. Optimally, packaging should be in low-density polyethylene bags, as high humidity combined with porous packing may result in up to 90% losses of iodine after 1 year of storage in high-density polyethylene bags.

Health Economics of Salt Iodization

Salt iodization remains the most cost-effective way of delivering iodine and of improving cognition in iodine-deficient populations [25, 26]. Worldwide, the annual costs of salt iodization are estimated at 0.02–0.05 US$ per child covered, and the costs per child death averted are US$1000 and per disability-adjusted life year (DALY) gained are US$34–36 US [25]. Looked at in another way, prior to widespread salt iodization, the annual potential losses attributable to iodine deficiency in the developing world have been estimated to be US$35.7 billion as compared with an estimated US$0.5 billion annual cost for salt iodization (i.e. a 70:1 benefit:cost ratio) [1]. The World Bank [26] strongly recommends that governments invest in micronutrient programmes, including salt iodization, to promote development, concluding: 'Probably no other technology offers as large an opportunity to improve lives at such low cost and in such a short time.'

Supplementation

In some regions, iodization of salt may not be practical for control of iodine deficiency, at least in the short term. This may occur in remote areas where communications are poor or where there are numerous small-scale salt producers. In these areas, iodized oil supplements can be used [3]. Iodized oil is prepared by esterification of the unsaturated fatty acids in seed or vegetable oils, and addition of iodine to the double bonds. It can be given orally or by intramuscular injection [3]. The intramuscular route has a longer duration of action, but oral administration is more common because it is simpler. Usual doses are 200–400 mg iodine/year and it is often targeted to women of childbearing age, pregnant women, and children [3] (Table 3.2.3.4). Its disadvantages are an uneven level of iodine in the body over time and the need for direct contact with individuals with the accompanying increased programme costs.

Iodine can also be given as KI or KIO_3 as drops or tablets. Single oral doses of potassium iodide monthly (30 mg) or biweekly (8 mg) can provide adequate iodine for school-age children [27]. Lugol's iodine, containing ≈6 mg iodine per drop, and similar preparations are often available as antiseptics in rural dispensaries in developing

Table 3.2.3.4 Recommendations for iodine supplementation in pregnancy and infancy in areas where <90% of households are using iodized salt and the median UI is <100 µg/L in schoolchildren

Women of childbearing age	A single annual oral dose of 400 mg of iodine as iodized oil OR A daily oral dose of iodine as potassium iodide should be given so that the total iodine intake meets the reference nutrient intake (RNI) of 150 µg/d of iodine
Women who are pregnant or lactating	A single annual oral dose of 400 mg of iodine as iodized oil OR A daily oral dose of iodine as potassium iodide should be given so that the total iodine intake meets the RNI of 250 µg/d iodine. • Iodine supplements should not be given to a woman who has already been given iodized oil during her current pregnancy or up to 3 months before her current pregnancy started
Children aged 0–6 months	A single oral dose of 100 mg of iodine as iodized oil OR A daily oral dose of iodine as potassium iodide should be given so that the total iodine intake meets the of 90 µg/d of iodine • Should be given iodine supplements only if the mother was not supplemented during pregnancy or if the child is not being breast-fed
Children aged 7–24 months old	A single annual oral dose of 200 mg of iodine as iodized oil as soon as possible after reaching 7 months of age OR A daily oral dose of iodine as potassium iodide should be given so that the total iodine intake meets the RNI of 90 µg/d of iodine

countries and offer another simple way to deliver iodine locally. In countries or regions where a salt iodization programme covers ≥90% of households and has been sustained for ≥2 years, and the median UI indicates iodine sufficiency (Table 3.2.3.4), pregnant and lactating women do not need iodine supplementation [3]. In iodine-deficient countries or regions that have weak iodized salt distribution, supplements should be given to pregnant women, lactating women, and infants, according to the guidelines in Table 3.2.3.4 [3]. In a recent controlled trial, lactating women who received one dose of 400 mg iodine as oral iodized oil soon after delivery provided adequate iodine to their infants through breast milk for at least 6 months, enabling the infants to achieve euthyroidism [28].

Clinical Nutrition

Preterm Infants

Balance studies in healthy preterm infants have suggested iodine intakes of at least 30 µg/kg body weight/day are required to maintain positive balance, and experts generally recommend iodine intakes of 30–60 µg/kg/day for this group [29]. Formula milks for preterm infants contain 20–170 µg iodine/L, and, depending on the dietary iodine intake of the mother, breast milk generally contains 50–150 µg/L. Thus, particularly during the first postnatal weeks when feed volumes are often low, enterally fed preterm infants may not achieve the recommended intake of iodine [29]. US and European clinical nutrition societies recommend parenteral iodine intakes of 1 µg/kg body weight/day [30], far below fetal accretion rates. This conservative recommendation assumes parenterally fed preterm infants will absorb iodine through the skin from topical iodinated disinfectants, and also receive small amounts of adventitious iodine in other infusions.

Because of concerns over possible iodine excess, use of iodinated antiseptics in infants may be decreasing, putting infants at risk of iodine deficiency [29]. If parentally fed preterm infants are not exposed to adventitious sources of iodine, they may receive only 1–3 µg iodine/kg body weight/day, and be in negative iodine balance during the first few postnatal weeks [29]. Several authors have argued that iodine deficiency should be avoided during this period because it may transiently lower thyroid hormone levels in the first weeks of life, and transient hypothyroxinaemia in preterm infants has been linked to impaired neurodevelopment [31].

Children and Adults

A daily dose of 1 µg iodine/kg body weight is recommended for children receiving parenteral nutrition [29]. For adults, commercially available products for enteral nutrition generally supply 75–110 µg iodine/serving. A technical review recommended iodine intakes of 70–140 µg/day during parenteral nutrition [32]. Although most parenteral nutrition formulations do not contain iodine, deficiency is not likely to occur because of cutaneous absorption from iodine-containing disinfectants and other adventitious sources of iodine. It is likely that thyroidal iodine stores are often adequate to meet the needs of patients requiring total parenteral nutrition for less than 3 months; in iodine-sufficient adults, thyroidal iodine content is 15–20 mg [1]. For these reasons, supplemental iodine is not routinely recommended for subjects receiving total parenteral nutrition [33].

Correction of Iodine Deficiency and Thyroid Disorders in Populations

Several reviews have examined the relationship between correction of iodine deficiency and the pattern of thyroid diseases in populations [34, 35]. In summary, as a population moves from severe iodine deficiency to mild iodine deficiency and then to iodine sufficiency, there is a modest shift from excess hypothyroidism to excess hyperthyroidism, which is transient, and then a small shift back towards excess mild hypothyroidism. Severe iodine deficiency causes more hypothyroidism because, despite an increase in thyroid activity to maximize iodine uptake and recycling, there is simply not enough iodine to maintain thyroid hormone production. In mild-to-moderate iodine deficiency, the thyroid gland is able to compensate for deficient dietary intake by increasing thyroid activity and this maintains thyroid hormone production, but at a price: in some individuals, chronic stimulation of the thyroid will lead to thyroid nodularity and autonomy [34]. This increase in nodularity

subsequently increases risk of hyperthyroidism if iodine intakes are raised by supplementation or fortification. However, this is transient and since iodine sufficiency normalizes thyroid activity this results, in the long-term, in reduced nodularity and autonomy [35]. The small increase in mild hypothyroidism that occurs with optimal or excessive iodine intakes may be linked to thyroid autoimmunity and may also transient, but more long-term studies are needed [35]. The overall incidence of thyroid carcinoma in populations does not appear to be influenced by iodine intake. The distribution of the subtypes of thyroid carcinoma is related to iodine intake [36]; in areas of higher iodine intake, there appear to be fewer of the more aggressive follicular and anaplastic carcinomas, but more papillary carcinomas. When iodine prophylaxis is introduced in populations, there may be an increase in the ratio of papillary to follicular carcinoma [36], and this shift towards less malignant types of thyroid cancer, as well as a lower radiation dose to the thyroid in case of nuclear fallout, are benefits of the correction of mild-to-moderate iodine deficiency.

3.2.4 Radiation-Induced Thyroid Disease

Shunichi Yamashita, Furio Pacini, and Rossella Elisei

Introduction

Radiation is a mitogen which may cause damage to the cell DNA. When sufficiently severe, the damage may result in cell death. When the damage is less severe, the consequences to the cell depend upon the gene and cell system that are affected. The thyroid gland is particularly sensitive to the effects of radiation and the evidence that radiation may damage the thyroid gland is overwhelming. Both external and internal radiation have been associated with thyroid diseases (cancer and hypothyroidism, with or without thyroid autoimmunity) both *in vitro* and *in vivo*. External radiation to the thyroid was first recognized as a cause of thyroid carcinoma in the 1950s, when cases were found in individuals who had been given radiotherapy during childhood for an enlarged thymus [1]. Since then, numerous studies have confirmed and extended this initial observation.

Radioactive isotopes are used in several situations in humans. They are given in very large doses in the treatment of thyroid cancer, when the dose used is intended to kill all thyroid cancer cells, and in smaller doses in the treatment of thyrotoxicosis, with the intent to produce hypothyroidism. In these conditions the radiation doses are sufficiently high to kill the cells, thus no unwanted secondary thyroid disease occurs. Low doses of iodine isotopes are also used as tracers for diagnostic evaluation of the thyroid gland. In this situation, no cell killing is observed and there is the theoretical possibility for thyroid cell damage. However, no convincing evidence of subsequent thyroid disorders has so far been provided.

Many animal studies have shown that radioiodine is carcinogenic to the thyroid. Some of the earlier data suggested that internal radiation by radioiodine was less effective than external radiation, but according to one more recent study in rats [2], the carcinogenic potential of ^{131}I and X-rays appears to be the same. In both cases, the dose–response relationship seems to be linear, indicating that low doses also carry a risk. Iodine-131 is 20–30% as effective as external X- or χ-rays.

Thyroid Carcinoma After External Irradiation

Methodology in Epidemiological Studies

The relationship between radiation and thyroid carcinoma was first recognized in 1950 [1], and thyroid carcinoma was the first solid malignant tumour found to be increased among Japanese atomic bomb survivors [3]. This relationship was confirmed subsequently by many epidemiological studies [4].

Two major limitations should be taken into account in studies of the relationship between radiation and thyroid carcinoma. One is due to the fact that many patients are unaware of, or uncertain about, prior radiation exposure, especially when therapeutic irradiation was administered at a young age (recall bias), taking into account that radiation-induced thyroid carcinoma occurs several years later. The second and perhaps more relevant limitation is related to the frequent occurrence of thyroid nodules in the general population (4–7% by palpation and up to 50% by ultrasonography in people over 60 years). Moreover, most thyroid tumours are indolent and frequently not recognized clinically. Thus, the diagnosis of thyroid tumours depends on the extent of the diagnostic procedures used (diagnostic bias).

In case-control studies, the cases are patients with thyroid cancer identified by entry into a tumour registry. The controls are matched subjects free from thyroid carcinoma. Information on risk factors, such as radiation exposure, is obtained and the distribution in the two groups is compared. In such studies diagnostic bias is minimized, but recall bias may be important. In cohort studies, exposure to radiation is generally well documented, and recall bias is minimized. The frequency of thyroid carcinoma in the radiation-exposed group is compared with a group of similar subjects not exposed to radiation. In this case, diagnostic bias may be important. A final additional caveat is due to the fact that retrospective estimates of doses delivered to the thyroid are necessary to prove the

Box 3.2.4.1 Most common indices of cancer risk from radiation exposure

- RR (relative risk) = *O/E* (*n* observed in radiation-exposed/*n* expected in non-exposed)
- SIR (standardized incidence ratio) = *O/E* when *E* is derived from a registry
- ERR (excess relative risk) = *O/E*-1
- ERR/gray = ERR/mean dose (Gy) in the group
- EAR (excess absolute risk)/gray = *O-E*/PYG (person-year-gray of exposure to the risk)

aetiological weight of radiation in thyroid cancer (dose–effect relationship). These estimates may be difficult to obtain and are subject to error.

Most epidemiological studies dealing with the risk of developing radiation-induced thyroid cancer use the relative risk (RR) as an index, i.e. the ratio between the observed (*O*) number of cancers in the radiation-exposed group and the expected (*E*) number of cancers in the non-exposed group (RR = *O*/*E*). When the expected number is obtained from a registry, the RR is called the standardized incidence ratio. The most frequently used indices of risk estimates are reported in Box 3.2.4.1.

Risk estimates for radiation-induced thyroid cancer have been calculated in people exposed to external radiation. According to the National Council of Radiation Protection (NCRP) [5], the excess absolute risk is 2.5×10^{-4}/Gy per year for persons exposed under the age of 18. For adults, the risk per year is assumed to be half this value. Because of their smaller number of years at risk, the lifetime risk for adults is about one-quarter the risk for children.

In a pooled analysis [6] the excess absolute risk was 4.4×10^{-4}/Gy per year for persons exposed before the age of 15, confirming that the RR is largely dependent upon age at exposure with young children carrying the highest risk. As shown in Tables 3.2.4.1 and 3.2.4.2, little risk is carried after the age of 20 and almost none after the age of 40, as demonstrated in the study of atomic bomb survivors in Hiroshima and Nagasaki [7].

External Irradiation to the Head and Neck for Benign Diseases

Irradiation to the head and neck has been performed in children since 1920 for the treatment of benign conditions such as enlargement of the thymus, tonsils, adenoids, or neck lymph nodes, skin angioma, acne, otitis, or tinea capitis [4, 8–10]. This modality of treatment was particularly popular in the United States, where in 1970 as many as 76% of children with thyroid carcinoma had a history of radiation exposure [11]. In Europe, it was less frequently used: in two large referral centres for thyroid cancer, the Institut Gustave-Roussy in Villejuif, France, and the Department of Endocrinology in Pisa, Italy, the incidence of radiation-induced thyroid carcinoma in children or adolescents was 10% and 7%, respectively.

Ron and colleagues [6] reported an analysis of radiation exposure and thyroid cancer from seven large studies of a total of 58 000 children exposed to external radiation, in whom individual doses to the thyroid were known. About 700 thyroid carcinomas were observed. The excess relative risk per gray (ERR/Gy) was 7.7 (95% CI 2.1–28.7). The authors concluded that 88% of thyroid carcinomas that were found in children exposed to 1 Gy were attributable to radiation. The excess absolute risk was 4.4/10 000 population-year-gray of exposure (95% CI 1.9–10.1). The risk of thyroid cancer significantly increased after a mean dose as low as 100 mGy to the thyroid. There was no evidence for a threshold dose below which the effect disappeared. At higher doses (up to 1500 cGy), there was a linear relationship between dose and risk of cancer. At doses higher than 1500 cGy, the risk per gray decreased, probably because of cell killing, but the overall risk remained elevated.

In a study of 2634 patients from the Michael Reese Hospital in Chicago [12], whose thyroids received a mean dose of 590 mGy for benign disorders during childhood, about 60% developed thyroid nodules and 15% developed thyroid carcinoma within 40 years after radiation. These studies indicate clearly that the risk of thyroid cancer after exposure to external radiation is indeed very high, suggesting that the thyroid gland is very sensitive to radiation, especially during childhood (Table 3.2.4.2).

In most studies, the latency period between the time of radiation exposure and the appearance of the thyroid nodule ranges between 5 and 15 years. In the pooled analysis of seven studies mentioned earlier [6], only two cases were observed within the first 5 years after exposure; the ERR clearly increased between 5 and 9 years after exposure, with a peak at 15–19 years, an excess risk still being apparent at 40 years [12].

Since 1970, external radiation for benign disorders has been virtually abandoned in most countries.

Table 3.2.4.1 Thyroid cancer excess relative risk (ERR) from exposure to external radiation in adults

Study	Irradiated subjects	Mean does (cGy)	ERR/Gy
Atomic bomb	11 000	26	0.8
Neck cancer therapy	82 816	11	3.1
Tuberculous adenitis	124	820	1.2

External Irradiation to the Head and Neck for Malignant Diseases

In case of external radiation to the head and neck for malignant disease, the dose delivered to the thyroid may be very high, and usually greater than that delivered for the treatment of benign conditions. Animal experiments have shown that for doses larger than 15–20 Gy, the risk of thyroid tumour is increased but the risk per gray decreases. This finding has been attributed to cell killing, which decreases the number of cells that may become neoplastic, and explains the high frequency of hypothyroidism observed in those animals.

In humans, high-dose radiation therapy to the neck (more than 20 Gy), as used for Hodgkin's disease, results in a high rate of hypothyroidism, but also in an increased risk of thyroid cancer [13]. The final outcome of the thyroid damage is probably related to the distance between the thyroid gland and the radiation field. If this is far from the thyroid, as in case of thoracic or abdominal radiation fields in children, the thyroid gland may receive radiation doses of some hundred milligray, not enough to produce hypothyroidism but sufficient to trigger thyroid cancer [14, 15]. Recently, it has been reported that all survivors of human cancer treated with craniospinal external radiotherapy during childhood require long-term observation, up to 25 years after the exposure, since their risk of developing thyroid cancer and other thyroid dysfunctions is increased with respect to the general population without a specific age-related plateau [16].

Atomic Bombs in Hiroshima and Nagasaki

After the atomic bombing in Hiroshima and Nagasaki in 1945, the body dose was mainly due to external irradiation (X-rays and neutrons). Contamination by radioactive isotopes of iodine is poorly known. The health consequences were studied in a cohort of 94 000 survivors and of 26 000 individuals who resided in Hiroshima and Nagasaki shortly after the bombing. A total of 225 thyroid cancers were diagnosed between 1958 and 1987 among the 79 972 survivors who were alive and free of cancer as of January 1958 and who had radiation dose estimates [7]. From a histological point of view, these tumours are very similar to conventional sporadic papillary thyroid cancer and, at variance with the post-Chernobyl thyroid tumours, the solid variant is very rare among atomic bomb survivors. However, molecular oncology analysis of 50 adult-onset papillary thyroid cancer exposed to A-bomb radiation showed that the prevalence of RET/PTC rearrangements was significantly correlated with the radiation dose and that other unknown gene alterations tended to be more frequent with increased radiation dose [17]. These findings suggest that radiation-associated gene alterations, mainly chromosomal rearrangements, other than RET/PTC might be involved in the adult-onset thyroid cancer of subjects who were exposed to high radiation dose.

Factors Affecting Sensitivity to Radiation-Induced Thyroid Cancer

Age and Sex

A major risk factor is a young age at the time of irradiation. The risk of thyroid cancer after external irradiation in children less than 5 years of age is two times higher than in children treated between 5 and 9 years and five times higher than in children treated between 10 and 14 years [6]. From the Lifespan Study of atomic bomb survivors in Hiroshima and Nagasaki [16], it is known that little risk is carried for exposures after the age of 20 and almost none after the age of 40. The excess risk of thyroid cancer was 9.5, 3.0, 0.3, and 0.2 in the age categories 0–9, 10–19, 20–39, and over 40 years, respectively, at the time of bombing. The excess risk was not significant for subjects exposed above the age of 15–20 years. This increased risk of very young children to develop thyroid cancer after radiation exposure can be explained, at least in part, by the higher proliferative activity of thyroid cells during intrauterine development and childhood [18]. The high susceptibility of young children to radiation has been confirmed in the thyroid cancer studies after the Chernobyl nuclear reactor accident (see next), supporting the concept that the radiation effect is maximal during periods of rapid cell proliferation, as in the case of the developing thyroid of very young children. Data on irradiation in adults are scarce, but estimates of the ERR/Gy are largely below those of individuals exposed during childhood, and it is likely the risk is negligible.

Gender does not seem to influence the risk of developing radiation-induced thyroid cancer. Although females are 2–3 times more likely to develop both benign and malignant thyroid nodules after irradiation, this finding reflects the higher natural incidence of thyroid nodules and cancer in the female general population. Very recently a new study on the association between radiation dose and thyroid cancer incidence among Japanese survivors who were adults at the time of the atomic bombings of Hiroshima and Nagasaki has shown that the exposure to ionizing radiation in adults was positively associated with thyroid cancer among women atomic bomb survivors. However, this association was lower than that observed in those who were exposed during childhood [19].

Fractionation and Dose Rate

External radiation therapy for benign and malignant diseases is given at a high dose rate. Lower dose rates or fractionation of the dose may theoretically allow radiation-induced DNA lesions to be repaired, thus decreasing the carcinogenic effects of radiation. In the pooled analysis of seven studies, fractionation of the dose was associated with a 30% reduction of the ERR/Gy [6]. However, in a recent update of thyroid cancer after radiation therapy for malignant disorders in childhood, no reduction in ERR/Gy was observed with fractionation.

The importance of the dose rate is suggested by several observations. In children treated for skin angioma of the neck, a dose–effect relationship was observed after external radiation at a high dose rate, but no such relation was found after brachytherapy at a low dose rate. The incidence of thyroid nodules is similar in two regions of China where natural radiation is different (i.e. 140 mGy and 50 mGy/lifetime, respectively) [20]. In contrast, an increased RR (1.7) of thyroid cancer was found among 27 000 medical diagnostic radiographers in China, who probably received more than 1 Gy to the thyroid during their working life [21]. No such increase was observed in similar workers in industrialized countries.

Genetic Predisposition

Several clinical observations suggest that genetic predisposition, such as defects in the DNA repair mechanisms, may affect the risk of developing radiation-induced thyroid cancer [22, 23]. Patients who experience one radiation-related cancer are more likely to

develop a second radiation-related cancer. Sibling pairs, exposed to radiation, develop thyroid tumours more often than would be expected by chance [22, 23]. The risk of thyroid cancer in patients treated with radiotherapy during childhood for a cancer (other than neuroblastoma) is 3–10 times higher than in children treated for benign conditions. Those treated for neuroblastoma have a fivefold risk of thyroid cancer with respect to patients treated for other cancers, suggesting a common predisposition for neuroblastoma and thyroid cancer.

The search for the gene(s) predisposing to radiation-induced thyroid cancer is currently in progress in pedigrees showing recurrence of thyroid cancer. No linkage has been found as yet with genes known to be involved in thyroid tumorigenesis, such as *ras, p53, BRaf*, or *RET/PTC*. A distinct genome-wide gene expression profiling has been reported in post-Chernobyl papillary thyroid cancer when compared with that occurring naturally, suggesting a greater susceptibility to thyroid cell radiation damage [24].

Thyroid Carcinoma after Exposure to Radioactive Iodine, and the Chernobyl Experience

Iodine-131, being physiologically accumulated in the thyroid by an active mechanism, has been widely used for several decades in the diagnostic evaluation of the thyroid gland and in the treatment of patients with hyperthyroidism and differentiated thyroid cancer. The radiation dose delivered by ^{131}I to the thyroid is 1000- to 10 000-fold higher than that delivered to other tissues. Thus, even a relatively low amount of ^{131}I may deliver a significant, potentially carcinogenic radiation dose to the thyroid gland. Increasing the radiation dose beyond a few hundred megabecquerels, increases the likelihood of obtaining cell killing and decreases the possibility of tumoural changes.

The role of radioactive iodine for medical use in the development of thyroid cancer has been addressed in several studies, which showed no significant risk and led to the conclusion that ^{131}I is sufficiently safe both as a diagnostic and a therapeutic tool. However, most patients included in these studies were treated as adults, whereas the post-Chernobyl epidemic of thyroid cancer occurred mainly in children and adolescents, supporting evidence that the young thyroid is particularly sensitive to the effect of radiation. This event has renewed concern about the carcinogenic risk of medical use of ^{131}I, at least in young patients.

Exposure to ^{131}I for Diagnostic Purposes

The most informative analysis in this setting was performed in Sweden on 34 104 patients exposed to diagnostic doses of ^{131}I between 1950 and 1969, for a mean thyroid dose estimate of 110 cGy [25]. A small increase in the number of observed thyroid cancers (n = 67) was found with respect to the expected number (n = 50). However, the increase was confined to patients undergoing thyroid scan for suspicion of thyroid cancer. When the analysis was limited to patients tested for reasons other than thyroid cancer, no increase was observed.

In the same Swedish cohort, the incidence of thyroid nodules was compared in a subset of 1005 women and 248 matched controls. The average length of follow-up was 26 years and the average age at exposure was 26 years. No difference was found in the two groups; the incidence of nodules was 10.6 and 11.7, respectively. Similar findings have been reported in other surveys in the United States and in Germany.

Table 3.2.4.3 Thyroid cancer excess relative risk (ERR)/Gy after exposure to ^{131}I before the age of 20 years

Study	Irradiated subjects	Mean does (cGy)	ERR/Gy
Swedish diagnostic ^{131}I	2408	150	0.25
Food and Drug Administration diagnostic ^{131}I	3503	80	0.10
Utah ^{131}I fallout	2473	17	7.9
Marshall islanders	127	1240	0.32
Juvenile hyperthyroidism	602	8800	0.3

Data taken from Shore RE, *Radiation Research*, 1992; 131: 98–111.
From Shore RE. Issues and epidemiological evidence regarding radiation-induced thyroid cancer. *Radiat Res*, 1992; 131: 98–111.

The conclusion drawn from this study is that diagnostic use of ^{131}I has no untoward health effect on the thyroid. However, a note of caution is needed because only a minority of the exposed patients were children. The ERR of thyroid cancer after exposure to ^{131}I before age 20 and in adults is reported in Tables 3.2.4.3 and 3.2.4.4, respectively.

Exposure to ^{131}I for Therapeutic Purposes

Radioiodine is used widely to treat hyperthyroidism caused either by Graves' disease, toxic nodular goitre, or metastatic thyroid cancer. No evidence of an increased risk of thyroid cancer after treatment of hyperthyroidism with ^{131}I has been reported. In a Swedish study, including 10 552 adult patients (mean age 57 years) followed for a mean period of 15 years, the relative risk of thyroid cancer was not significantly increased (RR 1.29; 95% CI 0.76–2.03). The average estimated radiation dose to the thyroid was 100 Gy [26].

In a study carried out in the United States [27] in hyperthyroid patients, after a mean follow-up of 21 years, ^{131}I treatment was not found to be linked to total cancer deaths (standardized mortality ratio (SMR) 1.02), or to the development of any cancer other than thyroid cancer (SMR 3.94; 95% CI 2.52–5.86). The SMR was 2.08 in patients with Graves' disease and 6.53 in those with toxic nodular goitre. The excess number of deaths was small (observed/expected 27/10), and the underlying disease, rather than radiation, seemed to play the major role. This result is not surprising. The large dose

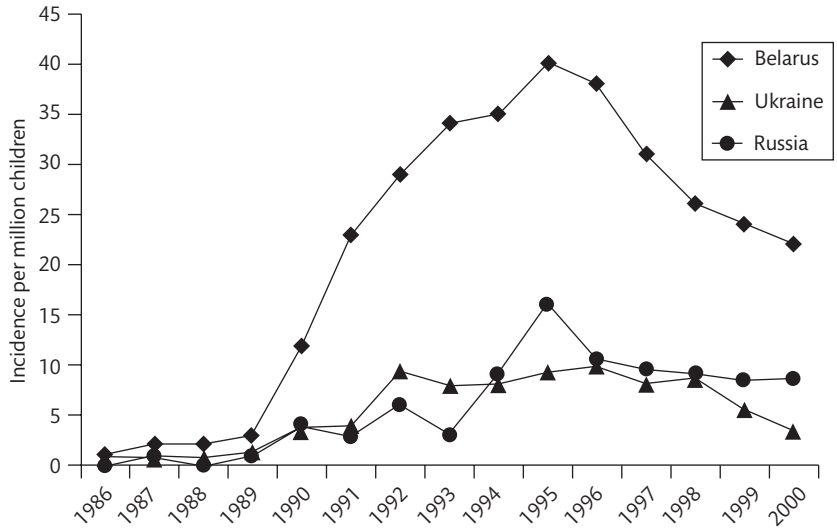

Figure 3.2.4.1 New cases of thyroid carcinoma per year diagnosed in Belarus, Ukraine, and Russia in children and adolescents exposed to radiation fallout after the Chernobyl accident.

delivered for the treatment of hyperthyroidism is frequently sufficient to produce hypothyroidism, through cell killing. Indeed, the risk of hypothyroidism at 2 years increases linearly with the thyroid dose, for radioactive concentrations ranging from 0.9 to 8.3 MBq/g.

As for the diagnostic use of ^{131}I, the hyperthyroid patients treated with radioiodine were adults. In a few hundred children treated with ^{131}I, no significant increase in the incidence of thyroid cancer has been observed [26]. However, in view of the high sensitivity of the young thyroid gland to radiation, it is probably advisable to avoid treating hyperthyroidism in young children and adolescents with ^{131}I.

As far as the treatment of differentiated thyroid cancer with ^{131}I is concerned, the only theoretical risk is the possibility that ^{131}I might act as an additional mutagen, inducing the progression of thyroid cancer to a more aggressive and less well-differentiated phenotype. At the present moment, no evidence supports this possibility. The other potential hazard of ^{131}I therapy of thyroid cancer is the occurrence of secondary effects on other organs when accumulating high radiation doses during several courses of treatment. Controversial data on this issue have been reported so far [28, 29].

Post-Chernobyl Thyroid Cancer

Circumstances of the Accident

In April 1986, the explosion of one of the reactors at the nuclear power plant in Chernobyl, Ukraine released large amounts of radioactive particles into the atmosphere, including ^{131}I (32–46 MCi), ^{132}I (27 MCi; resulting from the decay of ^{132}Tc), and ^{133}I (68 MCi). Most likely, radioiodines were released intermittently over a period of 10 days or more after the explosion. The time and place of deposition varied, depending on the direction of the wind and other meteorological conditions. The most contaminated territories were southern Belarus, northern Ukraine, and to a lesser extent the Bryansk and Kaluga regions of southern Russia.

As a result of the accident, a tremendous increase in the number of childhood papillary thyroid cancers occurred in the following years [30] (Figure 3.2.4.1). The magnitude of this increase and the geographical and temporal distribution of the cases strongly suggest that thyroid cancer was due to the reactor explosion and, in particular, to the huge amount of iodine radioisotopes released. The initial scepticism, allowing the possibility that the increased incidence of thyroid cancer might be due to ascertainment bias following intensive screening, has been totally discouraged by subsequent compelling evidence. Many of the tumours diagnosed in the first years were relatively large, invasive, and associated with lymph node metastases, unlike those detected during screening programmes, which are minimal, limited to the thyroid, and not aggressive [31]. The prevalence of childhood thyroid cancer exceeded that of any other country in the world and, very importantly, decreased dramatically in children conceived and born after the accident.

Being volatile, radioactive isotopes could be first inhaled and, after they were deposited on the ground, ingested. The time at which ingestion occurred varied considerably, but the milk chain, particularly in children, was the major route of ingestion: at this time, short-lived isotopes of iodine were no longer present. Several factors contributed to the high radiation exposure of the population. Immediate protective countermeasures, such as advising and evacuating the people at risk and distributing iodine prophylaxis, were not undertaken. Furthermore, the most contaminated regions were in a state of moderate iodine deficiency, which is responsible for increased iodine uptake. All these factors combined give enough explanation of why the most serious health consequence of the disaster was thyroid cancer, and why mostly children were affected [32].

In the case of radioactive contamination, the thyroid gland is a critical organ at risk. Its contamination depends upon the magnitude of contamination, the amount of radioactive iodine taken up by the gland, and the thyroid mass itself. Whatever the level of contamination, the thyroid dose is always higher in children than in adults. The thyroid dose is dependent on the final concentration, namely the ratio between radioiodine uptake and thyroid mass. In children, the uptake is similar to adults but, the thyroid mass being smaller, the dose per gram of tissue is greater, and extremely high in newborn and very young children.

In children who remained in the contaminated territories and drank locally produced milk, most of the radiation dose to the thyroid was due to ^{131}I and only a small amount to short-lived isotopes. The thyroid dose in children evacuated soon after the accident was lower, and mainly due to short-lived isotopes. Although dosimetric data are imprecise, the mean thyroid dose has been estimated to be nearly 700 mSv in Belarus. In Ukraine, 79% of the children received a thyroid dose below or equal to 300 mSv, 10.5% received from 300 mSv to 1 Sv, and 10.5% received more than 1 Sv [33]. As a term of comparison, in children exposed to external irradiation [6] the risk of thyroid cancer was significant even for thyroid doses as low as 100 mSv.

In most of the children that developed thyroid cancer the estimated thyroid dose was equal to or less than 300 mGy. An excess thyroid cancer incidence has been observed even in areas where the mean thyroid dose in children was estimated at 50–100 mGy.

Clinical Features of Post-Chernobyl Thyroid Cancer

The increase in the number of thyroid carcinomas in children and adolescents has been observed since 1990, only 4 years after the Chernobyl accident, in southern Belarus [34] and northern Ukraine, and from 1994 in southern Russia [35]. In the Gomel region, the most contaminated area of Belarus, the incidence between 1986 and 1996 was 13/100 000 children/year, compared to a baseline incidence of less than 1 per year. To date, more than 5000 cases of thyroid cancer have been reported among those who were children or adolescents at the time of the accident and living in the three most contaminated countries, Belarus, Ukraine, and Russia [30].

As shown in Figure 3.2.4.2, most of the cases were registered in children below age 10 at the time of the accident, and nearly two-thirds in those younger than 5 years. Thyroid cancer cases have also been registered up to 20 years after the nuclear accident in children who were already conceived but still *in utero*, at that time [36]. With respect to the 12 years before the accident, in the 12 years after the accident the increase of thyroid cancer in Belarus was 75-fold in children aged 3–14 years at the time of diagnosis, 10.1-fold in adolescents (15–18 years at diagnosis), 3.7-fold in young adults (19–29 years), and 3.4-fold in adults (Table 3.2.4.5). This increase in adults is much less important than that observed in children and it is likely to be due to greater attention to thyroid diseases after the nuclear accident.

Table 3.2.4.5 Thyroid cancer in Belarus before and after the Chernobyl accident

Age	1971–1985	1986–2000	Fold of increase
0–14	8	703	87.8
15–18	21	267	12.7
≥19	1465	6719	4.6
Total	1494	7689	5.1

Over 90% of the cancers were papillary. In the years following the accident most cancers were classified as a solid or follicular variant of papillary thyroid cancer (Figure 3.2.4.3), that is, the less frequently observed variant among naturally occurring papillary carcinomas. The clinical and pathological features were those of an aggressive tumour, as demonstrated by the histological appearance, the large size, the frequent multifocality and extracapsular invasion, and the frequency of node and lung metastases early in the course of the disease [31]. However, later studies showed a decline over time in the proportion of the solid variant and an increase in the proportion of the classic variant. These changes correlated both with the increasing age and increasing latency period and it is not yet clear which of these two variables could be mostly responsible for these changing patterns, which are also associated with a change in the molecular features of these tumours [37].

The comparison between post-Chernobyl thyroid carcinomas diagnosed in Belarus and naturally occurring cases diagnosed in age-matched patients in Italy and France showed different clinical and epidemiological features [38]. Post-Chernobyl tumours were much less influenced by gender (female:male ratio 1.6:1 versus 2.5:1 in Italy and France), were more advanced at presentation, were more frequently papillary, and were mainly diagnosed before age 15, while in Italy and France the majority were diagnosed after age 14.

As far as treatment and outcome are concerned, the available follow-up data indicate that post-Chernobyl thyroid carcinoma, when appropriately treated with a combination of total thyroidectomy, radioiodine, and hormone suppressive therapy,

has the same favourable outcome as naturally occurring papillary cancer. Definitive cure is achieved in many patients, even in those with node and lung involvement, the quality of life is good, and the death rate does not exceed the usual 1–2% reported in many series of paediatric thyroid cancer [39].

A similar observation has been recently reported in a study focused on external radiation-induced thyroid carcinoma. Although these tumours showed generally more aggressive features, the similar prognostic factors for their outcome indicate that they should be treated and followed in the same way as naturally occurring thyroid cancer [40].

Genetics of Post-Chernobyl Thyroid Cancer

Post-Chernobyl tumours show interesting genetic peculiarities when investigated by molecular biology. Molecular studies of the early post-Chernobyl thyroid cancer showed that a very high proportion harboured a RET/PTC rearrangement with a higher prevalence of RET/PTC3 [41–44]. Also the subtype of *RET/PTC* rearrangement showed a peculiar pattern. Several authors reported that *RET/PTC3* (and more rare variants of *RET/PTC3*) was the form more frequently expressed in radiation-induced tumours, thus suggesting that RET/PTC3 might represent a marker for these tumours. A correlation was also established between the solid variant of papillary tumours and the activation of *RET/PTC3* [43]. Interestingly, over the years and with the elongation of the latency period, the prevalence of RET/rearrangements became lower and more similar to that of naturally occurring thyroid carcinoma (Table 3.2.4.6). Also, the relative prevalence of RET/PTC1 and 3 subtypes changed in favour of RET/PTC1 [37].

The presence of RET/PTC rearrangements in radiation-induced cancer is in keeping with the *in vitro* findings that RET/PTC rearrangements can be induced in human thyroid cells after exposure to 0.1–10 Gy γ-radiation [45] and that *RET* gene fragmentation induced by ionizing radiation exposure is significantly higher than fragmentation of any other DNA region [46]. The generation of a RET/PTC3 rearrangement seems to be particularly facilitated by the alignment of ELE1 (i.e. the partner of RET/PTC3 rearrangement) and RET introns in opposite orientation [47]. Since *RET/PTC* is also frequently found in paediatric papillary thyroid cancer without known exposure to radiation [43, 48], it is also possible that age *per se* may play an important role. Alternatively, one can speculate that virtually all paediatric papillary thyroid cancers are radiation-induced cancers, developing in children with an increased susceptibility to spontaneous background radiation.

It has been noted that no point mutations of BRAF oncogene have been found in post-Chernobyl childhood thyroid carcinomas [49]. BRAF V600E activating mutation is present in about 40% of naturally occurring thyroid cancers in adults but is almost absent in children. The question of whether the very low frequency of BRAF mutations in post-Chernobyl childhood carcinoma is related to the young age of patients rather than the inability of ionizing radiation to induce oncogene point mutations is still not clarified. However, the finding of BRAF rearrangements in radiation-induced but not in naturally occurring thyroid cancer suggests that the oncogene alterations determined by ionizing radiations are mainly chromosomal rearrangements more than single point mutations [50]. In recent years, studies on genomic profiling have suggested distinct patterns in radiation-induced and sporadic thyroid cancer and in particular the expression of seven genes was found to be completely different in the two groups [24, 51].

Thyroid Cancer after the Fukushima Nuclear Power Plant Accident

Following the Fukushima accident in March 2011, the large-scale sophisticated thyroid ultrasound screening under the strict examination protocol launched from October 2011 in Fukushima Prefecture of Japan demonstrated a high detection rate of thyroid cancer in young individuals revealing 116 and 71 cases in the first and second rounds, respectively, among the same cohort of approximately 300 000 subjects, aged at the time of accident from 0 to 18 years old [52]. The postoperative pathological diagnosis revealed 121 cases (98.6%) of papillary thyroid adenocarcinoma (PTC), which included 110 cases of the classical type, 4 cases of the follicular variant, 3 cases of the diffuse sclerosing variant, and 4 cases of the cribriform-morular variant [53]. Intrathyroidal spread was observed in 61.6%, and calcifications, such as psammoma bodies, in 78.4%. The rates of lymph node metastasis and extrathyroidal tumour extension were also high, especially the rate of lymph node metastasis, which exceeded 70%. These findings, as well as a high rate of intrathyroidal spread and of calcifications, however, are common for childhood PTC.

Molecular characteristics of young thyroid cancers in Fukushima demonstrated that the frequency of *BRAF* gene mutations among all genetic alterations in cancer tissue is high, nearly the same as in adult thyroid cancers, and the frequency of gene rearrangement is substantially lower than that in Chernobyl [54].

These findings raise concerns among residents and the public that it might be due to putative exposure to radiation from the accident at Fukushima Daiichi Nuclear Power Plant. However, it is now apparent that effective doses to the whole body in the general population after the accident have been estimated to be less than several mSv for the majority of people, including infants and children [55]. No radiation level corresponding to thyroid dose exceeding 50 mSv was detected among 1080 children directly examined with scintillation survey meter at the end of March 2011 [56]. Especially in case of low-dose exposures, relevance to confounding

factors, such as hereditary predisposition, iodine-intake condition, hyperthyrotropinaemia, obesity, smoking, various hormone levels, and possible exposure to carcinogenic chemicals need to be addressed. So far, the international agencies and scientific experts support the notion that in view of low doses to the public, the increase of radiation-related risk for thyroid cancer is highly unlikely. The reasons are as follows. Exposure doses in Fukushima are significantly lower than those in Chernobyl. There is no apparent regional difference in the rate of thyroid cancer cases among the residential areas at the time of the earthquake and, hence, exposure status of the patients. The mean age of the subjects diagnosed with thyroid cancer was 10–15 at the time of accident, while there were no cases in younger children (aged 0–5 for the first 4 years), who are more vulnerable to radiation exposure. Although it is expected that thyroid cancer would also be detected at certain frequencies in those who were infants at the time of accident after some years, its causes need to be specially investigated.

Finally the lessons from Fukushima emphasize the importance of correct and sound understanding of radiation risk on the thyroid cancers and of difference of Chernobyl [57], and clearly demonstrate the necessity of a special attention on its overdiagnosis of PTC in children as well as in adults, following the long-term strategies for thyroid health monitoring after nuclear accidents in future [58].

Radiation-Induced Thyroid Diseases Other Than Thyroid Tumours

Thyroid cancer and benign thyroid nodules after thyroid radiation exposure occur as stochastic effects. Depending on the radiation dose, deterministic effects resulting in hypothyroidism and acute thyroiditis may also occur. Another documented consequence of radiation is the possibility of developing chronic autoimmune thyroid disorders.

Hypothyroidism is caused by radiation doses of the order of more than several gray to the thyroid. Such doses are used in the treatment of Graves' disease and toxic nodular goitre, and in these conditions hypothyroidism should be considered the aim rather than an untoward effect of treatment. Primary 'spontaneous' hypothyroidism (or subclinical hypothyroidism) was reported in survivors of the atomic bomb in Nagasaki [59]. In a study of 2587 survivors, 43 were diagnosed with hypothyroidism, 27 of whom were thyroid antibody positive and 16 were thyroid antibody negative, with no gender differences. Since an association was observed between thyroid dose and prevalence of antibody positivity, but not antibody negativity, primary hypothyroidism could conceivably have stemmed from an underlying autoimmune thyroid disorder. However, more recently, the same group reported that 55–58 years after radiation exposure, autoimmune thyroid disorders were not found to be significantly associated with radiation exposure while, in the same study, the authors confirmed a significant linear dose–response relationship in the prevalence of both thyroid cancer and benign thyroid nodules and that the relationship was higher in individuals who were exposed at younger ages [60].

The occurrence of thyroid autoimmunity after external irradiation to the head and neck has been reported in several studies. An increased incidence of thyroid antibodies was found by De Groot *et al.* [61] in individuals who received radiation during childhood for benign disorders. Variable degrees of thyroid lymphocytic infiltration have been reported in more than two-thirds of individuals who received radiation several years before thyroidectomy for nodular thyroid lesions. In patients who received radiation of the neck for Hodgkin's disease, 3% or more developed Graves' disease (a 7- to 20-fold excess risk) and 1% thyroiditis.

Hypothyroidism has also been reported after exposure to internal radiation (radioactive iodine). In the people exposed to the fallout of the Marshall Islands accident [62], hypothyroidism was noted within 10 years after the accident. On this occasion most of the cases were not associated with an autoimmune thyroid reaction.

In contrast, an increased prevalence of antithyroid antibodies (19.5%), without hypothyroidism, has been reported in children living in a Belarus village heavily contaminated by the post-Chernobyl radioactive fallout, as opposed to children living in a non-contaminated village (3.8% prevalence) [63]. The susceptibility to develop thyroid autoimmunity increased with age at the time of exposure and, in girls, reached its maximum at puberty, suggesting that puberty (oestrogen) and radiation have a cumulative effect in the development of thyroid antibodies in girls. However, a more recent study demonstrated that the increased prevalence of thyroid antibodies in exposed children was a real but transient phenomenon not accompanied by the development of 'overt' hypothyroidism or other thyroid dysfunction 13–15 years after the Chernobyl accident [64]. A relationship between prevalence of subclinical hypothyroidism and individual ^{131}I thyroid doses due to environmental exposure has been reported in a very large cohort of people exposed to the post-Chernobyl radioactive fallout during childhood. However, the same authors suggest further prospective studies since the radiation increase in hypothyroidism was quite small (10% per gray) [65]. In this regard it is worth noting that autoimmune hypothyroidism can naturally take place over decades [66] and, consequently, an unexposed age- and sex-matched control group should be analysed, especially as the cohort mean age increases. Furthermore, it should also be taken into account that differences in other environmental factors, such as iodine deficiency, may play some roles in favouring the development of autoimmune phenomena [67].

3.2.5 Autoimmune Thyroid Disease

Anthony P. Weetman

The Spectrum of Thyroid Autoimmunity

This chapter assumes a basic knowledge of immunology; readers unfamiliar with this topic can obtain further details about the fundamental processes involved in self/non-self-discrimination by the immune system elsewhere [1]. The range of thyroid autoimmunity is shown in Table 3.2.5.1. The most frequent manifestation is probably the presence of focal thyroiditis, which can be found in around 40% of Caucasian women at autopsy, and is half as frequent in men [2]. Focal thyroiditis is often accompanied by the formation of thyroid antibodies, discussed later, but it is presently unclear whether all examples of focal thyroiditis have a truly autoimmune basis, especially if negative for thyroid antibodies. Careful longitudinal community studies have shown that individuals with positive thyroid antibodies (and presumably an underlying focal thyroiditis) have an increased risk of developing overt or clinical autoimmune hypothyroidism, which in women might be expected to occur in around 2% per year over a 20-year follow-up period [3]. In men, the risk is threefold greater. Individuals who have a sustained elevated thyroid-stimulating hormone (TSH) but normal free thyroxine (fT_4) levels, a state termed subclinical hypothyroidism, have a similar risk of progression to clinical hypothyroidism, and it may be assumed that these patients initially had focal autoimmune thyroiditis which progressed, albeit without the autoimmune response giving rise to detectable thyroid antibodies. When individuals have both subclinical hypothyroidism and positive thyroid antibodies, the relative risk of progression to clinical hypothyroidism is substantially increased, especially for men. Juvenile thyroiditis may be self-limiting.

Postpartum thyroiditis, discussed in detail in Chapter 9.5, arises from subclinical autoimmune hypothyroidism. The underlying autoimmune process is enhanced 3–6 months postpartum, for reasons which remain obscure, and at this point biochemically or clinically evident thyroid dysfunction occurs, only to remit months later as the postpartum exacerbation subsides. The occurrence of permanent clinical hypothyroidism over subsequent years in 10–20% of women presumably results from a continued and worsening autoimmune injury, as found in any type of subclinical hypothyroidism. Like postpartum thyroiditis, silent (or painless) thyroiditis causes a transient disturbance of thyroid function, most often presenting with mild destructive thyrotoxicosis followed by hypothyroidism, and indeed in the early literature, postpartum and silent thyroiditis were not distinguished. Excess iodide is an inciting factor in some cases, and others are due to inadvertent exposure to thyroid hormone (e.g. thyroid tissue contamination of meat products), but in most cases the condition seems to be a spontaneous exacerbation of an underlying autoimmune process and goitre, permanent hypothyroidism, or thyroid antibodies are present in half of such individuals several years after presentation.

The term 'Hashimoto's thyroiditis' is strictly a histological definition, with the features as described next. Clinically, patients present with a painless, lymphocytic goitre of variable size, with or without hypothyroidism, hence the alternative name, goitrous thyroiditis. Thyroid antibodies are strongly positive in almost all cases. Primary myxoedema, or atrophic thyroiditis, presents with clinical hypothyroidism, because the thyroid has usually been severely damaged by the autoimmune process, as the name implies. It seems that there is usually a continuum from one to the other, with fibrosis and follicular destruction gradually dominating in a previously lymphocytic goitre.

At first sight, Graves' disease appears as a distinct autoimmune disorder, characterized by the presence of stimulating antibodies against the TSH receptor, but it is now clear that such antibodies can also occur in occasional patients with autoimmune hypothyroidism, in whom their effects are masked by a more dominant autoimmune process leading to hypothyroidism. Moreover, up to 20% of Graves' patients treated successfully with antithyroid drugs develop spontaneous hypothyroidism over the subsequent 20 years, most likely due to supervening destructive autoimmunity. In some unusual incidences with patients, fluctuation between hyper- and hypothyroidism occurs over weeks or months, and alterations in the relative levels of TSH-receptor antibodies with stimulating and blocking capabilities may explain this phenomenon. The term 'Hashitoxicosis' is used to describe occasional patients with clinical Graves' disease but a histological picture of Hashimoto's thyroiditis, again demonstrating the close relationship between these disorders, and their sharing of common pathogenetic features.

Table 3.2.5.1 The range of thyroid autoimmunity

	Goitre	Thyroid function	Features
Focal thyroiditis	No	Normal or subclinical hypothyroidism (elevated TSH; normal free T_4)	May progress to overt hypothyroidism; associated with positive thyroid antibodies* and with thyroid cancer
Hashimoto's (or goitrous) thyroiditis	Variable size	Normal or hypothyroid (clinical or subclinical)	Almost always thyroid antibody-positive
Atrophic thyroiditis (or primary myxoedema)	No	Hypothyroid	May evolve from goitrous thyroiditis; usually thyroid antibody-positive
Silent thyroiditis	Small or absent	Transient thyrotoxicosis and/or hypothyroidism	May progress to permanent hypothyroidism; often thyroid antibody-positive
Postpartum thyroiditis	Small	Transient thyrotoxicosis and/or hypothyroidism	Occurs within a year of delivery; thyroid antibody-positive in most cases
Graves' disease	Variable size	Hyperthyroid	Associated with ophthalmopathy; positive for TSH-receptor stimulating antibodies and usually for other thyroid antibodies

*Thyroglobulin and/or thyroid peroxidase antibodies.

Pathological Features

Autoimmune Thyroiditis

In focal thyroiditis the thyroid is usually normal in size and contains foci of lymphocytes which are predominantly T cells, although lymphoid follicles can also occur. Thyroid cells adjacent to these foci are usually atrophic and deficient in colloid, but away from the foci, thyroid follicular architecture is normal [4]. Focal thyroiditis may also be prominent adjacent to a papillary carcinoma or other neoplasm. By contrast, the whole thyroid is usually involved in Hashimoto's thyroiditis. The lymphocytic infiltrate is more extensive, diffuse, and composed mainly of T cells, with prominent germinal centres containing B cells scattered through the gland (Figure 3.2.5.1). Macrophages, dendritic cells, and sometimes giant cells may be prominent. The thyroid follicles suffer variable degrees of destruction, depending largely on chronicity, and in the process undergo hyperplasia and oxyphil metaplasia, giving rise to so-called Hürthle or Askanazy cells. These cells are generally absent in juvenile autoimmune thyroiditis.

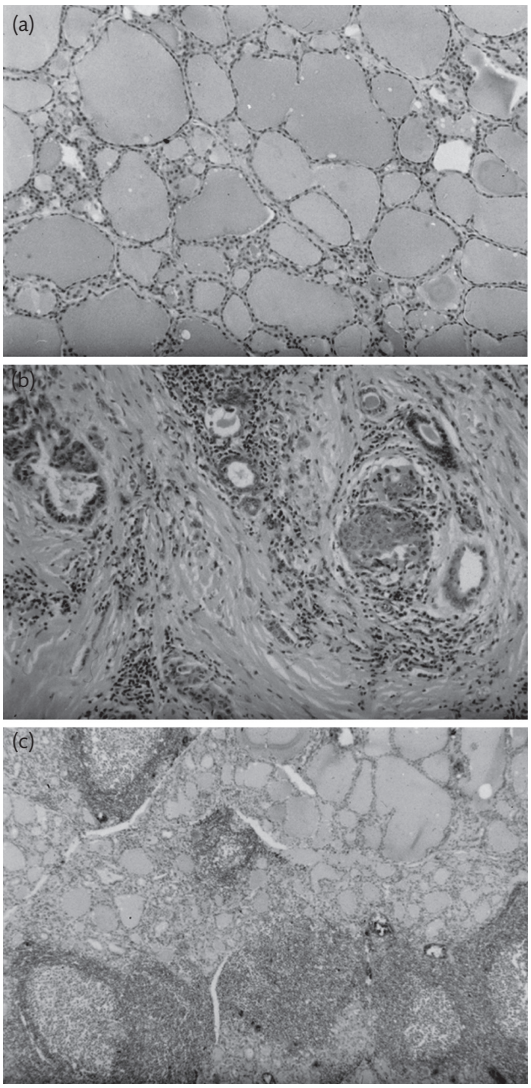

Figure 3.2.5.1 Histological features of (a) normal thyroid, (b) atrophic thyroiditis, and (c) Hashimoto's thyroiditis.
Original magnification ×100; photomicrographs courtesy of Dr K. Suvarna.

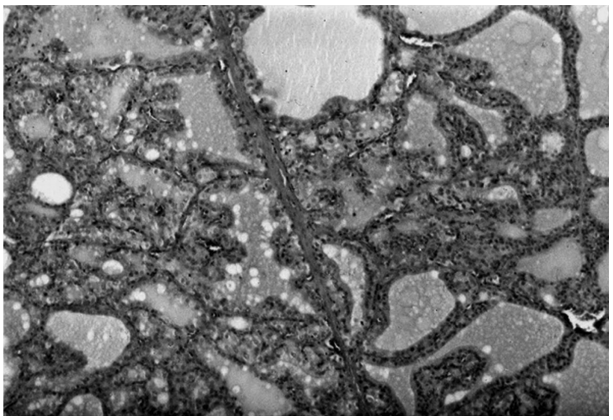

Figure 3.2.5.2 Histological features of Graves' disease.
Original magnification ×100; photomicrographs courtesy of Dr K. Suvarna.

However, the relative proportion of lymphocytic infiltrate, thyroid follicular cell change, and fibrosis varies greatly, in keeping with the suggestion made previously that there is a broad spectrum of changes which may ultimately result in atrophic thyroiditis. In this condition, the thyroid is small, has extensive fibrosis mixed with a scattered lymphocytic infiltrate, and there is a marked reduction in thyroid follicular cells. A distinct subset of patients with Hashimoto thyroiditis has been delineated recently with high circulating IgG4 levels and IgG4-positive plasma cells in the thyroid, accompanied by extensive fibrosis, and a high frequency of hypothyroidism [5]. The pathology in postpartum and silent thyroiditis generally resembles mild to moderate Hashimoto's thyroiditis, although without the oxyphil metaplasia. Germinal centres are usually absent.

Graves' Disease

It is now unusual to see the full histological picture of Graves' disease as patients are almost all treated with antithyroid drugs which diminish the lymphocytic infiltrate.(4) Even after such treatment, however, there is often a diffuse or focal lymphocytic thyroiditis, predominantly of T cells, sometimes with germinal centre formation. As an aside, lymphoid hyperplasia may also involve the lymph nodes, thymus, and spleen in Graves' disease, once again being reversed by antithyroid drugs. The thyroid follicles are both hypertrophied and hyperplastic, with scalloping and reduction in colloid (Figure 3.2.5.2). The epithelial cells are columnar and extend as papillae into the lumen. These changes are also attenuated by antithyroid drugs, so that after prolonged treatment, the colloid re-accumulates, the papillae regress, and the epithelium becomes cuboidal.

Factors Determining Susceptibility

A complex combination of genetic, environmental, and endogenous factors determines susceptibility (Figure 3.2.5.3). These factors operate differently in individuals, so that the factors leading to disease in one patient will differ from the next, which makes analysis of the importance of each factor difficult with present tools. Genetic effects are seen most clearly in children and adolescents,

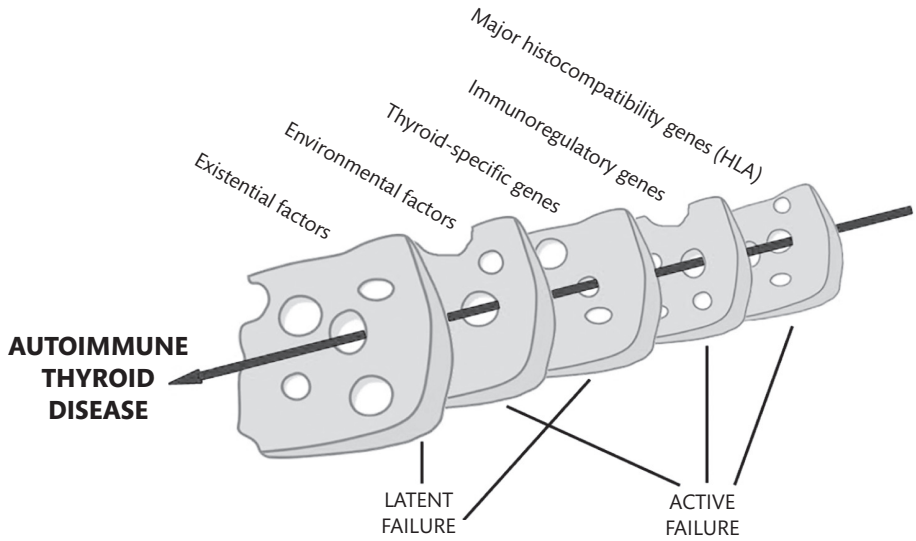

Figure 3.2.5.3 Interaction of genetic, exogenous, and endogenous or 'existential' factors in the pathogenesis of autoimmune thyroid disease. Individual factors are frequent in the general population and by themselves do not cause disease; it is their concatenation which creates the necessary conditions, as in the Swiss cheese model of accident causation.

with environmental factors having an increasing chance to operate with age.

Genetic Factors

These are dealt with extensively in Chapter 3.2.1. However, a brief discussion is given here, in relation to genetic effects on the autoimmune process. It is obvious clinically that thyroid diseases cluster in families more often than expected by chance, although the association of Graves' disease and autoimmune hypothyroidism in such families, and their coassociation with autoimmune polyglandular syndrome type 2, indicates that at least some of the susceptibility is determined by genes that control a generalized tendency to organ-specific autoimmunity. One such determinant in Caucasians is the HLA-DR3 specificity, which is associated with all of the major autoimmune endocrinopathies [6, 7].

The reason why the highly polymorphic alleles of HLA class II genes (also called major histocompatibility complex or MHC class II genes) are associated with autoimmunity is that their products are expressed by antigen-presenting cells and are crucial in initiating any immune response (Figure 3.2.5.4). Autoimmune disease may arise because a certain class II allele is able to bind and present a crucial fragment of an autoantigen, called an epitope, to a $CD4_+$ T cell. Alternatively, the effect of class II alleles in determining immune responsiveness may be exerted in the thymus during development, at which stage future autoreactive T cells may be deleted (negative selection) or allowed to develop (positive selection). Finally, some class II molecules may determine selection of regulatory T cells, and deficiencies in these cells have been postulated as a cause of autoimmunity. It still remains unclear whether other genes in linkage disequilibium with HLA-D region genes confer additional susceptibility and it is possible that class I genes have a role independent of those in the class II region.

The existence of non-HLA susceptibility genes is shown by the higher frequency of thyroid autoimmunity in monozygotic twins than in HLA-identical siblings, which in turn is higher than non-HLA-identical siblings. The critical role of CTLA-4 in costimulation of T-cell responses is discussed next and this has made it an excellent candidate to test as a susceptibility gene. It is now clear that polymorphisms in this gene have a significant role in autoimmune thyroid disease as well as several other autoimmune disorders that are associated with thyroid disease clinically. Polymorphisms in other T-cell regulatory genes, including *PTPN22* and *interleukin-2 receptor/CD25*, can similarly increase susceptibility to autoimmune thyroid disease and related disorders. Overall it is now clear that many other genes, including those that encode autoantigens such as thyroglobulin and the TSH receptor, exert small effects which contribute to these diseases and their influence varies between individuals, which in turn may explain the diverse clinical presentations of thyroid autoimmunity.

Environmental Factors

The lack of complete concordance for thyroid autoimmunity in monozygotic twins, and the clinically obvious lack of a family history in many patients with autoimmune thyroid disease, point to a role for environmental factors in determining susceptibility. Furthermore, at least part of the family clustering of disease could be the result of shared exposure to environmental triggers. Some of the best evidence for the involvement of the environmental factors comes from epidemiological changes [8] and from animal models of experimental autoimmune thyroiditis (Table 3.2.5.2) which resemble Hashimoto's thyroiditis [9]. Excess dietary iodide exacerbates the severity of the lymphocytic thyroiditis in rats with experimental autoimmune thyroiditis, and leads to enhanced production of thyroglobulin antibodies, and similar observations have

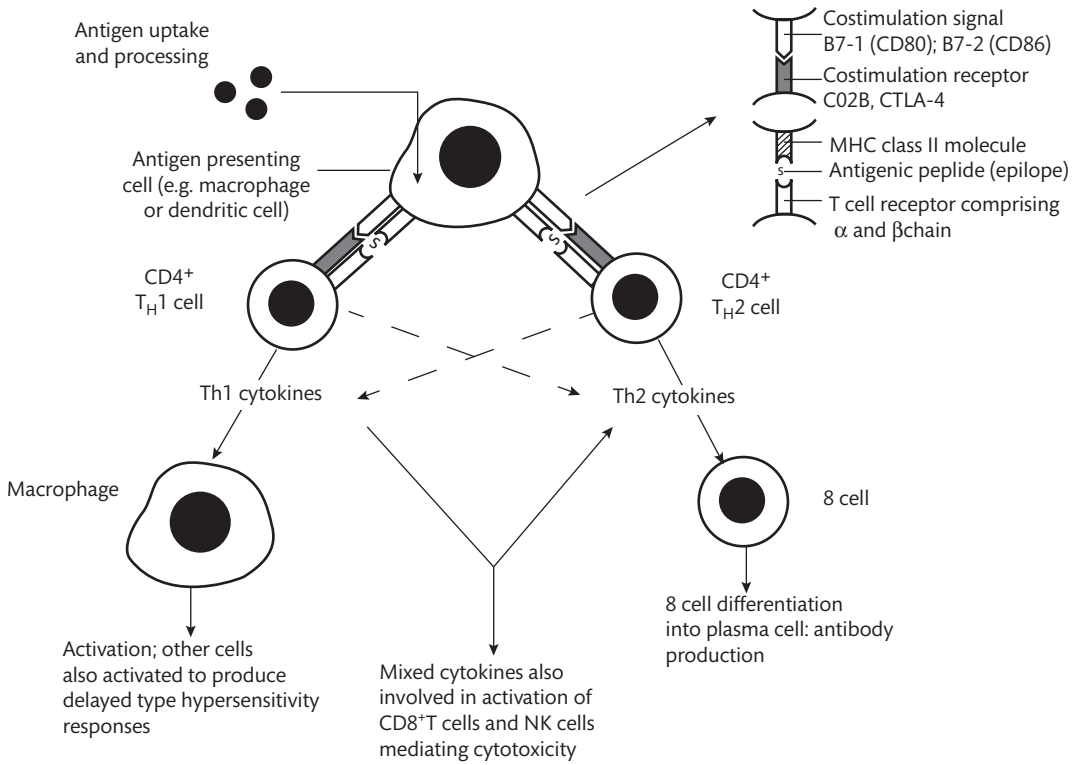

Figure 3.2.5.4 Key steps in antigen presentation and T-cell activation. The dotted line represents an inhibitory pathway.
Reproduced with permission from Weetman AP. Recent progress in autoimmune thyroid disease: an overview for the clinician. *Thyroid Today*, 1996; 19(2): 1Ð9.

been made in the obese strain chicken and non-obese diabetic (NOD) mouse which develop spontaneous autoimmune hypothyroidism. Excess iodide may act directly on the immune system, the formation of an important part of a major T-cell epitope on the iodinated thyroid antigen thyroglobulin, or the generation of toxic metabolites within the thyroid which damage thyroid cells. There is epidemiological evidence to support a similar effect of excess iodide on human autoimmune thyroiditis. Selenium deficiency may predispose to thyroid autoimmunity although trials of selenium supplementation have little obvious effect on established thyroiditis [10].

Infections could precipitate an autoimmune response by target cell damage, leading to release of autoantigens, by altering target cell expression of autoantigen or immunoregulatory molecules, such as HLA, or by molecular mimicry, in which an immune response against micro-organism antigens that resemble host autoantigens triggers an autoimmune response. Despite the appeal of the notion, and the success of animal models, there is surprisingly little evidence

Table 3.2.5.2 The main experimental models of autoimmune thyroiditis

Model	Species	Antigen	
Immunization	Mouse, rat, rabbit, guinea-pig	TG, TPO, TSH-R	Strain-dependent, transient, and transferable using T cells
Thymectomy-induced	Mouse, rat	TG	May need additional sublethal irradiation
T-cell manipulation	Mouse	TG	Transfer of specific T cells induces thyroiditis
Spontaneous	Chicken, dog, rat	Mainly TG	Thyroiditis occurs in OS chickens, beagles, NOD mice, and BB and Buffalo strain rats (NOD and BB animals have autoimmune diabetes)
Transplantation	Severe combined immunodeficiency mouse or nude mouse	TG, TPO, TSH-R	Transplanted thyroid tissues from Graves' and Hashimoto patients survive but the animal does not develop disease
cDNA immunization	Mouse, hamster	TSH-R	TSH-R antibodies and altered thyroid function produced; some recent models include orbital changes resembling ophthalmopathy
Immunization with fibroblasts transfected with TSH-R and MHC class II	Mouse	TSH-R	TSH-R antibodies and altered thyroid function produced

MHC, major histocompatibility complex; TG, thyroglobulin; TPO, thyroid peroxidase; TSH-R, thyroid-stimulating hormone receptor.

linking infection to human autoimmune disease. Autoimmune hypothyroidism occurs with increased frequency after congenital rubella infection, and some, but not all, epidemiological as well as serological studies have suggested a role for *Yersinia* infection in Graves' disease. On the other hand, studies showing a lower frequency of thyroid and other types of autoimmunity in areas with a poor standard of hygiene suggest that in some settings infections may enhance immune responses in a way that avoids the emergence of autoimmunity, perhaps through skewing of the cytokine secretion of T helper cells, discussed next [11]. Despite many attempts, no convincing role for retroviruses in autoimmune thyroid disease has been proven. Taking the opposite view, subacute thyroiditis is caused by a wide variety of viruses, and gives rise to thyroid destruction, yet rarely (if ever) triggers autoimmune thyroid disease. Only low and infrequent levels of thyroid antibodies occur in the course of infection and then disappear, although subacute thyroiditis may lead to permanent hypothyroidism in individuals who have coincidental subclinical autoimmune thyroiditis.

Stress appears to be an important precipitant of Graves' disease, possibly mediated via its neuroendocrine effects. The obese strain chicken, which develops spontaneous autoimmune thyroiditis, has an abnormal corticosteroid secretion profile that may be one of the genetic determinants of this disease [9].

As the therapeutic armamentarium expands, an increasing number of iatrogenic factors have been found to precipitate autoimmune thyroid disease. Mantle irradiation for lymphoma and other conditions is associated with an increased frequency of Graves' disease and autoimmune thyroiditis, and rare cases of Graves' disease have been reported following radioiodine treatment of nodular thyroid disease. While these examples could be the result of thyroid injury, leading to autoantigen release, the lack of a parallel response in the wake of virally induced thyroid damage suggests additional mechanisms, such as a differentially suppressive effect of radiation on critical immunoregulatory T cells. An increased prevalence of thyroid autoantibodies has also been reported in children exposed to fallout from the Chernobyl nuclear reactor explosion [12]. Lithium treatment is also associated with an increased prevalence of thyroid autoantibodies, hypothyroidism, and probably Graves' disease.

Therapeutic doses of cytokines precipitate autoimmune hypothyroidism, but rarely Graves' disease [13]. The major culprit is α-interferon, probably because it is the most extensively used, but granulocyte–macrophage colony stimulating factor, interleukin-2 (IL-2), and IL-4 have also been implicated. How these effects relate to the role of the same cytokines, at far lower endogenous concentrations, in untreated patients is unknown. However, an association exists between attacks of allergic rhinitis and the time of relapse of Graves' disease, which may well depend on the nonspecific enhancing effects of cytokines released during the allergic response. A variety of new cancer therapies, in particular kinase inhibitors (like sunitinib) and those that modulate CTLA-4 and the programmed death receptor protein PD1, are associated with destructive thyroiditis, sometimes with autoimmune features [14].

Environmental pollutants and toxins are theoretically important factors but remain underinvestigated. Administration of anthracene derivatives to genetically predisposed rats can precipitate experimental autoimmune thyroiditis. The potential of pollutants to operate in this way in man is illustrated by the association between cigarette smoking and thyroid-associated ophthalmopathy (Chapter 3.3.8) as well as, to a lesser extent, Graves' disease, whereas smoking appears to decrease the risk of Hashimoto's thyroiditis [14]. Alcohol has a modest protective effect against the development of thyroid autoimmunity [15].

Endogenous Factors

The most impressive of these is pregnancy, which can lead to postpartum thyroiditis in around 5% of ostensibly healthy women (Chapter 9.5). However, the frequency of Graves' disease is also increased in the 2 years postpartum and permanent hypothyroidism is frequently encountered after an episode of transient autoimmune hypothyroidism, indicating that pregnancy can produce a longer-lasting bias of the autoimmune response. Hyperprolactinaemia has only been inconsistently associated with an increased frequency of autoimmune thyroiditis, but clear evidence for a role of sex hormones has come from work on experimental autoimmune thyroiditis. Female animals given testosterone have a reduced frequency of thyroiditis, while castrated males, or those given oestrogen, have an increased frequency, which approaches that of females [9]. These effects explain in large part the much higher rates of autoimmune thyroid disease in women, although it remains to be seen whether any other effects are encoded on the sex chromosomes to explain this dichotomy. Alterations in T-cell regulation during pregnancy, fetal microchimerism or skewed inactivation of the X chromosome are alternative possibilities [16]. Ageing is associated with an increase in thyroid autoimmunity, although healthy centenarians may be relatively protected.

Autoantigens

There are three major autoantigens in autoimmune thyroid disease, detailed next, but there are also a number of specific and nonspecific autoantigens whose involvement is suggested by molecular cloning of candidates or by the demonstration of antibodies to cytoskeletal or nuclear components. Thyroid hormones are occasionally the target of autoantibody formation. These antibodies have no physiological consequences but can interfere in some assays for thyroid hormones, although this is now less of a problem with improved methods. The significance of autoantibodies against pendrin and the sodium iodide symporter, found in up to 10% of patients, is not yet known [17].

Thyroglobulin

Thyroglobulin is a homodimeric 660 kDa glycosylated iodoprotein which is secreted by thyroid follicular cells and stored in the luminal colloid: thyroglobulin also circulates. There are around 100 tyrosine molecules in each molecule and around 25 are normally iodinated, but this varies greatly depending on iodine uptake and thyroid activity. The iodination reaction depends on thyroid peroxidase and occurs at the apical border of the thyroid cells. Four thyroglobulin domains, termed A to D, have been identified from analysis of internal homology, and contain between them four to eight hormonogenic sites, two of which, at residues 5 and 2746, correspond to sites of preferential T_4 and T_3 synthesis, respectively. When stimulated by TSH or thyroid-stimulating antibodies, thyroglobulin is endocytosed and hydrolysed in lysosomes to release T_3 and T_4.

Although iodination of thyroglobulin plays a major role in the antigenicity of the molecule in animal models of autoimmune thyroiditis, the place of iodination in human autoimmune thyroid disease is less clear, with continuing uncertainty over whether the hormonogenic sites are part of T- or B-cell epitopes. As the immune response diversifies with time, an increasing number of epitopes are recognized, especially by sera with high levels of thyroglobulin antibodies, but patients with autoimmune thyroid disease show greater restriction of epitope recognition by autoantibodies than those who have autoantibodies but remain clinically euthyroid. These epitopes are largely conformational, although certain Hashimoto sera recognize linear determinants; all thyroglobulin antibodies cloned from patients so far recognize native but not denatured thyroglobulin. The immunopathogenic non-dominant nature of thyroid autoantibody epitopes suggests that the disease may arise from unmasking of cryptic epitopes which leads to a loss of tolerance [17].

The antibody response to thyroglobulin is relatively restricted, with a predominance of IgG1 and IgG4 subclasses and over-representation of certain immunoglobulin variable (V) genes. However, thyroglobulin antibodies, even of the IgG1 subclass, do not fix complement due to the wide spacing of epitopes, which prevents cross-linking [18]. The potential role of these antibodies in pathogenesis is considered next. Less is known about T-cell epitopes on thyroglobulin, information about which could lead to important insights regarding molecular mimicry with other self-determinants or microbial antigens.

Thyroid Peroxidase

Thyroid peroxidase is a glycosylated haemoprotein which exists in two alternatively spliced forms of 100 to 105 kDa. The predominant form, TPO-1, is responsible for tyrosine iodination and coupling to form thyroid hormones and is predominantly located at the apical border of the thyroid cell, anchored by a transmembrane segment near the carboxyl terminus, with the catalytic domain facing the follicular lumen. TPO-2 has no enzymatic activity and is restricted to the endoplasmic reticulum: its role in autoimmunity is unknown.

Initial studies of B-cell epitopes on thyroid peroxidase found two sequences, C2 (amino acids 590–622) and C21 (710–722), which are linear epitopes recognized by the majority of Hashimoto sera and a smaller proportion of Graves' sera [19]. It is likely that these and other linear determinants identified subsequently are only the target of antibodies late in disease when degradation of thyroid peroxidase allows spreading of the immune response. In the initial stages, however, conformational epitopes are probably involved in antibody binding, and these have been identified by human and mouse monoclonal antibodies. There are two large overlapping domains, A and B, which are the target of more than 80% of thyroid peroxidase antibodies in Graves' disease and Hashimoto's thyroiditis and, in the absence of thyroid peroxidase crystals, modelling has allowed prediction of the structure of these. Furthermore the immunoglobulin V gene usage of thyroid peroxidase antibodies is remarkably restricted, with domain B-binding antibodies using a particular light-chain sequence (Vκ 012), irrespective of heavy chain, although heavy chain V gene usage is also relatively restricted. Relative binding of thyroid peroxidase antibodies to the individual domains varies little over time, indicating a genetic component to the control of thyroid peroxidase antibody formation. Thyroid peroxidase antibodies in general show the same type of IgG subclass restriction as those against thyroglobulin but are able to fix complement.

T-cell epitopes are multiple and individual patients respond to different combinations of epitopes without any apparent correlation with disease type or chronicity [9]. As the T-cell response is likely to have had many months to diversify or 'spread' by the time of diagnosis, this observation is not surprising, but it does emphasize how difficult identification of any dominant epitope (which might cross-react with a microbial epitope) will be.

TSH Receptor

The TSH receptor is a typical G-protein-coupled receptor, with an extracellular domain of 398 amino acids, a transmembrane region of 266 amino acids organized in seven loops, and an intracellular domain of 93 amino acids. There are two subunits, A (55 kDa) and B (40 kDa), which correspond to the extracellular and transmembrane domains and are joined by disulphide bonds. The A-subunit, uniquely for this type of receptor, can be shed from the cell surface, which may well have immunological consequences by allowing greater access of the autoantigen to the immune system [20].

Although clearly highly expressed in the thyroid, where the receptor is fundamental for cell activation, there is now considerable evidence that the TSH receptor is expressed in fat, particularly preadipocytes, where it may make a contribution to thyroid-associated ophthalmopathy (see Chapter 3.3.10). The main physiological regulator of the TSH receptor is obviously TSH, which causes a rise in intracellular cyclic adenosine monophosphate (AMP) and these actions are mimicked by thyroid-stimulating antibodies in Graves' disease. The interaction of TSH-receptor antibodies with the receptor is even more complex, with additional antibodies blocking the effect of TSH, contributing to hypothyroidism in around 10% of patients [21], and others (neutral antibodies) do not stimulate function but may induce apoptosis, at least *in vitro* [22]. The terminology of these antibodies has been obscure, and **Table 3.2.5.3** gives an overview.

As would be predicted from the heterogeneous nature of TSH-receptor antibodies, multiple B-cell epitopes have been identified. In summary, the majority are conformational and comprise discontinuous sequences. Both stimulating and blocking antibodies bind to sites on the receptor which overlap with, but are distinct from, the TSH biding site. The greatest separation between the binding of these three entities occurs at the N-terminal region of the receptor. Much is still to be determined, including whether receptor desensitization might explain the poor correlation between circulating TSH-receptor-stimulating antibody levels and the degree of abnormal thyroid function in patients. TSH-receptor-stimulating antibodies show restriction immunoglobulin of heavy and light chain usage, implying oligoclonality of the B-cell repertoire.

TSH-receptor T-cell epitopes have been identified and, as with thyroid peroxidase, there is considerable heterogeneity both within and between patients in the regions recognized, with no clear dominant epitope. Certain TSH-receptor sequences are recognized by 10–20% of healthy individuals, but it is not known whether these represent potentially pathogenic T cells kept in check by regulatory mechanisms or low-affinity, non-specific interactions of unlikely relevance to the initiation of Graves' disease.

Table 3.2.5.3 Nomenclature and assay of the major types of TSH-receptor antibodies

Antibody	Assay
Long-acting thyroid stimulator (LATS)	The original assay for TSAb which measured the effects of TSH-R antibodies on radioiodine release in the intact mouse
LATS-protector (LATS-P)	Assayed by measuring inhibition (protection) of LATS interaction with thyroid; now superseded by new assays
Thyroid-stimulating antibodies (TSAb)	Usually measurement of cAMP production by primary cultures of thyroid cells, thyroid cell lines (for example, FRTL-5) or cells transfected with TSH-R. Other functions such as iodide uptake can be used as endpoints instead
Thyroid-blocking antibodies	Measurement of inhibition of cAMP production after TSH-mediated stimulation of thyroid cells or TSH-R transfected cells
TSH-binding inhibiting immunoglobulins (TBII)	Measurement of the inhibition of labelled TSH (or a labelled-thyroid-stimulating monoclonal antibody) binding to purified or recombinant TSH-R by serum antibodies

TSH-R, thyroid-stimulating hormone receptor.

T-cell Function in Autoimmune Thyroid Disease

Animal Models

T cells play a vital role in the pathogenesis of experimental autoimmune thyroiditis. Disease is easily transferable with T cells, whereas attempts to transfer disease using serum or antibodies produce only weak or inconsistent effects at best. Full-blown disease requires the transfer of both $CD4^+$ and $CD8^+$ cells from an animal with experimental autoimmune thyroiditis to a naive recipient (disease being established in the donor by immunization with thyroglobulin in adjuvant). However, a subpopulation within the $CD4^+$ cells also has an important regulatory function, being capable of preventing the action of thyroglobulin-specific, disease-inducing T cells [9]. In essence, these findings are consistent with a model in which autoreactive T cells are largely, but not completely, deleted or rendered anergic in the thymus during development. These T cells are normally kept in check, either because they are controlled by a regulatory T-cell subset or through clonal ignorance in which the T cells fail to react to antigen in the absence of an appropriate costimulatory signal (Figure 3.2.5.5). Animal strains particularly prone to experimental autoimmune thyroiditis have genetic defects either in

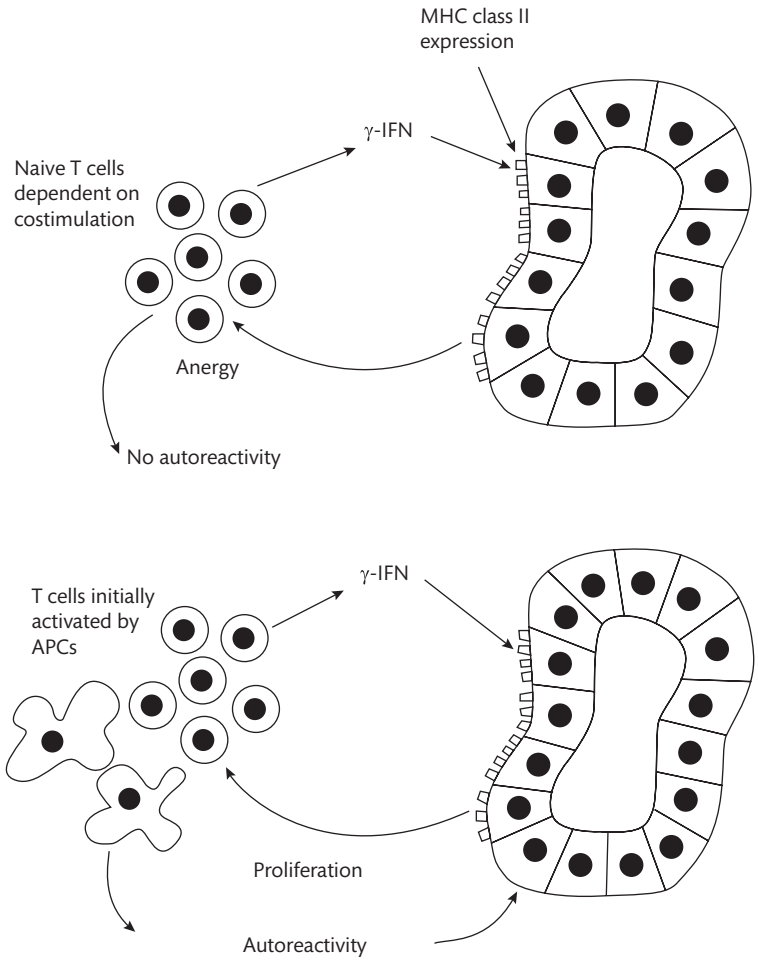

Figure 3.2.5.5 Alternative outcomes of major histocompatibility complex (MHC) class II molecule expression by thyroid cells, depending on the provision of costimulatory signals from antigen-presenting cells (APCs).

Table 3.2.5.4 Interaction of experimental manipulations in animal models of autoimmune thyroiditis

Factor	Probable site of action
Genetic background Thymectomy (irradiation) Intrathymic antigen	Thymic selection of T cells
Infection Sex hormones Adjuvant	Peripheral autoreactive T cells escaping intrathymic tolerance
Genetic background	Recognition of autoantigen

T-cell subset depletion	
Cytokines	
Toxins	

positive/negative selection of T cells (which make it more likely that the adult animal has sufficient autoreactive T cells to develop disease), or in the regulatory T-cell subsets, and these defects interact with environmental factors to result in disease (Table 3.2.5.4).

An appropriate balance of Th1 and Th2 cells (Table 3.2.5.5) is needed for full expression of disease, and the reciprocal inhibition between these two subsets (Figure 3.2.5.4) may be one of the most important regulatory pathways controlling the activity of autoreactive T cells. For instance, blocking IL-2 receptor activation or removing γ-interferon leads to a granulomatous rather than lymphocytic thyroiditis, and the production of high levels of thyroglobulin antibodies, due to preferential Th2 activation [23]. Typical experimental autoimmune thyroiditis is most likely Th1-dependent.

Table 3.2.5.5 Features of $CD4^+$ T-cell helper (Th) cell subsets in the mouse; similar but not identical profiles are found in humans. Further subsets are also recognized, especially Th-17 cells which secrete IL-17, TNF, and IL-6, and are highly pro-inflammatory

	Th1	Th2
Cytokine profile		
IL-2	++	–
IL-3	++	++
IL-4	–	++
IL-5	–	++
IL-6	–	++
IL-10	–	++
γ-interferon (-IFN)	++	+
Tumour necrosis factor (TNF)	++	–
Lymphotoxin	++	+
Function		
Delayed-type hypersensitivity; host defence against intracellular pathogens	++	+
B-cell help (for antibody synthesis)	+	++
Eosinophil/mast cell production; host defence against parasites and a pathological role in allergy and asthma	–	++

Further support for this T-cell-dependent mode of pathogenesis comes from the induction of experimental autoimmune thyroiditis by modulation of the T-cell repertoire alone, without the need to immunize animals with thyroid antigen (Table 3.2.5.2). Certain strains of rat or mice develop experimental autoimmune thyroiditis after thymectomy, sometimes coupled with sublethal irradiation, when performed at a critical stage of postnatal development [9], and T-cell depletion/reconstitution or cyclosporin A can have similar effects. More recently knockout mouse models have shown a crucial role both for Th1 cytokines and for the pro-inflammatory Th-17 pathway in generating thyroiditis [24].

Disease in these models is reversed by a subset of $CD4^+$ T cells from untreated donors. One major regulatory $CD4^+$ T-cell population can be identified because it expresses CD25 and Foxp3. Depletion of this T-cell subset causes severe thyroiditis in certain mouse strains and this subset also appears to be reduced when thymectomy is performed, knockout models have also confirmed the importance of T-regulatory cells in maintaining freedom from thyroiditis [24]. From these studies it is clear that thyroid-reactive T cells are present early after birth and that depletion of a critical, regulatory subset of $CD4^+$ T cells can induce organ-specific autoimmune disease. Transgenic mice have been used to confirm that tolerance, imposed in the thymus or periphery, is a major step in the production of thyroid reactivity: by contrast, B cells were not tolerized in animals overexpressing a membrane-bound antigen specifically on thyroid cells, presumably because the antigen is sequestered from B but not T cells [25]. These B cells are harmless (or 'ignorant') unless specific T cells are available in a non-tolerized state, in which case help in the form of B-cell stimulation might be provided, leading to thyroid antibody formation. The frequency of thyroid antibodies (and focal thyroiditis) in the healthy population may be due to the existence of such untolerized B cells, which can be partially activated if T-cell tolerance is disrupted or bypassed, for example by the provision of B-cell-stimulatory cytokines by non-thyroid-specific T cells.

Human Studies

The methods used to examine thyroid-reactive T cells in humans are shown in Table 3.2.5.6 and, despite their limitations, have provided important insights into the pathogenesis of autoimmune thyroid disease. A major problem has been the difficulty of access to critical thyroid-infiltrating T cells in untreated patients: blood-borne lymphocytes contain only a small proportion of thyroid-specific T cells which happen to be trafficking at the time of sampling, and although Graves' thyroid tissue is often available for study, such patients have usually received treatment with antithyroid drugs which reduce the severity of the lymphocytic infiltrate, making the remaining T cells unrepresentative. Furthermore, it is obvious that any immune response, initially directed against a single epitope on a single antigen, rapidly diversifies to involve other epitopes and antigens, and this phenomenon of determinant spreading makes any analysis of T-cell reactivity in autoimmune diseases as chronic as those affecting the thyroid very difficult to interpret.

T-cell Phenotypes

Perhaps the simplest type of analysis, but giving easily misunderstood information, is the definition of T-cell phenotypes using

Table 3.2.5.6 Methods used for examining T-cell responses to thyroid antigens

Assay	Comment
Phenotypic analysis	Measures expression of T-cell surface molecules or cytokines but provides only indirect evidence of function
Proliferation	Measures [^{3}H]thymidine incorporation after *in vitro* stimulation with antigen
Migration inhibition factor (MIF) assay	Measures production of MIF, a poorly characterized cytokine, in response to antigen; no longer in use
ELISpot assay	Measures production of cytokines (for example, IL-1, γ-IFN) by individual T cells, usually after stimulation *in vitro*
Flow cytometry after activation by antigen *in vitro*	Measures cell surface expression of markers of activation (for example, CD69)
Immunoglobulin or antibody production	An indirect assay of Th2-type responses by T cells cultured with autologous B cells
Cytotoxicity	Measures killing of target cells incubated with cytotoxic T cells

monoclonal antibodies against an array of surface molecules. From such studies on peripheral blood, it is now fairly clear that CD8$^+$ T-cell numbers are decreased in Graves' disease, active Hashimoto's thyroiditis, and postpartum thyroiditis, giving a rise in the ratio of CD4 to CD8 cells, and so-called activated T cells, expressing HLA-DR and other activation molecules, are also increased. However, the cause and meaning of these changes remain unclear, and their original interpretation as showing a defect in so-called T-suppressor cells is now regarded as naive. It should also be noted that similar changes are found in other autoimmune diseases.

Thyroid-infiltrating T cells are a mix of CD4$^+$ and CD8$^+$ cells, many expressing activation markers, and CD4$^+$ cells often predominate in Hashimoto's thyroiditis. Most of the T cells express the αβ T-cell receptor, but a minor population of uncertain significance expresses the γδ receptor. Analysis of clonality within the T-cell population expressing the αβ receptor families by the unfractionated thyroid-infiltrating T-cell population in Hashimoto's thyroiditis and Graves' disease shows no evidence of restriction, even in the activated T-cell population which might be predicted to contain the most disease-specific cells. Although it is likely that the autoimmune response begins with a clonally restricted response, this response rapidly diversifies, particularly when multiple thyroid autoantigens are known to be involved. Detailed analysis of the T-cell infiltrate in autoimmune thyroiditis shows that there is an influx of recent thymic emigrants early on in the disease process, which in turn implies that there may be some disturbance of central tolerance, in addition to a problem with peripheral tolerance, in these patients [26].

Functional Responses

Thyroglobulin-, thyroid peroxidase-, and TSH-receptor-reactive T cells can be identified in the circulating and thyroid lymphocyte populations of patients with thyroid autoimmunity but such responses tend to be weak and epitope mapping studies have generally revealed a remarkably heterogeneous response.

Recent work has identified the importance of regulatory T cells, now known to have a central role in maintaining tolerance to autoantigens [27]. Perhaps the clearest evidence for their importance comes from the rare, lethal disorder IPEX (immunodysregulation polyendocrinopathy enteropathy X-linked) syndrome in which there are mutations in the *FOXP3* gene that result in a defect in immunoregulatory T cells which express CD25 and Foxp3. Babies with this syndrome have very early onset autoimmune disorders including thyroid disease. Further possible examples of thyroid autoimmunity appearing in the wake of a disturbance of T-cell-mediated immunoregulation occur during reconstitution of the immune system after monoclonal antibody treatment directed against lymphocytes, or after antiretroviral treatment for HIV [28].

Analysis of cytokine production in thyroid autoimmunity, either *in situ* or by cultured T cells, has shown a complex picture, with both Th1 and Th2 cytokines being present [29]. There is also an increase in pro-inflammatory Th17 production by intrathyroidal lymphocytes [30]. It is likely that a Th1 (and Th17) pattern predominates in autoimmune hypothyroidism, but the expected Th2 predominance in Graves' disease, shown by IL-4 production, is not apparent, either because the disease has been studied too late or because other cytokines known to be produced in the thyroid, such as IL-6, IL-10, and IL-13, are able to sustain antibody production. Besides CD4$^+$ T cells, CD8$^+$ T cells, macrophages, and the thyroid follicular cells themselves all contribute to the intrathyroidal cytokine profile, and the pathogenic implications of such cytokines are discussed next.

Antigen Presentation to T Cells

Antigen presentation is the fundamental first step in any immune response (**Figure 3.2.5.4**) and in most cases is believed to be a function of specialized antigen-presenting cells, such as dendritic cells, macrophages, or B cells. These have the ability to take up antigen, process it into the form of epitopes, and present the epitope, bound to a MHC class II molecule, to a CD4$^+$ T cell which recognizes this bimolecular complex through a specific T-cell receptor. In addition, a number of other molecules on the antigen-presenting cell interact with the T cell, either to stabilize this interaction or deliver additional or costimulatory signals. T cells vary in their requirement for costimulatory signalling to achieve activation; broadly speaking, naive T cells depend more on such signals than memory or activated T cells. Some antigen-presenting cell-derived signals may also mediate T-cell inhibition. For instance, the B7 surface proteins, CD80 and CD86, cause T-cell activation when they bind to CD28 on a T cell, but if they bind instead to CTLA-4, T-cell anergy ensues. Moreover, T cells dependent on costimulatory signals are rendered anergic if antigen presentation occurs in the absence of the signal. This alternative outcome from antigen presentation is an important mechanism for determining peripheral tolerance, although much remains to be learned about what determines T-cell requirements for costimulatory signals.

Against this background, the identification of MHC class II molecule expression by thyroid cells in Hashimoto's thyroiditis and Graves' disease, but not under normal conditions, was initially taken as evidence that such expression could initiate or perpetuate the autoimmune response through the presentation of thyroid antigens by thyrocytes which, in effect, had been converted to antigen-presenting cells [31]. Such class II expression is not an intrinsic property of thyroid cells in the disease state, but depends instead on the cytokine γ-interferon released by the infiltrating T cells, and therefore cannot be the initiating step in thyroid autoimmunity: in experimental autoimmune thyroiditis, when class II

molecules are expressed *de novo* on thyroid cells in transgenic mice, thyroiditis does not appear [32].

Thyroid-specific T cells can be stimulated to proliferate in response to antigen presented by class II-positive thyroid cells, but using cloned T cells it is apparent that this is not a universal property, as T cells requiring B7 costimulation cannot be stimulated by thyroid cells, which do not express B7 proteins [33]. Moreover, the T cells that fail to respond are rendered anergic, as subsequent attempts at stimulation using conventional antigen-presenting cells fail, and this is achieved by at least two mechanisms, one partially reversible by addition of appropriate cytokines (especially IL-2) and the other dependent on Fas-mediated signalling (see next). Therefore the peripheral tolerance induced by thyroid cells is complex and appears, teleologically, to be an appropriate mechanism for inducing peripheral tolerance in potentially autoreactive T cells, which could otherwise respond to released autoantigen, for instance, after viral thyroiditis (**Figure 3.2.5.5**). The local production of γ-interferon during the infection may ensure sufficient MHC class II expression by thyroid cells to ensure that autoimmune responses are not initiated, but this backfires in the setting of an already ongoing autoimmune response. In this case, conventional antigen-presenting cells provide initial costimulatory signals and the resulting T cells, no longer dependent on costimulatory signals, will be further stimulated by class II-positive thyroid cells.

B-cell Function in Autoimmune Thyroid Disease

As already discussed, B cells specific for certain thyroid antigens are not deleted during development in transgenic animal models [25]. Such ignorant but potentially autoaggressive populations of B cells may become activated non-specifically in response to the right combination of cytokines, leading to autoantibody production. It is unknown in humans which thyroid autoantigens, if any, can actually induce B-cell tolerance, either through deletion or anergy mechanisms. Judging by the frequent appearance of low levels of low-affinity IgM class thyroglobulin antibodies in healthy individuals, B cells specific for thyroglobulin are frequently not tolerized, but whether such natural autoantibodies have a pathogenic role is uncertain. Maturation of the B-cell response, leading to the production of high levels of high-affinity, IgG class thyroglobulin antibodies, requires $CD4^+$ T-cell help, and it is these antibodies that characterize autoimmune thyroid disease.

TSH receptor and thyroid peroxidase are much more localized to the thyroid than thyroglobulin and therefore might be expected to impose even less tolerance on B cells than thyroglobulin, which circulates at relatively high levels. However, little is known about the frequency of B cells with these specificities in normal individuals. *A priori,* it would seem that TSH-receptor-specific B cells are uncommon, particularly those capable of producing thyroid-stimulating antibodies, and there is even the possibility that such antibodies are the product of only a very small number of B-cell clones.

Circulating B-cell numbers are largely normal in autoimmune thyroid disease, although increases in the $CD5^+$ B-cell subset, responsible for synthesis of polyreactive natural autoantibodies, can occur. Such increases in $CD5^+$ B cells occur in other autoimmune diseases and have no known pathogenic role in thyroiditis. B cells and plasma cells are found in varying numbers in the thyroid, and may be organized in germinal follicles, especially in Hashimoto's thyroiditis. Rarely, these follicles can show light-chain restriction, from which a single dominant clone may emerge to produce non-Hodgkin's lymphoma, a recognized complication of Hashimoto's thyroiditis.

Although both blood-borne and thyroid lymphocytes can produce thyroid antibodies *in vitro* after mitogen stimulation, only the thyroid lymphocytes produce antibody spontaneously, so that the thyroid seems likely to be a major source of antibodies *in vivo*. In addition, however, the bone marrow and lymph nodes draining the thyroid are sites of thyroid antibody production. The decline in thyroid antibody production which occurs after thyroid ablation is explicable as the result of either removal of thyroidal B cells or removal of thyroid antigen and thyroid-specific helper T cells [9]. In simple terms of B-cell population size, it would seem that the thyroid is not the major site of antibody synthesis, but the real importance of this compartment may lie in the ability of B cells to take up specific autoantigen. B cells are uniquely able to amplify the T-cell response to any given autoantigen and may even break T-cell tolerance by presentation of cryptic self-epitopes generated by processing within the B cell. Thus, within the thyroid, the autoimmune response will be sustained and increased by B-cell-mediated presentation of locally derived thyroglobulin, thyroid peroxidase, and TSH receptor, and supported by the intrathyroidal production of cytokines which cause B-cell proliferation and differentiation (**Figure 3.2.5.6**). This information has been behind attempts to treat Graves' disease and ophthalmopathy with rituximab, a monoclonal antibody that depletes B cells but not plasma cells, although results so far remain rather equivocal [34].

Mechanisms Altering Thyroid Function

It is now clear that TSH-receptor-stimulating antibodies cause Graves' disease, but there is no clear correlation between the circulating level of these antibodies and the severity of hyperthyroidism. The most likely reason for this discrepancy is that humoral and cellular factors, identical to those operating in autoimmune hypothyroidism, are also active in Graves' disease, and it is the balance between the level of stimulatory antibodies and these conflicting processes, including antibodies which block the TSH receptor, that determines the degree of hyperthyroidism. As already noted, the natural history of Graves' disease tends to thyroid destruction over 20 years in a small proportion of patients [9].

The mechanisms mediating hypothyroidism are less clear, in particular with regard to the relative importance of each in the pathogenesis of thyroid cell dysfunction and destruction, and these processes are considered next.

Humoral Immunity

The role of thyroglobulin antibodies is uncertain, as they do not fix complement, but these antibodies may be involved in mediating antibody-dependent cell-mediated cytotoxicity. In this, the effector cell is a natural killer cell which binds to the antibody via Fc receptors on the natural killer cell surface. This allows the natural killer cell to destroy a specific target cell, in this case a thyroid cell, as otherwise natural killer cell-mediated destruction is not

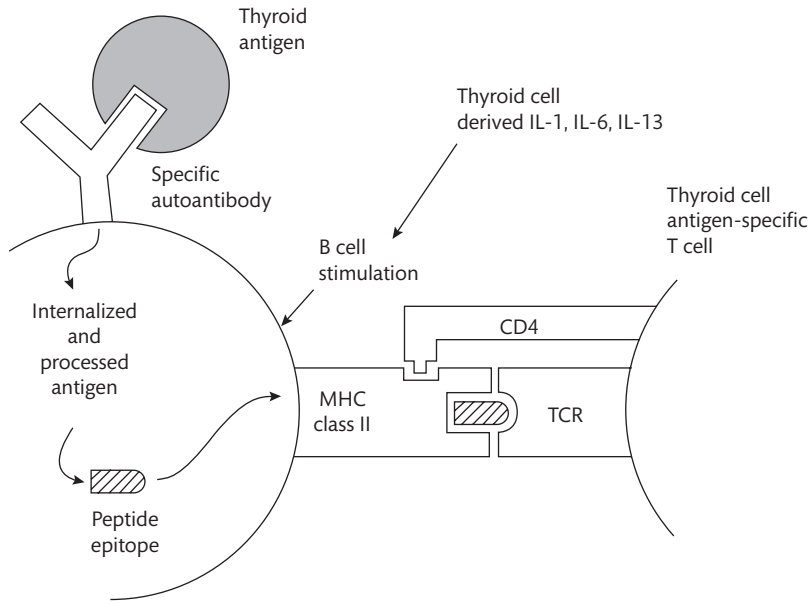

Figure 3.2.5.6 Cognate interaction of B cells, capturing specific thyroid antigens by surface autoantibody, and T cells.

restricted by recognition of specific antigen. Antibody-dependent cell-mediated cytotoxicity is demonstrable *in vitro* with both thyroglobulin and thyroid peroxidase antibodies, small numbers of natural killer cells appear in the thyroid infiltrate, and monocytes may also be involved in this destructive pathway [35]. However, transplacental transfer of thyroglobulin antibodies is not accompanied by thyroid dysfunction, and similar considerations apply to the frequent presence of thyroglobulin antibodies in euthyroid individuals. Thyroid peroxidase antibodies can fix complement but, for similar reasons, would seem to be of minor importance as primary mediators of thyroid cell destruction. Thyroid peroxidase may well be sequestered from access by autoantibodies until late in the disease process, when cell-mediated injury will permit access and antibody binding.

A second reason for the failure of complement-fixing thyroid peroxidase antibodies to destroy thyroid cells is that, in common with all nucleated cells, thyroid cells express complement regulatory proteins which prevent lethal injury by interfering with C3 convertase activity or by impairing terminal complement component formation. The most important of these regulatory proteins functionally is CD59, and its expression is upregulated by IL-1, γ-interferon, and tumour necrosis factor, all of which are produced by the lymphocytic infiltrate, thus enhancing the ability of thyroid cells to defend themselves from complement attack [36]. There is good evidence that complement is activated in thyroid autoimmunity, with elevated serum levels of terminal complement complexes, and local deposition of such complexes around the thyroid follicles in both Graves' disease and Hashimoto's thyroiditis. Unless formed in overwhelming amounts, complement membrane attack complexes do not overcome the thyroid cell's defences, but none the less, sublethal effects of complement attack are demonstrable *in vitro*, and include impaired responses to TSH stimulation and the release of cytokines, reactive oxygen metabolites, and prostaglandins, which will contribute to the local inflammatory response.[36] Antithyroid drugs block this pro-inflammatory response to complement attack, which may explain the selective immunomodulatory effects of these drugs.

A final mechanism by which antibodies can cause hypothyroidism is through their direct effects on cell function, most clearly illustrated by TSH-receptor antibodies. Although all patients with Graves' disease must, by definition, have TSH-receptor stimulating antibodies, these may be absent in the serum of occasional patients [37]. As well as assay insensitivity as an explanation, it is possible in these cases that there is exclusively intrathyroidal production of autoantibody which is sufficient to sustain disease.

Cell-Mediated Immunity

Cytokines released locally by the infiltrating lymphocytes and macrophages may have a number of effects that exacerbate thyroid injury. Some of these effects are related to the metabolic activity of the thyroid cells, such as decreased synthesis of thyroglobulin or thyroid peroxidase, which will ultimately impair thyroid hormone production (Table 3.2.5.7), while others evoke responses by

Table 3.2.5.7 Functional effects of cytokines on human thyroid cells

Cytokine	Growth	Iodide uptake	cAMP production	Expression of TG or TPO
IL-1	↑ but can also ↑ PGE_2, causing ↓ growth	↓	↓	Biphasic: ↑ at low concentration and ↓ at high concentration
IL-6	↑ (with TSH)	0	↓/0	↓/0
	↓ (with EGF)			
γ-IFN	↓ (with TNF)/0	↓	Variable	↓
TNF-α	0 (alone)	↓	↓/0	↓

↑, increase, ↓, decrease, 0, no effect. TG, thyroglobulin; TPO, thyroid peroxidase; PGE_2, prostaglandin E_2; EGF, epidermal growth factor; γ-IFN: γ-interferon; TNF-α: tumour necrosis factor-α.

thyroid cells which have direct immunological relevance. One of these has already been discussed, namely the expression of MHC class II molecules induced by γ-interferon, but many other effects are being uncovered. Adhesion molecules allow cytotoxic T cells and natural killer cells to bind initially to their targets, and the upregulation of thyroid cell adhesion molecule expression by cytokines will enhance the susceptibility of thyroid cells to such attack.[9] Nitric oxide and reactive oxygen species may play a key role in thyroid injury and their production by thyroid cells is initiated by the intrathyroidal pro-inflammatory environment which exists in autoimmune thyroiditis [9, 38]. Finally, IL-1, IL-6, IL-8, IL-12, IL-13, IL-14, IL-15, and IL-16 are all produced by thyroid cells themselves in response to inflammatory cytokines, especially IL-1[29], and this may set up a mutually reinforcing pathway of cytokine interactions which results in escalation and perpetuation of the autoimmune process (Figure 3.2.5.7).

As well as thyroid cells, vascular endothelial cells in the thyroid are exposed to cytokines which upregulate expression of selectins and other molecules essential to the egress of inflammatory cells from the blood. Thyroid cells can also produce an array of chemokines, molecules which are able to enhance the recruitment of lymphocytes to the gland in disease. Chemokine synthesis may also be critical in the formation of lymphoid germinal centres in chronically affected thyroid tissue [39]. The process of adhesion molecule expression and chemokine synthesis must be essential to the recruitment of lymphocytes to the infiltrate, although it is unknown what proportion of these are blood-derived and what proportion result from local expansion.

Specific cytotoxic T cells have long been thought to be key mediators of thyroid cell destruction in autoimmune thyroiditis, but evidence for their existence is surprisingly sparse and best documented in experimental autoimmune thyroiditis [9]. As well as releasing cytokines, cytotoxic T cells kill either by insertion of perforin into the target cell membrane, or by interaction of Fas ligand on the T-cell surface with the widely expressed Fas molecule on the target cell. Perforin-expressing T cells are present in the thyroid infiltrate in both Hashimoto's thyroiditis and Graves' disease, with slightly differing phenotypes in the two conditions [40]. This certainly indicates the potential for perforin-mediated cell destruction, although attention has also focused on Fas-mediated apoptosis as a major mechanism for thyroid cell death [41]. This interest has been sparked by the demonstration of Fas ligand expression by thyroid cells in Hashimoto's thyroiditis, but not other conditions. Fas ligand expression was enhanced *in vitro* by IL-1β but not by other cytokines, suggesting that, in addition to the classical pathway of apoptosis mediated by T cells, Fas and Fas ligand on thyroid cells could interact and lead to cell suicide. Normally Fas ligand expression is limited to sites of immunological privilege, such as the trophoblast and Sertoli cells, where it is clear that suicide is not an outcome: instead, Fas ligand expression at these sites ensures tolerance by deleting any autoaggressive Fas-expressing lymphocytes specific for these tissues. Thus, a major effect of thyroid cell Fas ligand expression *in vivo* may be the evasion of thyroid cell recognition by T cells.

In summary, thyroid cell dysfunction and destruction result from a wide array of insults (Figure 3.2.5.8) and, in the initial stage at least, seem dependent on cell-mediated autoimmune processes. It is likely that within the same clinically identified disease there are interindividual differences in the relative contributions from each type of injury. This variation would account for the diversity

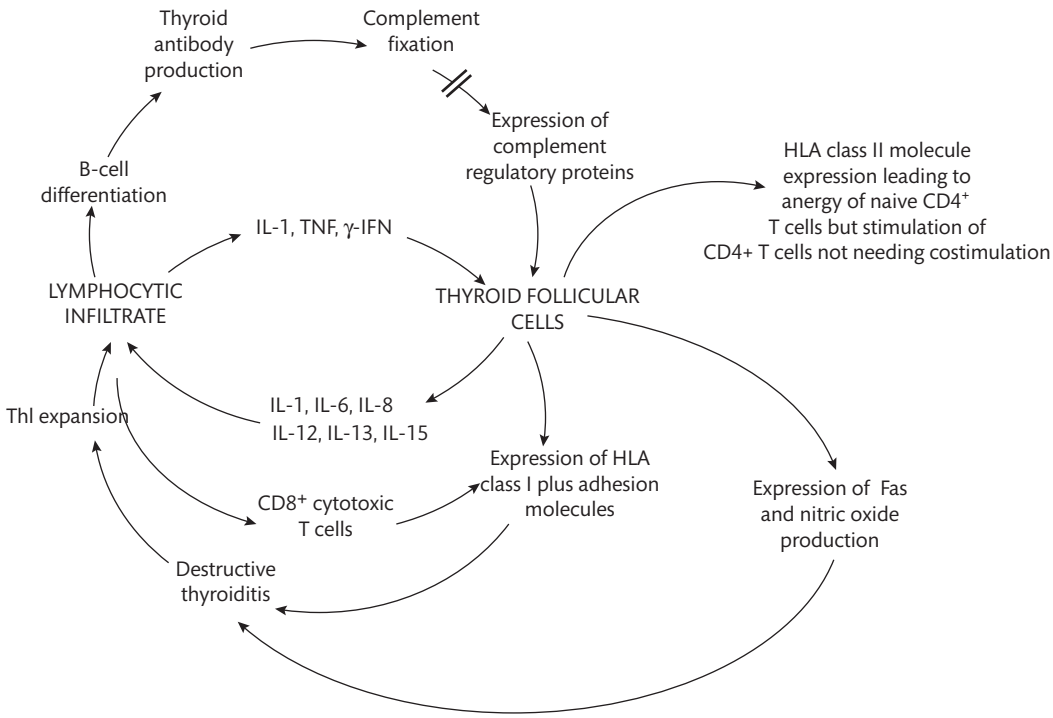

Figure 3.2.5.7 Cytokine interactions between the immune system and thyroid cells in autoimmune thyroid disease.

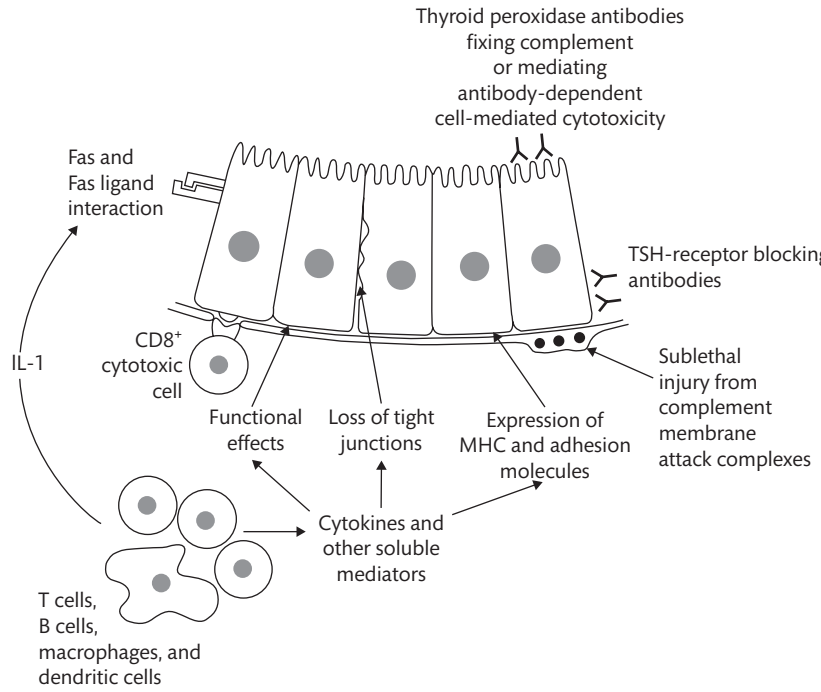

Figure 3.2.5.8 Main mechanisms involved in thyroid cell dysfunction in autoimmune hypothyroidism.

of pathological processes previously described, and because of this complexity, it is highly improbable that only two types of mechanism predominate, one resulting in atrophic thyroiditis and the other in goitrous thyroiditis.

Use of Thyroid Autoantibodies in Diagnosis

Although thyroglobulin and thyroid peroxidase antibodies appear to have a secondary rather than a primary role in disease pathogenesis, none the less they are invaluable markers of the presence of autoimmune thyroid disease. After considering the assays available, this section will review the results from antibody testing and then consider the use of TSH-receptor antibodies in diagnosis.

Thyroglobulin and Thyroid Peroxidase Antibodies

There are essentially four methods for assaying thyroglobulin and thyroid peroxidase antibodies. The two oldest are haemagglutination and indirect immunofluorescence, which depend on dilution of the test serum to determine the level of antibodies. Although robust and providing reasonably sensitive and specific results, the more modern methods of enzyme-linked immunosorbent assay (ELISA) and radioimmunoassay allow truly quantitative determination of antibodies and, in the case of assays for thyroid peroxidase antibodies, can use antigen of high purity, if necessary for research purposes. Thyroid peroxidase was previously called the microsomal antigen, and assays for these antibodies have relied on positive immunofluorescence staining with an appropriate pattern or, in the case of haemagglutination, have used an excess of thyroglobulin to absorb out thyroglobulin antibody activity when testing crude microsomal extracts of thyroid homogenate. Comparison of assays based on haemagglutination with microsomal antigen and more modern methods with purified or even recombinant thyroid peroxidase has shown a good correlation between the two, although those assays based on thyroid peroxidase are more sensitive. Further improvement in assay standardization has come from the use of reference positive serum samples, and increased sensitivity has been achieved with the use of immunometric assays, which are now automated, utilize chemiluminescence, and are widely available. Nonetheless there are still significant differences in the cut-offs for positivity between assay kits from different manufacturers [42].

With the most sensitive assays, up to 20% of healthy women have thyroglobulin and/or thyroid peroxidase antibodies, although in the majority the levels are very low. Using more conventional assays, 11% of women and 3% of men were positive in a large community-based survey in the United Kingdom [3] and similar results have been reported elsewhere. Antibodies are not entirely stable, appearing or disappearing in 17% and 2% of women, respectively, over a 20-year period [3]. In healthy individuals, the presence of such antibodies is a marker of future thyroid dysfunction, especially if coupled with subclinical hypothyroidism, and all patients with positive thyroid antibodies should be offered annual screening to detect early thyroid failure, while patients with subclinical hypothyroidism should have antibodies measured to stratify their risk.

Thyroid peroxidase antibodies are found in 80–90% of Graves' sera and 95–100% of Hashimoto sera, with thyroglobulin antibodies in up to 70% of Graves' and 90–100% of Hashimoto sera, using sensitive assays. Occasional patients with Hashimoto's thyroiditis are negative for serum thyroid antibodies, although synthesis can usually be detected locally within the thyroid, presumably at too low a level to be detectable in serum. In most patients, thyroglobulin antibodies are accompanied by thyroid peroxidase antibodies, but some patients only have one or the other type.

Box 3.2.5.1 Conditions associated with an increased prevalence of thyroglobulin and thyroid peroxidase antibodies

- Polyglandular disease
  - Insulin-dependent diabetes mellitus
  - Addison's disease
  - Premature ovarian failure
  - Lymphocytic hypophysitis
- Conditions associated with autoimmune polyglandular syndromes
  - Vitiligo
  - Pernicious anaemia
  - Alopecia
  - Myasthenia gravis
  - Coeliac disease and dermatitis herpetiformis
  - Autoimmune serositis
- Rheumatological disorders
  - Rheumatoid arthritis
  - Systemic lupus erythematosus
  - Sjögren's syndrome
  - Polymyalgia rheumatica/temporal arteritis
  - Relapsing polychondritis
  - Systemic sclerosis
- Other disorders
  - Chronic active hepatitis
  - Primary biliary cirrhosis

Thyroglobulin and thyroid peroxidase antibodies are found in a variety of other conditions at higher frequency than would be expected by chance (Box 3.2.5.1).

Antibody testing is certainly useful in patients with Addison's disease, as around 25% may develop thyroid dysfunction due to associated autoimmune polyglandular syndrome type 2. Similar considerations apply to pernicious anaemia, coeliac disease and, more debatably, other autoimmune disorders which are associated with a high frequency of thyroid autoimmunity [43]. Another situation where prospective thyroid antibody testing is particularly worthwhile is in patients starting amiodarone, as those with antibodies are more likely to develop amiodarone-induced hypothyroidism. The presence of thyroid antibodies is also useful in predicting the risk of thyroid dysfunction after treatment with γ-interferon.

On the other hand, measurement of thyroid antibodies can be misleading in goitre, as patients with multinodular goitre can have thyroid antibodies in association with focal thyroiditis, although the antibodies are usually only at low or moderate levels. Similarly, around 25% of patients with papillary or follicular thyroid cancer have thyroglobulin and/or thyroid peroxidase antibodies. There does appear to be an association between Hashimoto's thyroiditis and differentiated thyroid cancer, as well as with lymphoma: there is controversy regarding the prognostic value of thyroglobulin antibodies in thyroid cancer, possibly related to epitope recognition differences and the assays used [44]. Such antibodies can interfere with the assay of thyroglobulin in thyroid cancer follow-up.

Thyroid peroxidase antibody positivity is strongly related to postpartum thyroiditis, giving rise to the suggestion that it may be worthwhile screening all pregnant women antepartum, but the positive predictive value of thyroid peroxidase antibodies is quite low and some cases have been reported in women who are thyroid peroxidase antibody-negative. Universal screening is not currently recommended, although the TSH should be checked in all pregnant women already known to be thyroid antibody-positive [45]. Because of the high frequency of postpartum thyroiditis in type 1 diabetes mellitus and other autoimmune disorders, there is a strong case for TSH measurement (and thyroid peroxidase antibody screening if the TSH exceeds 2.5 mU/L) in this group of women antepartum. Women with positive thyroid antibodies, even without clinical thyroid dysfunction, are at risk of recurrent first trimester miscarriage, but it seems that early thyroxine treatment may not have the benefits that were originally predicted in this group [46]. There is also evidence that the presence of thyroid antibodies, in the absence of an elevated TSH, may be associated with a lack of well-being, depression, and even rare cases of encephalopathy [47]. Whether these associations are due to a direct effect of the antibodies, or the underlying effects of an autoimmune response, is not known.

TSH-Receptor Antibodies

The terminology of TSH-receptor antibodies (Table 3.2.5.3) has evolved from the methods used for their measurement. In essence there are two current methods: the binding assay, which measures the capacity of immunoglobulins to inhibit the binding of labelled TSH (or a labelled monoclonal TSH-receptor antibody) to purified or recombinant TSH receptor; and bioassays which measure the stimulatory or inhibitory effects of immunoglobulins on some aspect of thyroid cell function [48]. Generally, cyclic AMP production is used as the endpoint in bioassays, but there has been an irreversible move away from using primary cultures of animal or human thyroid cells in these assays, with their attendant problems of supply and standardization, to using either cell lines, such as rat FRTL-5 cells, or Chinese hamster ovary cells transfected with TSH receptor. With the most sensitive bioassays for TSH-receptor-stimulating antibodies almost all patients with Graves' disease are positive, but these antibodies are rarely found in the absence of Graves' disease, and then are associated with a greatly increased risk of future hyperthyroidism. This is shown most clearly by the finding that 30–50% of euthyroid patients with thyroid-associated ophthalmopathy have TSH-receptor antibodies, and this proportion increases if the most sensitive assays are used; the majority of these patients subsequently develop hyperthyroidism.

As would be predicted, there is only a weak correlation between levels of TSH-receptor antibodies measured in the binding and stimulatory bioassays. Current binding assays have a greater than 95% sensitivity and specificity for the diagnosis of Graves' disease but these antibodies must be used with knowledge of the clinical context. For instance, 10% of patients with autoimmune hypothyroidism will have TSH-receptor blocking antibodies that will be detected as positive in the binding assay, but the thyroid status makes the interpretation of the result clear [21]. Neutral antibodies with binding but not biological activity may also be detected. Antibodies against the TSH receptor are present at much lower concentrations than thyroid peroxidase antibodies and this makes the development of robust and simple solid-phase assays very difficult, compounded by problems in expressing the TSH receptor in its native form.

TSH-receptor antibody testing is not necessary for the diagnosis of Graves' disease when this is clinically obvious, for instance because there is coincident ophthalmopathy, or when such information will not influence management, for instance if the decision has already been made to proceed with radioiodine treatment. However, as the cost and precision of TSH-receptor binding assays

are now reasonable, there is an increasing tendency to use these assays to diagnose Graves' disease in cases where determining the aetiology of hyperthyroidism is required, and to rule out destructive thyroiditis. Other diagnostic tools (such as measurement of thyroid peroxidase antibodies or thyroid iodine uptake, or performing a thyroid scan) are either less convenient to undertake or less specific and sensitive. Prediction of outcome after antithyroid drugs has been another frequently suggested use for these assays, but although there is no doubt that the presence of high levels of TSH-receptor antibodies before treatment, or detectable levels after treatment, is associated with a higher rate of relapse, the sensitivity and specificity of these measurements are too poor to be used alone routinely in clinical practice [49]. However, when pretreatment serum TSH-binding inhibiting immunoglobulins (TBII) is combined with other measurements (age, goitre size, and HLA/*PTPN22* genotype), a score can be generated which has better predictive value [50].

The one clear situation where measurement of TSH-receptor antibodies is definitely indicated is during pregnancy in Graves' disease: a high level of maternal antibodies is a strong predictor of neonatal thyrotoxicosis, which occurs in 1–5% of women with Graves' disease who become pregnant. Current recommendations are that TSH-receptor antibody measurement should be made in early pregnancy in (i) women taking an antithyroid drug for Graves' disease, and (ii) women with a history of Graves' disease successfully treated by radioiodine or surgery. Measurement should be repeated at 18–22 weeks in (i) those still requiring an antithyroid drug to maintain euthyroidism, and (ii) those who were antibody-positive after surgery or radioiodine on initial screening; further tests in later pregnancy as well as fetal monitoring are required in those women who are positive for TSH-receptor antibodies at this stage [45].

3.2.6 Thyroiditis

Elizabeth N. Pearce and Alan P. Farwell

Introduction

Thyroiditis comprises a diverse group of disorders that are among the most common endocrine abnormalities encountered in clinical practice. These disorders range from the extremely common chronic lymphocytic thyroiditis (Hashimoto's thyroiditis) to the extremely rare invasive fibrous thyroiditis (Riedel's thyroiditis) (Box 3.2.6.1). Clinical presentations are also diverse, ranging from

Box 3.2.6.1 Types of thyroiditis (most common to least common)

- Chronic autoimmune thyroiditis (Hashimoto's thyroiditis)
- Postpartum thyroiditis
- Sporadic silent thyroiditis
- Subacute granulomatous thyroiditis (De Quervain's thyroiditis)
- Radiation thyroiditis
- Infectious thyroiditis
- Invasive fibrous thyroiditis (Riedel's thyroiditis)
- Miscellaneous *(all are rare apart from drug-associated)*
  - Sarcoid
  - Amyloid
  - Drug-associated
  - Traumatic
  - Palpation-induced

an incidental finding of a goitre to potentially life-threatening illness, from hypothyroidism to thyrotoxicosis. The term 'thyroiditis' implies that the disorders described in this section are inflammatory processes involving the thyroid gland. However, some of the lesions are not inflammatory, but are included in the thyroiditis category largely for convenience. A rational approach to such patients, including history, physical examination, laboratory evaluation, radionuclide or ultrasonographic imaging, and fine-needle aspiration biopsy, will allow the appropriate diagnosis to be made in the vast majority of cases.

This chapter will review the following forms of thyroiditis: Hashimoto's, subacute, infectious, and Riedel's. Other forms of thyroiditis are discussed within other chapters, as follows: postpartum and painless sporadic thyroiditis (Chapter 9.4), radiation thyroiditis (Chapter 3.2.4), drug-induced thyroiditis (Chapter 3.1.4), thyroiditis associated with neoplasms (Chapter 3.5.5), and focal thyroiditis associated with non-toxic nodular goitre (Chapter 3.5.1).

Chronic Autoimmune Thyroiditis (Hashimoto's)

Chronic autoimmune thyroiditis, also known as chronic lymphocytic thyroiditis and Hashimoto's thyroiditis, was first described by Hashimoto in 1912 (Table 3.2.6.1). He described four patients with goitre, the thyroid histology of which were all characterized by diffuse lymphocytic infiltration, atrophy of parenchymal cells, fibrosis, and eosinophilic change in some of the parenchymal cells. While this condition is common, there are several variants that differ somewhat from the one initially described by Hashimoto [1]. Classically, the disorder occurs as a painless diffuse goitre (goitrous form) in a young or middle-aged woman, with or without concomitant hypothyroidism. The atrophic form of Hashimoto's thyroiditis is less common and is usually diagnosed by serology in the hypothyroid patient with a normal-sized or atrophic thyroid. The hallmarks of this disorder are high circulating titres of antibodies to thyroid peroxidase (primarily) and thyroglobulin (less often).

In iodine-sufficient countries, the most common cause of goitre, hypothyroidism, and elevated thyroid antibody levels is Hashimoto's thyroiditis. The incidence of autoimmune thyroiditis has increased over the past three generations, perhaps due to the increase in iodine intake that has occurred in many regions globally. Elevated serum thyroid antibody concentrations are found in approximately 10% of the US population and in up to 25% of US women over the age of 60 [3]. About 45% of older women will have lymphocytic infiltration within the thyroid gland. Autoimmune thyroiditis has a female predominance, with reported female to male ratios ranging between 5:1 and 9:1.

Aetiology and Pathogenesis

Hashimoto's thyroiditis is an autoimmune disease. Thyroid autoimmunity tends to aggregate in families, suggesting a genetic component. This likely results from the interplay of genes which confer susceptibility and environmental triggers. Genes regulating the immune system as well as thyroid-specific genes have been implicated

Table 3.2.6.1 Comparison between the syndromes of thyroiditis

	Hashimoto's thyroiditis	Painless sporadic/postpartum thyroiditis	Subacute thyroiditis	Infectious thyroiditis	Riedel's thyroiditis
Age of onset (years)	All ages, peak 30–50	Sporadic: all ages, peak 30–40 Postpartum: childbearing years	Peak onset 40–50	Children, 20–40	30–60
Sex ratio (F:M)	8–9:1	Sporadic—2:1	5:1	1:1	3–4:1
Frequency	General population 10%, elderly women 25%	Postpartum: 1–17% Sporadic: unknown	12.1 cases per 100 000 person-years	Rare	Extremely rare
Aetiology	Autoimmune	Autoimmune	Viral (?)	Infectious organisms	Unknown
Genetic predisposition	Moderate	Low	Moderate	Low	Low
Pathology	Lymphocytic infiltration, germinal centres, fibrosis	Lymphocytic infiltration	Giant cells, granulomas	Abscess formation	Dense fibrosis
Prodrome	None	Postpartum: pregnancy Sporadic: none	Viral illness	None	None
Goitre	Usually non-painful, persistent	Non-painful, persistent	Painful, transient	Painful, transient	Non-painful, persistent
Fever and malaise	No	No	Yes	Yes	No
Thyroid antibodies	High titre, persistent	High titre, persistent	Low titre/absent, transient	Absent	Present in most patients
Thyroid function	Euthyroid or hypothyroid	Thyrotoxicosis followed by hypothyroidism	Thyrotoxicosis followed by hypothyroidism	Usually euthyroid	Usually euthyroid
ESR	Normal	Normal	High	High	Normal
Radioactive iodine uptake (24 h)	Increased, normal, or decreased	<5%	<5%	Normal	Low/normal
Relapse	Persistent	Postpartum: common with subsequent pregnancies Sporadic: 2% [2]	1–4%	Common only with pyriform sinus fistula	Persistent
Permanent hypothyroidism	Frequent	Common	5%	Rare	Occasionally

[4]. Smoking decreases risk for hypothyroidism and thyroid autoimmunity [5]. Environmental factors which increase the risk for Hashimoto's thyroiditis include excessive iodine intake, selenium deficiency, and exposure to ionizing radiation [6]. It has been speculated that viral infection with human parvovirus B19 or hepatitis C virus may serve as a trigger for Hashimoto's thyroiditis [7].

In Hashimoto's thyroiditis T cells attack the thyroid gland, leading to exposure of thyroid antigens such as thyroid peroxidase (TPO) and thyroglobulin, against which antibodies are produced. TPO antibodies are detectable in about 90% of patients with Hashimoto's thyroiditis. Thyroglobulin antibodies are in about 35–60% of patients with Hashimoto's thyroiditis [8]. Thyroid-stimulating hormone (TSH) receptor antibodies that block TSH binding but do not stimulate thyroid cell function may play a role in the clinical presentation of Hashimoto's thyroiditis, producing or exacerbating hypothyroidism in the absence of significant thyroid gland destruction [9]. Such antibodies have been reported to bind to epitopes near the carboxyl end of the TSH receptor extracellular domain, in contrast to thyroid-stimulating antibodies, which bind to epitopes near the N-terminus [10]. The prevalence of TSH receptor blocking antibodies in adult hypothyroid patients has been reported to be as high as 10% [11] and a decrease in the titre of these antibodies is likely to be responsible for 'remission' of hypothyroidism in occasional patients with Hashimoto's thyroiditis [12]. Antibodies to colloid antigen, other thyroid autoantigens, thyroxine (T_4), and triiodothyronine (T_3), as well as other growth-promoting and inhibiting antibodies may also be present.

Pathologically, there is lymphocytic infiltration of equal proportions of T and B cells and the formation of germinal centres (Figure 3.2.6.1a). The follicular cells undergo metaplasia into larger, eosinophilic cells known as Hürthle or Askanazy cells which are packed with mitochondria. These cells exhibit high metabolic activity but ineffective hormonogenesis. There is ongoing cellular destruction and progressive fibrosis, which may be extensive. The quantity of parenchymal tissue left in the thyroid is variable, as the pathological involvement ranges from focal regions to an entire lobe to the entire gland.

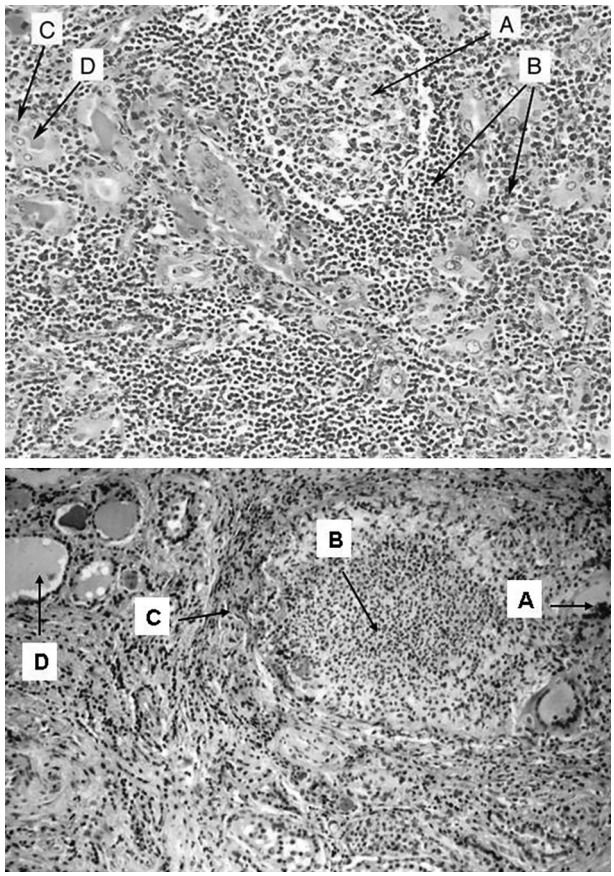

Figure 3.2.6.1 Typical pathological changes of Hashimoto's thyroiditis and subacute thyroiditis. (a) Hashimoto's thyroiditis. A, lymphoid follicle with germinal centres; B, small lymphocytes and plasma cells; C, thyroid follicles with Hürthle cell metaplasia; D, minimal colloid material. (b) Subacute thyroiditis. A, multinucleate giant cell; B, mixed inflammatory infiltrate; C, fibrous band; D, residual follicles. Haematoxylin and eosin, ×200.

Clinical Features

Hashimoto's thyroiditis occurs most frequently in middle-aged women but can occur at any age. The usual presentation is with symptoms of, or biochemical evidence for, hypothyroidism, although patients occasionally present with simple goitre. The usual course is for slow enlargement of the thyroid over years; however, the thyroid occasionally may enlarge rapidly and can produce compressive symptoms of dyspnoea and/or dysphagia. Rarely, Hashimoto's thyroiditis may be painful [13] and must be distinguished from subacute thyroiditis (see next). Systemic symptoms of hypothyroidism will be present in up to 20% of patients at the time of diagnosis [14], although this incidence is a little higher with the atrophic form of the disorder.

Physical examination typically reveals a firm bumpy non-tender goitre, which is generally symmetrical and often has a palpable pyramidal lobe. Regional lymph node enlargement may be observed. While nodular thyroid disease can, and frequently does, occur in Hashimoto's thyroiditis, suspicious nodules should be evaluated with a fine-needle aspiration biopsy to rule out a coexistent malignancy [15]. Ophthalmopathy is present in a small subset of patients with Hashimoto's thyroiditis and may be severe [16].

Laboratory Evaluation and Diagnosis

The hallmark of Hashimoto's thyroiditis is elevated TPO antibody levels. The majority of individuals with elevated TPO antibody levels are biochemically euthyroid. Up to 10% of postmenopausal women with an elevated TPO antibody level will have an increased TSH but a minority of these (about 0.5%) will have overt hypothyroidism [1]. Individuals with elevated TPO antibody levels have been reported to develop overt hypothyroidism at a rate of 2–4% per year [17] (see Chapter 3.1.8). Mild thyrotoxicosis ('Hashitoxicosis') has rarely been reported to be the initial manifestation in some patients with Hashimoto's thyroiditis [18]. The clinical course in these patients follows a pattern similar to that observed in sporadic silent or postpartum thyroiditis (Chapter 9.4), suggesting that differentiation between these disorders may be largely semantic. Finally, while the hallmark of the disease is a painless goitre, occasionally Hashimoto's thyroiditis can be quite painful.

While the diagnosis of Hashimoto's thyroiditis is confirmed by the presence of TPO antibodies, the titre of antibodies does not necessarily indicate the severity of the disease or even if hypothyroidism is present. Serum T4 and TSH concentrations depend solely on the level of thyroidal dysfunction that is present. Serum T3 concentrations are often preserved in all but the most severely hypothyroid patients and, thus, are of little clinical value. Similarly, the radioactive iodine uptake is usually not helpful, as it may be elevated, normal, or depressed. Thyroid isotope scanning usually reveals patchy uptake and, in general, provides little useful information unless a dominant thyroid nodule is present. Ultrasound examination of the thyroid frequently reveals marked hypoechogenicity with pseudonodules [19].

When imaged, an enlarged thymus gland is frequently found in Hashimoto's thyroiditis and may be important in the pathogenesis of the condition. In both affected patients and their relatives, there is an association with other autoimmune diseases including type 1 diabetes mellitus, pernicious anaemia, Addison's disease, and vitiligo. Thyroid lymphoma is rare; however, the risk is increased in those individuals with Hashimoto's thyroiditis by a factor of 67 [20]. In patients in whom a fine-needle aspiration biopsy is performed, lymphocyte subsets should be determined on the biopsy specimen if the more typical pathological features of Hashimoto's thyroiditis are not present.

Treatment

Treatment of Hashimoto's thyroiditis consists of thyroid hormone replacement if hypothyroidism is present. L-thyroxine is the hormone of choice for thyroid hormone replacement therapy because of its consistent potency and prolonged duration of action. The average daily adult replacement dose of L-thyroxine sodium is 1.6 μg/kg body weight. Institution of therapy in healthy younger individuals can begin at full replacement doses. Because of the prolonged half-life of thyroxine (7 days), new steady-state concentrations of the hormone will not be achieved until 4–6 weeks after a change in dose. Thus, re-evaluation with determination of serum TSH concentration need not be performed at intervals of less than 4–6 weeks. The goal of thyroxine replacement therapy is to achieve a TSH value in the normal range, as over-replacement of thyroxine suppressing TSH values to the subnormal range may induce osteoporosis and cause cardiac dysfunction [21]. In non-compliant young patients, the cumulative weekly doses of L-thyroxine may be given as a single weekly dose which is safe, effective, and well tolerated. In older individuals or those with known cardiovascular disease, institution of therapy at a lower daily dose of L-thyroxine (25 μg/day) is indicated to avoid exacerbation of underlying and undiagnosed cardiac disease. Daily doses of thyroxine may be interrupted periodically because of intercurrent medical or surgical illnesses that prohibit taking medications by mouth. A lapse of several days of hormone replacement is unlikely to have any significant metabolic consequences. However, if more prolonged interruption in oral therapy is necessary, L-thyroxine may be given intravenously at a dose 25–50% less than the patient's daily oral requirements. Euthyroid asymptomatic patients require monitoring, but no treatment. Recommendations for treatment of subclinical hypothyroidism (increased TSH without a corresponding low free T4 concentration) have varied, but the general consensus is that levothyroxine treatment should be initiated when the serum TSH is >10 mIU/L and treatment considered for TSH values 5–10 mIU/L, particularly in the setting of hypothyroid symptoms or detectable TPO antibodies [22].

In addition to replacement therapy, thyroid hormone therapy may be considered in patients with a serum TSH in the normal range in an attempt to decrease the size of a goitre. While goitre suppression with L-thyroxine is frequently not fruitful, in the subset of patients with Hashimoto's thyroiditis early in the course of the disease and before fibrosis develops such therapy may be useful. However, goitre suppression with L-thyroxine is unlikely to be successful if the initial TSH is less than 1 mIU/L. The goal of L-thyroxine suppression therapy is to decrease the serum TSH into the subnormal range. Patients on L-thyroxine suppression therapy should be re-evaluated periodically and the suppressive hormone dose should be reduced or discontinued if significant goitre reduction is not achieved. Surgery is occasionally indicated for compressive goitres with local obstructive symptoms.

Subacute Thyroiditis

Subacute thyroiditis, like painless sporadic and postpartum thyroiditis, is a spontaneously remitting inflammatory disorder of the thyroid that lasts for weeks to months [1, 23] (Table 3.2.6.1). This disorder has a number of eponyms, including De Quervain's thyroiditis, giant cell thyroiditis, pseudogranulomatous thyroiditis, subacute painful thyroiditis, and subacute granulomatous thyroiditis. Mygind first described subacute thyroiditis in 1895 by reporting 18 cases of 'thyroiditis akuta simplex' [23]. The pathology of subacute thyroiditis was initially described by Fritz De Quervain in 1904, when he reported giant cells and granulomatous-type changes in the thyroids of affected patients. Subacute thyroiditis is the most common cause of a painful thyroid and may account for up to 5% of clinical thyroid abnormalities [1, 23, 24]. Women are more frequently affected than men. The peak incidence is in the fourth and fifth decades [25]. This disorder is rarely observed in children and older people. Although 'subacute thyroiditis' implies a temporal quality that could apply to any inflammation of the thyroid, this term is specifically refers to the granulomatous appearance of the thyroid found on pathological examination.

Aetiology and Pathogenesis

Infectious Association

Although there is no clear evidence for a specific aetiology, indirect evidence suggests that subacute thyroiditis may be triggered by a viral infection [26]. The condition is often preceded by a prodrome consisting of myalgias, malaise, low-grade fevers, fatigue, and often by an upper respiratory tract infection. It has been found to occur seasonally with the highest incidence in the summer months, which coincide with the peak incidence of enterovirus (echovirus, Coxsackie virus A and B) infection [26]. During mumps epidemics the incidence of subacute thyroiditis has reported to increase. Interestingly, antibodies to the mumps virus have been detected in patients with subacute thyroiditis who do not have clinical evidence of mumps. Subacute thyroiditis has also been associated with measles, influenza, the common cold, adenovirus, infectious

mononucleosis, Coxsackie virus, myocarditis, cat-scratch fever, St Louis encephalitis, hepatitis A, and the parvovirus B19 infection. Antibodies to Coxsackie virus, adenovirus, influenza, and mumps have been detected in the convalescent phase of this disease [27]. Coxsackie virus is most commonly associated with subacute thyroiditis and, in fact, Coxsackie virus antibody titres have been shown to directly follow the course of the thyroid disease [26].

Autoimmune Association

Unlike painless sporadic or postpartum thyroiditis, there is no clear association between subacute thyroiditis and thyroid autoimmunity. Serum thyroid peroxidase and thyroglobulin antibody levels are usually normal. When present, antithyroid antibodies are thought to represent a transient, non-specific response to the release of thyroid antigens rather than being causal [28].

Antibodies to the thyrotropin (TSH) receptor have been detected in some patients during the course of subacute thyroiditis [29]. Although most studies have reported no correlation between the presence of thyrotropin-receptor-binding inhibitory or thyrotropin-receptor-stimulating antibodies and the thyrotoxic phase of the thyroiditis, thyroid-blocking antibodies may be associated with the development of hypothyroidism. It is thought that the appearance of the TSH receptor antibodies results from an immune response that occurs after there is damage to the thyrocytes, specifically membrane desquamation. Following recovery from the inflammatory process of subacute thyroiditis, all immunological phenomena disappear [28].

Genetic Association

There is likely a genetic predisposition for subacute thyroiditis, an association with HLA-Bw35 having been reported in multiple ethnic groups [30, 31]. A case of simultaneous development of subacute thyroiditis in identical twins, both heterozygous for the HLA-Bw35 haplotype, has been described [32]. Other genes may also be implicated, as for example, in the case of an epidemic of 'atypical' subacute thyroiditis described in Netherlands in which HLA-B15/62 was found in five of the 11 patients tested, while only one patient tested positive for HLA-Bw35 [33]. In addition, a weak association of subacute thyroiditis with HLA-DRw8 has been reported in Japanese patients [34].

Pathology

Destruction of the follicular epithelium and loss of follicular integrity are typically seen on pathological examination. The histopathological changes differ from those seen in Hashimoto's thyroiditis (**Figure 3.2.6.1b**). Lesions may be of varying stages of development and are patchy in distribution, with infiltration of mononuclear cells in affected regions, partial or complete loss of colloid, and fragmentation and duplication of the basement membrane [35]. Macrophages congregate around masses of colloid, both within the follicles and in the interstitial tissues, producing so-called giant cells that are the hallmark of subacute thyroiditis. True giant cells and granulomas do appear in this disorder as well.

During recovery, the inflammation regresses and there is a variable amount of fibrosis and fibrotic band formation. Follicular regeneration occurs without caseation, haemorrhage, or calcification. Recovery is generally complete. Only in very rare instances does complete destruction of the thyroid parenchyma lead to permanent hypothyroidism. In the few electron microscope studies reported, viral inclusion bodies have not been demonstrated [35].

Clinical Features

The manifestations may be preceded by an upper respiratory tract infection, or a prodromal phase of malaise, generalized myalgias, pharyngitis, and low-grade fevers [36]. Pain or swelling in the thyroid region usually develops 2–4 weeks later, accompanied by higher fever; approximately 50% of patients will have symptoms of thyrotoxicosis [1]. Pain and tenderness may be moderate or severe (or even exquisite). Involvement may in occur in both lobes simultaneously, or may move from one lobe to the other. Pain may radiate from the thyroid up to the angle of the jaw, to the ear, or to the anterior chest. Pain is often worsened by head movements, swallowing, or coughing. Although some patients have no systemic symptoms, many complain of myalgias, fatigue, extreme malaise, and diffuse arthralgia. The systemic reaction may be minimal or severe, and fever may be as high as 40°C. Rarely, subacute thyroiditis presents as a non-tender solitary nodule.

On physical examination, patients appear uncomfortable. The thyroid will be exquisitely tender to palpation over one or both lobes, will feel firm, and may contain palpable nodules. Overlying skin is occasionally warm and erythematous. Cervical lymphadenopathy is not typically present. While most patients are only mildly to moderately ill, subacute thyroiditis occasionally presents with marked fever, severe thyrotoxicosis, and obstructive symptoms due to pronounced thyroid inflammation and oedema.

Laboratory Evaluation

During the painful phase, the hallmark of subacute thyroiditis is an elevated erythrocyte sedimentation rate (ESR), often markedly so. In fact, a normal ESR makes the diagnosis of subacute thyroiditis unlikely. The white blood cell count is normal or mildly increased. There may be a normochromic normocytic anaemia. There are also increases in serum ferritin, soluble intercellular adhesion molecule-1, selectin, interleukin-6 levels, and C-reactive protein during the inflammatory phase [37–40]. Alkaline phosphatase and other hepatic enzymes may be elevated in the early phase [41]. It has been suggested that subacute thyroiditis may actually represent a multisystem disease also affecting the thyroid.

The thyrotoxic phase is caused by leakage of preformed thyroid hormone from the damaged thyroid gland into the circulation, a stage typically lasting from 2 to 4 months. In about one-third of patients, the initial phase is followed by a subsequent hypothyroid phase during which stored intrathyroidal hormone is depleted, but the gland has not recovered sufficiently to resume normal thyroid hormone synthesis [36]. In the thyrotoxic phase, the serum T_4 concentration will be disproportionately elevated relative to the serum T_3 concentration, with a ratio >20:1, reflecting the intrathyroidal T_4 and T_3 stores [42]. The acute illness likely also decreases the peripheral deiodination of T_4 to T_3, resulting in lower-than-expected serum T_3 concentrations. Serum TSH concentrations will be low to undetectable. Antibodies directed against thyroglobulin and TPO are either absent or present at low levels; these develop several weeks after disease onset and tend to disappear thereafter.

The radioactive iodine uptake during the thyrotoxic phase is low, usually <2% at 24 h. A normal radioactive iodine uptake during the thyrotoxic phase of the illness essentially rules out subacute thyroiditis as a diagnosis [43]. Ultrasound examination may show generalized, multiple, or single regions of hypoechogenicity [44] that can masquerade as nodules

Diagnosis

Subacute thyroiditis must be differentiated from the other aetiologies for anterior neck pain, including acute haemorrhage into a nodule or cyst, infectious thyroiditis, and rapidly enlarging thyroid carcinoma. Painful Hashimoto's thyroiditis usually involves the entire gland, with high titres of TPO and thyroglobulin antibodies. Infectious thyroiditis typically presents with a much greater leukocytosis, more inflammation in tissues surrounding the thyroid, and often evidence for extrathyroidal systemic infection. The radioactive iodine uptake is usually normal in infectious thyroiditis and the scan will reveal decreased uptake in the region of suppuration.

Rarely, rapidly infiltrating cancer of the thyroid can present with a clinical and laboratory evidence indistinguishable from subacute thyroiditis, requiring fine-needle aspiration biopsy for the diagnosis. Amiodarone may cause thyroiditis which is occasionally painful. Both sporadic silent and postpartum thyroiditis follow a similar clinical course as subacute thyroiditis but lack the clinical feature of a painful goitre. In addition, patients with painless or postpartum thyroiditis often exhibit high titres of TPO antibodies and the ESR is normal to only slightly elevated. Fine-needle aspiration biopsies may occasionally be useful to exclude other diagnoses; typical findings include follicular epithelial cells showing degenerative changes on a background of cellular debris, lymphocytes, and large numbers of macrophages [45, 46]. However, caution is occasionally needed in interpreting cytology, since the atypical cells produced by the acute inflammation may be read as papillary carcinoma [47]. Since papillary cancer is rarely an emergency, waiting 1–3 months and repeating an ultrasound may demonstrate regression of the nodule that is consistent with subacute thyroiditis rather than papillary cancer.

Course and Management

Despite the differing aetiologies, the clinical course of subacute thyroiditis is similar to that of painless sporadic and postpartum thyroiditis (see Chapter 9.4). The initial phase is characterized by pain and thyrotoxicosis in most patients and may last up to 3–4 months. Symptoms of thyrotoxicosis are usually mild, likely due to the relatively low levels of serum T3. If thyrotoxic symptoms are present, β -adrenergic blocking drugs such as propranolol or atenolol are may be used. Antithyroid drugs are contraindicated in the management of subacute thyroiditis because the gland is not hyperfunctioning.

Salicylates and non-steroidal anti-inflammatory drugs can be used for the management of thyroid pain in mild to moderate cases. In more severe cases, oral glucocorticoids provide relief of pain and swelling, usually within 24–48 hours [48]. A starting dose of 40 mg of prednisone has typically been recommended, although a recent study suggested that doses as low as 15 mg/day prednisolone may be effective for most patients, as long as the dose is tapered slowly [49]. In fact, if pain fails to begin to improve after the first 24 hours of glucocorticoid therapy, the diagnosis of subacute thyroiditis should be questioned. Despite the clinical response to corticosteroids, the underlying inflammatory process may persist, and symptoms are likely to recur if the dose is tapered too rapidly. Up to one-third of patients will have recurrent thyroid pain upon discontinuation of prednisone, which responds to restarting the corticosteroid. Full-dose corticosteroids are given for a week, followed by tapering of the dose over at least 4 weeks.

Determining the radioactive iodine uptake before discontinuation of glucocorticoids may be helpful in identifying patients at high risk for relapse. If the radioactive iodine uptake is still low, the inflammatory process is ongoing and corticosteroids should not be stopped. However, once the radioactive iodine uptake has normalized, the corticosteroid can be withdrawn safely. Patients with exacerbations of symptoms after withdrawal or tapering of corticosteroids usually respond to restarting or increasing the corticosteroids for an additional few weeks. While subacute thyroiditis is a self-limited disease and the vast majority of patients respond to the measures just discussed, occasional patients have repeated exacerbations of pain and inflammation.

The acute phase is frequently followed by a period of transient (1–2 months) asymptomatic euthyroidism. Hypothyroidism, lasting for up to 6–9 months, may be the final phase before full recovery. Hypothyroidism may be permanent in up to 5% of patients. Relapse of subacute thyroiditis is rare, occurring in less than 1–4% of patients [50]. However, some patients with a history of subacute thyroiditis were found to be particularly sensitive to the inhibitory effects of exogenously administered iodides, suggesting a persistent thyroid abnormality [51]. Thus, long-term follow-up of patients after an episode of subacute thyroiditis is recommended.

Infectious Thyroiditis

Infectious thyroiditis is also known as acute thyroiditis, suppurative thyroiditis, bacterial thyroiditis, and pyogenic thyroiditis (Table 3.2.6.1). Bacterial infections of the thyroid are rare, with only 224 cases having been reported in the literature from 1900 to 1980 [52] and only 60 cases reported in the paediatric literature [53]. Bacterial infections are the aetiology of most cases of infectious thyroiditis and the infections are generally suppurative and acute. Infectious thyroiditis caused by fungal and parasitic infections are more frequently chronic and indolent. In this section, emphasis will be placed on bacterial infections.

Aetiology and Pathogenesis

The thyroid gland's high iodine content, significant vascularity, lymphatic drainage, as well as its protective capsule provide the thyroid gland with notable resistance to infection [54]. The most common predisposing factor to infections of the thyroid appears to be pre-existing thyroid disease. Simple goitre, nodular goitre, Hashimoto's thyroiditis, or thyroid carcinoma has been observed in up to two-thirds of women and one-half of men with infectious thyroiditis [52]. Patients with HIV infection are a population particularly at risk for bacterial thyroiditis [55]. As with other opportunistic infections in patients with HIV infection, infections of the thyroid gland are often chronic and insidious in onset.

Table 3.2.6.2 Pathogenesis of acute suppurative thyroiditis

Organism	Frequency (%)	
	Prior to 1983 [52]	Current [54]
Bacterial	68	76
Parasitic	15	15
Mycobacterial	9	9
Fungal	5	<1
Syphilitic	3	0

In the adult, *Staphylococcus aureus* and *Streptococcus pyogenes* are the offending pathogens in about 40% of patients [54] (Table 3.2.6.2). In children, α - and β -haemolytic streptococcus and a variety of anaerobes account for about 70% of cases, while mixed pathogens are identified in over 50% of cases [53]. In comparison to an earlier review examining all reported cases of suppurative thyroiditis up until 1983 [56], the most recent review [53] reports that fungal infections are exceedingly rare and syphilitic infections have not been recently reported. Cases of thyroidal infections with methicillin-resistant *Staphylococcus aureus* (MRSA) have been reported [57]. Other thyroidal bacterial pathogens that have been shown to cause infectious thyroiditis include *Salmonella Actinomyces, Actinobacillus actinomycetemcomitans, Brucella melitensis, Clostridium septicum, Eikenella corrodens, Enterobacter, Escherichia coli, Haemophilus influenzae, Klebsiella, Pseudomonas aeruginosa, Serratia marcescens*, and *Acinetobacter baumannii* [54].

Infection and suppuration may result from direct spread from a nearby infection, or via the bloodstream or lymphatics. The seminal observation regarding the pathogenesis of bacterial thyroiditis was made in 1979 when Takai *et al.* reported seven cases of infectious thyroiditis due to a fistula originating from the left pyriform sinus [58]. Subsequently, multiple case series of patients with infectious thyroiditis have described pyriform sinus fistulae, primarily left-sided, especially in those with recurrent episodes. Additional reports identified infected embryonic cysts from the third and fourth brachial pouches and thyroglossal duct cysts as routes of thyroidal infection. On pathological examination, characteristic changes of acute bacterial inflammation, including necrosis and abscess formation, are frequently seen.

Clinical Manifestations

Bacterial thyroiditis is often preceded by an upper respiratory tract infection, which may induce inflammation of the fistula and promote the transmission of pathogens to the thyroid. Consistent with these observations, bacterial thyroiditis is more common in the late autumn and late spring. Over 90% of patients will present with thyroidal pain, tenderness, fever, and local compression resulting in dysphagia and dysphonia; the pain is often referred diffusely to adjacent structures. Systemic symptoms such as fever, chills, tachycardia, and malaise may be present.

Laboratory and Radiologic Findings

Thyroid function tests are usually normal [59]; however, cases of hypothyroidism and thyrotoxicosis have been reported and thyroid function should be assessed. A nuclear medicine thyroid scan may show the suppurative region as a 'cold' area, whereas an ultrasound examination may demonstrate a hypoechoic lesion [60]. The polymorphonuclear leucocyte count and the sedimentation rate are usually elevated. The organism frequently can be identified by Gram's stain and culture.

Diagnosis

The diagnosis is made with a fine-needle aspiration, Gram's stain, and culture. Symptomatically, infectious thyroiditis may be difficult to differentiate from subacute thyroiditis in the early phases, although the characteristic thyroid function changes in the latter disease should be helpful in discriminating between the two. Leucocytosis and an elevated ESR are not discriminatory tests as they are commonly observed in both subacute thyroiditis and infectious thyroiditis. In general, patients with bacterial thyroiditis have a greater febrile response than those with subacute thyroiditis. Once abscess formation has occurred, the local redness, lymphadenopathy, hyperpyrexia, and leucocytosis should lead to the correct diagnosis. Malignant neoplasms and haemorrhages into cysts may sometimes present with manifestations that mimic this disorder.

Course and Management

The prognosis of bacterial thyroiditis is often dependent on the prompt recognition and treatment of this disorder, as mortality may approach 100% if the diagnosis is delayed and appropriate antimicrobial therapy is not instituted. Much depends upon the identification of the microorganism either from needle aspirate, incision, and drainage, or occasionally from blood culture. If no organisms are seen on the Gram's stain, nafcillin and gentamicin or a third-generation cephalosporin is appropriate initial therapy in adults while clindamycin or a penicillin with a β-lactamase inhibitor is reasonable in children. If an abscess develops and prompt response to antibiotics does not occur, incision and drainage is necessary. Sometimes partial lobectomy must be performed, especially if the disease is recurrent. Usually the lesions heal with reasonable speed after initiation of the correct antimicrobial agent, and recurrences are uncommon. Mortality from acute bacterial thyroiditis has markedly improved from the 20–25% reported in the early 1900s, with an extensive review by Berger estimating an overall mortality of 8.6% [52]. A ten-year review involving over 100 patients failed to list mortality as a complication of acute bacterial thyroiditis [61].

Sclerosing Thyroiditis (Riedel's Thyroiditis)

Sclerosing thyroiditis is also historically known as invasive fibrous thyroiditis, Riedel's thyroiditis, struma fibrosa, and chronic fibrous thyroiditis. In 2011 it was linked to the newly-described entity immunoglobulin G4 (IgG4)-related disease, a systemic disorder that also includes other manifestations such as hypophysitis, parotid and lacrimal gland enlargement, interstitial pneumonitis, interstitial nephritis, retroperitoneal fibrosis, prostatitis, autoimmune pancreatitis, lymphadenopathy, inflammatory aortic aneurysm, and inflammatory pseudotumor [62]. Sclerosing thyroiditis is a rare disorder of unknown cause, characterized pathologically by dense fibrous tissue which replaces the normal thyroid parenchyma and extends into adjacent tissues, such as muscles, parathyroid glands, blood vessels, and nerves [63] (Table 3.2.6.1). The first report by Riedel in 1896 described cases of chronic sclerosing thyroiditis, primarily

affecting women, which frequently caused pressure symptoms in the neck and tended to progress ultimately to complete destruction of the thyroid gland. Riedel's interesting description was that of a 'specific inflammation of mysterious nature producing an iron-hard tumefaction of the thyroid' [64].

This condition is quite rare. Among thyroidectomies performed for all disorders, an incidence between 0.03 and 0.98% has been reported. At the Mayo Clinic, the operative incidence over 64 years was 0.06%, and the incidence in outpatients was 1.06/100 000 [65]. Because the manifestations frequently lead to surgery, the incidence of invasive fibrous thyroiditis among patients undergoing thyroidectomy is much greater than the incidence in patients with goitres in general.

Aetiology

The cause of this disorder remains unknown. Thyroid antibodies have been reported in 67–90% of patients [63, 66]. This observation, in addition to the presence of both B and T cells in the inflammatory infiltrate, suggests a possible autoimmune mechanism, although no direct relationship has been shown. Patients with concomitant invasive fibrous thyroiditis and autoimmune diseases such as type 1 diabetes mellitus, pernicious anaemia, and Addison's disease have been reported [67–69]. The expression of HLA-DR, heat-shock protein (HSP72), and soluble intercell adhesion molecule-1 (ICAM-1) receptor in invasive fibrous thyroiditis tissue suggests a role for an active cell-mediated immune response early in the evolution of this condition [70].

Marked tissue eosinophilia and eosinophil degranulation have been observed in Riedel's struma [71]. These findings may suggest that the release of eosinophil-derived products may play a role in the fibrogenic stimulus. The nature of these products is not yet known.

Whatever the ultimate aetiology is, it will have to account for the extrathyroidal fibrosclerosis and other manifestations of IgG4-related disease as well. Areas of extrathyroidal fibrosclerosis include salivary gland fibrosis, sclerosing cholangitis, pseudo tumours of the orbits, fibrous mediastinitis, retroperitoneal fibrosis, and lachrymal gland fibrosis. Long-term follow-up of patients with invasive fibrous thyroiditis has shown that about one-third develop fibrosing disorders of the retroperitoneal space (often with ureteral obstruction), chest, or orbit, almost always with a single extracervical site involved [72]. Conversely, less than 1% of patients with retroperitoneal fibrosis have invasive fibrous thyroiditis. The association of certain drugs with retroperitoneal fibrosis has not been observed with invasive fibrous thyroiditis. There does not seem to be a genetic predisposition for this condition.

Clinical Features

The age of onset varies between 25 and 81 years, although most cases are diagnosed in the fourth to sixth decades. The female to male ratio is about 4:1 [72, 73].

The clinical presentation is of a painless goitre that is gradually or rapidly enlarging; constitutional symptoms of inflammation are rare. The extensive fibrosis is progressive and may eventually cause compression of adjacent structures, particularly the trachea and oesophagus. Local compressive symptoms include a marked sense of pressure or severe dyspnoea, with symptoms out of proportion to the size of the goitre. Hoarseness may result if there is involvement of the recurrent laryngeal nerve. In some patients, the fibrotic process affects the entire gland causing hypothyroidism; the prevalence of hypothyroidism in this population is between 25 and 80% [63]. Hypoparathyroidism can develop when parathyroid gland infiltration occurs [72].

On examination, the thyroid gland is stony hard, often described as 'woody' in texture, densely adherent to adjacent cervical structures (such as muscles, blood vessels, and nerves), and may move poorly on swallowing. The lesion may be limited to one lobe. It has a harder consistency than a carcinoma and is usually non-tender. Although adjacent lymph nodes are only occasionally enlarged, when they are present a diagnosis of carcinoma is often suspected.

Laboratory and Radiologic Findings

At presentation, most patients with Riedel's thyroiditis are euthyroid; however, as noted earlier, some patients do develop hypothyroidism. Thyroid antibodies may be detected in the majority of these patients. Calcium and phosphorus levels should be evaluated at presentation to identify those patients who also have concurrent hypoparathyroidism. Thyroid radionuclide imaging can show either a heterogeneous pattern or low isotope uptake; the 'cold' areas reflect the fibrosis. The extent of the fibrosis can best be determined on either CT or MRI; the affected regions appear homogeneous and hypointense on T_1- and T_2-weighted MRI images [74]. Ultrasound examinations can be helpful as the areas affected appear hypoechoic; on colour flow Doppler, the fibrotic areas are avascular. 18F-FDG PET-CT will show intense uptake in areas of fibrotic inflammation and can be used to evaluate for the presence of extrathyroidal disease manifestations [75]. The white blood cell count and sedimentation rate are usually normal, but can be elevated. In IgG4-related disease serum IgG4 levels are typically >135 mg/dL, and levels correlate with the number of involved organs [62].

Pathology consists of an exuberant fibrosis involving part of or the entire thyroid [63]. Fibrotic extension beyond the capsule of the thyroid into adjacent structures such as nerves, blood vessels, muscles, parathyroid glands, trachea, and oesophagus is characteristic. Pathological diagnostic criteria for this condition includes complete destruction of involved thyroid tissue with absence of normal lobulation, lack of a granulomatous reaction, and extension of the fibrosis beyond the thyroid into adjacent muscle, nerves, blood vessels, and adipose. Histological examination reveals almost no thyroid follicles and few plasma cells, eosinophils, and Hürthle cells. Lymphocytes are also sparse, in contrast to the findings in Hashimoto's thyroiditis, although occasionally a few foci of lymphocytes may be observed. An associated arteritis and phlebitis with intimal proliferation, medial destruction, adventitial inflammation, and thrombosis may also occur. Similar features are observed in the extracervical fibrosclerotic lesions, retroperitoneal and mediastinal regions, orbit, and lachrymal glands, and in sclerosing cholangitis.

Diagnosis and Treatment

The diagnosis is made by biopsy of the goitre in order to differentiate this disorder from carcinoma. However, a fine-needle aspiration biopsy is usually inadequate due to the extreme hardness of the gland and, thus, an open biopsy is often required.

Treatment of Riedel's thyroiditis is surgical to relieve compressive symptoms. Extensive resection is often impossible due to fibrosis of surrounding structures, but wedge resection, especially over the isthmus to relieve tracheal compression, is often extremely effective.

Despite its invasive nature, recurrences of obstruction after resection are rare. Thyroid hormone therapy is indicated only if hypothyroidism is present, as suppression therapy is ineffective. Calcium and vitamin D therapy is indicated in those patients with associated hypoparathyroidism. There have been several reports of disease improvement with glucocorticoid therapy, and relapses have reversed with the reinstitution of steroids; however, it has not been helpful in all instances [63]. Tamoxifen has been reported to cause disease regression in a few case reports. Its mechanism of action is unclear; however, it may play a role in fibroblastic proliferation inhibition [76]. A small open-label trial demonstrated that rituximab treatment for patients with IgG4-related disease is associated with clinical improvement in the majority and remission in up to half [77].

Prognosis

Riedel's thyroiditis is usually slowly progressive; however, it may stabilize or remit spontaneously. Mortality rates range from 6% to 10%, with deaths usually attributed to asphyxia secondary to tracheal compression or laryngospasm [66]. However, these mortality rates are derived from older literature, and may not reflect (the presumably lower) current rates. In many instances, the condition is self-limiting, and improvement often persists after isthmic wedge resection. Following surgery, the disease can remit or be self-limiting. Repeat surgery is only rarely required.

3.3

Thyrotoxicosis and Related Disorders

3.3.1 Clinical Assessment and Systemic Manifestations of Thyrotoxicosis

Claudio Marcocci and Filomena Cetani

Introduction

The term thyrotoxicosis refers to the clinical syndrome due to excessive serum concentrations of free thyroxine, free triiodothyronine, or both. The term hyperthyroidism is used to mean sustained increases in hormone biosynthesis and secretion by the thyroid gland, being Graves' disease the most common. Other causes responsible for thyrotoxicosis are destructive thyroiditis, excessive ingestion of thyroid hormones, or secretion of thyroid hormones from ectopic sites. The various causes of thyrotoxicosis are discussed in Chapter 3.3.5. The clinical features depend on the severity and duration of the disease, the age of the patient, the presence or absence of extrathyroidal manifestations, and the specific thyrotoxic disorder. Older patients have fewer symptoms and signs of sympathetic activation and more symptoms and signs of cardiovascular dysfunction. Rarely a patient with 'apathetic' hyperthyroidism will lack almost all usual clinical manifestations of thyrotoxicosis [1].

All organ systems are affected by thyroid hormone excess (Table 3.3.1.1). In Graves' disease some signs and symptoms are due to extrathyroidal immunological processes rather than the excessive levels of thyroid hormones (Table 3.3.1.2).

Table 3.3.1.1 Systemic effects of thyrotoxicosis

System	Effects
General	Heat intolerance, weight loss, fatigue, insomnia, nervousness, tremulousness
Skin	Fine, warm, and moist, hyperpigmentation, hyperhidrosis, onycholysis, fine and often straight hair, urticaria, pruritus
Eye	Exophthalmos, lid oedema, lid lag, globe lag, chemosis, ophthalmoplegia, optic nerve involvement
Mental	Irritability, restlessness, anxiety, inability to concentrate, lability, depression, psychiatric reactions
Neurological	Syncope, delirium, stupor, coma, choreoathetosis
Cardiovascular	Tachycardia, widened pulse pressure, and bounding pulse. Occasionally cardiomegaly, congestive heart failure, angina pectoris, and paroxysmal tachycardia or atrial fibrillation
Respiratory	Dyspnoea
Gastrointestinal	Hyperphagia, increased thirst, diarrhoea, or increased frequency of stools, hepatomegaly
Neuromuscular	Tremulousness, quickened, and hypermetric reflexes, weakness of proximal muscles, muscle atrophy, myopathy, periodic paralysis
Metabolic	Hypercalcaemia, decreased serum magnesium, increased bone alkaline phosphatase, hypercalciuria
Osseous	Osteopaenia or osteoporosis
Reproductive	Irregular menses or amenorrhoea, gynaecomastia, decreased fertility
Haematopoietic	Anaemia (usually normochromic, normocytic), lymphocytosis, splenomegaly, lymphadenopathy, enlarged thymus

Table 3.3.1.2 Clinical findings in patients with Graves' hyperthyroidism and controls[a]

	Hyperthyroid				Controls			
	Total	Age decades			Total	Age decades		
		2nd	3rd to 5th	6th to 8th		2nd	3rd to 5th	6th to 8th
Number	880	74	635	171	880	79	636	165
Symptoms (%)								
Palpitations	65	58	57	56	13	6	14	10
Increased perspiration	45	39	49	30	7	1	9	3
Heat intolerance	55	49	60	36	8	6	8	8
Weight loss	61	29	60	74	13	6	13	13
Weight gain	12	29	12	5	21	26	21	16
Increased appetite	42	61	12	5	5	9	21	16
Decreased appetite	11	5	10	16	6	6	7	4
Increased number of bowel movements	22	19	22	21	2	6	2	1
Increased appetite with weight loss	24	19	24	20	0	0	0	0
Tiredness	69	62	70	69	41	32	43	37
Irritability	45	47	35	33	18	16	21	10
Nervousness	69	59	71	64	15	11	17	12
Signs (%)								
Fine finger tremor	69	69	70	59	6	5	5	4
Pulse rate 90 beats/min	80	84	80	78	18	21	18	19
Atrial fibrillation[b]	3	0	1	9	–	–	–	–
Thyroid size (× normal)	1.9 ± 0.6	2.4 ± 0.6	2.0 ± 0.6	1.4 ± 0.4	1.3 ± 0.4	1.4 ± 0.6	1.3 ± 0.4	1.3 ± 0.4

[a] Source data from Nordyke RA, Gilbert FI Jr, Harada AS. Graves' disease. Influence of age on clinical findings. *Arch Intern Med*. 1988 Mar;148(3):626–31.
[b] The presence of atrial fibrillation was not assessed in control subjects.

Skin, Hair, and Nails

The skin is usually moist and warm because of vasodilatation, which represents a homeostatic mechanism for dissipating the increased heat generated in the body [2]. The patient may complain of cutaneous flushing, resting perspiration, and sweaty palms. Hyperpigmentation particularly at the knuckles and skin creases may be present. Vitiligo occurs in some patients with Graves' disease and Hashimoto's thyroiditis [3]. Dermographism, urticaria, purpura, and generalized erythematous eruptions may be less frequently observed. Pruritus is rare. The skin changes are reversed after restoration of euthyroidism.

The hair may be fine and soft, and hair loss can be excessive. Alopecia aerate and loss of axillary, pubic, body, and eyebrow hairs are uncommon.

Localizing non-pitting oedema on extensor surfaces, the so-called pretibial myxoedema, may be the hallmark to establish the diagnosis of Graves' disease (Figure 3.3.1.1).

The nails become shiny and may be soft and friable. The rate of nail growth is increased, and longitudinal striations associated with a flattening of the surface contour result in a scoop-shovel appearance. In many patients onycholysis may be present.

Eyes

Upper eyelid retraction, evident as the presence of a rim of sclera between the lid and the limbus, is frequent in all forms of thyrotoxicosis, and is responsible for the bright-eyed 'stare' or 'fish eyes' of the patient (Figure 3.3.1.2) [4]. Lid lag may be present because the upper lid lags behind the globe when the patient is asked to gaze downward; globe lag occurs when the globe lags behind the upper lid when the patient gazes slowly upward. In severe cases the movements of the lids are jerky and spasmodic, and a fine tremor of the lightly closed lids can be observed. It is important to differentiate these manifestations from those of Graves' disease [5] (see Chapters 3.3.9 and 3.3.10).

Thyroid Gland

Thyroid enlargement is usually associated with nodular goitre or Graves' disease (Figure 3.3.1.3a) and may be absent when thyrotoxicosis is due to excessive ingestion of thyroid hormones, unless goitre was present before treatment. An asymmetrical gland is generally found in patients with toxic adenoma or multinodular goitre (Figure 3.3.1.3b), but may occur also in Graves' disease. The pyramidal lobe should always be searched for, since enlargement indicates a diffuse involvement of the thyroid. The marked increase in the blood flow to the thyroid in Graves' disease is reflected clinically by the presence of a bruit or a thrill. Colour flow Doppler sonography shows hypervascularity and increased peak systolic velocity [6].

Respiratory System

Respiratory features are reported in Box 3.3.1.1. The frequency and the relative relevance of these changes is uncertain because available

Box 3.3.1.1 Respiratory changes in thyrotoxicosis

- Dyspnoea
- Respiratory muscle weakness
- Decreased vital capacity
- Decreased pulmonary compliance
- Increased ventilation
- Increased oxygen uptake
- Pulmonary artery dilatation and hypertension
- Increased carbon dioxide production
- Increased ventilatory response to hypercapnia

data are scarce and often conflicting. The increased metabolic rate stresses the lung, requiring a more rapid net rate of gas exchange to accommodate the increased oxygen consumption and carbon dioxide production [7]. Dyspnoea is present in patients with severe thyrotoxicosis [8] and is due to respiratory muscle weakness, reduction of vital capacity, decreased pulmonary compliance, and increase in respiratory dead space ventilation.

An atopic background, with elevated serum immunoglobulin E levels has been found in 30% of patients with Graves' hyperthyroidism [9].

A decrease of residual volume and vital and total lung capacities was early reported in a quarter of patients [8]. More recently, no significant differences in the mean baseline vital and total lung capacities, residual volume, static compliance, or pressure–volume curves between patients and controls have been reported [9].

Lung compliance may be altered by changes in the elastic properties or by vascular engorgement. Manifestations of respiratory muscle dysfunction include rapid, shallow respirations, respiratory dyskinesia, hypoventilation, respiratory acidosis, and easy fatigability [10]. Most patients with overt thyrotoxicosis have diminished proximal muscle strength. Chronic thyrotoxic myopathy affects the diaphragm and other respiratory muscles in up to 50% of severely affected patients, causing loss of maximal respiratory muscle power.

Thyrotoxicosis may affect the central regulatory response to a blood gas perturbation. This abnormality can be revealed by evaluating the increase of ventilation while breathing either a hyperoxic hypercapnic or a hypoxic isocapnic gas mixture. The mechanisms of these changes are not completely understood. Thyrotoxicosis, by increasing the ventilatory drive superimposed on underlying lung disease, may worsen dyspnoea and cause respiratory failure.

Resting heart rate, cardiac output, respiratory rate, and minute ventilation are increased [9]. The amount of oxygen required to perform any workload is increased. Pulmonary artery pressures of patients may rise more than usual with exercise, but this has not been evaluated carefully. Exercise normally decreases the mixed venous oxygen saturation and the dead space/tidal volume ratio; the opposite occurs in thyrotoxicosis.

Cardiac changes may affect the lungs either by pulmonary artery dilatation or by high-output cardiac failure [11]. The findings of an accentuated pulmonary second heart sound and a right ventricular heave suggest pulmonary hypertension with an increased risk of heart failure in 6–16% of thyrotoxic patients [11]. The exact pathogenesis remains unknown. Some patients may have symptomatic pulmonary hypertension that normalizes by restoring euthyroidism [11].

Mild increases of resting pulmonary artery pressure are common, and the pressure frequently rises significantly during exercise. A physical sign of thyrotoxicosis is the Means–Lerman sign, a scratchy coarse systolic ejection rub or murmur that is heard best along the left sternal border at the base of the heart.

Renal System

Most of the renal effects of thyrotoxicosis produce no symptoms except mild polyuria [12].

Renal plasma flow and glomerular filtration rate (GFR) are increased, probably because of the increase in cardiac output and decrease in peripheral resistance [12]. Intrarenal vasodilatation also occurs. The 24-h urine creatinine is significantly lower in thyrotoxic patients compared to normal subjects, likely because of loss of muscle mass and it occurs despite an increase in urea clearance. These changes normalized when the euthyroidism is restored.

Renal tubular mass is increased, and the morphological changes are accompanied by an increased renal tubular transport capacity. An activation of the renin–angiotensin system contributes to cardiac hypertrophy in these patients [13]. Serum cystatin C (CysC) levels are higher despite an increase in GFR. Thyroid hormone acting on general metabolism may influence the production rate of CysC, therefore thyroid status must be considered in the measurement of renal function using CysC equation [14].

Thyrotoxic patients rarely have abnormalities in water metabolism. Serum electrolytes are usually normal. Some patients have polydipsia and polyuria (up to 3–4 litres daily) that revert to normal after achieving euthyroidism.

Plasma atrial natriuretic hormone levels and renin activity are increased with no clinical consequences except for mild oedema. The total amount of exchangeable potassium is decreased, and the amount of exchangeable sodium tends to be increased. The level of exchangeable magnesium concentration is often decreased, and urinary magnesium is increased.

Renal tubular acidosis occasionally occurs and there is a failure to achieve maximal urinary acidification. It may occur in Graves' disease, also in the absence of nephrocalcinosis, and may persist after restoration of the euthyroid state. This condition may have an autoimmune basis [15].

Pitting oedema, involving legs, hands, ankles, and sacrum, may occur in thyrotoxic patients, because of renal salt and water retention in response to the reduction in effective arterial volume. Renal and salt retention contributes to an increase in blood volume and venous pressure.

Gastrointestinal System

The classic manifestations are rapid intestinal transit, increased frequency of semiformed stools, and weight loss from increased caloric requirement or malabsorption [16]. The mechanism underlying the gastrointestinal hypermotility has not been elucidated, but it disappears when euthyroidism is restored. An increase in appetite is common, but rarely seen in patients with mild disease. In severe disease, the increased food intake is usually inadequate to meet the increased caloric requirements, and variable weight loss occurs. Anorexia may occur in patients with severe thyrotoxicosis,

and in about one-third of elderly patients, where it contributes to the 'apathetic' picture.

Graves' disease may be associated with other autoimmune diseases, namely coeliac disease, atrophic gastritis, with or without pernicious anaemia.

The combination of biochemical thyrotoxicosis and persistent vomiting is also common in the context of hyperemesis gravidarum, often occurring in the first trimester of pregnancy. This self-limiting disorder, termed transient gestational hyperthyroidism, results from stimulation of thyroid-stimulating hormone (TSH) receptors by high levels of human chorionic gonadotrophin (hCG) produced by the placenta. This effect is due to the α-subunit homology between hCG and TSH [16].

Hepatic function may be altered, particularly when the disease is severe [16]; hypoproteinaemia and increased serum alkaline phosphatase and transaminase levels may be present.

Hepatic damage is usually self-limiting, but fulminant hepatitis has previously been described, precipitated by congestive cardiac failure and arrhythmia [16]. Histological hepatic changes are usually non-specific, but progressive liver damage with centrizonal necrosis and perivenular fibrosis and intrahepatic cholestasis have also been described.

In severe cases hepatomegaly and jaundice may occur. Graves' disease and autoimmune hepatitis coexist more often than can be expected by chance.

Liver disease is reversible in the vast majority of cases with restoration of euthyroidism [16].

Nervous System

Hyperactivity, emotional lability, distractibility, and anxiety may reflect changes in the nervous system, but the pathogenic mechanisms remain obscure [17]. Examination reveals a fine rhythmic tremor of the hands, tongue, and eyelids when slightly closed. Emotional lability causes patients to lose their tempers easily and to have episodes of crying without apparent reason. Rarely mental disturbance may be severe. Fatigue is due either to muscle weakness or to insomnia, which is frequently present.

Persistent fine tremor is the most prominent finding and may involves the hands, but also the feet, chin, lips, and tongue. Chorea seldom appears as a manifestation of thyrotoxicosis. Thyrotoxic crisis may rarely lead to coma and status epilepticus.

The electroencephalogram of most patients reveals increased fast-wave activity. The basal metabolic rate tends to correlate with the frequency of brain waves, but at the extremes of thyroid abnormality the correlation is frequently poor.

Muscle

Muscle weakness and fatigue are frequent [18]. Weakness is often most prominent in the proximal muscles of the limbs [18]. Occasionally, in severe untreated cases, muscle wasting occurs as a predominant feature (thyrotoxic myopathy). In extreme forms, the patient may be unable to rise from a sitting or lying position and may be unable to walk.

Muscle manifestations affect men more commonly than women. The involvement of ocular muscles may mimic myasthenia gravis. Graves' disease occurs in about 3–5% of patients with myasthenia gravis, and about 1% of patients with Graves' disease develop myasthenia gravis [19]. Hypokalaemic periodic paralysis may be associated with thyrotoxicosis and is characterized by sporadic attacks, most commonly involving flaccidity and paralysis of either legs, arms, or trunk, even though any muscle can be involved [19]. Hypokalaemic periodic paralysis is most frequent in Asian populations (see Chapter 3.3.2).

Whether patients with thyrotoxic periodic paralysis have an underlying genetic predisposition, compared with patients with non-thyrotoxic periodic paralysis is unknown. Familial hypokalaemic periodic paralysis has been associated with mutations of skeletal muscle calcium channel (CACNA1S), sodium channel (SCN4A), and voltage-gated potassium channel (KCNE3) [20]. However, such associations have not been found in patients with thyrotoxic periodic paralysis, except for one patient harbouring a KCNE3 mutation [21].

Skeletal System: Calcium and Phosphorus Metabolism

Thyrotoxicosis is associated with an increase of bone turnover and eventually bone loss, especially in postmenopausal women [22]. Patients with a long-standing history of thyrotoxicosis may have overt osteoporosis and an increased risk of fractures [23].

Bone turnover is increased, but the increase in bone resorption is relatively greater than that of bone formation; the urinary excretion of calcium, phosphorus, and hydroxyproline is increased [22]. Total and particularly ionized serum calcium may be slightly increased in as many as 27% and 47% of patients. Alkaline phosphatase and osteocalcin levels are also frequently increased [24]. Parathyroid hormone (PTH) and 1,25 dihydroxyvitamin D levels tend to be low as a result of the increased calcium released from bone. The alterations in bone metabolism are reversed when euthyroidism is restored [24, 25].

Thyrotoxicosis is a well-known risk factors for osteoporosis [22]. Thyroid hormone action on osteoblasts accounts for the increased circulating levels of alkaline phosphatase and osteocalcin. Despite the increased mineralization rate and osteoblastic activity, the increased bone formation cannot compensate for increments in bone resorption, and bone mass may be decreased. The pathological changes may include osteoporosis, osteomalacia, and osteitis fibrosa. A recent meta-analysis has shown that subclinical hyperthyroidism is also associated with femoral neck bone loss and potentially increased fracture risk [26]. Restoration of euthyroidism may reverse bone density in premenopausal [27] but not in postmenopausal women.

The skeletal effects of thyroid hormone replacement are unclear. Recently, some reports suggested that patients receiving chronic L-thyroxine treatment, particularly in doses that suppress TSH secretion may have a reduced bone mass [28]. Other studies [29, 30] suggested that L-thyroxine suppressive therapy, if carried out carefully and monitored, using the smallest suppressive dose, has no significant effect on bone mass, at least in premenopausal women

and in men, whereas in postmenopausal women some degree of bone loss can be observed. A recent cross-sectional study evaluated the prevalence and determinants of radiological vertebral fractures in women receiving L-thyroxine therapy for differentiated thyroid cancer. Vertebral fractures were found in 51 patients (28.5%), with significantly higher prevalence in patients with undetectable TSH ((44.6%) as compared with patients with TSH between 0.5 and 1.0 mU/L (24.0%) and >1 mU/L (4.3%) [31].

Thyroid acropachy, namely clubbing, periostitis, and swelling at peripheral sites occurs in approximately 1% of patients with Graves' disease, and is always associated with exophthalmos and pretibial myxoedema [32].

Haematopoietic System

In most patients the red blood cell mass is increased either for a direct effect of thyroid hormones on the erythroid marrow or an increased production of erythropoietin [33]. A parallel increase in plasma volume also occurs, and therefore the haematocrit value is normal.

Microcytosis may occur in about 37% of patients and usually resolves with the restoration of euthyroidism. Patients with severe thyrotoxicosis may develop a normocytic anaemia and less frequently iron deficiency anaemia.

Approximately 3% of patients with Graves' disease have pernicious anaemia, and a further 3% have antibodies to intrinsic factor but normal absorption of vitamin B_{12}. Autoantibodies against gastric parietal cells are present in about one-third of patients with Graves' disease, and the requirements for vitamin B_{12} and folic acid appear to be increased.

The total white blood cell count is often low because of a decrease in the number of neutrophils. The absolute lymphocyte count is normal or increased, leading to a relative lymphocytosis. A generalized lymphadenopathy may be present, and the spleen may be enlarged in 10% of patients with Graves' disease.

Blood platelets and the intrinsic clotting mechanism are normal. However, the concentration of factor VIII is often increased and returns to normal when thyrotoxicosis is treated. Furthermore, there is an enhanced sensitivity to coumarin anticoagulants because of an accelerated clearance of vitamin K-dependent clotting factors [33].

Cardiovascular System

The cardiovascular manifestations are among the most characteristic symptoms and signs of the disorder (Box 3.3.1.2) [34]. Tissue blood flow is increased in response to accelerated metabolism and increased oxygen consumption. Haemodynamic changes are characterized by an elevated cardiac output and a decreased peripheral vascular resistance. Thyroid hormone itself may be involved directly through its action on the smooth muscle of blood vessels [34]. Moreover, the finding in thyrotoxic patients of elevated levels of plasma adrenomedullin and proadrenomedullin-N-terminal 20-peptide, which have a potent vasodilatory activity, raises the possibility that both might also decrease the vascular resistance [35].

Box 3.3.1.2 Cardiovascular symptoms and signs of thyrotoxicosis

- Palpitations
- Paroxysmal tachycardia
- Orthopnoea
- Exercise intolerance
- Hyperdynamic precordium
- Third heart sound
- Atrial fibrillation
- Widened pulse pressure
- Cardiac flow murmurs

Nearly all patients have tachycardia and a bounding pulse. The common complaint of palpitations usually indicates a resting tachycardia. The heart rate is also elevated during sleep. The heart may be enlarged, but echocardiography is usually normal. In elderly patients the cardiovascular manifestations may be limited to resting tachycardia [36]; other classic thyrotoxic symptoms may be absent.

Thyrotoxic patients may have chest pain similar to that angina pectoris, probably caused by either relative myocardial ischaemia or coronary artery spasm. In elderly patients, however, the increased myocardial oxygen demand due to thyrotoxicosis may unmask coronary artery disease. The plasma level of homocysteine in thyrotoxic patients did not differ significantly from that of controls [34]. Conversely, hyperhomocystinaemia has been found in hypothyroid patients and, combined with lipid abnormalities, may increase the risk of coronary disease [34].

At physical examination tachycardia is the most common findings. Systolic blood pressure is elevated and diastolic blood pressure is decreased [37]; the mean blood pressure is usually normal. An exaggerated increase in systolic blood pressure may be present in older patients due to the loss of elasticity of the larger arteries. Auscultation may reveal a systolic ejection murmur and a gallop rhythm caused by rapid flow of blood through the aortic outflow tract. Systolic murmurs may arise from valve prolapse, left ventricular dilatation, or dysfunction of the mitral valve. A systolic 'scratch' is heard in the pulmonary area corresponding to contact between the pleural and pericardial surfaces during cardiac contraction. Heart failure rarely occurs, unless an underlying cardiac disease is also present [34].

Sinus tachycardia is present in the majority of patients. Cardiac arrhythmias are almost invariably supraventricular. Approximately 10% of patients with thyrotoxicosis have atrial fibrillation, and a similar percentage of patients with unexplained atrial fibrillation are thyrotoxic [34]. Tachycardia may be the presenting symptom of thyrotoxicosis, particularly in older people. In elderly patients with subclinical thyrotoxicosis the risk of persistent atrial fibrillation is approximately three times that of normal subjects [34]. Ventricular premature contractions are rare. Angina pectoris and myocardial infarction may rarely occur in the absence of coronary artery disease.

Thyrotoxicosis itself may cause heart failure in elderly and, much less often, in young patients. Thyrotoxic patients with heart failure are generally old and, therefore, at risk of underlying heart disease. Elderly patients with rhythm disturbances have the greatest risk of heart failure [38]. In young patients, or in the absence of underlying heart disease, the heart failure is thought to be 'high output'

likely due to a circulatory congestion caused by fluid retention. In thyrotoxicosis, cardiac output is near to maximal at rest and cannot increase in response to exercise, stress, surgery, or pregnancy [38]. As a consequence, atrial filling pressures rise, leading to pulmonary and peripheral oedema. This situation may worsen if atrial fibrillation is present. Left ventricular function is impaired because by the persistent tachyarrhythmia. Sustained tachycardia causes abnormal ventricular systolic and diastolic function, which resolves when arrhythmia is treated. β-adrenergic receptor blockade-mediated slowing of the heart rate can rapidly reverse even severe degrees of left ventricular dysfunction in thyrotoxic patients.

Endocrine System

Thyrotoxicosis affects the secretion of most pituitary hormones. Children with thyrotoxicosis grow more rapidly than normal children [39]. The height and bone ages are accelerated, but their relationship remains normal. Growth acceleration suggests that growth hormone (GH) secretion might be greater than normal. Serum GH concentrations, however, are lower in thyrotoxic patients than normal subjects probably due to the increased metabolic clearance rate. Serum IgF1 concentration is higher in thyrotoxic patients and returns to normal after restoration of euthyroidism. Basal secretion of prolactin (PRL) and its response to thyrotropin-releasing hormone (TRH) may also be decreased. No physiological or clinical consequences of these abnormalities are known.

The half-life of cortisol is shortened, but both the number of bursts of adrenocorticotrophic hormone (ACTH) and those of cortisol secretion are increased and maintain serum cortisol levels [40]. A subtle impairment of adrenocortical reserve has been reported in thyrotoxicosis [40]. The plasma concentration of corticosteroid-binding globulin is normal. The urinary excretion of the free cortisol and 17-hydroxycorticosteroids is normal or slightly increased, whereas the urinary excretion of 17-ketosteroids may be reduced [40]. The turnover rate of aldosterone is increased, but its plasma concentration is normal. Plasma renin activity is increased, and sensitivity to angiotensin II is reduced.

β-adrenergic receptor blockade ameliorates most of the cardiovascular manifestations of thyrotoxicosis suggesting that catecholamines play a causative role, but the secretion rate and plasma levels of adrenaline and noradrenaline are normal [41]. The sympathetic hyperactivity appears to be the consequence of a direct effect of thyroid hormones on peripheral tissues. Thyrotoxicosis in early life may cause delayed sexual maturation, although physical development is normal and skeletal growth may be accelerated.

Thyrotoxicosis, after puberty, influences the reproductive function [42], especially in women. An increase in libido occurs in both genders. The intermenstrual interval may be prolonged or shortened, and menstrual flow initially diminishes and ultimately ceases. Fertility may be reduced. In some women, menstrual cycles are predominantly anovulatory with oligomenorrhoea, but in most, ovulation occurs. It is unclear whether these changes are due to a direct action of thyroid hormones on either the ovary and uterus or the pituitary and hypothalamus, or both. With treatment, menstrual cycles return to their regular pattern. Thyrotoxicosis in prepubertal girls may result in slightly delayed menarche. In premenopausal women, basal plasma concentrations of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are normal but may display an enhanced responsiveness to LH [42].

An increase in libido has also been reported in men [43]. An increase in sex hormone-binding globulin is present and because of its increase, testosterone levels are elevated, but free testosterone levels are normal. The metabolic clearance rates of testosterone and, to some extent, of oestradiol are decreased. Conversion rates of androstenedione to testosterone, oestrone, and oestradiol, and of testosterone to dihydrotestosterone are increased. Extragonadal conversion of androgens to oestrogens is increased and this may account for finding gynaecomastia in a minority of thyrotoxic men. A reduction of sperm motility (asthenozoospermia) has been reported in about 60% of adult thyrotoxic patients; it normalizes after treatment with antithyroid drugs [44]. Other seminal fluid alterations, namely low sperm count and an increased number of spermatozoa with altered morphology, has been found in about 42% and 40%, respectively. One limit of these studies is that semen parameters have been evaluated in infertile couples in whom fertility of the partner has not always been studied. Premature ejaculation, erectile dysfunction, and hypoactive sexual desire have also been reported.

Energy Metabolism: Protein, Carbohydrate, and Lipid Metabolism

One of the most prominent symptoms is heat intolerance reflecting an increase in the basal metabolism of many substrates [45] leading to an increased consumption of adenosine triphosphate (ATP) and oxygen. The consequent thermogenesis is responsible for heat intolerance. Despite the increased food intake, a state of chronic caloric inadequacy often ensues, depending on the degree of increased metabolism, and becomes more pronounced with age. In addition to losing fat stores, there is often a loss of muscle mass, making weakness a common complaint. Both synthesis and degradation of proteins are increased.

Both glucose absorption and glucose production are increased. The oral glucose tolerance test is often abnormal [46]. Pre-existing diabetes mellitus is aggravated by thyrotoxicosis, one cause being increased degradation of insulin.

Both synthesis and clearance of cholesterol and triglycerides are increased, but the latter effect predominates [47]. Plasma phospholipid and low-density lipoprotein (LDL) cholesterol concentrations fall, while high-density lipoprotein (HDL) cholesterol levels increase. Thyroid hormones also may influence cholesterol metabolism by increasing its conversion to bile acid and its clearance through the membrane surface LDL receptors. In this regard, *in vitro* studies indicate that triiodothyronine increases LDL receptor promoter activity and surface LDL receptor protein [48].

Although fatty acid synthesis is increased in both adipose tissue and liver, degradation of most lipids appears to be stimulated more than synthesis; body lipid deposits consequently become depleted and plasma concentrations of various lipid components fall. Several studies have investigated the relationship between leptin level and thyroid status. Two studies reported a relative hypoleptinaemia, but most have found no effect of thyrotoxicosis on leptin levels [49].

Vitamin Metabolism in Thyrotoxicosis

Vitamin A concentrations tend to be low and a minor impairment of dark adaptation has been detected in some patients. Serum PTH levels are low and the conversion of 25-hydroxyvitamin D to 1,25-hydroxyvitamin D is diminished, resulting in lowered serum concentrations of the latter [50]. Calcium balance is negative as a result of decreased intestinal absorption and increased urinary loss. The serum concentration of vitamin E tends to be reduced because serum concentrations of HDL and LDL, in which vitamin E is incorporated, are decreased.

Differential Diagnosis of Thyrotoxicosis

The condition that most frequently simulates thyrotoxicosis is an anxiety state characterized by nervous irritability, fatigue, and insomnia. Fatigue is pronounced and differs from that in thyrotoxicosis because it is not accompanied by a desire to be active. Tachycardia is common during examination but, in contrast to thyrotoxicosis, the sleeping pulse rate is normal. Hyperreflexia is present in both disorders.

Phaeochromocytoma may closely resemble thyrotoxicosis. Tachycardia and hypermetabolism are common to both conditions. The patient may have weight loss despite a good appetite and hyperglycaemia with glycosuria.

Myeloproliferative disorders may mimic thyrotoxicosis because of increased sweating, weight loss, and tachycardia, especially if anaemia is present. In diabetes mellitus, weight loss despite a good appetite, muscle wasting, and occasionally diarrhoea may suggest thyrotoxicosis.

3.3.2 Thyrotoxic Periodic Paralysis

Annie W.C. Kung and C.L. Cheung

Epidemiology

The association of thyrotoxicosis and periodic paralysis was first described in 1902 in a Caucasian patient. However, it soon became evident that thyrotoxic periodic paralysis (TPP) affects mainly Asian populations, in particular the Chinese and Japanese, although isolated cases have also been reported in other ethnic groups such as Caucasians, Hispanics, African Americans, and American Indians. The incidence of TPP in non-Asian thyrotoxic patients is around 0.1%, whereas in the Chinese and Japanese, TPP affects 1.8% and 1.9% respectively, of the thyrotoxic patients [1–3]. Despite a higher incidence of thyrotoxicosis in women, TPP affects mainly men, with a male to female ratio ranging from 17: 1 to 70: 1, according to different series. In the Chinese population, TPP affects 13% of male and 0.17% of female thyrotoxic patients. In the Japanese population, TPP was reported to occur in 8.2% of male and 0.4% of female thyrotoxic patients in the 1970s, but in 1991, the reported incidence decreased to 4.3% and 0.04% respectively [4].

Clinical Features

TPP patients are usually between 20 and 40 years of age, similar to the age distribution for thyrotoxicosis. Isolated cases were reported in paediatric age group [5]. The paralytic attacks are characterized by transient, recurrent episodes of muscle weakness. Attacks involve proximal more than the distal muscles, with an initial involvement of the lower limbs and subsequently the truncal muscles, and finally all four limbs. The degree of weakness varies from mild weakness to total flaccid paralysis and hyporeflexia. Some patients may experience prodromal symptoms of aches, cramps, or stiffness

in the affected muscles. Weakness usually affects skeletal muscles only. However, total paralysis of respiratory, bulbar, and ocular muscles has been reported in severe cases [6–8]. Recovery is usually complete, but the duration of paralysis can vary from a few hours in a mild attack to 36–72 h in a severe attack. Electromyographic studies have confirmed the myopathic changes with intact peripheral nerve function. The presentation of TPP may be confused with Guillain-Barre syndrome, acute spinal cord compression, myelitis, and hysteria. The attacks of weakness are similar to those of familial hypokalaemic periodic paralysis (FHPP) except for the presence of hyperthyroidism. While FHPP is an autosomal dominant condition affecting mainly Caucasians, TPP is a sporadic disease found mainly in Asian males, and familial cases of TPP are extremely rare.

High carbohydrate loads and strenuous exercise are well recognized precipitating factors for TPP [9]. The paralytic attacks do not occur during exercise but occur during the resting period that follow strenuous exercise, and the attacks may be aborted by continuation of exercise. In subtropical cities such as Hong Kong, attacks are most common during the seasons of summer and fall. This seasonal variation is probably associated with an increased intake of sugary drinks as well as outdoor activities and exercise in these weather conditions. In tropical cities such as Singapore, seasonal variation is not seen. Attacks usually occur in the middle of the night or early morning, which coincides with a period of rest following a heavy meal or exercise. Paralysis can be induced in these patients with high carbohydrate loads with or without insulin infusion, strenuous exercise, or even thyroxine therapy. However, attacks cannot be induced once the patient has become euthyroid. Although high carbohydrate loads and strenuous exercise are well recognized precipitating factors for TPP, they were implicated in only 16 and 10 out of 135 cases in a prospective observational study, respectively [10]. Other precipitation factors include trauma, stress, alcohol consumption (especially binge drinking), acute urinary tract infection, and drugs (such as steroids and non-steroidal anti-inflammatory drugs) [10].

Hypokalaemia is the hallmark of TPP. Plasma potassium concentrations have been reported to be as low as 1.1 mmol/L. Some patients may have a near to normal plasma potassium concentration if they are admitted during the recovery phase of the attack. Mortality due to cardiac arrhythmia associated with the hypokalaemia has been reported. The complication of rhabdomyolysis may occur in a severe attack. Potassium concentration returns to normal when the patient recovers spontaneously from the weakness. The degree of hypokalaemia and the severity of weakness have no correlation with the severity of hyperthyroidism and the serum thyroid hormone concentration. Indeed, many patients have relatively few symptoms of hyperthyroidism and TPP may be their only manifestation of thyrotoxicosis. Apart from hypokalaemia, patients may also experience mild to moderate hypophosphataemia and hypomagnesaemia. These are also a result of intracellular shift as these electrolyte abnormalities would return to normal spontaneously when the patient recovers from the paralysis.

The underlying cause of hyperthyroidism in the majority of TPP patients is Graves' disease. However, TPP can also be associated with thyroiditis (either spontaneous or induced by interferon therapy), toxic nodular goitre, toxic adenoma, TSH-secreting pituitary tumour, and even overdosage of thyroid hormone. TPP is usually the early presentation of the underlying thyroid disease. In the case of Graves' disease, TPP can also be a presenting feature of relapse of the disease. Paralysis only occurs when the patient is thyrotoxic but not euthyroid.

Muscle biopsies from patients with TPP have revealed a variety of abnormalities. The most consistent finding is proliferation and focal dilation of the sarcoplasmic reticulum and transverse tubular system, with prominent vacuoles arising from the sarcoplasmic reticulum [11]. It is uncertain whether these vacuoles represent coalescence of dilated sarcoplasmic reticulum or sequestrated areas of focal myofibrial necrosis.

Genetics

A number of genetic association studies on TPP had been reported. Associations with the human leukocyte antigen (HLA) genotypes HLA B46, DR9, and DQBl*0303 were reported in Hong Kong Chinese, A2 Bw22, AW19, and B17 in Singapore Chinese, and DRW8 in Japanese [12]. However, it is uncertain whether these associations were related to the genetic predisposition to Graves' disease rather than to TPP, especially when the majority of these TPP patients had an underlying autoimmune thyroid disease.

In view of the similar presentations between TPP and FHPP, the role of the voltage-dependent calcium channel or dihydropyridine-sensitive L-type calcium channel receptor ($Ca_v1.1$), which is associated with FHPP-1, was studied in TPP patients. None of the few mutation hot spots associated with FHPP was present in Asian or non-Asian patients with TPP [13, 14]. However, certain single nucleotide polymorphisms (SNPs) of $Ca_v1.1$, including nucleotide (nt)—476, intron 2 nt 57, and intron 26 nt 67 were associated with TPP in southern Chinese [13]. The location of these SNPs lies at or close to the TRE of the gene, and it is likely that they affect the binding affinity of TRE and modulate the stimulation of thyroid hormone on the $Ca_v1.1$ gene. Similarly, isolated case reports with mutations in other skeletal muscle ionic channels were reported in Caucasian subjects but were not identified in other populations.

In view of the insulin resistance and increased Na/K-ATPase activity and increased adrenergic response observed in TPP patients, the genes encoding for the 1-, 2-, ß1-, ß2-, and ß4-subunits of Na/K-ATPase and ß-adrenergic receptor were examined. So far, no mutations or polymorphisms in these genes have been identified to be associated with TPP.

Since TPP is considered a channelopathy, with hypokalaemic being the hallmark of the disease, an international collaborative sequencing project of candidate genes of potassium voltage-gated channel subfamily J (KCNJ) gene family discovered a novel unreported gene, KCNJ18 that encodes inwardly rectifying potassium (Kir) channel 2.6, as a novel susceptibility gene of TPP. Mutations in KCNJ18 were found to be highly prevalent in TPP patients from Singapore (25.9%), and Brazil, France, and the United States (33.3%), but not in patients from Hong Kong (1.2%) or Thailand (0%). Subsequently, genome-wide association studies conducted in Hong Kong and Thailand found a common variant on chromosome 17q24.3 near KCNJ2, that encodes Kir2.1, was significantly associated with TPP. Notably, mutation in KCNJ2 has been implicated in Andersen–Tawil syndrome (ATS), a rare genetic disease that is characterized by periodic paralysis and arrhythmia. Thyrotoxicosis has been reported to severely exacerbate the periodic paralysis in

ATS patients [15]. Altogether, these genetic studies uncovered the importance of both common and rare variant in members of KCNJ gene family in TPP susceptibility.

Pathogenesis

The pathogenesis of TPP remains unclear. Hypokalaemia is due to a rapid and massive shift of plasma potassium from the extracellular into the intracellular compartment, mainly into the muscles, and is not due to depletion through losses in urine or faeces. This massive shift of potassium is believed to be due to increased sodium-potassium adenosine triphosphatase (Na^+, K^+-ATPase) pump activity in these patients. It is known that thyroid hormone can increase Na^+, K^+-ATPase activity in skeletal muscle, liver, and kidney, and also induce influx of plasma potassium into the intracellular space [16]. Thyroid hormone responsive element has been described in the promotor region of the α1 and β1 subunits of the Na^+, K^+-ATPase pump. The action of thyroid hormone on Na^+, K^+-ATPase activity is believed to be mediated through both transcriptional and post-transcriptional levels. Thyroid hormone also increases the number and sensitivity of β-adrenergic receptors. The increased β-adrenergic stimulation further increases Na^+, K^+-ATPase activity, which may explain why non-selective β-blockers can prevent attacks of TPP. The finding that selective β_1 antagonists do not protect patients from paralytic attacks is consistent with the specific role of β_2 receptor in mediating the catecholamine-induced increase in Na^+, K^+-ATPase activity in skeletal muscle [17].

As it is difficult to determine potassium transport in intact skeletal muscles during TPP and in between attacks, most studies have resorted to measurement of the potassium flux and sodium pump activity in peripheral tissues such as the red blood cells, leucocytes, and platelets. Various groups have shown that the number of Na^+, K^+-ATPase pumps, as well as Na^+, K^+-ATPase mediated cation influx, were increased in leucocytes [18] and platelets [19] in thyrotoxic patients with or without TPP when compared to healthy controls. However, TPP patients have significantly higher pump capacity and activity than those with plain thyrotoxicosis. When thyrotoxicosis is controlled, the Na^+, K^+-ATPase activity in TPP patients returns to levels similar to those of healthy subjects.

Insulin stimulates Na^+, K^+-ATPase and plays a permissive role for the potassium shift in TPP. Serum insulin levels vary widely in spontaneous attacks or during induction of paralysis, but hyperinsulinaemia during the attack or after glucose challenge has been reported in TPP [20]. The hyperinsulinaemic response may explain the association of the paralysis with heavy meals or sweet snacks. Exercise releases potassium from muscle while rest promotes influx of potassium, which may explain why mild exercise may abort an attack. It would thus appear that TPP subjects have an underlying predisposition for activation of Na^+, K^+-ATPase activity, and that thyroid hormone and insulin enhance the exaggerated response of the pump activity in these subjects. It is of interest to note that Na^+, K^+-ATPase activity is possibly increased by androgens and inhibited by oestrogens, and this may explain the male predilection for TPP [21].

As aforementioned, KCNJ gene family plays an important role in TPP susceptibility, thus it is expected that the Kir channels that encoded by KCNJs are involved in the pathogenesis of TPP. The inward and outward K^+ movement is controlled by not only Na^+, K^+-ATPase, but also Kir channels. TPP susceptibility genes *KCNJ2* and *KCNJ18* encode Kir2.1 and Kir2.6, which form functional homotetramer and heterotetramer in skeletal muscle and regulate excitability of muscles. Mutations in Kir2.6 exert dominant negative effect and reduce the whole cell current [22] predisposing the sarcolemma to hypokalaemia-induced depolarization that in turn leads to Na^+ channel inactivation and inexcitability of muscles. Notably, thyroid response element is present in the promoter region of *KCNJ18* [23], therefore this potentially explains why the attack is induced by hyperthyroidism and resolved once euthyroid state is achieved. On the other hand, the genetic variant rs312691 is located in a long non-coding RNA that regulates KCNJ2 expression during hyperthyroid state [24]. This explains the underlying mechanism how genetic variation in KCNJ2 and KCNJ18 affect TPP susceptibility.

Treatment

Treatment of TPP consists of two components: the acute management of the paralytic attack and the definitive treatment of hyperthyroidism. During the paralysis associated with marked hypokalaemia, treatment with intravenous potassium can hasten the recovery of muscle function and prevent cardiac arrhythmia. However, the serum potassium level has to be monitored closely, as rebound hyperkalaemia may occur when the potassium is being shifted back into the extracellular compartment. The use of oral potassium supplements during the early phase of weakness can sometimes help to prevent further progression to complete paralysis. Whereas potassium replacement is most effective during paralysis, regular potassium supplements are not effective for prophylaxis against further paralytic attack. Further attacks of paralysis can be prevented by the administration of spironolactone or propranolol. The most effective agent is propranolol, a non-selective ß-blocker. At a dose of 40 mg four times a day, propranolol can prevent paralysis induced by high carbohydrate load in about two-thirds of those with a history of TPP [25]. The selective $ß_1$-antagonist, metoprolol, does not protect patients from paralytic attacks. Thyroxine and acetazolamide have been reported to reduce the frequency of attacks in FHPP whereas the reverse is the case with TPP.

Patients should be advised to avoid the factors that may precipitate the attack, including heavy carbohydrate intake, alcohol ingestion, and excessive exertion. However, since patients will not have further paralytic attacks when they are euthyroid, adequate control of hyperthyroidism is necessary. Definitive treatment of the hyperthyroidism with radioactive iodine or thyroidectomy is indicated. It has to be noted that TPP may occur after radioactive iodine therapy when the patient is still toxic, and addition of antithyroid drugs for several weeks after radioactive iodine therapy may be necessary to establish a euthyroid state. When treatment leads to hypothyroidism, careful monitoring of the thyroxine replacement therapy is essential to avoid overtreatment, which may lead to a recurrence of paralytic attack.

3.3.3 Thyrotoxic Storm

Leonard Wartofsky, Dorina Ylli, and Joanna Klubo-Gwiezdzinska

Introduction

Thyrotoxic storm is arguably the most serious complication of hyperthyroidism and occurs in 1–2% of hospital admissions for thyrotoxicosis with an incidence of 0.2 per 100 000 hospitalized patient per year [1] and mortality rate ranging from 10% to 75% in hospitalized patients [2–4]. It is difficult to distinguish between thyrotoxic storm and uncomplicated thyrotoxicosis simply on the basis of routine function tests. Rather, the clinical diagnosis is based on the identification of signs and symptoms typically seen in thyrotoxic storm suggesting organ decompensation. Some of these typical manifestations include fever (temperature usually above 38.5°C), tachycardia out of proportion to the fever, central nervous system signs varying

Table 3.3.3.1 Diagnostic criteria for thyroid storm

Thermoregulatory dysfunction	Score	Cardiovascular dysfunction	Score
Temperature		**Tachycardia**	
99–99.9 °F (37.2–37.7°C)	5	90–109 beats/min	5
100–100.9 °F (37.8–38.2°C)	10	110–119 beats/min	10
101–101.9 °F (38.3–38.8°C)	15	120–129 beats/min	15
102–102.9 °F (38.9–39.3°C)	20	130–139 beats/min	20
103–103.9 °F (39.4–39.9°C)	25	≥140 beats/min	25
≥104 °F (40°C) or higher	30	**Congestive heart failure**	
Central nervous system effects		Absent	0
Absent	0	Mild (oedema)	5
Mild agitation	10	Moderate (bibasilar rales)	10
Delirium, psychosis, lethargy	20	Severe (pulmonary oedema)	15
Seizure or coma	30	**Atrial fibrillation**	
Gastrointestinal dysfunction		Absent	0
Absent	0	Present	10
Diarrhoea, nausea, vomiting, or abdominal pain	10	**History of precipitating event (surgery, infection, etc.)**	
Unexplained jaundice	20	Absent	0
		Present	10
Based upon the total score, the likelihood of the diagnosis of thyrotoxic storm is: unlikely <25; impending 25–44; highly likely >45.

from confusion to apathy and even coma, and gastrointestinal dysfunction, which can include nausea, vomiting, diarrhoea, and, in severe cases, jaundice. A scale has been developed to aid in diagnosis (Table 3.3.3.1) [2]. The earliest possible diagnosis and treatment initiation are required to avoid a fatal outcome.

Clinical Features

The patient's history may include hyperthyroidism but decompensation into thyrotoxic crisis usually follows some precipitating event, as indicated in Box 3.3.3.1. Most patients will have obvious signs and symptoms of thyrotoxicosis, including goitre and perhaps Graves' ophthalmopathy. However, in older patients, particularly those who may have an underlying toxic multinodular goitre rather than Graves' disease, the thyrotoxic storm may atypically present as masked or apathetic thyrotoxicosis [5]. Even more rarely, thyrotoxic storm may occur with subacute thyroiditis or factitious thyrotoxicosis due to thyroxine overdose [6, 7].

In hospitalized patients, infection is the most common precipitating event associated with thyrotoxic storm [1]. The differential diagnosis between true storm and uncomplicated infection in a thyrotoxic patient may be quite difficult, because of the likely presence of signs of tachycardia and fever in both. In this regard, very high fever seemingly out of proportion to an apparent infection along with dramatic diaphoresis could be a strong clinical clue to impending thyrotoxic storm. As the storm progresses, symptoms of central nervous system dysfunction will appear in various forms as increasing agitation, confusion, paranoia, psychosis, and even coma [8]. Cases of status epilepticus and stroke have also been reported [9]. Less frequent events associated with thyroid storm include pregnancy, during labour, placenta praevia, hydatidiform mole [10], cytotoxic chemotherapy for acute leukaemia, aspirin overdose [11–13], organophosphate intoxication [14], new anticancer medication (sorafenib) [15], nivolumab, ipilimumab [16, 17] and thyroid trauma such as repetitive examination of a large Graves' gland and surgery.

Box 3.3.3.1 Events associated with precipitation of thyrotoxic storm

- More common:
  - Withdrawal of antithyroid drug treatment
  - Iodine-131 treatment
  - Sepsis, infection
  - Surgery, trauma
  - Iodinated contrast dyes
  - Parturition
  - Vigorous palpation of thyroid
  - Burn injury
  - Diabetic ketoacidosis
  - Pulmonary thromboembolism
- Less common
  - Hypoglycaemia
  - Emotional stress
  - Subacute thyroiditis
  - Thyroxine overdosage
  - Cytotoxic chemotherapy
  - Aspirin overdosage
  - Organophosphates
  - Seizure disorder

Treatment delay increases the likelihood of irreversible progression and ultimate demise. Hence, when the diagnosis is likely but indefinite, treatment for thyrotoxic storm should be initiated.

Cardiovascular Manifestations

Cardiovascular manifestations are present due to influence of thyroid hormones on the heart, arteries, and veins. Rhythm disturbances commonly seen include sinus tachycardia, atrial fibrillation, or other supraventricular tachyarrhythmias. The signs and symptoms of congestive heart failure may be present at any age but prevail in older people. Most patients will have systolic hypertension with widened pulse pressure. Due to high oxygen demand and coronary artery spasm, myocardial infarction can be observed, even in young patients [18, 19]. A relatively rare complication is pulmonary hypertension, presumed to be on an autoimmune basis when associated with Graves' disease but may also be secondary to an augmented blood volume, cardiac output, and sympathetic tone, leading to pulmonary vasoconstriction and increased pulmonary arterial pressure, a condition usually reversible after treatment with antithyroid drugs. The other possible reason for pulmonary hypertension is pulmonary embolism due to the thrombotic or hypercoagulable state observed in severe hyperthyroidism.

Gastrointestinal Manifestations

The most common symptoms are diffuse abdominal pain, vomiting, or diarrhoea which can cause volume depletion, postural hypotension, and shock with vascular collapse. The pathophysiological mechanisms are complex, but impaired neurohormonal regulation of gastric myoelectrical activity with delayed gastric emptying plays an important role [20]. Other gastrointestinal manifestations could include presentation as an acute abdomen [21], intestinal obstruction [22], and/or hepatomegaly, splenomegaly, and various abnormalities in liver function tests. The presence of jaundice is another poor prognostic sign and warrants immediate and vigorous therapy.

Acid–Base Balance and Renal and Electrolyte Manifestations

Due to augmented lipolysis and ketogenesis, ketoacidosis may occur with lactic acidosis due to basal metabolic demands exceeding oxygen delivery and/or reduced hepatic clearance of lactic acid. Renal failure is not uncommon and can progress due to glomerulosclerosis, proteinuria, and oxidative stress. Also, a postrenal urinary retention due to dyssynergy of the detrusor muscle is possible [23]. Moreover, Graves' disease can be accompanied by autoimmune complex-mediated nephritis [24].

Neuropsychiatric Manifestations

Presentation of a wide range of central nervous system signs and symptoms in the hyperthyroid patient has been described as a key component for the differential diagnosis of thyroid storm to compensated thyrotoxicosis [25]. Moreover, the presence of central nervous system derangement was associated with increased risk of mortality [26]. In patients with neurological symptoms, a high index of suspicion for cerebral thrombosis should be considered [27].

Hyperthermia

Hyperthermia in thyroid crisis can represent both as defective thermoregulation by the hypothalamus and/or increased basal metabolic rate. However, sometimes pyrexia is not observed in elderly patients as part of the complex of so-called apathetic thyrotoxicosis with storm [7].

Haematological Manifestations

Hyperthyroidism may be associated with hypercoagulability due to increased concentrations of fibrinogen, factors VIII and IX, tissue plasminogen activator inhibitor 1, von Willebrand's factor, and tendency to augmented platelet plug formation [28] and increase erythropoietin secretion. Major thromboembolic complications can be responsible for 18% of deaths caused by thyrotoxicosis [28–33]. Therapeutic initiatives should be undertaken in thyroid storm to prevent thromboembolic complications. Optimal treatment requires a balance between anticoagulant dosage and the effect of vitamin K antagonists that can be potentiated by thyrotoxicosis [32].

Laboratory Findings

Relatively similar estimates of serum total T_4 and T_3, T_3 resin uptake, and the 24-h radioiodine uptake will be found in thyrotoxic storm as in uncomplicated thyrotoxicosis. Indeed, serum total T_3 levels may be within normal or low limits, as in the case of diabetic ketoacidosis or underlying systemic illness [34, 35] congruent with the 'euthyroid sick syndrome'. Thus, a low serum T_3 may obscure the diagnosis of thyrotoxicosis.

Other laboratory abnormalities may include a modest hyperglycaemia in the absence of diabetes mellitus, probably as a result of augmented glycogenolysis and catecholamines. However, when thyrotoxicosis is prolonged, hypoglycaemia may occur, particularly in older people [36]. Although most haematology values tend to be normal, a moderate leucocytosis with a mild shift to the left is common even in the absence of infection. Increased serum calcium levels may be seen perhaps due to both haemoconcentration and the effects of thyroid hormone on bone resorption, but serum sodium, potassium, and chloride are usually normal. Hepatic dysfunction will result in elevated levels of serum lactate dehydrogenase, glutamic oxaloacetate transaminase, and bilirubin. Because serum cortisol levels should be elevated as in any other acute stressful situation, a normal value may be interpreted as being inappropriately low. In view of the known, albeit rare coincidence of adrenal insufficiency with Graves' disease, one should maintain a reasonably high index of suspicion for this disorder, particularly if there is hypotension and suggestive electrolyte abnormalities.

Pathogenesis

The precise pathogenesis underlying the precipitation of thyroid storm remains incompletely understood. The serum hormone levels themselves do not appear to be critical. One illustrative model is provided by children with extraordinarily high serum T_4 and T_3 concentrations after accidental ingestion of T_4 in whom storm is not seen. However, the dramatic clinical improvement seen in storm after an abrupt decrease in serum T_4 or T_3 by peritoneal dialysis or plasmapheresis suggests that hormone elevation does play a role [37, 38]. In general, serum total T_4 and T_3 values do not differ significantly from those in uncomplicated thyrotoxicosis, although the levels in an affected person could be higher than the values before the precipitating event.

We believe that the critical factor relates to the actual 'free' concentration of thyroid hormone and not the 'total' measured hormone in blood. This former concentration is directly associated with the relationship of the hormone to its circulating binding proteins. Thus, any perturbation of hormone binding could increase the absolute concentration of free hormone. Conditions associated with decrease in binding affinity include surgery, anaesthesia, stress, infection, burns [39], and ketoacidosis [34, 40]. While this explanation may apply in thyroid storm [41], the pathogenesis may involve more than one factor. For example, because older patients with a systemic illness would have decreased binding and higher free T_4, a more cautious approach to radioiodine therapy in such patients is recommended to avoid thyrotoxic crisis [42].

A possible interaction between the effects of thyroid hormone and catecholamines has been a subject of both research and clinical interest for decades. Although normal serum catecholamine levels and urinary excretion rates mitigate against the idea of augmented adrenergic activity, dramatic clinical improvement follows the use of agents that either deplete tissue catecholamines, such as reserpine, or block β -adrenergic receptors, such as propranolol.

Treatment of Thyroid Storm

A four-part approach is recommended for the treatment of thyroid storm. First, antithyroid drugs are used to reduce the increased thyroid hormone production and release of T_4 and T_3. Second, treatment to block the effects of the remaining but excessive circulating concentrations of free T_4 and T_3. The third arm involves treatments against the underlying systemic decompensation (e.g. fever, congestive failure, and shock). The fourth addresses any underlying precipitating illness such as infection or ketoacidosis.

Therapy Directed to the Thyroid Gland

Inhibition of new synthesis of the thyroid hormones is achieved by administration of thionamide antithyroid drugs, such as carbimazole, propylthiouracil, or methimazole (tapazole). These drugs are given by mouth or if necessary per rectum. There is an intravenous form of thiamazole used in European countries. Propylthiouracil can be started at a loading dose of 500–1000 mg, then 250 mg every 4 h [43]. In the case of methimazole, the daily dose is approximately one-tenth of that of propylthiouracil or 60–80 mg/d [43]. Some experienced clinicians believe that propylthiouracil will provide more rapid clinical improvement because of the additional advantage of inhibiting conversion of T_4 to T_3, a property not shared by methimazole. However recent studies have not observed significant differences in disease severity or mortality between patients with thyroid storm treated with methimazole (MMI) or propylthiouracil (PTU) [44].

Because thionamides reduce new hormone synthesis but not thyroidal secretion of preformed glandular stores of hormone, either inorganic iodine or lithium carbonate may be used for this purpose. Iodides may be given either orally as Lugol's solution or as a saturated solution of potassium iodide (5 drops every 6 h) [43]. The sequence of administration of iodine and antithyroid drugs to thyrotoxic patients is very important. Use of iodine without prior thionamide dosage is to be avoided because the iodine will enhance thyroid hormone synthesis, enrich hormone stores within the gland, and thereby permit further exaggeration of thyrotoxicosis. However, when iodine is administered subsequent to, and in conjunction with full doses of antithyroid drugs, dramatic rapid decreases in serum T_4 are seen, with values approaching the normal range within 4 or 5 days [45].

Other agents that may be used in this manner are the radiographic contrast dyes ipodate (Oragrafin) and iopanoic acid (Telepaque). After a loading dose of 3 g, ipodate may be administered as 1 g orally on a daily basis and, like iodine, should only be employed with simultaneous thionamide.

In patients who may be allergic to iodine, lithium carbonate may be used [46], although some caution has been raised in regard to its use in the setting of storm [47]. Lithium should be administered initially as 300 mg every 6 h, with subsequent adjustment of dosage as necessary to maintain serum lithium levels at about 1 mmol/L.

Therapy Directed at the Continuing Effects of Thyroid Hormone in the Periphery

Therapies to reduce high levels of circulating T_4 and T_3 should be applied. Peritoneal dialysis or plasmapheresis [37, 38] have been used, as has experimental haemoperfusion through a resin bed [48] or charcoal columns [49, 50]. Such aggressive management should be considered in a severe case. Oral administration of cholestyramine resin [51] provides a less aggressive means of removing T_4 and T_3, by binding thyroid hormone entering the gut via enterohepatic recirculation; the resin–hormone complex is then excreted. A highly aggressive approach has been employed in which plasmapheresis for rapid lowering of serum T_3 and T_4 was followed by immediate total thyroidectomy [52].

Hughes [53] was the first to treat a patient with thyrotoxic storm using a β -adrenergic blocker to ameliorate the manifestations of thyroid hormone excess. Propranolol is used at an oral dosage of 60–80 mg every 4 h [43]. Indeed, because of the more rapid metabolism of the drug in severe thyrotoxicosis, even larger oral doses, or preferably intravenous doses, should be given. Initial intravenous doses of 0.5–1 mg should be given cautiously while the patient's cardiac rhythm is continuously monitored, with subsequent doses of 2–3 mg given intravenously over 10–15 min every several hours,

while awaiting clinical improvement from the effect of orally administered drug.

One caution in patients with significant underlying intrinsic cardiac disease relates to the adverse effect of adrenergic blockade in neutralizing the little remaining sympathetic drive to the myocardium. Although use of propranolol might be contraindicated in patients with moderate to severe congestive heart failure, it may be used judiciously in patients with minor cardiac compromise related to their thyrotoxicosis [54].

Patients with thyrotoxic storm, particularly those with cardiac decompensation, should be managed in an intensive care setting. Careful monitoring of fluids, volume status, and central haemodynamics is essential in these patients. In patients refractory or with contraindications to the use of propranolol, reserpine [55], guanethidine, or selective β1-blocking agents can be considered instead. A very short acting β-adrenergic blocker, esmolol, has also been used in thyroid storm with success. An initial loading dose of 0.25–0.5 mg/kg is followed by continuous infusion of 0.05–0.1 mg/kg per min [56, 57].

In spite of a theoretical risk of hypercalcaemia in thyrotoxicosis, supplementation with vitamin D_3 may actually suppress calcium release from bones [58]. In a recent study, the administration of L-carnitine 2 g/day [59] in thyrotoxic storm facilitated a dose reduction of methimazole. The mechanism appears to be related to an inhibition by L-carnitine of T_3 and T_4 entry into cell nuclei [60, 61] however, the utility of this adjunct to therapy requires confirmation.

Therapy Directed at Systemic Decompensation

Fluid depletion caused by the hyperpyrexia and diaphoresis, as well as by vomiting or diarrhoea if present, must be vigorously replaced to avoid vascular collapse and help correct hypercalcaemia. Intravenous fluids containing 10% dextrose in addition to electrolytes will better restore depleted hepatic glycogen. For fever, acetaminophen rather than salicylates is the preferred antipyretic, because salicylates inhibit thyroid hormone binding and could increase free hormone blood levels. External cooling with alcohol sponging, ice packs, or a hypothermia blanket also may be used. Vitamin supplements may be added to the intravenous fluids to replace probable coexistent deficiency. When present, congestive heart failure should be treated with the usual measures, including digoxin and diuretics, although somewhat greater than usual doses of digoxin may be required.

Hypotension not readily reversed by adequate hydration may temporarily require pressor therapy and glucocorticoids given on the basis of both postulated relative adrenal insufficiency and the ability to inhibit conversion of T_4 to T_3. An initial dose of 300 mg hydrocortisone followed by 100 mg every 8 h during the first 24–36 h should be adequate. Thyroid storm has been reported to recur when steroids had been discontinued after initial clinical improvement [62].

Therapy Directed at the Precipitating Illness

Thyrotoxicosis may have existed in many patients presenting in thyroid storm until some precipitating event, such as infection, led to increments in free T_4. Thus, therapy is not complete unless a diagnosis of the precipitating event is made, and early treatment for the underlying illness is implemented. This is not a problem in obvious cases, such as trauma, surgery, or labour, however, patients with enhanced thyroid secretion caused by withdrawal of thiourea treatment, iodine administration, iodinated contrast dyes, or ^{131}I may require some specific attention. Since the premature withdrawal of treatment could result in an exacerbation of thyrotoxicosis, an effective blockade of hormone biosynthesis and release must be continued beyond the period of immediate improvement.

Conditions such as ketoacidosis, pulmonary thromboembolism, or stroke may underlie thyrotoxic crisis and require the same vigorous management ordinarily indicated. In the patient with thyrotoxic crisis in whom none of the latter precipitating factors is apparent, a diligent search for some focus of infection must be carried out. Broad-spectrum antibiotic coverage on an empirical basis may be required initially while awaiting results of cultures. In most patients who survive thyrotoxic crisis, clinical improvement is dramatic within 12 or 24 h. The subsequent 72–96 h will be marked by continued progressive recovery. During this recovery period, supportive therapy such as corticosteroids, antipyretics, and intravenous fluids, may be tapered and gradually withdrawn on the basis of patient status.

After the crisis, attention may be turned to consideration of future short- and long-term management of the patient's thyrotoxicosis. Radioiodine treatment is often precluded by the recent use of inorganic iodine in virtually all cases of storm, but it could be considered at a later date. Continuing treatment with antithyroid drugs alone in the hope of the patient's sustaining a spontaneous remission is also possible. Surgery may be chosen, as many physicians favour a more definitive form of therapy. Should thyroidectomy be considered, thyrotoxicosis must have been adequately treated beforehand, to obviate any likelihood of another episode of crisis during or immediately following the surgery. When a surgical approach is selected, a total thyroidectomy is the procedure of choice [63].

3.3.4 Subclinical Hyperthyroidism

Simon H.S. Pearce

Introduction

Subclinical hyperthyroidism (SH) is characterized by a serum thyroid stimulating hormone (TSH, thyrotropin) concentration that is below the reference range, with circulating thyroid hormone levels (both thyroxine and triiodothyronine) that are within normal limits. In a minority of patients SH represents a state of mild thyroid autonomy or borderline hyperthyroidism. However, it is frequently an asymptomatic state and in many people it is also a transient biochemical finding that does not persist. In addition, a number of medications can cause SH or a low TSH: most obviously levothyroxine, but also glucocorticoids, opiates, and compounds containing iodine. The reference range for TSH in young adults is generally between 0.4 mU/L and 4.0 mU/L. With overt hyperthyroidism, the serum TSH concentration becomes undetectable in most assays, at levels of 0.05 mU/L or less, which is often referred to as 'fully suppressed'. This allows SH to be divided into two different grades: those patients with a low but detectable serum TSH in the 0.05 to 0.4 mU/L range (grade 1 SH), and those with a fully suppressed TSH <0.05 mU/L (grade 2 SH) (Table 3.3.4.1) [1]. The former, less severe form is more frequently transient and will resolve over 1 year in around 70% of cases [2]. The latter, grade 2 SH more closely resembles hyperthyroidism with a fully suppressed TSH and is more likely to be persistent, and in the absence of external precipitating factors is still present in 80% or more of patients after one year. It is therefore key to distinguish individuals who have mild or transient SH, as a consequence of medication, intercurrent illness or advanced age who will require no treatment, from those who have intrinsic thyroid disease causing mild thyroid autonomy who may benefit from specific management of their thyroid condition.

Epidemiology and Biochemical Prognosis

SH prevalence increases with advancing age and is more frequent in women. Around 1% of a US population up to the age of 80 years who had no known thyroid disease and who were free of interfering medications were found to have a serum TSH below 0.4 mU/L [3]. The prevalence increased to 3% in participants over 80 years old. As SH is frequently a transient state, information based on a single measurement of TSH may overestimate the prevalence. In a UK study from Tayside in which TSH was measured twice, SH persisting for more than 4 months was found in 0.6% of adults, with a yearly incidence of 30 cases per 100 000 population [4]. The peak prevalence of both grades of SH was in subjects between the ages of 75 and 85 years, and 77% occurred in women. The severity of SH could be divided, with approximately a quarter having grade 2 SH (TSH <0.1 mU/L) and three-quarters with a serum TSH between 0.1 and 0.4 mU/L [4]. Despite the careful ascertainment of these cases with a persistent abnormality of serum TSH, there was still a significant spontaneous remission rate, with 40% of subjects with grade 1 SH and 30% of grade 2 SH subjects reverting to euthyroidism over 7 years of follow-up. Conversely, over the first year of follow-up progression to overt hyperthyroidism was found in 5% and 10% of patients with grades 1 and 2 SH, respectively [4]. The rate of progression to overt hyperthyroidism is also dependent on aetiology, with 34% of SH patients who had positive TRAb antibodies diagnostic of Graves' disease developing overt hyperthyroidism over a 3-year

Table 3.3.4.1 Subclinical hyperthyroidism in comparison to other thyroid states

Test	Non-thyroidal illness	Euthyroid	Subclinical hyperthyroidism grade 1	Subclinical hyperthyroidism grade 2	T3 thyrotoxicosis	Overt hyperthyroidism
TSH	N or low	N	0.05–0.4 mU/L	≤0.05 mU/L	≤0.05 mU/L	≤0.05 mU/L
fT_3	Low	N	N	N	High	High
fT_4	N	N	N	N	N	High

N, normal; fT_3, serum-free triiodothyronine; fT_4, serum-free thyroxine.

follow-up period [5]. Thus, SH has a significant spontaneous remission rate, even after repeated 'confirmatory' measurements. The rate of progression to overt hyperthyroidism is low and dependent both on the grade of SH and any underlying intrinsic thyroid condition.

Thyroid Function: Physiology and Ageing

Even in healthy people, thyroid function as assessed with serum free thyroid hormones and TSH is not static over time. For instance, there is a circadian rhythm of TSH secretion, which is greater during the hours of darkness, with around a 25% variation in an individual's serum TSH from the nocturnal peak to the midday trough [6]. Furthermore, there is a seasonal variation of TSH among the population, with higher levels in winter months (7). With rising serum chorionic gonadotropin (hCG) levels in early pregnancy, there is also a physiological stimulation of the thyroid through the direct action of hCG on the TSH receptor. This leads to a low or even fully suppressed TSH during the first trimester of many pregnancies. The degree of TSH suppression is proportional to hCG concentration leading to lower serum TSH levels in twin pregnancies [8]. In addition, there are complex changes in serum TSH with advancing age, such that the reference interval expands both at the upper and lower limits. An Italian study of healthy community-dwelling elderly individuals showed that around one-fifth of Centenarians had a serum TSH below what would be considered the lower limit of the reference range for younger individuals [9]. Thus, many apparently healthy older individuals might be considered to have subclinical thyroid disease, both SH and subclinical hypothyroidism based on TSH reference ranges derived from younger people.

There are several different changes in the thyroid axis with age. A conventional analysis is that TSH secretion by the pituitary gland is reduced with advancing age [10]. A lower amplitude of nocturnal TSH pulses has been observed in healthy elderly volunteers, which may be as a result of decreased hypothalamic thyrotropin-releasing hormone (TRH) secretion. Indeed, a blunted TSH response to TRH stimulation has been demonstrated in elderly subjects [11, 12], suggesting increased pituitary sensitivity to circulating thyroid hormone levels. However, in common with hepatic drug clearance, thyroid hormone clearance is also known to decrease with increasing age [12]. In parallel, thyroxine secretion may also be reduced, resulting in unchanged total and fT_4 concentrations. In contrast to this, total and fT_3 levels decrease in older people, which is proposed to be due to reduced peripheral conversion of T_4 to T_3. Thus, either a central change in sensitivity to thyroid hormone feedback, reduced pituitary sensitivity to TRH or reduced peripheral hormone clearance leading to reduced axis tone and less throughput of thyroid hormone (i.e. less production, less clearance), or a combination of these mechanisms, contribute to the changes observed in the hypothalamic–pituitary–thyroid (HPT) axis with ageing [10–13].

Serum thyroid hormones, including TSH also change during acute or significant illnesses. In particular, any serious condition or one with an inflammatory or infective component can lead to the changes known as 'non-thyroidal illness' or sick-euthyroid syndrome [14] (Table 3.3.4.1). A low serum fT_3, or a reduction in fT_3 that remains within the lower limit of the reference range, is the typical first change. However, with chronicity there is frequently a transient reduction in serum TSH, leading to the pattern of SH. This 'non-thyroidal illness' pattern of blood tests is the likely explanation for the significant spontaneous recovery rate seen in epidemiological studies of SH. Lastly, in patients who are hypopituitary, central hypothyroidism may be accompanied by a low serum TSH, which may precede any drop in serum free thyroxine concentration and mimic a state of SH. Thus, an understanding of these normal physiological and pathophysiological changes is needed to interpret low serum TSH levels, particularly in older people where intercurrent illness is common and low TSH is less likely to signify intrinsic thyroid disease.

Medications

Several drugs may cause a low serum TSH through different mechanisms (Table 3.3.4.2). Minor levothyroxine or liothyronine (T_3) overtreatment may cause a reduction or complete suppression of serum TSH without elevating serum fT_4 or fT_3. Several other drugs directly suppress TSH secretion at the hypothalamo-pituitary level including opiates, glucocorticoids, levodopa, and the retinoic acid derivative, etretinate. Whether these drugs actually cause a state of mild central hypothyroidism is unclear, but on occasions a low fT_4 may be found during high-dose opiate treatment in conjunction with hypogonadotropic hypogonadism and/or secondary adrenal insufficiency, suggesting that this might be the case. Metformin may also reduce serum TSH in some patient groups such as those with an underlying thyroid condition, type 2 diabetes, or polycystic ovarian syndrome [15]. This effect is likely to be owing to adenosine monophosphate (AMP) kinase activation leading to a central inhibition of TSH secretion, but has not been robustly demonstrated in otherwise healthy people. Drugs containing iodine, including amiodarone and radiographic contrast media (iopaque) may also cause a transient reduction in serum TSH, or even frank thyrotoxicosis by augmenting the production of thyroid hormone in patients with pre-existing mild thyroid autonomy. This typically resolves spontaneously within 12 weeks of a dose of contrast media, but amiodarone has a much larger volume of distribution and its effects may linger for more than a year.

Table 3.3.4.2 Factors that can cause low serum TSH

Factor	Mechanism
Physiological/Pathological	
Pregnancy	hCG stimulation of thyroid
Trophoblastic tumours	
Germ cell tumours	
Ageing	Reduced HPT axis activity
Non-thyroidal illness	
Pituitary disease	
Drugs	
Levothyroxine (T_4)	Central suppression of pituitary TSH secretion
Liothyronine (T_3)	
Opiates	
Glucocorticoids	
Levodopa	
Dopamine	
Dobutamine	
Octreotide	
Etretinate	
Metformin	
Amiodarone	Stimulation of thyroid hormone secretion
Iodinated contrast media	

Aetiology

Once medication use and intercurrent illness are excluded, low TSH and SH can be the manifestation of mild hyperthyroidism. This is most typically due to a single or multiple autonomous follicular thyroid adenomas, which when thyrotoxicosis is more severe would be known as solitary toxic nodule or toxic multinodular goitre. However, in many individuals the degree of autonomy is mild and may commonly be fluctuant, with sometimes a serum TSH at the lower end of reference range, sometimes reduced but detectable (grade 1 SH) and sometimes a fully suppressed TSH (grade 2 SH). These fluctuations may depend upon changes in dietary iodine intake, and a transient period of grade 2 SH may also be seen in such a patient following iodinated radiographic contrast media, which later recovers. It is clear though that there is not inevitable progression to overt hyperthyroidism even in cases of persistent grade 2 SH. Therefore, it is incorrect to conceptualize SH as an 'early' manifestation of nodular thyrotoxicosis; even though there will be progression in a 2–5% of cases each year, spontaneous remission is generally more probable than progression to overt disease [4]. As well as autonomous thyroid nodules, SH is less commonly associated with Graves' disease, demonstrable by its coexistence with detectable TSH receptor antibodies (TRAbs) [5]. Indeed, SH may be discovered when an apparently euthyroid patient is investigated for Graves' orbitopathy. In these circumstances there is a higher risk of progression to overt hyperthyroidism, but a decline into overt hypothyroidism is also possible in the presence of high TRAb titres. As well as these potential thyroid diseases, as mentioned just now, other factors related to the fitness, chronological age and the ageing status of the patient need to be considered before making a judgement about the aetiology of SH. If the patient is frail, with multiple comorbidities or prematurely aged, it is more likely that SH is due to their 'stage of life' rather than any intrinsic thyroid disease.

Investigations

The most helpful investigation for SH is the passage of time, as many cases will resolve and some will worsen, unveiling an underlying intrinsic thyroid condition. Unless there are unusual circumstances following an initial low TSH measurement, it is satisfactory to repeat thyroid function testing including fT_3 in 3 and 6 months' time [1]. If grade 2 hyperthyroidism persists, or there are other clues to the presence of intrinsic thyroid disease, then it is worth measuring TRAb antibodies and obtaining a ^{99}-Tc nuclide thyroid uptake scan to identify any potential 'hot' autonomous nodules. Pregnancy should be excluded where appropriate and interfering medications and coexisting non-thyroidal illnesses should be considered. With regards complications of SH, physical examination will reveal the presence of atrial fibrillation, but an electrocardiograph (ECG) or 24-hour Holter monitor record should be obtained if there is doubt or a suggestive history of paroxysmal palpitations. Similarly, measurement of bone mineral content by dual X-ray absorptiometry (DXA) may be helpful, although densitometry-defined osteoporosis is highly prevalent in older individuals rendering this test rather non-discriminatory.

Prognosis and Complications

Several large epidemiological studies have shown that community-dwelling older people who have SH have a higher incidence of atrial fibrillation than euthyroid people during 10 or more years of follow-up [16, 17]. Furthermore, some but not all epidemiological studies have shown an increased mortality in SH people compared to euthyroid individuals [17–19] (**Figure 3.3.4.1**). Indeed, meta-analysis confirms an increased risk of atrial fibrillation, heart failure, cardiovascular mortality, and all-cause mortality in populations with a TSH <0.1 mU/L [20, 21]. Pertinently, there are numerous minor abnormalities of cardiac function that can be detected in younger patients with either SH due to endogenous thyroid autonomy or levothyroxine overtreatment [22]. Similarly, bone mineral density, fractures, dementia, and cognitive impairment have all also been associated with low TSH in large epidemiological studies [23–26]. A plausible case can therefore be made that there are clear adverse associations of SH at a population level and thus it should be aggressively treated. However, there are numerous caveats to this approach, not least that there is no good quality-controlled trial showing clinical benefit from treatment of SH. Therefore, we are a long way from being able to causally implicate SH in the adverse patient outcomes that it is epidemiologically associated with.

One fundamental problem in extrapolating the results of epidemiological studies to an individual is that we know SH is commonly a transient state, so that after the 10 years of follow-up in an observational study, only a minority of people who initially had SH are likely to still have a low TSH [2, 4]. Furthermore, the majority of people who were categorized as SH in these studies had a low but not

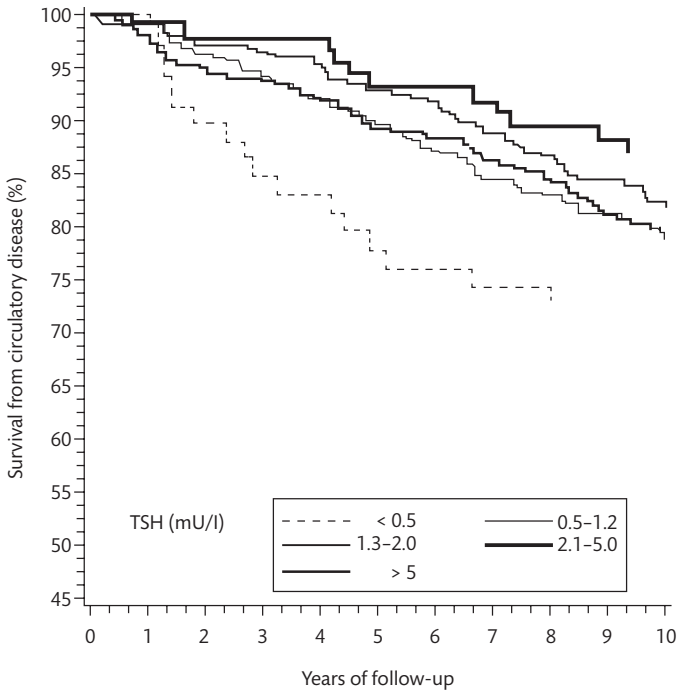

Figure 3.3.4.1 Kaplan–Meier survival curves showing the relation between survival from circulatory disease and serum thyrotropin (TSH) concentration. The lowest serum TSH group (<0.5 mU/L) has an excess mortality, but many people in this groups will have TSH at the lower end of the normal reference range; few will have grade 2 subclinical hyperthyroidism.

Reproduced from Parle JV, Maisonneuve P, Sheppard MC, Boyle P, Franklyn JA. Prediction of all-cause and cardiovascular mortality in elderly people from one low serum thyrotropin result: a 10-year cohort study. *Lancet*, 2001; 358: 861–5. Copyright © 2001 Elsevier.

suppressed TSH (grade 1 SH), which is more compatible with a 'non-thyroidal illness' pattern of thyroid function than with true thyroid autonomy. Indeed, while cardiovascular disease and osteoporosis could be aetiologically linked to thyroid autonomy, the pathophysiological mechanism for dementia and Alzheimer's disease is less clear. It therefore seems likely that in many patients low serum TSH is a marker for advanced biological age. When we compare these low TSH people to their euthyroid peers, there is an excess burden of many diseases associated with ageing, which include all the aforementioned conditions, and which might wrongly be regarded as the direct complications of SH. Nevertheless, some patients with grade 2 SH will have genuine thyroid autonomy and identifying these individuals in order to treat their underlying thyroid condition and prevent complications is the key to appropriate management.

Management

Most patients with grade 1 SH do not have thyroid autonomy and do not require specific treatment. Intermittent follow-up with once- or twice-yearly monitoring of serum TSH, fT_4 and fT_3 is sufficient to determine if there is remission of the biochemical abnormalities or if there is progression [1]. A key indicator of likely thyroid autonomy in patients with grade 2 SH is the serum fT_3 value. There is an age-related decline in the serum fT_3 reference range, such that an fT_3 value around 6.0 pmol/L is at the upper limit of normal for an 85-year-old, as compared to 6.5 or 7.0 in younger people [27]. In contrast, with frailty and comorbidity fT_3 tends to be subnormal or at the lower limits of the reference range (≤4.0 pmol/L). Thus, in the presence of persistent grade 2 SH and an fT_3 ≥5.5pmol/L, then thyroid autonomy is a serious consideration. The decision about

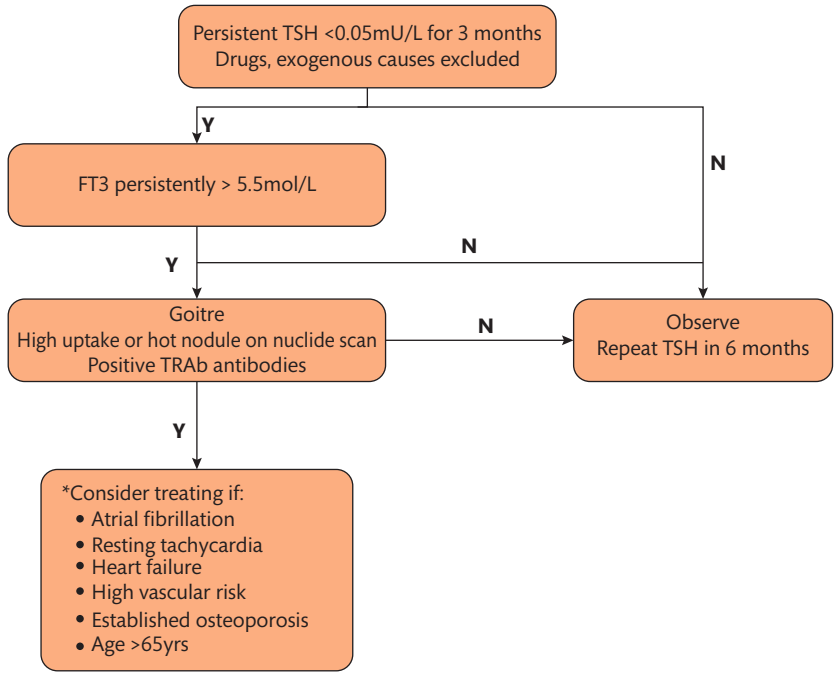

Figure 3.3.4.2 Algorithm for management of subclinical hyperthyroidism.

*First-line treatment should be antithyroid drugs in most cases.

whether to treat a patient will depend on the patient's age, the presence of potential complications (atrial fibrillation in particular) and the degree of certainty about the diagnosis of their thyroid condition (Figure 3.3.4.2). If a decision is to treat, the choice is between antithyroid drug therapy (e.g. carbimazole or methimazole) and ^{131}I radioiodine therapy. In addition, β-blockers should be prescribed for people with atrial fibrillation or other tachyarrhythmias. If investigations suggest nodular thyroid disease, then radioiodine should be considered as a curative treatment. The downside to radioiodine is that it may precipitate a period of overt hyperthyroidism (in 5–10%), or occasionally thyroid eye disease; both of which may be more troublesome to the patient than their original problem. In addition, 50% of people who receive radioiodine will ultimately become hypothyroid and dependent on daily levothyroxine. These are significant drawbacks and long-term low dose antithyroid drugs may be a superior choice, particularly for older patients. Furthermore, in the presence of TRAb antibodies, indicating Graves' disease, then antithyroid drugs are the treatment of choice, as there is an excellent chance of long-term remission follow a 12-month course. Decision-making concerning the optimal choice of therapy is hindered by lack of randomized studies. However, two uncontrolled studies have shown improvement in cardiovascular abnormalities [28, 29] and two small studies have also shown improvement in bone mineral content, both following radioiodine and antithyroid drugs [30, 31].

Summary Points

- SH is characterized by a low serum TSH with normal circulating fT_4 and fT_3.
- The commonest causes of SH are medication use and non-thyroidal illness.
- Large population studies of elderly people show that SH is associated with several adverse outcomes including atrial fibrillation (AF), heart failure, osteoporosis, and death.
- There is no randomized controlled trial (RCT) evidence that demonstrates treatment of low TSH will improve outcome.
- Treatment should be considered in patients with a fully suppressed serum TSH (<0.05 mU/L), with evidence of thyroid autonomy (fT_3 >5.5 pmol/L) and complications that may be attributed to SH.

3.3.5 Causes and Laboratory Investigations of Thyrotoxicosis

Francesco Latrofa and Paolo Vitti

Introduction

The term thyrotoxicosis identifies the clinical syndrome caused by elevated circulating thyroid hormones of all sources, while hyperthyroidism includes only the disorders due to an increased secretion of hormones by the thyroid gland. Hyperthyroidism is the most frequent cause of thyrotoxicosis. Unregulated discharge of preformed thyroid hormones due to destructive processes of the gland (destructive thyrotoxicosis) and exogenous ingestion or extrathyroidal production of thyroid hormones (thyrotoxicosis of non-thyroidal origin) are less common causes of thyrotoxicosis. Although careful history taking and physical examination often direct towards the diagnosis of thyrotoxicosis, laboratory confirmation by measurement of thyroid-stimulating hormone (TSH) and thyroid hormones is always needed. Once thyrotoxicosis is confirmed, laboratory testing and thyroid imaging are required to identify the cause of thyrotoxicosis.

Causes of Thyrotoxicosis

Classification

From a clinical standpoint it is useful to classify the different causes of thyrotoxicosis according to their pathogenic mechanisms. A practical classification distinguishes the forms of thyrotoxicosis into the two broad syndromes of thyroidal and non-thyroidal origin (Table 3.3.5.1). The first group can be further divided in forms associated with thyroid hormone hypersecretion (hyperthyroidism) and in forms induced by the release of preformed hormones, as consequence of destructive processes (destructive thyrotoxicosis). The second group includes a heterogeneous group of disorders, in which the thyroid is not the source of thyroid hormone. The most useful test in differentiating hyperthyroidism from the other causes of thyrotoxicosis is thyroidal radioiodine uptake (RAIU), which is high or high–normal in hyperthyroidism and low in destructive thyrotoxicosis and in thyrotoxicosis of non-thyroidal origin.

Causes of Hyperthyroidism

Graves' Disease

Graves' disease is the most frequent cause of hyperthyroidism, accounting for more than 70% of cases in iodine-sufficient areas, where its prevalence may be as high as 2% in women [1]. In Graves' disease, hyperthyroidism is caused by an autoimmune reaction to the thyroid, leading to the production of autoantibodies to the TSH receptor (TSHR autoantibodies) [2]. These antibodies mimic the action of TSH in stimulating the TSH receptor on thyroid follicular cells (TSHR-S autoantibodies).

As the effect of TSHR-S autoantibodies is exerted on all follicular cells, a diffusely enlarged thyroid is the hallmark of the disease, but in some cases thyroid nodules can develop. Graves' ophthalmopathy and, rarely, pretibial myxoedema are other typical physical findings. On careful physical exam, 30–45% of patients with Graves' disease have some signs of Graves' ophthalmopathy. When obviously present, Graves' ophthalmopathy is extremely useful in supporting Graves' disease as the cause of thyrotoxicosis. Pretibial myxoedema is only rarely observed in Graves' disease, but almost never observed without it.

Toxic Adenoma and Multinodular Toxic Goitre

Toxic adenoma and multinodular toxic goitre are frequent causes of hyperthyroidism, especially in iodine-deficient areas. Toxic adenomas are monoclonal benign encapsulated tumours

Table 3.3.5.1 Classification of known causes of thyrotoxicosis, with their distinctive diagnostic features and radioiodine uptake (RAIU) findings

Disease	Distinctive features	Neck RAIU
Thyrotoxicosis of thyroidal origin associated with hyperthyroidism		
Graves' disease	Diffuse goitre Ophthalmopathy Positive TSHR autoantibodies	High
Toxic adenoma	Single 'hot' nodule at thyroid scan	High
Multinodular toxic goitre	Multiple 'hot' nodules at thyroid scan	High
Iodine-induced thyrotoxicosis	High urinary iodine	Low to high
TSH-secreting adenomas	Inappropriately high TSH level	High
Familial gestational hyperthyroidism	Pregnancy-associated DNA analysis	Presumably high
Trophoblastic tumours	High chorionic gonadotropin	High
Neonatal transfer thyrotoxicosis	Positive TSHR autoantibodies	High
Non-autoimmune congenital and familial hyperthyroidism	TSH receptor gene mutations by DNA analysis	High
Type I amiodarone-induced thyrotoxicosis	High urinary iodine	Normal, high, low
Other drugs-induced hyperthyroidism	Positive TSHR autoantibodies	High
Thyrotoxicosis of thyroidal origin associated with thyroid destruction		
Subacute thyroiditis	Neck pain High ESR	Low
Silent thyroiditis	Positive thyroid autoantibodies	Low
Type II amiodarone-induced thyrotoxicosis	High urinary iodine	Low
Other drugs-induced thyrotoxicosis	Negative TSHR autoantibodies	Low
Thyrotoxicosis of non-thyroidal origin		
Factitious thyrotoxicosis	History Low serum thyroglobulin	Low
Dermoid tumours (struma ovarii)	Abdominal RAIU	Low
Metastatic differentiated thyroid cancer	Bone RAIU	Low

that synthesize thyroid hormones independently of TSH stimulation. They are characterized by heterozygous gain-of-function mutations involving the TSHR or the Gsα protein genes which induce a permanent and TSH-independent activation of the adenylate-cyclase pathway. Somatic mutations of the *TSHR* gene, which cause amino acid changes leading to constitutive activation of the *TSHR*, are the cause of 20–80% of toxic adenomas, while the rate of mutations of the Gsα protein range from 8% to 75% [3]. The natural history of toxic adenoma is characterized by one autonomous adenoma developing in an otherwise normal thyroid, slowly growing over many years. The coexistence or two or more toxic adenomas (multiple adenomatosis) is uncommon. In the early phases, the amount of secreted thyroid hormones is not sufficient to completely suppress TSH secretion (partial autonomy) and the function of the extranodular tissue. With further growth of the nodule, TSH suppression becomes complete, while circulating thyroid hormones are in the upper range of normal values (complete autonomy). Eventually, overt thyrotoxicosis ensues, with frankly elevated thyroid hormone levels (hyperthyroidism). The rate of progression is quite slow. The risk of overt hyperthyroidism is higher for adenomas greater than 3 cm in size.

Multinodular toxic goitre is also often detected in iodine-deficient countries, in which accounts for up to 60% of cases of thyrotoxicosis. The prevalence of multinodular toxic goitre in these iodine-deficient areas has been reduced by iodine prophylaxis [4]. The same somatic activating mutations of the TSHR demonstrated in toxic adenoma have been observed in toxic multinodular goitre as well [5]. However, in many nodules neither TSHR nor Gsα protein mutations have been observed [3]. The clonal development of follicles with high replicative capacity will induce the onset of non-functioning (cold) or hyperfunctioning (hot) nodules, in which the uptake and thyroid hormone synthesis is independent from TSH stimulation. The natural history of multinodular toxic goitre is similar to that of toxic adenoma, with the slow formation of multiple autonomously functioning nodular areas in the setting of an overall nodular goitre. The only known mechanism inducing subclinical hyperthyroidism and overt thyrotoxicosis is the administration of excessive amount of iodine. Because of the slow progression through several degrees of thyrotoxicosis and of their advanced age, patients with multinodular toxic goitre may report few symptoms.

Thyroid-Stimulating Hormone-Secreting Adenoma

TSH secretion by a benign pituitary adenoma, which is characterized by a partial or complete loss of the feedback regulation by thyroid hormones (central hyperthyroidism), causes a sustained stimulation of the thyroid gland, with the subsequent development of goitre and hyperthyroidism (see Chapter 3.3.11). An increased prevalence has been reported, probably as a consequence of the introduction of ultra-sensitive assays for TSH measurement, that enables an earlier detection of an inappropriate secretion of TSH.

hCG-Dependent Hyperthyroidism

Due to its partial homology with TSH, hCG can act as a weak (about 1/10 00th less potent) TSH agonist. When present in large amounts in the bloodstream, it can overstimulate the thyroid gland, inducing hyperthyroidism. Human chorionic gonadotropin (hCG) is secreted in large amounts by placental tissue in normal pregnancy and also by trophoblastic tumours.

Trophoblastic Tumours

Hyperthyroidism may ensue in patients with a hydatidiform mola or a choriocarcinoma as well as with chorionic tumour of the testes, as a consequence of the large quantities of hCG produced by the tumour. Thyrotoxicosis is common in trophoblastic tumours and 200–400 IU/ml of hCG are associated with high fT_4 and fT_3. However, clinical overt thyrotoxicosis is observed in a minority (10%) of patients, when hCG is extraordinarily high (>3000 IU/ml). The routine use of ultrasonography during pregnancy has led to earlier diagnosis of hydatidiform mola, when the tumour mass is smaller and the thyrotoxicosis less likely.

Hyperemesis Gravidarum

Hyperemesis gravidarum is characterized by prominent nausea and vomiting, weight loss, ketosis, and electrolyte abnormalities. It occurs in 1.5% of pregnancy and is more common in twin pregnancies because of the higher serum hCG concentrations. In 25% to 75% of cases have been reported increased levels of fT_4 and fT_3, which correlates with serum hCG concentrations. A minority of women with hyperemesis gravidarum experience a clinically evident thyrotoxicosis (gestational hyperthyroidism) [6]. It resolves spontaneously within the first 3 to 4 months of gestation.

Familial Gestational Hyperthyroidism

Two families with recurrent hyperemesis gravidarum and gestational hyperthyroidism due to a mutation in the TSHR gene causing increased responsiveness to hCG have been reported [7, 8]. Hyperthyroidism only manifests during pregnancy and recurs every time an affected woman becomes pregnant.

Fetal and Neonatal Autoimmune Hyperthyroidism

TSHR-S autoantibodies in the serum of mothers with Graves' disease can cross the placenta and cause fetal and neonatal hyperthyroidism, through direct stimulation of the fetal and neonatal thyroid. Usually the mother is affected by Graves' disease, in the majority of cases presenting with hyperthyroidism, but sometimes with hypothyroidism after thyroidectomy or ^{131}I treatment. Transplacental passage of TSHR-S autoantibodies from maternal to fetal circulation increases from low levels at 15 weeks to reach maternal levels by 30 weeks of gestation. Hyperthyroid fetus presents with tachycardia, hyperactivity, poor growth, and occasionally acceleration of skeletal maturation. Fetal goitre may occur. In severe and untreated hyperthyroidism intrauterine death has been reported.

Neonatal hyperthyroidism can be very severe and is characterized by tachycardia, jaundice, heart failure, failure to thrive. A goitre is usually present. The disease is transient and resolves within 3 to 12 weeks after birth, when TSHR-S autoantibodies disappear.

Non-Autoimmune Congenital and Familial Hyperthyroidism

After the first report of congenital hyperthyroidism caused by a germline activating mutation of the *TSHR* gene [9], only few cases of non-autoimmune neonatal hyperthyroidism have been described. The diagnosis should be suspected when a neonate presents with severe hyperthyroidism and goitre and the mother has no history of Graves' disease.

Familial hyperthyroidism due to autosomal dominant activating germline mutations of the TSHR has been described [10]. In the few cases reported, hyperthyroidism and goitre developed in adulthood because the effect of the mutation is mild. Germline mutations of the TSHR gene are uncommon in juvenile thyrotoxicosis.

Cases of congenital hyperthyroidism from mutations of the Gsα protein have been also reported, associated with McCune–Albright syndrome.

Causes of Destructive (Low RAIU) Thyrotoxicosis

Subacute Thyroiditis

Subacute thyroiditis (or granulomatous or giant cells or de Quervain's thyroiditis) is reported in Chapter 3.2.6.

Painless Thyroiditis

Painless thyroiditis (or sporadic or silent thyroiditis) is an autoimmune thyroid disorder, characterized by a transient phase of thyrotoxicosis, similar to subacute thyroiditis, in absence of neck pain and general symptoms (see Chapter 3.2.5).

Postpartum Thyroiditis

Postpartum thyroiditis (PPT) is the painless thyroiditis that occurs in susceptible women within 12 months after delivery (see Chapter 9.4).

Other Forms of Destructive Thyrotoxicosis

Rarely, destructive thyrotoxicosis can be precipitated by anterior neck injuries. Thyrotoxic crises following thyroid surgery have now become extremely rare with the optimal use of antithyroid drugs and with the refinement of surgical procedures. Thyrotoxicosis may transiently worsen or recur in patients with Graves' disease, toxic adenomas, and multinodular toxic goitre who are treated with radioiodine. Two mechanisms are responsible for this phenomenon: ongoing thyroid hyperfunction before radioiodine fully takes effect and radiation-induced thyroid destruction.

Iodine-Induced Thyrotoxicosis

Iodine deficiency increases thyrocyte proliferation and mutation rates, inducing the development of multifocal autonomous growth and of cell clones harbouring activating mutations of the TSHR.

Some of these nodules maintain the ability to store iodine and can become autonomous causing thyrotoxicosis after iodine load or even iodine supplementation. Iodine-induced thyrotoxicosis is by far more prevalent in aged patients and in areas of iodine deficiency (Table 3.3.5.2). Another predisposing condition is euthyroid or latent Graves' disease or Graves' disease in remission. In individual thyrotoxic patients, iodine contamination may be caused by a variety of medications and diagnostics, including lipid-soluble contrast media, disinfectants and drugs and some foods containing large amounts of iodine (Table 3.3.5.3).

Drugs

Amiodarone

The antiarrhythmic amiodarone, which contains a large amount of iodine, can cause thyrotoxicosis by two mechanisms. In iodine-deficient regions, where several elder people have nodular thyroid autonomy, and in patients with euthyroid Graves' disease, it can precipitate hyperthyroidism (type I amiodarone-induced thyrotoxicosis) [11]. In patients with no underlying thyroid disease, it can cause a thyroiditis with the release of preformed hormones (type II amiodarone-induced thyrotoxicosis). Distinction between the two forms is useful for the appropriate treatment but some patients present with a mixed form.

Lithium

Treatment with lithium is more frequently associated with hypothyroidism than thyrotoxicosis. Thyrotoxicosis due to destructive thyroiditis is more commonly reported.

Interferon

For a long period, the mainstay in the treatment of hepatitis C (HCV) has been the combination of IFN-α with ribavirin (RBV). Monotherapy with IFN-α has been shown to induce the development of thyroid autoantibodies in 20.6% and thyroid dysfunction in 2.7% of patients, while the combined treatment (IFN-α plus RBV) caused development of thyroid autoantibodies in 5.0% and thyroid dysfunction in 12.8% of patients [12]. Fifty per cent (50%) of patients with positive TPOAb before treatment developed thyroid dysfunction in comparison with 5.4% of autoantibody-negative patients. Thyrotoxicosis is usually a destructive process, presents with a mild or subclinical course, is transient, lasting just a few weeks or months while Graves' disease is uncommon. Destructive thyroiditis occurs in 5% of patients treated with IFN-α, and can lead to permanent hypothyroidism. Serum TSH should be measured every 2–3 months during IFN-α treatment, and 6 months after its discontinuation.

Highly Active Antiretroviral Therapy (HAART)

Patients infected with HIV have a higher prevalence of thyroid dysfunction when compared with the general population, euthyroid sick syndrome, Graves' disease and subclinical hypothyroidism being the most frequently reported [13].

Interleukin-2

Thyroid diseases have been reported in 10–50% of patients treated with interleukin-2, alone or in combination with other immunotherapies [14]. Hypothyroidism, thyrotoxicosis, and hypothyroidism after a phase of thyrotoxicosis have been reported.

Denileukin Diftitox

It can induce thyrotoxicosis by destructive thyroiditis or triggering of autoimmunity in predisposed individuals [15].

Thalidomide and Lenalidomide

Both hypothyroidism and thyrotoxicosis have been reported [16]. Interference with thyroid hormone secretion, reduction of iodine uptake, destructive thyroiditis by ischaemia, or immune-mediated mechanisms have been proposed as the potential causes of thyroid dysfunction.

Alemtuzumab

Alemtuzumab causes thyroid dysfunction in 30% of patients, with onset ranging from 6 to 61 month [17]. About half of the cases have been Graves' disease with or without ophthalmopathy.

Immune Checkpoint Inhibitors

Blocking of immune checkpoints, such as cytotoxic T-lymphocyte antigen-4 (CTLA4) and programmed death-1 (PD1), two coinhibitor receptors that are expressed on activated T cells, has emerged as an option for treatment of cancer.

Anti-CTLA4 Monoclonal Antibodies

Ipilimumab and tremelimumab are mAbs directed against CTLA4. Hypophysitis, which can cause central hypothyroidism, is the most severe and dose-limiting endocrine adverse effect. Thyroid disorders have been reported in 0–7.4% of patients treated with ipilimumab, with an incidence of hyperthyroidism of 0–2.8% [18]. Thyroid disorders occur in 0.5–5.2% of patients treated with tremelimumab

Anti-PD-1 Monoclonal Antibodies

PD-1 is a negative regulatory receptor expressed on T and B lymphocytes and natural killer cells which limits their response. Nivolumab and pembrolizumab are anti-PD-1 mAb approved for treatment of advanced malignant tumours. Thyroid dysfunction has been observed in 9% of treated patients, with 3% developing hyperthyroidism [19].

Thyrotoxicosis of Extrathyroidal Origin

Thyrotoxicosis Factitia

The term thyrotoxicosis factitia describes the voluntary excessive ingestion of thyroid hormone preparations with the purpose of mimicking thyrotoxicosis (from the Latin *factitius* = fake). However, the term has been widely applied to all forms of thyrotoxicosis due to the ingestion of thyroid hormones. True thyrotoxicosis factitia is most often observed in women with psychiatric disturbances, with access to the thyroid medication. Very often thyroid hormone is taken for weight reduction or to receive medical attention. The diagnosis is rarely obtained at history taking and denial of thyroid hormone assumption may be extreme. Accidental or suicidal ingestion of large amounts of thyroid hormone has been also described, but this can usually be diagnosed by history alone. Sometimes, thyroid hormone is inadvertently taken as a component of 'herbal' or 'alternative' medications, usually for weight reduction. Finally, accidental

grinding of cattle thyroids in hamburger meat has been reported as the cause of an outbreak of thyrotoxicosis among hamburger consumers in the US [20].

Struma Ovarii

Struma ovarii is a on ovarian tumour, usually a teratoma composed of at least 50% thyroid cells. It comprises about 3% of ovarian teratomas, is bilateral in 10% and malignant in 5% of cases. Thyrotoxicosis occurs in 10% of cases.

Functional Metastatic Thyroid Carcinoma

Differentiated thyroid carcinoma, even when metastatic and with large tumour burdens, does not usually produce relevant amounts of thyroid hormones. Very rarely however, thyroid carcinomas of the follicular histotype, extensively metastatic to the bone may cause thyrotoxicosis. Coexistent TSHR-S autoantibodies are an extremely rare cause of thyrotoxicosis in patients with metastatic thyroid cancer.

Laboratory Diagnosis of Thyrotoxicosis

Thyroid-Stimulating Hormone

The mainstay of the diagnosis of thyrotoxicosis is measurement of serum TSH and thyroid hormones. In fact, many laboratories measure only TSH in the initial assessment and measurement of thyroid hormones is automatically added only if TSH is abnormal ('TSH reflex'). Indeed, TSH concentration is inversely log-linearly proportional to fT_4 level [21]. The current immunoassays are very sensitive and can measure TSH levels well below the normal range, with a functional sensitivity of less than 0.02 mU/L. Since pituitary TSH secretion is tightly downregulated by thyroid hormone level, TSH is undetectable in most cases of thyrotoxicosis. The only remarkable exception are TSH-secreting adenomas, in which a high or inappropriately normal TSH level is found in spite of overt thyrotoxicosis. Because of the sensitivity of the assay, low (less than 0.4 mU/L) but detectable TSH levels can be found. These levels are encountered in subclinical thyrotoxicosis and in other conditions, such as non-thyroidal illnesses, endogenous or exogenous corticosteroid excess. TSH is a heterogeneous molecule and different TSH isoforms circulate in the blood and are present in pituitary extracts used for assay standardization [22]. Although current methods have eliminated cross-reactivity with other glycoprotein hormones, they may detect different epitopes of abnormal TSH isoforms, secreted by some euthyroid individuals and some patients with pituitary diseases. Rarely, the presence in the serum of antimouse immunoglobulin antibodies may interfere in the TSH assay, causing falsely elevated TSH levels.

Thyroid Hormone

Measurement of serum thyroid hormone levels is mandatory in all patients with suspected thyrotoxicosis, for a proper evaluation of a low TSH level and for an estimation of the severity of the disease. The active form of the hormones in serum is the very small amount of freely circulating T_4 (free T_4–fT_4) and T_3 (free T_3–fT_4), which can enter cells, interacting with the specific receptors. Total T_4 (tT_4) and total T_3 (tT_3) can be easily and inexpensively measured by radioimmunoassay, but their levels are influenced by the levels of binding protein, which vary in healthy subjects and may change in several conditions [23]. Thus, total thyroid hormone levels may not parallel those of free thyroid hormones, and their measurement is nowadays considered less useful in the evaluation of thyrotoxicosis. Free thyroid hormone levels measurements, although not completely exempt from flaws, are therefore more satisfactory, since they provide a more accurate measurement of the active hormone [24].

In iodine-sufficient countries a single measurement of fT_4 is sufficient to confirm or reject the suspicion of thyrotoxicosis and, after TSH measurement, this is the test most often used in North America for thyroid function screening [25]. In contrast, in iodine-deficient countries, a significant proportion of hyperthyroid patients (up to 12%) may have elevated fT_3 and normal fT_4 levels (T_3-toxicosis). Conversely, fT_4 can be falsely elevated in conditions causing reduced peripheral conversion of T_4 to T_3. In our practice, when thyrotoxicosis is suspected, we initially assess both fT_4 and fT_3 levels along with TSH with little additional expense in order to obtain a complete assessment of the thyroid function status.

Laboratory Investigations in the Differential Diagnosis of Thyrotoxicosis

In many cases, history and physical examination can readily identify the cause of thyrotoxicosis. However, in many other situations, a careful differential diagnosis is needed in order to establish an etiological diagnosis. Classically, RAIU has represented a mainstay of the differential diagnosis of thyrotoxicosis. RAIU is easily performed by administering a minimal (tracer) dose of radioactive iodine and then measuring the percent of administered radioactivity accumulated in the neck. In iodine-sufficient countries the upper limit of RAIU, 24 hours after the administration of the tracer, is around 25%, while it may reach 40% in areas with mild to moderate iodine deficiency. Whenever excessive active formation of thyroid hormone takes place in the thyroid gland, RAIU is increased, since the thyroidal machinery for iodine trapping and organification is activated. Therefore, a high RAIU readily identifies true hyperthyroidism (e.g. with thyroid hyperfunction). In contrast, thyrotoxicosis with a low RAIU indicates either thyroidal destruction, with release of preformed hormone, or an extrathyroidal source of thyroid hormone. In thyroid destruction, the damaged follicular cells transiently lose their capability of iodine trapping, while when exogenous hormones are administered in excess, the suppression of the pituitary secretion of TSH causes shutting-off of the trapping capacity of follicular cells. The only exception to this rule is iodine-induced thyrotoxicosis, in which a low RAIU can be observed because of dilution of the tracer dose in the large body pool of iodine, in spite of true hyperthyroidism.

Nowadays, RAIU is not performed in the initial assessment of a thyrotoxic patient and a vast array of laboratory and imaging techniques have provided excellent tools for accurately identifying the cause of thyrotoxicosis without the information provided by RAIU. RAIU is still useful in difficult cases, to broadly define forms of thyrotoxicosis according to their pathogenesis and orderly proceed with adjunctive diagnostic tools.

Graves' Disease

TSH Receptor Autoantibodies

Since the cause of Graves' disease hyperthyroidism is uncontrolled thyroid gland stimulation by circulating TSHR autoantibodies, their detection in the serum of thyrotoxic patients is particularly useful in establishing the diagnosis of Graves' disease. Serum TSHR-S autoantibodies can be measured by different methods [2, 26]. They were originally detected with *in vivo* bioassays, and thereafter by *in vitro* systems. The most common tests assess the displacement of labelled TSH or TSHR autoantibodies from the TSHR by the immunoglobulin fraction of patients' sera. These methods are termed TSH binding-inhibition (TBI) tests and do not distinguish between TSHR-S autoantibodies and TSHR blocking (TSHR-B) autoantibodies, which can be also detected in thyroid autoimmune disorders [2]. TSHR-S autoantibodies can be tested in cellular systems carrying a functional TSH receptor, detecting the release of cAMP in the culture medium upon challenge with serum or purified immunoglobulins (TSHR-S autoantibodies assay) [2]. In a modification of the assay, TSHR-B autoantibodies can be detected as well. Since TSHR-S autoantibodies are properly the cause of hyperthyroidism in Graves' disease, their assay should be considered the gold standard in the diagnosis of Graves' disease. Unfortunately, the assay is quite expensive and requires cell-culture capabilities, making it available only to research centres. For clinical purposes, the TBI assays are most often used. By last generation assays, positive TBI tests are found in 75–95% of patients, with a high specificity (99%) [27]. TSHR autoantibodies showing inhibition of TSH binding to TSHR but not TSHR stimulating activity have been demonstrated in serum of subjects with no evidence of autoimmune thyroid diseases [28]. A TBI test is strictly needed in the minority of cases of Graves' disease, in which the clinical picture is unclear, for example in the differential diagnosis of hyperemesis gravidarum, in the nodular variants of Graves' disease that must be differentiated from toxic nodular goitre, in patients with exophthalmos without thyrotoxicosis (euthyroid Graves' disease). The presence of high levels of TSHR autoantibodies at the end of antithyroid drug therapy has a high positive predictive value and specificity for relapse of hyperthyroidism but a low negative predictive value and sensitivity [29].

Whereas TSHR-S autoantibodies interact mainly with the N-terminal components of the ectodomain, TSHR-B autoantibodies interact to a greater extent with the C terminus and to a lower degree with the N terminus and the mid-region of the TSHR [2, 30]. An assay based on a chimeric receptor in which residues 261–370 of TSHR have been substituted by the homologous portion of the LH/hCG receptor (Mc4) has been proposed to be more accurate in the detection of TSAb as well as in detecting both TSAb and TBAb autoantibodies [31, 32].

Thyroid Peroxidase (TPO) and Thyroglobulin (Tg) Autoantibodies

TPO autoantibodies can be found by commercial assays in up to 90% of patients with untreated Graves' disease, while Tg autoantibodies are less frequently positive, in 50–80% of cases. Both autoantibodies however are also present in other forms of thyroid autoimmune disorders, some of which may cause thyrotoxicosis, such as postpartum thyroiditis and silent thyroiditis. A relatively high percentage (up to 25%) of positive thyroid autoantibodies tests is also found in normal subjects, especially women [33]. Thus, TPO and Tg autoantibodies tests do not establish the diagnosis of Graves' disease as the cause of thyrotoxicosis, but may be useful as complementary tests in confirming the presence of thyroid autoimmunity.

The finding of autoantibodies cross-reacting with Tg and TPO (TgPO Ab) in patients with autoimmune thyroid diseases, which suggested a role for cross-reactivity of B cell response to Tg and TPO, has not been confirmed [34].

Total thyroid ablation (thyroidectomy plus 131-I) induces the disappearance of thyroid autoantibodies [35].

Other Thyroid Autoantibodies

Autoantibodies to megalin were detected in 50% of patients with chronic autoimmune thyroiditis and in some patients with Graves' disease and thyroid carcinoma [36]. A role of Na/I symporter as autoantigen in thyroid autoimmunity has been proposed by some authors but excluded by others. Neither megalin nor Na/I symporter autoantibodies are routinely used for diagnosing autoimmune thyroid diseases.

Thyroid RAIU and Scan

In untreated hyperthyroid Graves' disease patients, a high value of RAIU at the 24th hour is always found. As a distinctive feature, in some cases the 3rd or 6th hour value can be even higher than at the 24th hour, as an expression of an extremely high iodine turnover. The test is very useful to rule out transient thyrotoxicosis due to Hashitoxicosis or painless or subacute thyroiditis, factitious thyrotoxicosis, and type II amiodarone-induced thyrotoxicosis [11].

Thyroid imaging with radioisotopes can be performed with radioiodine at the time RAIU is done or using ^{99m}pertechnetate. Thyroid scanning in Graves' disease is useful only when coexisting nodules are detected and their functional status needs to be evaluated.

Thyroid Ultrasound

The ultrasound appearance of the thyroid gland undergoes typical changes during Graves' disease hyperthyroidism. Because of the reduction in the colloid content and of the lymphocytic infiltrate, the gland becomes diffusely hypoechoic. A similar pattern is also observed in chronic goitrous thyroiditis and, when diffuse, indicates the presence of thyroid autoimmunity. Therefore, thyroid ultrasound can be useful in confirming the suspicion of thyroid autoimmunity, during the evaluation of thyrotoxicosis. Marked hypoechogenicity at the end of antithyroid drug therapy may predict recurrence of thyrotoxicosis [37]. As an adjunctive value, thyroid ultrasound scanning also allows an accurate measurement of the goitre size, an information that is important in the choice of the most appropriate treatment. Thyroid ultrasound accurately distinguishes true thyroid nodules from the lobulations that can be occasionally felt at palpation in Graves' disease glands.

The measurement of blood flow to the thyroid gland by colour Doppler ultrasonography has been also used in Graves' disease patients. In untreated Graves' disease the colour Doppler pattern is characterized by markedly increased signals with a patchy distribution [38]. Colour Doppler studies of the thyroid gland can therefore be used similarly to RAIU in distinguishing Graves' disease from other forms of thyrotoxicosis, for example, amiodarone-induced

destructive thyrotoxicosis [39] or subacute thyroiditis and, possibly, painless thyroiditis.

Toxic Adenoma

When a single nodule is palpated in the thyroid of a patient being evaluated for thyrotoxicosis, the presence of a toxic adenoma must be always suspected. In confirming the diagnosis of thyrotoxicosis, it is important to measure both fT_4 and fT_3 levels, since T_3-toxicosis is distinctly frequent in toxic adenomas.

^{99m}Technetium or radioiodine thyroid scanning are extremely helpful in confirming the diagnosis, yielding typical findings (Figure 3.3.5.1). The nodule will appear 'warm', with the extranodular thyroid tissue clearly visible, when partial autonomy is present. In this case, parallel thyroid function tests will show a low but detectable TSH, and thyroid hormone levels in the upper part of normal range. Only the nodule is visible on the scan when TSH is completely suppressed (e.g. in case of complete autonomy or overt thyrotoxicosis).

Ultrasound scanning of the neck provides no direct diagnostic information on the functional property of the nodule, but it is useful in detecting coexisting cold nodules and accurately defines the size of the nodule. Preliminary reports have shown a distinctive colour Doppler pattern in autonomously functioning thyroid nodules, characterized by an increased blood flow in the nodular tissue, in good correlation with radionuclide scans. However, the technique is not able to distinguish benign from malignant nodules and is therefore of limited value.

Ultrasound elastography has showed high sensitivity and specificity in differentiating benign from malignant thyroid nodules [40]. The risk of malignancy in hot nodules is extremely low, although occasionally reported. Therefore, in presence of a low TSH, fine needle aspiration is only needed when coexisting nodules detected by palpation or ultrasound are cold at radionuclide scanning.

Toxic Multinodular Goitre

The same range of thyroid function test alterations described in toxic adenomas can be observed in toxic multinodular goitre, from a subnormal TSH level to an undetectable TSH level with frankly elevated thyroid hormone levels. The diagnosis of toxic multinodular goitre can often be suspected on history and physical findings.

Thyroid radionuclide scanning is quite useful in identifying and mapping autonomous nodules and distinguishing them from other coexistent, cold nodules. Scanning is also useful in adjunct to TSHR autoantibodies measurement in distinguishing true toxic multinodular goitre from Graves' hyperthyroidism which develops on a pre-existing non-toxic multinodular goitre. RAIU is always elevated, unless iodine overload is present.

Thyroid ultrasonography is also useful to measure goitre size and, in association with radionuclide scanning images, to identify cold nodules, amenable to fine needle aspiration biopsy.

TSH-Secreting Adenomas

The presence of a TSH-secreting adenoma should be suspected when a detectable TSH level in presence of clearly elevated circulating thyroid hormone levels (inappropriate secretion of TSH) is found. The first step in the evaluation of inappropriate secretion of TSH is making sure that artefacts in the measurement of TSH or thyroid hormone levels are not the cause of the laboratory findings. Falsely elevated TSH levels can be observed occasionally when heterophilic antibodies are present in the patient's serum. These antibodies are antimouse immunoglobulins that bind both the solid-phase and the labelled mouse antibodies employed in most TSH immunoradiometric assays, causing bridging between the two and therefore mimicking the presence of TSH [22]. The problem can be overcome by incubating the patient's serum with mouse immunoglobulins prior to TSH testing, thus precipitating the heterophilic antibody [41]. The most recent TSH commercial assays contain these antibodies in their incubation buffers, making this problem quite rare nowadays. Macro TSH is composed by anti-TSH autoantibodies which complex monomeric TSH. It is considered to be inactive and therefore a cause of falsely high TSH value. Falsely elevated fT_4 and fT_3 levels must also be excluded in the preliminary evaluation of suspected inappropriate secretion of TSH.

Mild spurious elevations of fT_4 and fT_3 can occasionally be found in presence of thyroid hormone autoantibodies, genetic or drug-induced alterations of thyroxine-binding globulin and in non-thyroidal illnesses [24]. The two-step methods for measurement of free thyroid hormones may be useful to rule out these conditions. About 50% of immunoassays use the biotin-streptavidin interaction as an immobilizing system and can be influenced by the ingestion of biotin (vitamin B_7). A low to medium dose of biotin is commonly present in multivitamin preparations while patients with progressive multiple sclerosis are treated with high doses of biotin (10 000 times the recommended daily intake of approximately 30 μg). In some assays, serum biotin can induce both falsely low TSH and falsely high fT_4 and fT_3 levels. A washout period ranging from 8 hours to more than 3 days has been suggested to eliminate biotin interference [42].

Once these artefacts have been excluded, extensive laboratory testing is required to clarify the cause of inappropriate secretion of TSH. True inappropriate secretion of TSH is observed in two conditions: TSH-secreting pituitary adenoma and resistance to thyroid hormone. In theory, only TSH-secreting adenomas cause true and symptomatic hyperthyroidism (see next).

The syndrome of resistance to thyroid hormone is caused by a relative insensitivity of the thyroid hormone receptor to the action of its ligand. Therefore, higher thyroid hormone concentrations are needed to down regulate TSH secretion. In the majority of patients, the defect is due to mutations of thyroid hormone β-receptor gene [43]. As a consequence of the defect, the pituitary set-point for TSH suppression is set at a higher level of circulating thyroid hormone (i.e. a higher level of thyroid hormone is required for TSH suppression). After its first identification [44] a few cases of mutations of TRα have been reported. In these patients TSH is normal, fT_4 low/low-normal and T_3 high/high-normal.

Differential Diagnosis

When the suspicion of inappropriate secretion of TSH is confirmed, the presence of a TSH-secreting adenoma must be differentiated from resistance to thyroid hormone. Because of the overlapping clinical presentation and because no single test accurately allows clear-cut differentiation between the two conditions, extensive baseline and dynamic laboratory testing is usually required (Table 3.3.5.4).

A number of tests have been used to confirm the presence of thyrotoxicosis at the tissue level, including measurement of biochemical markers of thyrotoxicosis such as sex hormone binding globulin,

Table 3.3.5.4 Laboratory investigations in the differential diagnosis of the syndrome of inappropriate secretion of TSH

Test	TSH-secreting adenomas	RTH	Comment
Peripheral markers of thyroid hormone action	High	Normal-high	Non-specific
α-subunit/TSH molar ratio	>1	1	High in menopause
TSH after T_3-suppression test	Unchanged or slightly reduced	Frankly reduced or suppressed	Hazardous in elderly and cardiopathic patient
TSH after TRH	Unchanged	Increased	
Pituitary imaging	Positive	Negative	Confirmatory

alkaline phosphatase, cholesterol, and creatine phosphokinase. Unfortunately, these parameters are quite non-specific and may be elevated (or reduced) in a number of other conditions. At variance with normal pituitary, TSH-secreting adenomas secrete the α-subunit of TSH in molar excess with respect to TSH. A serum α-subunit/TSH ratio higher than 1 is observed in approximately 90% of patients with TSH-secreting adenoma. High ratios can be also observed in postmenopausal women and even in normal subjects, making this test alone unable to establish the diagnosis. Growth hormone (GH), IGF-I, and prolactin serum measurements are useful, since about 30% of TSH-secreting adenomas cosecrete GH and prolactin.

Dynamic testing aims at demonstrating the unresponsiveness of TSH-secreting adenomas to normal stimuli. In most (92%) TSH-secreting tumours the TSH level fails to increase in response to a standard thyrotropin-releasing hormone (TRH) stimulation test, while a normal or increased response is observed in resistance to thyroid hormone [45]. Diagnostic protocols to test the response of pituitary TSH to exogenous triiodothyronine are also used. Triiodothyronine is administered orally and the dose is increased every three days, starting from 50 up to 200 mcg/daily. Before every increase basal and TRH-stimulated TSH is measured, together with peripheral markers of thyroid hormone action [46]. In TSH-secreting adenomas, only partial or no suppression of TSH secretion is observed, while complete or partial suppression is observed in resistance to thyroid hormone. Alternatively, 80–100 μg triiodothyronine can be administered for 8–10 days. Using this protocol, complete TSH suppression is obtained in normal subjects, while no changes or slight reduction in TSH levels are observed in all patients with TSH-secreting adenomas. On the other hand, clear-cut reductions of TSH levels are observed in patients with resistance to thyroid hormone [45]. The test is contraindicated in elderly patients and in patients with arrhythmias and/or coronary artery disease. The demonstration of a mutation of TRβ gene is sufficient to establish the diagnosis of syndrome of resistance to thyroid hormone.

Pituitary imaging is very important in confirming the diagnosis of TSH-secreting adenomas. Ninety per cent (90%) of TSH-secreting adenomas are larger than 1 cm at diagnosis and therefore easily detected at pituitary MRI scanning. As a complement, radiolabelled octreotide pituitary scintigraphy can be useful in detecting small tumours, although it can be positive in other types of pituitary tumours.

hCG-Dependent Thyrotoxicosis

The presence of a trophoblastic tumour should be suspected when thyrotoxicosis is found in an amenorrhoeic woman, especially when a palpable abdominal mass is found. The diagnosis is readily confirmed by the finding of extremely high circulating hCG levels and of a pelvic mass at ultrasonography. In trophoblastic tumours serum hCG levels usually exceed 200 IU/ml, whereas the peak concentration of normal pregnant women is 100 IU/ml.

The diagnosis of thyrotoxicosis during hyperemesis gravidarum can be particularly challenging and it is one of exclusion. Because of weight loss and malnutrition, fT_3 levels may be disproportionately low or even normal in comparison with fT_4 levels, due to a reduced peripheral conversion of T_4 to T_3. The TSH level is often low during early normal pregnancy, but seldom undetectable, as it is in true thyrotoxicosis. The only distinctive laboratory feature is an inappropriately high hCG level, but large overlap with normal pregnancies exists. Therefore, the diagnosis of thyrotoxicosis in hyperemesis gravidarum relies mainly on the clinical picture and on appropriate exclusion of other more common forms of hyperthyroidism by appropriate testing. RAIU, as any other *in vivo* radioisotopic procedure, is contraindicated in pregnancy.

Fetal and Neonatal Hyperthyroidism

Women with a past or present history of Graves' disease should be carefully monitored throughout pregnancy. Fetuses and neonates of pregnant women who have been previously treated with radioiodine or surgery are at high risk because they lack protective effect of antithyroid drugs administered to the mother. The presence of a fetal heart rate over 160 bpm, in the absence of other fetal abnormalities is suggestive of fetal hyperthyroidism. TSHR autoantibodies should be measured starting at 22 weeks of gestation in mother with Graves' disease; only high levels can cause fetal or neonatal autoimmune hyperthyroidism.

The persistence of high levels of TSHR autoantibodies in the maternal serum by the end of pregnancy, when the transplacental passage is maximal, is a predictor of hyperthyroidism in the neonate. Fetal cord blood sampling is a risky procedure, and it is not generally recommended. Conversely, it is very useful to test neonatal cord blood at the time of delivery for thyroid function tests and TSHR autoantibodies. When the mother has been treated with high-dose antithyroid drugs, the neonate should be re-tested 10 days after birth, since transplacental passage of methimazole or propylthiouracil may initially mask hyperthyroidism.

Neonatal hyperthyroidism in the absence of a maternal history of Graves' disease and with negative TSHR autoantibodies should raise the suspicion of non-autoimmune congenital hyperthyroidism. Familiar hyperthyroidism should be suspected when relatives are affected and serum TSHR autoantibodies are absent. In

both types of hyperthyroidism sequencing of the TSHR gene is required to confirm the diagnosis.

Iodine-Induced Thyrotoxicosis

Excessive iodine assumption should be always suspected when hyperthyroidism abruptly appears in a patient with a history of nodular thyroid disease. A careful history taking often identifies the source of iodine and all patients should be asked about recent assumption of any of the compounds listed in Table 3.3.5.3 (online). With the exception of type II amiodarone-induced thyrotoxicosis, RAIU is usually low in thyrotoxic patients with heavy iodine contamination, but it is almost never suppressed, a feature that allows distinction from subacute and painless thyroiditis. The iodine/creatinine urinary ratio is the gold standard in confirming iodine contamination and is high in all cases.

Amiodarone-Induced Thyrotoxicosis

When a history of amiodarone assumption is elicited in a thyrotoxic patient, further testing is required to distinguish between type I and type II forms of amiodarone-induced thyrotoxicosis [11]. Type I (non-destructive) amiodarone-induced thyrotoxicosis differs little from other forms of iodine-induced thyrotoxicosis and an underlying thyroid disease such as Graves' disease or nodular thyroid disease is usually detected with the appropriate diagnostic tools. Accordingly, RAIU is usually low, but not suppressed and may be normal or increased. In contrast, in type II (destructive) amiodarone-induced thyrotoxicosis, RAIU is always low or suppressed and often no clear underlying thyroid disorder can be identified. Flow by colour Doppler sonography is a useful tool in differentiating the two forms of amiodarone-induced thyrotoxicosis, vascularity being increased in type I and absent in type II [39].

Drug-Induced Thyrotoxicosis

As just reported, destructive thyroiditis or triggering of autoimmunity in predisposed individuals are the mechanisms of drug-induced thyrotoxicosis. Evaluation to differentiate Graves' hyperthyroidism from low RAIU thyrotoxicosis is recommended, in order to advice the proper treatment.

Subacute, Painless, and Postpartum Thyroiditis

Classically, subacute, painless, and postpartum thyroiditis are characterized by a low (<1%) RAIU during the thyrotoxic phase. This test alone, in the presence of a suggestive clinical presentation allows the diagnosis in almost all cases. Serum T_4 concentration is disproportionately elevated compared with T_3 concentration, reflecting the preferential release of T_4 from the injured thyroid. In subacute thyroiditis, a very high (always >50 and often >100 mm/hr) erythrocyte sedimentation rate (ESR) is a distinctive diagnostic feature. C-reactive protein is also elevated and a mild leukocytosis is often observed.

High levels of TPO and Tg autoantibodies are usually found in postpartum and painless thyroiditis, as a marker of prominent thyroid autoimmunity, while only weakly and transiently positive tests are occasionally found in subacute thyroiditis. Ultrasound findings are generally characterized by patchy areas of hypoechogenicity in subacute thyroiditis, while a more diffuse hypoechoic pattern, closely resembling Hashimoto's thyroiditis is found in postpartum and painless thyroiditis. The colour Doppler pattern shows reduced vascularity in the three disorders. Occasionally, and especially when patients are first seen in the recovery or hypothyroid phase, a more subtle picture can emerge from testing with a low but not nil RAIU, and with only mild elevations of ESR, making the differential diagnosis more difficult.

Thyrotoxicosis of Extrathyroidal Origin

An extrathyroidal source of thyroid hormone should be suspected when the other, more frequent causes of low RAIU thyrotoxicosis have been ruled out. When thyrotoxicosis factitia is suspected, a serum Tg measurement can be extremely useful in confirming the diagnosis, since this disorder represents the only condition in which thyrotoxicosis is associated with an undetectable Tg level [47]. At the time of Tg measurement, however, it is important to test the patient's serum for Tg autoantibodies, since these may cause falsely low Tg levels [48]. Colour Doppler shows hypovascularity in thyrotoxicosis factitia.

The suspicion of struma ovarii can be confirmed at the time of RAIU, simply by scanning the pelvic area with the probe. The presence of functional thyroid tissue is demonstrated by a significantly increased uptake of iodine in the ovarian region. Further imaging (CT or ultrasound scan) will confirm the presence of an ovarian mass. The levels of CA 125 are elevated in both malignant and benign tumours.

When the source of thyroid hormone is metastatic thyroid follicular cancer, the presence of the latter is usually evident from the history. Since all patients with differentiated thyroid cancer after thyroidectomy take levothyroxine, thyroid function tests should be repeated after withdrawal of the medication, in order to rule out iatrogenic thyrotoxicosis. Whole body radioiodine scanning will show multiple foci of uptake in several skeletal regions.

3.3.6 Antithyroid Drugs for Thyrotoxicosis

Luigi Bartalena

Introduction

Hyperthyroidism due to Graves' disease can be treated either conservatively (antithyroid drugs, ATDs) or by reduction/ablation of thyroid tissue by radioiodine (RAI) or thyroidectomy [1, 2]. ATDs are the first-line treatment for newly diagnosed Graves' hyperthyroidism in Europe, Latin America, Asia, and Oceania, whereas RAI is preferred in North America [1, 3, 4] (Figure 3.3.6.1). When hyperthyroidism is caused by toxic adenoma or multinodular goitre, ATDs are only a tool to control hyperthyroidism prior to definitive treatment, because ATD discontinuation is inevitably followed by a recurrence of hyperthyroidism [5].

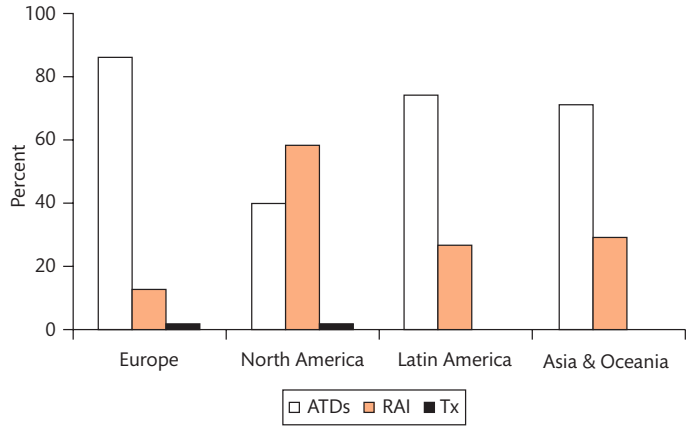

Figure 3.3.6.1 First-line treatment for newly diagnosed hyperthyroidism due to Graves' disease in different continents. Data are derived from Burch *et al*. [3] and Bartalena *et al*. [4].

ATDs belong to the family of thionamides and include propylthiouracil (PTU), carbimazole (CBZ), and its active metabolite, methimazole (MMI). Carbimazole is mainly used in the United Kingdom, MMI in the other European countries and Asia, while PTU has traditionally been the most commonly used ATD in North and Latin America [1]. However, recent data suggest that MMI has become the more common ATD in North America as well [6, 7].

Pharmacological Characteristics

ATDs are oral drugs completely absorbed from the gastrointestinal tract. Because of its longer half-life, MMI is given as a single daily dose, whereas PTU often requires fractionated doses. CBZ is rapidly converted to MMI. Therapeutic potency of MMI is 10–50-fold higher than that of PTU [2] (Table 3.3.6.1). PTU is not available in several countries.

Table 3.3.6.1 Pharmacological features of methimazole (MMI) and propylthiouracil (PTU)

	MMI	PTU*
Relative potency	10–50	1
Route of administration	oral	oral
Absorption from gastrointestinal (GI) tract	complete	complete
Half-life in serum (h)	6–8	1–2
Duration of action (h)	>24	8–12
Transplacental transfer	yes	yes
Passage into milk	yes	yes
Excretion	renal	renal
Administration schedule	once daily	2–3 times daily
Cost	low	moderate
Mechanism of action	TPO inhibition	TPO inhibition
		Type 1 deiodinase inhibition

*not available in several countries; TPO, thyroid peroxidase.

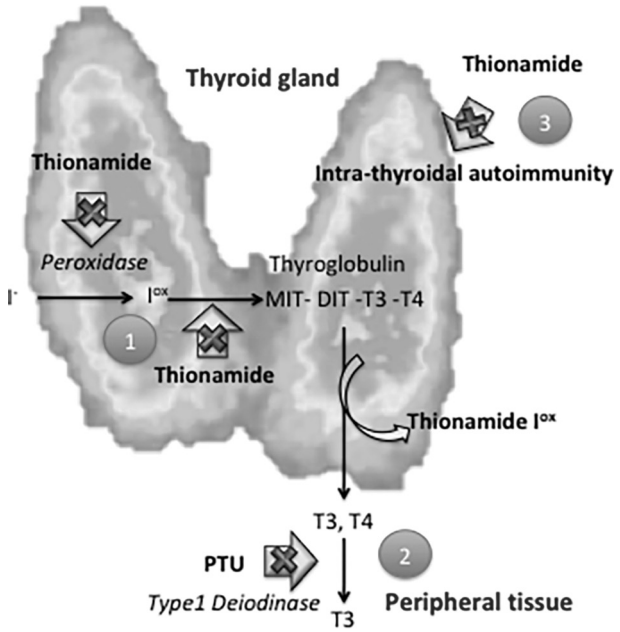

Figure 3.3.6.2 Mechanism of action of thionamides. The main action (**1**) is inhibition of thyroid peroxidase, leading to inhibition of thyroid hormone synthesis. In addition, propylthiouracil (PTU) (**2**) inhibits type 1 deiodinase activity, causing a decrease in the peripheral conversion of thyroxine (T4) to the metabolically active hormone, triiodothyronine (T_3). Finally, thionamides exert some immunosuppressive actions (**3**) that might be relevant.

ATDs mainly act by blocking thyroid hormone synthesis through inhibition of thyroid peroxidase (Figure 3.3.6.2). In addition, PTU inhibits type 1 deiodinase, the enzyme that peripherally converts thyroxine (T_4) to the metabolically active hormone, triiodothyronine (T_3). ATDs also exerts some immunosuppressive effects that may contribute to their therapeutic action in Graves' hyperthyroidism [8]. Whether the latter are direct or mainly indirect (i.e. bound to normalization of thyroid status) is still unsettled.

Adverse Events

In general, ATD treatments is safe. Side effects of thionamides are usually mild and self-limiting; major adverse events occur in less than 5% of cases, more frequently, particularly with MMI, during the initial phases of treatment, when high doses are often employed [9] (Table 3.3.6.2). If one thionamide causes an adverse event, the other thionamide can substitute, but cross-reactivity is frequent (about 50%) [10]. Accordingly, this strategy should not in principle be recommended.

Frequent side effects, such as itching or skin reactions, do not need ATD withdrawal, are usually transient, and can be controlled by antihistamines.

Agranulocytosis (neutrophil count <500 per mm^3) is one of the most feared adverse events of thionamides, with a reported incidence of about 0.3–0.6% [9], although a recent report suggested it may be as high as 1.2% [11]. Immediate drug discontinuation, prompt antibacterial treatment, and supportive measures are imperative; the efficacy of granulocyte colony-stimulating factor in accelerating recovery has recently been questioned [11]. There seems to be a dose-dependency of this serious complication in the case of MMI [12], which usually occurs within the first 3 months of treatment, while this relation is lacking for PTU [12]. Agranulocytosis seems to be more common in older people [13]. Recent studies have shown that genetic variants of NOX3 [14], HLA-B*27:05 [15], HLA-B*38:02, and HLA-DRB1*08:02 [16] confer increased susceptibility to ATD-induced agranulocytosis. Onset of agranulocytosis is generally abrupt. Accordingly, the usefulness of regular monitoring of white blood cell count is questionable, but patients should be advised that in case of fever, sore throat, or other signs of infections, a leukocyte count should be promptly obtained [17].

Aplasia cutis, the congenital (localized or disseminated) absence of skin, has been rarely reported in infants born to hyperthyroid mothers receiving MMI during pregnancy, but not in those treated with PTU [9]. Very rare cases of **embryopathy** (particularly,

Table 3.3.6.2 Adverse events of antithyroid drugs

	Adverse event	Frequency
Blood		
	Mild leucopoenia	Relatively frequent*
	Agranulocytosis	Uncommon (0.3–0.6%)
	Aplastic anaemia	Very rare
	Thrombocytopenia	Very rare
	Pancytopenia	Very rare
Skin		
	Skin rash	Very common*
	Urticaria	Very common*
	Itching	Very common*
	Generalized dermatitis	Very rare
	Alopecia	Very rare
Liver		
	Hepatocellular necrosis	Rare (PTU)
	Cholestasis	Very rare (MMI)
Collagen		
	Arthralgias	Common
	SLE-like syndrome	Very rare (PTU>MMI)
	Vasculitis	Very rare (PTU)
Embryopathy		
	Choanal atresia, oesophageal atresia, aplasia cutis	Very rare (MMI)
	Situs inversus ± dextrocardia, unilateral kidney a/dysgenesis, cardiac outflow tract defect	Very rare (PTU)
	Unilateral kidney a/dysgenesis, cardiac outflow tract defect	Very rare (PTU)
Miscellaneous		
	Loss of taste or smell	Rare (MMI)
	Hypothrombinaemia	Rare (PTU)
	Insulin autoantibodies	Very rare
	Pancreatitis	Very rare

choanal, and oesophageal atresia) were reported in infants whose mothers were given CBZ/MMI in early pregnancy [18]. It should be noted that although usually rarer and usually milder, cases of malformations, involving face and neck and urinary tract, have been observed also in the offspring of mothers treated with PTU [19] (see later section in this chapter on pregnancy and lactation).

Because PTU can be associated, although rarely, with severe **hepatoxicity** potentially lethal or requiring liver transplant, MMI rather than PTU should be prescribed as first-line ATD both in adults and children [8, 17, 20]. Hepatic abnormalities, with cholestatic features (but occasionally with necrotic features as well), may rarely occur also in patients treated with MMI [21], but they are usually milder and reversible after MMI withdrawal [21].

A rare but severe adverse event of ATDs is **vasculitis,** more common in PTU-treated patients [21]. Antineutrophil cytoplasmic antibodies (ANCA) are more frequently found in treated Graves' patients than in untreated patients or controls [22]. Vasculitis may manifest with arthritis, vasculitic rash, respiratory symptoms, or acute renal dysfunction. This rare complication develops early during MMI treatment, while the risk of vasculitis increases with time in PTU-treated patients [23]. Vasculitis requires prompt thionamide withdrawal; treatment with glucocorticoids or other immunosuppressive drugs may be necessary.

Because of potential thionamide adverse events, patients should be carefully informed and advised to get in touch promptly with their caregiver [17].

Dose Regimens

ATDs can be administered with two different regimens: the **Titration method,** in which the lowest thionamide dose maintaining euthyroidism is used, and the **Block-and-Replace method,** in which high doses of thionamides are persistently given combined with levothyroxine replacement to avoid hypothyroidism [24].

In the Titration method, treatment is usually initiated with 15–40 mg/day of MMI (in a single dose or divided doses) or 300–400 mg of PTU (always in divided doses). The choice of the initial daily dose depends on the severity of hyperthyroidism [17]. Thyroid function should be periodically assessed by measuring serum-free T_4 and T_3 concentrations, while serum thyroid-stimulating hormone (TSH) remains suppressed for several weeks after restoration of euthyroidism. The daily thionamide dose is tapered down to the lowest effective dose, generally 2.5–5 mg of MMI or 50–100 mg of PTU. Normalization of thyroid function usually occurs within 4–12 weeks. Evaluation of thyroid status should be made every 4–6 weeks for the first 4–6 months, and then every 3–4 months.

In the Block-and-Replace method, high doses of thionamides are administered (with no adjustment) together with levothyroxine. The rationale is that high doses of ATDs might have a greater immunosuppressive effect abating the autoimmune process and leading to permanent remission, but this putative effect remains to be demonstrated. With the Block-and-Replace method avoidance of hypothyroidism seems easier than with the Titration method, and the number of visits lower [24]. On the other hand, the prolonged use of higher doses of thionamides (e.g. 30–40 mg/day of MMI) might expose the patient to a potentially higher risk of adverse events [24]. This conclusion might not be tenable any longer in view of the lower than in the past doses of ATDs used also in the Block-and-Replace method [25]. The high number of daily tablets (unless high-dose tablets are available) may, however, decrease compliance with therapy. The Block-and-Replace regimen does not offer any advantage in terms of permanent remission of hyperthyroidism, while it may bear a slightly higher risk of side effects [24].

Duration of Treatment

Using the Titration method, a 18-month treatment is associated with a significantly lower relapse rate than a 6-month treatment [24]. There seems to be little advantage to prolong treatment up to 24 or 42 months [24], although the use of high doses of thionamides may result in a longer relapse-free period following thionamide withdrawal [26]. Using the Block-and-Replace regimen, extension of ATD treatment from 6 months to 12 months does not enhance the chance of a permanent remission of hyperthyroidism [27]. This view is not shared by some authors who have advocated the efficacy of very long treatment with low doses of thionamides [28].

Outcome of Treatment

The major limitation of ATD treatment is the high relapse rate after drug withdrawal. As many as 30–70% of patients experience a relapse of hyperthyroidism [9], in the majority of cases within one year after ATD discontinuation [29]. Hyperthyroidism may however relapse even years after ATD withdrawal [25]. A substantial proportion of thionamide-treated patients become spontaneously hypothyroid with time [30], indicating that a lifelong follow-up is needed after ATD treatment.

There is no reliable single predictor of ATD treatment outcome. However, patients with large goitres that do not shrink, severe hyperthyroidism difficult to control even with high ATD doses, detectable TRAb levels at the end of the treatment course, are indeed very good candidates to have a relapse of hyperthyroidism [31] (Table 3.3.6.3). Failure of TRAb to become undetectable almost invariably predicts relapse of hyperthyroidism following thionamide withdrawal, but also patients whose TRAb levels become undetectable during

Table 3.3.6.3 Risk factors for relapse of hyperthyroidism after antithyroid drug treatment

Factor	Impact on relapse
Large goitre	Strong
Age <40 years	Likely (controversial)
Male gender	Uncertain
Difficult control of hyperthyroidism with high ATD doses	Strong
Smoking	Strong
Detectable TRAb at the end of the ATD course*	Strong
Postpartum period	Strong

TRAb, TSH-receptor antibody. *Relapses are frequent also in patients whose TRAb tests are negative at the end of ATD treatment.

treatment have a relatively high chance of experiencing a relapse of Graves' hyperthyroidism [31]. Persistence of high TRAb levels during ATD treatment might represent an indication to switch to a definitive treatment of hyperthyroidism by RAI or thyroidectomy even before completion of the ATD course [32].

Men have a lower remission rate than women, while young age (less than 40 years) seems to be associated with a higher relapse rate [31], possibly because hyperthyroidism tends to be less severe in older people. Smoking might reduce the likelihood of a permanent remission after ATD treatment [33] (Table 3.3.6.3).

Recently, a predictive score (GREAT, Graves' Recurrent Events After Therapy), calculated as the sum of scores given to four clinical markers (age, serum-free thyroxine levels, serum TRAb levels, goitre size by palpation) assessed at diagnosis, has been developed [34] and has received an initial external validation as a good predictor of relapse after a course of ATDs [35–37]. Another (clinical severity score, CSS), based on the Merseburg triad (hyperthyroidism, goitre, and orbitopathy) has been shown to predict control of hyperthyroidism at 6 and 12 months of ATD treatment, but no information is insofar available on its predictivity of recurrences after ATD withdrawal. Predictive scores, by grouping single risk factors at diagnosis, might contribute to selecting the most appropriate treatment (conservative vs. ablative) in an individual patient at diagnosis

While in children and adolescents a second course of ATD treatment may be proposed if hyperthyroidism recurs, in adults relapse of hyperthyroidism after ATD therapy commonly is an indication to switch to definitive therapy (RAI or thyroidectomy), although a shared decision-making process is advised, keeping patient choice in due consideration.

ATD Treatment During Pregnancy and Lactation

Untreated hyperthyroidism is risky for the mother (pre-eclampsia, congestive heart failure), the fetus (accelerated bone maturation, growth retardation, prematurity, stillbirth, small risk of malformations), and pregnancy outcome (miscarriage, preterm delivery) [38]. Thus, restoration and stable maintenance of euthyroidism are warranted, although, in general, Graves' hyperthyroidism tends spontaneously to improve during pregnancy [39]. Conversely, Graves' hyperthyroidism may develop or be exacerbated in the postpartum period [40], although the relapse associated with the postpartum period appears to be more prone to undergo permanent remission and should probably be treated conservatively [41]. ATDs are the treatment of choice for Graves' pregnant women, because RAI therapy is contraindicated in pregnancy (as well as during lactation), and surgery is only exceptionally indicated, in this case in the second trimester [9, 17]. As mentioned in the paragraph on adverse events of thionamides, rare cases of aplasia cutis and 'CBZ/MMI embryopathy' have been reported in the offspring of mothers given MMI [18]. However, milder and less frequent malformations were also associated with prenatal exposure to PTU [19]. Thus, if PTU may still be preferred, for its lower risk, during the first trimester of pregnancy when organogenesis occurs, the current recommendation, in view of the possible severe PTU-related hepatoxicity, is that the pregnant woman be switched to MMI after the sixteenth week of pregnancy [17, 42]. In women whose preconception hyperthyroidism is controlled with very low doses of thionamides, an attempt might be made to stop treatment during pregnancy [19]. The goal of ATD treatment during pregnancy is to use the lowest dose of thionamides sufficient to maintain free thyroid hormones in the high-normal range, avoiding the risk of fetal hypothyroidism and goitre on one hand, and the risk that even mild maternal hypothyroidism may affect subsequent neuropsychological development in the offspring [17].

The use of thionamides during lactation appears to be safe, and doses of MMI up to 10 mg/day do not affect newborns' thyroid function. PTU is also safe for breastfeeding. In view of thionamide pharmacokinetics, it seems wise to suggest taking thionamide pill shortly after breastfeeding.

ATD Treatment of Hyperthyroidism in Children and Adolescents

Graves' disease is the most common cause of hyperthyroidism also in children and adolescents, and ATD treatment is the first-line treatment in the majority of them [20]. Remission rate after ATD treatment is lower in children than in adults. Thus, many if not most children/adolescents eventually require either RAI therapy or thyroidectomy [20]. Sometimes switching to definitive treatments is mandatory because of thionamide adverse events, which are more common in young patients. Although MMI may be associated also in children with a low but real risk of side effects, the risk is much higher using PTU [20]. In particular, PTU-induced liver failure may develop in 1:2000–1:4000 children treated with this drug [43], and reversible hepatotoxicity is likely much more frequent [43]. For these reasons, only MMI should be used in children/adolescents.

Neonatal Hyperthyroidism

Neonatal hyperthyroidism is due to the transplacental passage of maternal TSH-receptor autoantibodies. It is therefore a transient condition, which however requires a vigorous, although short-term, treatment with thionamides, in association with propranolol (or other β-blockers) and iodine [44].

ATD Treatment Before, During, and After RAI Therapy

Whether ATD pretreatment may decrease the effectiveness of subsequent RAI therapy has been long discussed. Two prospective, randomized studies demonstrated that MMI pretreatment does not decrease the effectiveness of RAI [45]. On the other hand, PTU pretreatment can cause a reduced cure rate [46]. Thus, it seems that only PTU pretreatment may cause a decrease in the efficacy of RAI, probably due to its longer radioprotective effect. This problem can however be overcome using higher therapeutic doses of RAI [47]. Thionamide pretreatment has the obvious beneficial effect of controlling hyperthyroidism: this is warranted in older people and in patients with relevant comorbidities [48]. ATDs should be withdrawn 5–7 days prior to RAI therapy. A short course of lithium carbonate for 2 weeks after RAI administration prevents effectively any

increase in serum thyroid hormone levels due either to ATD discontinuation or RAI cytotoxicity and is associated with a prompter control of hyperthyroidism and goitre shrinkage after RAI therapy [49]. There is convincing evidence that continuation of ATD treatment during RAI therapy or its reinstitution shortly after [50] is bound to a higher rate of treatment failure. Thus, ATD treatment should be restarted only in at-risk patients (old patients with associated comorbidities) and at least 7–10 days after RAI therapy.

ATD Treatment Before Thyroidectomy

Control of hyperthyroidism prior to thyroidectomy is mandatory. ATDs must be administered until euthyroidism is restored, and iodide (Lugol's solution or saturated solution of potassium iodide) or inorganic iodine should be added for 1–2 weeks prior to thyroid surgery. In case of urgent and emergent surgery that cannot be postponed, a combination of radiographic contrast agents, β-blockers and glucocorticoids should be added, because of the delayed effect of thionamides [51].

3.3.7 Radioiodine Treatment of Hyperthyroidism

Markus Luster and Michael Lassmann

Introduction

For more than 70 years radioactive iodine has been used successfully in the treatment of thyroid diseases in millions of patients. After the first therapy took place at the Massachusetts General Hospital in Boston in 1941 it was however, not until after the Second World War that I-131 became generally available for clinical applications [1].

The radioactive iodine isotope is chemically identical to 'stable' iodine (I-127) and thus becomes a part of the intrathyroidal organification and metabolism. Its principle of action is based on the emission of β-rays with a range of 0.5–2 mm in the tissue leading to high local radiation absorbed doses while sparing surrounding structures. The additional gamma-ray component of I-131 allows for scintigraphic imaging of the distribution in the gland and can also be used for pre- and post-therapeutic individual dosimetry (see next).

Several therapeutic options are available for the treatment of benign thyroid disorders, namely hyperthyroidism: surgical resection (hemithyroidectomy, near-total or total thyroidectomy), long-term antithyroid drug medication (ATD), radioiodine therapy (RAIT) [2–4] and more recently locally ablative procedures [5]. These different treatment modalities are used in varying frequencies depending on geographical location (e.g. iodine supply, availability and logistics, 'cultural' background, local experience), and patient specific features like goitre size, presence of local symptoms, age, and hormonal status.

The diversity of approaches on an international scale still remains impressive and is reflected by a great heterogeneity throughout Europe and also as compared to the United States where RAIT is still being applied more frequently than in most European countries [4, 6–9].

Radioiodine therapy was originally aimed at eliminating hyperthyroidism and thus leaving the patient euthyroid. Current strategies however established postradioiodine induction of hypothyroidism as treatment objective, thus included in the category of 'cure'. This definition holds especially true for the management of Graves' disease (GD) when long-term hypothyroidism was the rule and stabilization of euthyroidism failed in the majority of cases. In fact, the term 'ablation', meaning removal or destruction, has been increasingly used to characterize the outcome of RAIT and administration of larger amounts of radioiodine have tended to make this a self-fulfilling prophecy. Although many clinicians prefer that the end result of treatment should be the more easily managed hypothyroidism, others are still reluctant to give up the therapeutic ideal of euthyroidism as the preferred result of radioiodine therapy and continue their efforts to solve the enigma of thyroid radiosensitivity.

Indications

The causes of hyperthyroidism include the following: (a) autoimmune hyperthyroidism called previously toxic diffuse goitre (GD); (b) toxic adenoma; (c) toxic multinodular goitre (Plummer's disease); (d) silent thyroiditis; and (e) painful subacute thyroiditis. The first three entities constitute a clear indication for radioiodine treatment, while silent thyroiditis and subacute thyroiditis for reasons of the underlying pathophysiology are not treated with radioiodine.

Recently, there has been an emerging role for I-131 in the treatment of subclinical hyperthyroidism caused by any of the three first thyroid dysfunctions. Another category that is frequently regarded as a suitable entity for this kind of treatment is *non-toxic goitre (NTG)* which encompass a group of patients who are euthyroid but may clinically benefit from a reduction of the organ volume [10–12]. The available treatment options in NTG patients in whom the risk of malignancy is considered low (i.e. was ruled out by fine needle aspiration cytology are 'wait and see' policy, surgery, thyroid hormone/iodine therapy, and radioiodine treatment). The main indications for radioiodine treatment of NTG are to reduce the size of goitre to relieve compressive signs or symptoms and secondly alleviate potential cosmetic problems for the patient. Surgery remains the fastest and most effective way to reduce goitre size and relieve any acute compressive symptoms and is mandatory if there are any doubts about malignancy, but in elderly, frail, and patients with comorbidities RAIT represents a feasible alternative [13]. Preparation with recombinant human thyroid-stimulating hormone (rhTSH) for the augmentation of the radioiodine uptake in hypofunctional areas of goitre was evaluated in prospective studies but is not formally approved for this setting [14–16].

Radioiodine is in most cases the first line treatment for GD and toxic adenoma, or it can be administered if hyperthyroidism is not controlled or recurs after antithyroid drug treatment [17]. Surgery needs to be considered if there are contraindications to radioiodine therapy.

Contraindications

Pregnancy and breast feeding are absolute contraindications to radioiodine treatment; all females of reproductive age should have a pregnancy test immediately before administration. It is recommended that women not attempt conception for 6–12 months after radioiodine treatment. I-131 is generally not indicated for patients who are incontinent of urine, whereas concomitant haemodialysis for renal failure represents no exclusion criterion and is routinely performed in experienced centres.

Technical Aspects and Response to Radioiodine

The effect of radioiodine therapy is gradual and varies substantially among individuals resulting in the necessity for repeated testing after the treatment to rule out persistent hyperthyroidism or short-term development of a hypothyroid state. After 4 to 6 weeks a follow-up visit may be sensible to evaluate the effect of the procedure. In case of pre-existing marked hyperthyroidism symptom relief should be achieved peritherapeutically by the administration of β-blocking agents and resumption of antithyroid drugs should be considered when tachycardia and/or palpitations are present. The potential influence of ATD on radioiodine kinetics and on the therapeutic outcome has led to the recommendation, that coadministration of methimazole and propylthiouracil should be avoided [18–22]. If tolerated restarting ATD should preferably be initiated approximately 1 week after the radioiodine has been administered.

Potential Side Effects

Acute Side Effects

Clinical exacerbation of hyperthyroidism after radioiodine treatment appears to be relatively uncommon and is usually of minor clinical significance. It presumably is related to radiation thyroiditis, with destruction of thyroid follicles and release of thyroglobulin and stored hormone into the circulation. There may be a transient rise in fT_4 and fT_3 levels several days following administration, and patients suffering from poorly controlled symptoms before radioiodine therapy may encounter an exacerbation of cardiac arrhythmia and heart failure. In some patients a 'thyroid storm' may develop. Intravenous infusion of antithyroid drugs, corticosteroids and β-blockers is the treatment of choice, but prophylactic measures and thorough initial work-up are crucial.

Patients with large goitres may notice transient swelling and dyspnoea in some cases and some discomfort may be associated with it. Slight irritation of the salivary gland function may be noted, but in contrast to thyroid cancer, the risk of permanent injury is negligible due to the much lower activities applied for therapy of thyrotoxicosis [4].

Hypothyroidism

The main (side-)effect of radioiodine treatment is permanent hypothyroidism. Its rates vary and incidence continues to increase over time, so that lifelong follow-up is essential. Pretreatment prediction is hardly possible using current variables; however, the appearance

is higher in GD than in toxic goitre and relatively uncommon in solitary hyperfunctioning nodules.

The most prominent radiobiological factor for the determination of overall outcome besides radiation sensitivity of the thyroid follicular cells remains to be the radiation absorbed dose to the thyroid tissue, its exact calculation however being one of the obstacles in therapeutic nuclear medicine.

Ophthalmopathy

GD is frequently accompanied by ophthalmopathy; the reported incidences largely depending on the diagnostic criteria employed [23–26]. Prospective, randomized, controlled trials have shown that radioiodine treatment is associated with a greater risk of the appearance or worsening of ophthalmopathy in Graves' patients than antithyroid treatment. The risk is especially increased in patients who smoke cigarettes in keeping with the importance of smoking as a susceptibility factor in the development of ophthalmopathy, thus patients should be strongly advised to quit smoking. Oral or intravenous administration of steroids helps preventing exacerbation of thyroid eye disease, and this approach has to be considered the standard of care in patients who have clinically active ophthalmopathy at the time of treatment [22–24, 26, 27]. A radiation absorbed dose below 200 Gy, a thyroid volume of more than 60–80 ml and use of radioiodine without steroid medication have been shown to be associated with a higher risk of worsening of eye symptoms. Despite the controversy regarding adequate management of patients with Graves' hyperthyroidism and thyroid eye disease, most authors agree that in the presence of predisposing risk factors such as large goitres or heavy smoking, ablative therapy should be recommended [27–33].

Radiation-Induced Cancers

A small excess of mortality from malignancy was reported in one investigation but the study was biased by the increased surveillance. In other large series, no effects of radioiodine therapy on survival have been observed, whereas some reports suggested an increased relative risk for the development of certain types of cancer (thyroid, stomach, bladder, kidney, and haematological malignancies). However, these observations still remain to be confirmed by monitoring larger patient samples, so that currently no definite conclusion with respect to risk for subsequent malignancies can be drawn [34–36].

Dosimetry

For the treatment of GD or Plummer's disease (toxic nodular goitre) I-131 is normally administered orally using activities between 100 MBq and 1500 MBq.

The rationale behind dosimetry for this kind of treatment is that the incidence of long-term hypothyroidism is higher with an earlier onset for patients treated with higher activities [37] resulting in an attempt to individualize and thus optimize therapy. A large variation exists in the literature on the value of target absorbed dose to be delivered to the hyperthyroid tissue to become euthyroid. Most authors indicate 70 Gy but absorbed doses as high as 200 Gy are reported [37].

For a pretherapeutic dosimetric assessment of the activity needed to achieve a certain prescribed absorbed dose to the target volume the formalism described in the EANM SOP on dosimetry prior to radioiodine therapy of benign thyroid diseases is recommended for use [38]:

$$A[MBq] = \frac{1}{\bar{E}} \cdot \frac{M[g] \cdot D[Gy]}{\int_0^\infty RIU(t)dt}.$$

The activity A to be administered is calculated from

M: Mass of the target volume,
D: Absorbed dose to be achieved in the target volume,

RIU(t): Relative radioiodine uptake (unit: %) as a function of time:

$$\bar{E} : \bar{E} = 2.808 \frac{Gy.g}{MBq.d}$$

Constant (valid for a thyroid with M = 20 g) which will typically introduce ≤5% error for masses M ≤90 g and produce results with adequate accuracy for most patients [38]. A simple mass-dependent expression for the factor 1/Ē is provided in the supplement of the EANM SOP and may be used for an improved estimate in large goitres [38].

Guidance to the assessment and details of the calculation procedures can be found in the EANM SOP [38]. In short, a determination of the mass of the target volume and of the pretherapeutic iodine biokinetics are needed. For measuring the biokinetics either repeated scans of the neck or probe measurements of the patient's thyroid are needed [39]. Care of the appropriate calibration of the measuring system should be taken.

The thyroid or the target volume mass is generally determined by ultrasound [40], by pretherapeutic scintigraphy [41], by computed tomography [42], by magnetic resonance imaging [43], or by I-124 PET [44–46].

This dosimetric approach assumes that the iodine kinetics of a tracer and of a therapeutic amount of administered activity are similar. For a confirmation of the absorbed dose achieved after therapy a post-therapeutic dose assessment is recommended as, according to some authors, a pretherapeutic tracer 'dose' may induce 'stunning'. This effect might limit the uptake of the therapeutic activity in the thyroid gland [47].

Due to the uncertainties related to all of these procedures described here, an overall systematic uncertainty of the dose assessment process of 30–50% must be assumed [48].

Special Considerations in Children

Hyperthyroidism in children is mostly caused by GD and the risk of relapse in this age group is much higher than in adults. There is good evidence that the fetal and young thyroid is particularly sensitive to radiation and it is therefore appropriate to avoid treating hyperthyroid children with radioiodine if reasonable and safe alternatives are available. This can be a challenging decision since surgical thyroidectomy in young children has been accompanied by a

relatively high morbidity and antithyroid drugs have a certain incidence of compliance problems and drug complications [49–51]. At the very least, an extended trial of antithyroid drugs is advisable, although occasionally drug toxicity makes this strategy impractical.

However, reports of radioiodine therapy in young children have shown that it is effective and late follow-up has shown no deleterious effects [52].

3.3.8 Surgery for Thyrotoxicosis

Nancy D. Perrier, Orlo H. Clark, and Sarah B. Fisher

Introduction

Thyrotoxicosis, or the constellation of symptoms resulting from hyperthyroidism, is most often due to a single hyperfunctioning nodule (toxic adenoma), toxic multinodular goitre (Plummer's disease), or diffuse toxic goitre (Graves' disease). Symptoms may include anxiety, fatigue, palpitations, weight loss, heat intolerance, diarrhoea, and/or menstrual irregularities (in women), and patients may present with tremor, tachycardia or atrial fibrillation (particularly in older patients), thyromegaly with an audible bruit, and/or proptosis (Graves' orbitopathy or thyroid eye disease (TED)). Thyrotoxicosis is managed in one of three ways: use of antithyroid medications (ATDs) to decrease thyroid hormone production, destruction of thyroid tissue with radioactive iodine (RAI), or surgical resection of the thyroid (thyroidectomy). Of the three, surgery is the most invasive but also the most definitive, and may be favoured over medical management or RAI depending on specific clinical factors, patient preferences, and healthcare infrastructure (Table 3.3.8.1 [1–3]).

Definitive indications for thyroidectomy in the setting of thyrotoxicosis include symptomatic compression, concomitant documented or suspected malignancy (including thyroid nodule(s) suspicious for malignancy or greater than 3–4 cm in size), or coexisting hyperparathyroidism requiring surgical intervention. Surgery may be the most timely and definitive therapy for women who are pregnant or lactating, or who are planning pregnancy (ideally upon return to normal thyroid levels), and is favoured for patients with moderate to severe TED. Surgery is also appropriate in situations in which immediate control of symptoms is necessary (concomitant cardiac comorbidities with exacerbation) or in thyroid storm refractory to medical therapy. Other considerations for surgery include medication intolerance or non-adherence, failure to achieve a euthyroid state with medication, and/or patient preference to avoid exposure

Table 3.3.8.1 Comparison of thyroidectomy, radioactive iodine ablation, and medical therapy for thyrotoxicosis

	Thyroidectomy	Radioactive iodine ablation (RAI)	Medical therapy
Time of onset	• Immediate	• 4–6 months	• 4–6 weeks
Advantages	• Immediately curative with quick onset • May be beneficial for patients with limited access to care • Cost-effective	• Less invasive than surgery • May be more cost-effective for patients above age 60	• Noninvasive • Non-ablative (retain native thyroid function) • Achieves remission in 40–50% of patients after 12–18 months
Disadvantages	• Typically requires medical therapy preoperatively • Invasive—risk of surgical injury • Results in iatrogenic hypothyroidism	• Requires medical therapy preprocedure in selected patients due to the risk of transient worsening of thyrotoxicosis • ~80% become hypothyroid within 2–3 months of treatment • 5–15% require repeat treatment • Requires isolation • Avoid radioactivity in women who are pregnant or lactating • 15–20% risk of inducing/aggravating Graves' orbitopathy*	• Medication non-adherence • Side effects Rare but serious: • Agranulocytosis • Hepatotoxicity • Birth defects (methimazole) • Vasculitis More common but less serious: • Rash • Arthralgias
Patient preferences[2]	Patients choosing surgery likely place a higher relative value on prompt and definitive control of symptoms and avoidance of radioactivity and/or side effects from medications, with less relative concern for potential surgical risks and need for lifelong hormone replacement	Patients choosing RAI likely place a higher relative value on definitive control of symptoms with avoidance of surgery and/or side effects from medications, with less relative concern for the rapid resolution of symptoms, need for lifelong hormone replacement, and worsening of Graves' orbitopathy	Patients choosing medication likely place a higher relative value on the possibility of remission and avoidance of lifelong hormone replacement, and avoidance of surgery or radioactive exposure, with less relative concern for medication side effects and/or disease recurrence

*Exacerbation of orbitopathy may be ameliorated by concomitant steroid use.

to radioactivity or prolonged medication use. Contraindications to thyroidectomy include severe medical comorbidity precluding operation or presence of terminal disease states substantially limiting life expectancy. Relative contraindications to thyroidectomy include previously operated or irradiated necks or concurrent pregnancy in the first or third trimesters due to the increased risk of fetal loss or the risk of preterm labour, respectively [1, 2].

The decision to proceed with thyroidectomy for thyrotoxicosis also depends on the pathogenesis of the disease. Patients with toxic adenomas or Plummer's disease are less likely to gain long-term control of hyperthyroidism with ATDs, and as such either RAI or thyroidectomy is favoured over medication. For patients with Plummer's disease, thyroidectomy offers near immediate resolution of hyperthyroidism with a low risk (<1%) of disease recurrence, as compared to 20% risk with RAI; treatment failure rates may be even higher in patients with very large goitres undergoing RAI. These benefits associated with surgery are balanced by the risk of hypothyroidism—100% post-thyroidectomy as compared to 3% at 1 year after RAI, and increasing thereafter [2]. As with all aetiologies for thyrotoxicosis, symptomatic compression, or concern for concurrent malignancy favours thyroidectomy.

Choices of Thyroid Surgery

Thyroid lobectomy, while inappropriate for patients with global glandular dysfunction as in Graves' or Plummer's disease, is advantageous for the patient with a toxic adenoma. In this setting the remainder of the gland is functionally suppressed but physiologically capable of normal function. Thyroid lobectomy for toxic adenoma is associated with a faster return to the euthyroid state (2–3 days versus 75% response rate at 3 months) and a lower risk of disease recurrence (<1% vs. 3–5.5%) as compared to RAI. Additionally, although rates of hypothyroidism after lobectomy for non-toxic nodules are as high as 20%, hypothyroidism after lobectomy for toxic adenoma is uncommon (2–3%) [2].

For the patient with global glandular dysfunction, a subtotal or total thyroidectomy is appropriate. Historically subtotal thyroidectomy (thyroidectomy leaving approximately 2.5 gm of tissue) was utilized to avoid postoperative hypothyroidism, and remains particularly useful in geographic areas in which hormone replacement is not readily available. The Hartley-Dunhill procedure, which also attempts to preserve thyroid function by performing a thyroid lobectomy with a subtotal lobectomy on the contralateral side, has the theoretical advantages of making it easier to tailor the size of the remnant and limiting reoperative dissection to one side in the case of disease recurrence, thus decreasing the risk of recurrent laryngeal nerve injury. In reality there are no observed differences in the rates of recurrent laryngeal nerve injury, permanent hypocalcaemia, wound complications, operative mortality, or disease recurrence between the two subtotal approaches [4, 5]. When choosing a subtotal approach, the size of the remnant can be tailored to the exact patient situation. Younger patients, those with TED, and those with high thyroid-stimulating immunoglobulin titres are at higher risk for disease recurrence and thus may benefit from a smaller remnant, whereas patients with concurrent Hashimoto's disease or toxic multinodular goitre may have a lower risk of recurrence and can be left with a larger functional thyroid remnant.

With the availability of synthetic hormone replacement, total or near-total thyroidectomy is now the favoured operative approach as compared to subtotal thyroidectomy, with a lower risk of disease recurrence (0% vs. 7.6% in one study of 346 patients; 0% vs.

30% in another study of 136 patients) and no major differences in the rates of permanent hypoparathyroidism, recurrent laryngeal nerve injury, or postoperative hematoma formation [6–9]. Total thyroidectomy carries a higher rate of temporary postoperative hypocalcaemia (20–30% vs. 4–13%) as compared to subtotal approaches, and it is important to counsel the patient preoperatively about this risk.

Preoperative Evaluation

Patients who present with dysphonia, change in vocal perception, or with a history of previous neck operation should undergo evaluation of the vocal cords preoperatively (most often with direct laryngoscopy or videostroboscopy). Once a decision has been made to pursue thyroidectomy patients should be rendered euthyroid with ATDs, β-blockade, and/or iodinated solutions such as Lugol's solution (LS) [2]. Antithyroid drugs (methimazole, propylthiouracil) inhibit thyroid hormone synthesis (with propylthiouracil also inhibiting T_4 to T_3 conversion), with onset of action over a 2- to 6-week period. Propylthiouracil is considered second line except in patients who are allergic or intolerant to methimazole. Adverse effects are rare but can be serious, with agranulocytosis occurring in 1 in 500 patients and most often presenting with fever and pharyngitis, usually within the first 90 days of drug use. Hepatoxicity occurs between 0.3 to 0.7 per 1000 patients and is usually manifested by cholestatic injury with methimazole and hepatocellular injury and/or fulminant liver failure with propylthiouracil; hepatotoxicity from both drugs typically presents within the first three months of use [2]. Skin rashes with pruritis can also occur. B-blockade is particularly useful in controlling symptoms during the initiation of ATDs, with relief of tachycardia, palpitations, tremors, anxiety, and heat sensitivity. Additionally, at high doses, some β-blockers may also inhibit peripheral conversion of T_4 to T_3 (propranolol, atenolol, and metoprolol) [1].

LS, a combination of elemental iodine and potassium iodide in distilled water, or its equivalents (saturated solution of potassium iodide—SSKI, or potassium iodide—KI, hereafter used interchangeably for the purposes of this chapter) are often used either alone or as adjuncts to β-blockade and/or ATDs in the preoperative setting. Currently the American Thyroid Association recommends preoperative treatment with LS in most patients with Graves' disease to decrease thyroid blood flow, vascularity, and intraoperative blood loss during thyroidectomy [2]. Although initially used as preoperative therapy prior to thyroidectomy in 1929, and recommended by the ATA [10], controversy remains regarding the utility of preoperative treatment with LS [11].

The strongest data supporting the use of LS prior to thyroidectomy comes from several small randomized trials. Erbil and colleagues [12] demonstrated decreased thyroid blood flow on Doppler ultrasound, decreased microvessel density on pathologic examination, and lower operative blood loss (54.4 ml vs. 108.7 ml, P <0.001) in 17 patients with Graves' disease treated preoperatively with LS versus 19 patients treated without. Similarly, Yilmaz and colleagues [13] randomized 40 patients with either Graves' disease or toxic multinodular goitre to preoperative treatment with LS versus without; the patients treated with LS had lower mean thyroid blood flow as measured on Doppler ultrasound and experienced significantly less intraoperative blood loss than those not treated (76 ml vs. 172 ml, P = 0.0001). Another group randomized patients with euthyroid Graves' disease undergoing thyroidectomy to pretreatment with SSKI versus none and demonstrated a trend towards less blood loss in the SSKI treated group (61.7 vs. 161.7 ml, P = 0.054) [14]. None of these studies included data on differences in postoperative complication rates between the groups, and some critics have questioned whether the observed differences translate to a clinically meaningful difference [15].

In a retrospective study of 162 patients with Graves' disease undergoing thyroidectomy without preoperative KI, Shinall and colleagues [15] demonstrated similar outcomes (operative blood loss, duration of operation, and rates of complications including nerve injury, permanent hypocalcaemia, and hematoma formation) as compared to 102 patients with toxic multinodular goitre undergoing thyroidectomy in whom preoperative KI is not indicated. They concluded that the equivalent results between the two groups suggests that medical therapy exclusive of iodinated solutions combined with expert surgical technique renders the utility of iodinated solutions obsolete. Another retrospective study concluded that postoperative morbidity rates among 382 patients with Graves' disease undergoing thyroidectomy without preoperative LS were similar to that of historical controls, with 1.1% (n = 4) requiring reoperation for haematoma, 3.7% (n = 14) developing permanent hypocalcaemia, and 2.4% (n = 9) sustaining permanent nerve injury [16].

While meaningful for the patient who experiences them, the rate of complications after thyroidectomy is generally low, and as such using complications as a measure of the success or failure of therapy with iodinated solutions such as Lugol's may not be realistic. The side effects incurred from a short course of LS or other iodinated solution are rare and generally well tolerated, and it is the authors' practice to use this adjunct therapy.

In patients in whom the need for thyroidectomy is urgent, or in whom ATDs fail to render a euthyroid state, cholestyramine and/or glucocorticoids (hydrocortisone 100 mg every 8 hours) may be considered as adjuncts in the perioperative period [2]. Additionally, iodinated contrast dyes such as iopanoat can be effective, and in the event of thyroid storm can be administered via a nasogastric tube. Iodinated preparations can be halted after the patient is rendered afebrile and the cardiac and neurologic status improve. These patients are at high risk of thyroid storm and the care team should prepare for the possibility with adequate IV access, vasoactive drugs, and appropriate preoperative counselling.

Surgical Procedure

The patient is positioned with the neck hyperextended and a rolled drape placed along the patient's spine to assist in opening the surgical field. A horizontal incision is made in a natural skin crease approximately 1 cm below the cricoid cartilage. The platysma is divided and superior and inferior subplatysmal skin flaps may be elevated. The midline raphe is separated longitudinally and the strap muscles are dissected laterally taking care to avoid or ligate anterior jugular veins. The plane between the sternothyroid and sternohyoid muscle is separated gently to the ansa cervicalis. The middle thyroid veins are divided close to the gland to allow for additional lateral

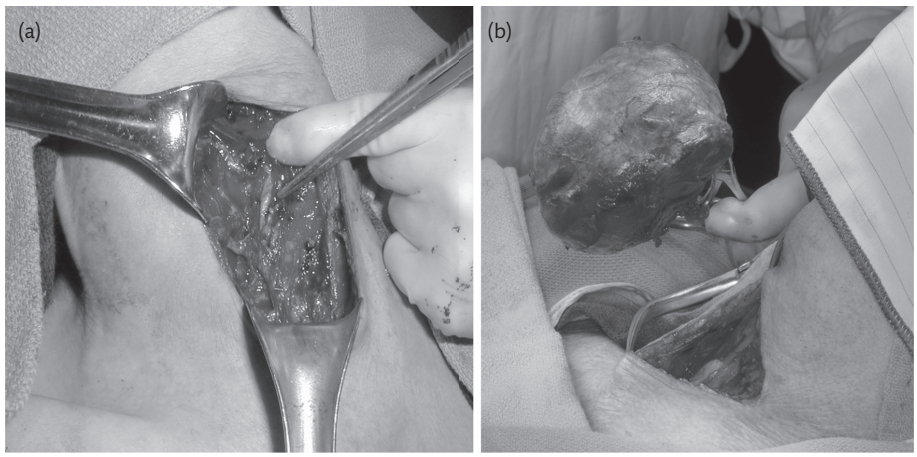

Figure 3.3.8.1 (a) The right recurrent laryngeal nerve; when dissecting around the nerve care is taken to avoid thermal injury from electrocautery, as demonstrated by the silk ligatures around small vascular bundles on either side of the nerve. (b) The noticeably enlarged thyroid gland after thyroidectomy in a symptomatic male.

retraction of the carotid sheath. As the thyroid is freed from surrounding tissues and rotated medially, careful dissection along the capsule of the gland should allow for identification of the recurrent laryngeal nerve (Figure 3.3.8.1). The superior thyroid artery and vein should be ligated as close to the thyroid as possible. Care should be taken to avoid injury to the external branch of the recurrent laryngeal nerve (just lateral to the cricothyroid muscle) and the superior parathyroid gland (typically at the level of the cricoid cartilage). The inferior thyroid artery and vein are approached similarly, with ligation close to the gland to avoid compromise of the parathyroid vascular supply. In the case of uncertainty regarding parathyroid location, frozen section of a portion of the suspected gland can be useful for parathyroid identification. Parathyroid autotransplantation should be considered for devascularized glands. Berry's ligament is encountered as the thyroid is separated from the anterior surface of the trachea, and represents a common site of nerve injury as small vessels in this area may bleed and obscure visualization. After completion of the initial side the procedure is repeated on the contralateral side, with the understanding that if the function of the recurrent laryngeal nerve is in question it is better to defer additional operation until postoperative vocal cord function is assessed.

Complications

Thyroidectomy can be performed safely with very low rates of morbidity and mortality. The most common serious complications following thyroidectomy are hypocalcaemia (transient or permanent), recurrent or superior laryngeal nerve injury (temporary or permanent), and postoperative hematoma. Surgeon experience (as measured by case volume) is well correlated with outcome [17, 18] and patients who undergo surgery by low-volume surgeons (<25 cases/year) are at an increased risk for any complication (odds ratio 1.51, $P = 0.002$). Among high volume thyroid surgeons the rates of permanent hypocalcaemia are <2%, permanent recurrent laryngeal nerve injury <1%, reoperation for hematoma 0.3–0.7%, and mortality less than 1 in 10 000 [2]. Transient hypocalcaemia is more common, with variable rates depending on study definition and ranging between 6 and 72% [19], and a median incidence of 27% in one meta-analysis [20].

When compared to patients undergoing total thyroidectomy for other indications, patients with Graves' disease have a higher rate of symptomatic postoperative hypocalcaemia [19, 21, 22] (OR 1.75, 95% CI 1.34–2.28 in one large meta-analysis [20]). Most often transient, the presumed mechanisms for the increased risk of hypocalcaemia are multifactorial and include parathyroid damage as well as other non-parathyroid mediated causes. From a technical perspective, the increased vascularity and friability of the gland makes visualization more difficult, and may place the parathyroid glands at a higher risk of inadvertent injury during operation. Additionally, the hyperthyroid biochemical profile may increase release of calcitonin during gland manipulation. The hyperthyroid state preoperatively stimulates bone turnover (thyrotoxic osteodystrophy) and urinary calcium loss resulting in depletion of whole body stores of calcium, with postoperative bone hunger noted after the hyperthyroid stimulus is effectively treated [19, 23] Technical factors, such as identifying and protecting all four parathyroid glands and leaving them on a well vascularized lateral pedicle during the operation is critical. Selective calcium and vitamin D supplementation both preoperatively and postoperatively have been proposed to decrease the rate of postoperative hypocalcaemia. One prospective study of 45 patients with Graves' disease treated with oral calcium supplementation for two weeks preoperatively demonstrated a lower rate of symptomatic hypocalcaemia (9% vs. 26%, $P < 0.05$) and a higher average postoperative calcium level (8.6 mg/dl vs. 8.3 mg/dl or 2.15 vs. 2.08 mmol/L, $P = 0.05$) as compared to patients with Graves' disease who did not receive preoperative supplementation [19]. It is the authors practice to correct vitamin D deficiency preoperatively, to selectively give preoperative calcium supplementation to patients with laboratory studies consistent with high bone turnover (elevated alkaline phosphatase and/or osteocalcin), and to monitor postoperative parathyroid hormone (PTH) levels [24] combined with serum calcium values and the presence or absence of symptoms to guide postoperative calcium supplementation.

Criteria to initiate supplementation include serum calcium <7.2 mg/dl, tingling or numbness in the postoperative period or serum PTH level <3.0 pg/ml on lab draws on the evening of the operation or on the morning prior to discharge after thyroidectomy.

Special Situations

Pregnancy

Pregnancy results in substantial physiologic changes in thyroid hormone production, which is often well tolerated in the healthy individual, but leads to unique considerations in the setting of thyroid dysfunction. Graves' disease is the most common cause of hyperthyroidism in pregnancy, occurring in 0.2% of women during pregnancy [25]. Graves' disease should be differentiated from gestational transient thyrotoxicosis, which is mediated by human chorionic gonadotropin (hCG) stimulation of the thyroid stimulating hormone (TSH) receptor, typically occurs in the first trimester, often is associated with hyperemesis, and is self-limited with typically milder symptoms. Pregnancy loss or stillbirth, prematurity, low birth weight, intrauterine growth restriction, thyroid storm, pregnancy induced hypertension, and maternal congestive heart failure are associated with poor control of maternal hyperthyroidism [26].

Treatment of thyrotoxicosis during pregnancy and after pregnancy/during lactation has unique considerations. Antithyroid drugs have been associated with birth defects (3–4% with methimazole, 2–3% with propylthiouracil) and their use should be avoided in the first trimester when possible, or used at the lowest necessary dose [25]. Radioactive iodine is contraindicated during pregnancy or lactation, and, when given to a woman of childbearing age, pregnancy should be avoided within 6 months [1]. Thyroidectomy can be considered for pregnant women with Graves' disease. If surgery is pursued and disease stability allows elective scheduling, thyroidectomy should be performed during the second trimester when the risk of preterm labour or pregnancy loss is lowest.

Paediatrics

Hyperthyroidism in childhood is rare, with only 1–5% of all Graves' disease presenting during this time, although Graves' disease remains the most common cause [27]. Antithyroid drugs are often the first line of therapy, but the rate of remission is lower than that seen in adults (20–30% after 2 years of therapy) [28]. Ablation therapy with RAI is acceptable in the paediatric population, and data suggest that paediatric glands may be more sensitive to RAI than adults, although there are similar limitations in efficacy for patients with large glands (>80 gm). In contrast to external radiation, which has a dose-dependent association with risk of thyroid cancer most pronounced at younger ages (<5 years), RAI has not been associated with later development of thyroid cancer. The effects of RAI on very young patients (<5 years) are not well described and as such thyroidectomy is generally favoured in this group. Thyroidectomy should be performed by an experienced endocrine surgeon [29]. The results are immediate and largely definitive, but there is a small risk of hypoparathyroidism, postoperative bleeding, and nerve injury. As with adults, children should be treated with ATDs, β-blockade, and/or iodinated solutions to achieve a euthyroid state prior to thyroidectomy.

Thyroid Eye Disease

Radioactive iodine ablation therapy is associated with new or worsening orbitopathy, or active TED, making these patients more appropriate for either medical management or thyroidectomy. Smoking cessation, corticosteroids at the time of therapy, and euthyroidism help prevent exacerbation and decrease the duration of TED [1]. Patients who smoke are more likely to develop TED when compared to non-smokers, and smoking reduces the effectiveness of treatments such as corticosteroids and RAI. Biologic drugs such as rituximab have had variable results when studied. Teprotumumab, a human monoclonal antibody against the insulin-like growth factor I receptor, has been suggested to be effective in reducing proptosis [30]. Care for the patient with TED should be coordinated by a multidisciplinary team of endocrinologists, surgeons, ophthalmologists, and radiation oncologists.

Summary

Thyrotoxicosis is managed with antithyroid medications (ATDs), radioactive iodine (RAI), or thyroidectomy, with patient comorbidities and preferences guiding therapy. Of the three modalities, surgery is the most invasive but also the most definitive. Thyroidectomy can be performed with minimal morbidity, particularly in experienced hands, and should be considered in the patient who places more relative emphasis on prompt and definitive control of symptoms with avoidance of radioactive therapy and/or medications, with less concern regarding operative risks and/or need for lifelong thyroid hormone replacement. Preoperative treatment with ATDs, β-blockers, and/or iodinated solutions to achieve a euthyroid state is recommended.

3.3.9 Management of Graves' Hyperthyroidism

Jacques Orgiazzi

Advantages and Disadvantages of the Various Treatment Modalities of Graves' Disease

For decades, Graves' disease therapeutic approaches have been debated and opposed [1] up to the present time when a large consensus has been reached in favour of the antithyroid drug treatment being the first-line option, even in the United States [2]. Table 3.3.9.1 summarizes the main characteristics of each type of treatment. The advantage-disadvantage balance of each modality should be discussed with the patients in order to reach as much as possible a personalized option based not only on disease presentation but also on patient's preference or professional and social

Table 3.3.9.1 Advantages and disadvantages of the various modalities of treatment of Graves' hyperthyroidism

Treatment modality	Advantages	Disadvantages
Antithyroid drug	• Possibility of long-term remission • No subsequent irreversible hypothyroidism	• Long duration (1–2 years) of treatment and repeated consultations • High relapse rate
Radio-iodine[1]	• Simplicity (depending on local regulation) • Low cost • Rarity of recurrence (depending in the dose)	• Delay of action • Transient expansion of anti-TSH-R autoimmunity • Occurrence or exacerbation of Graves' orbitopathy • Lifelong hypothyroidism
Surgery[2,3]	• Highest restoration rate of euthyroidism • Recurrence uncommon	• Highly experienced surgical-medical team mandatory • Low but unavoidable morbidity • Lifelong hypothyroidism • High cost

[1] Prior restoration of euthyroidism with antithyroid drugs is appropriate in severe cases.
[2] Prior restoration of euthyroidism requires a several weeks antithyroid drugs treatment,
[2, 3] Iatrogenic definitive hypothyroidism is no longer considered a complication but, on the contrary, a marker of no relapse risk.

obligations. These differences reflect the fact that no single approach is optimal and that patients may require multiple treatments to achieve full recovery [3]. In contrast, it has also been considered that hypothyroidism should no longer be considered as a complication of the 'radical' treatment options but as the ultimate goal to prevent the relapse of the disease [4]. The cost-effectiveness of the various treatment modalities has been evaluated [5]. Radioiodine is the more cost-effective primary treatment modality while surgery is the more costly. The cost of the medical treatment modality is intermediate, but inclusion of the relapse costs tends to level off the differences between the three modalities.

Treatment Modalities

Therapeutic modalities are discussed according to the various clinical presentations, including the usual case, the presence of a large goitre, children and adolescents, presence of orbitopathy, and pregnancy. Severe or acute forms (thyrotoxic storm) are discussed in Chapter 3.3.3.

Overview of Graves' Disease Management

Attention must be given to the quality and conditions of the communication with the patients who must be involved in the selection of the therapeutic strategy [6]. One could suggest considering three successive phases in the management of the patients:

a) Initial clinical and biological evaluation, assessment of disease severity, determination of thyroid function tests and antithyroid receptor antibodies (TRAb) serum level, blood count, and transaminase assay.

b) Restoration of euthyroidism with antithyroid drug treatment. This initial 1–3-month antithyroid drug treatment phase may be considered in every patient, even before subsequent radioactive iodine administration, especially in the more severe cases. This is the period during which the patient may be informed on medical prescriptions as well as antithyroid drug side effects and agreement to medications and biological controls.

c) Re-evaluation of patient's opinion, feelings, and compliance. This is the appropriate time for the selection of the further treatment modality.

The Usual Form of Hyperthyroid Graves' Disease

This corresponds to the 'average 40–50-year-old female patient' without a large goitre, without severe orbitopathy.

Antithyroid Drug Treatment

The Initial Antithyroid Drug (ATD) Treatment

The objective is to reach normal or near-normal serum free T_4 (fT_4) and free T_3 (fT_3) concentrations by 6–8 weeks. The initial dose of carbimazole (CBZ) or of its active derivative methyl-mercaptoimidazole (MMI), 30–40 or 15–30 mg daily, respectively, depends on the severity of the hyperthyroidism assessed clinically and on the serum levels of fT_4 and fT_3. Clinical and biological serum fT_4 and fT_3, but not thyroid-stimulating hormone (TSH) levels which may remain suppressed for several weeks, must re-evaluated after 3–4 weeks of treatment. As the serum concentrations of fT_4 and fT_3 decrease, the daily dose of MMI is reduced to 10–20 mg and that of CBZ to 20–30 mg. Further adjustment is necessary in order to prevent iatrogenic hypothyroidism. Patients should be instructed on the risk of the side effects of antithyroid drugs. At this stage, β-blocking medications (e.g. propranolol, 40–160 mg/d) are useful to alleviate cardiovascular symptoms, nervousness, and anxiety.

In newly diagnosed patients, the completion of this first phase is the point in time when to discuss and select, or confirm the subsequent treatment strategy.

The 'Medical' 12–18 Month Antithyroid Drug Treatment

Since the main drawback of the medical option is an overall 50% relapse rate after the end of the antithyroid drug course, it is important to try and select the appropriate treatment strategy. Male gender, young age, severity of hyperthyroidism, large thyroid volume, and high level of TRAb are the initial factors statistically correlated with a greater risk of relapse. A recent study has confirmed lower age (<40 years), higher serum fT_4 (≥ 40 pmol/L), higher serum TRAb (>20 IU/L), and larger goitre size at diagnosis as independent relapse risk factors which, combined with genetic markers, PTPN22 C/T polymorphism and human leukocyte antigen (HLA) subtypes

DQB1*02, DQA1*05, and DRB1*03, provide the basis for a continuous score, the Graves' Recurrent Events After Therapy (GREAT +) score, predictive of remission or relapse, with the potential to orient the allocation of a given patient to the medical or radical option [7]. Interestingly enough, even the clinical GREAT score, not including the genetic markers, may assess quantitatively the recurrence risk, as recently independently confirmed [8]. Importantly, remission rate is greater after prolonged antithyroid drug treatment (12–18 months) but not with a higher dose of antithyroid drug or the combination of levothyroxine and antithyroid drug, the so called 'block–replace' regimen. However, as the block–replace regimen prevents iatrogenic hypothyroidism, it allows for less frequent biological controls.

In practical terms, in the medical option, antithyroid drug treatment is then continued at 5 mg/day of MMI, or 5–15 mg/day of CBZ in the titration regimen, or maintained at higher dose in the block–replace regimen, associated with L-thyroxine started at 25 µg/day and progressively increased to reach 100–125 µg/day after 6–10 weeks. Clinical and biological follow-up is mandatory. Except in the occurrence of non-compliance or of untoward effects that the patient should be instructed to report without delay, the course of the treatment is usually uneventful, and in most cases correction of hyperthyroidism is sufficient to allow resumption of a normal life.

There is no single good marker to determine when to stop the antithyroid drug treatment after the 12–18-month course. After about 18 months of treatment, antithyroid drug is usually withdrawn, or tapered then stopped. In the case of the 'block–replace' modality it is advisable to shift to the 'titration' modality after 10–14 months of treatment so that the intrinsic functional thyroid status can be indirectly assessed through the required daily dose of antithyroid drug. Lack of goitre volume reduction, persistence of thyroid hypervascularity, persistence of suppressed level of TSH or the requirement for a full dose of antithyroid drug (titration regimen) are indicative of persistent disease activity and, consequently, of recurrence at drug withdrawal. Similar information is provided by persistently elevated serum levels of TRAb, while low or negative TRAb is not predictive of remission. Prolonged follow-up is necessary to avoid misinterpreting the period of euthyroidism that follows drug withdrawal as a true remission. Most relapses occur within months of cessation of antithyroid drug and 90% within 3 years.

There is no specific treatment strategy for relapsing Graves' disease. However, a radical approach appears more appropriate and acceptable to the patient. Nevertheless, after a second course of antithyroid drug treatment chances of relapse or remission are similar to the ones after the first course [9].

Ultra-Long Antithyroid Drug Treatment

In some patients, continuation of antithyroid drug treatment for 2 to 3 years, or even longer, appears an appropriate option. The necessary conditions for ultra-long antithyroid drug course are: (a) requirement for a low antithyroid drug dose (carbimazole 5 mg/day) or less; (b) patient's dependability and drug tolerance; and (c) moderate intensity of the disease, with absent or small goitre [10]. That such a low-dose maintenance treatment is efficient is suggested by the possible occurrence of a relapse at drug withdrawal or after iodine contamination.

Radioactive Iodine

Treatment with 131I radioactive iodine is now considered, as thyroidectomy, as a radical treatment for Graves' disease aiming at eradicating hyperthyroidism at the expense of definitive hypothyroidism. Some patients have concern about potential radiation danger to self and others. Also, in some countries local legislation restrict the ambulatory use of radioactive iodine treatment. And, in many places radioactive iodine is not administered to patients under 30–35 years of age, a rule which tends to be less rigid in specific cases, even in adolescents and children. Radioiodine as the first-line treatment should be considered for patients more likely to relapse after an antithyroid drug course, if monitoring of antithyroid drug treatment appears impractical, in case of intolerance to antithyroid drugs, and at relapse after an antithyroid drug course. In order to eradicate hyperthyroidism, ablative 131I doses range from 5.9 to 6.5 MBq/gram (160–176 µCi/g) of thyroid tissue for adjusted doses, or from 400 to 600 MBq (10.8–16.2 mCi) when 'fixed' doses are administered. Whether routine measurement of the effective half-life of intrathyroidal 131I is cost-effective has to be evaluated according to local iodine intake status. This range of doses eradicates hyperthyroidism in about two-thirds of patients and more than 60% are hypothyroid at 1 year [11]. Failure can be treated 6 months after initial irradiation with a second dose of 131I.

Although not required, except in older patients or in case of cardiovascular comorbidities to prevent a possible exacerbation of hyperthyroidism, antithyroid drug treatment prior to radioactive iodine administration would be prescribed by 20–40% of thyroidologists. Antithyroid drugs may also be prescribed after 131I administration to shorten the hyperthyroid lag phase until the irradiation effect [12]. Antithyroid drugs should be stopped 2 to 3 days prior to radioactive iodine therapy and resumed 3 to 5 days later [3]. They decrease the efficiency of radioactive iodine, but this is no longer an issue with the relatively high doses currently in use.

Prevention of post-irradiation hypothyroidism requires close follow-up or systematic L-thyroxine treatment, 100 µg/day, to be started at day 15. In any case, plasma fT_4 level should be tested 4 to 6 weeks post-irradiation, then monthly. The efficiency of the radioactive treatment is evaluated at 4 months. TSH should be followed-up until normalization in order not to miss post-irradiation subclinical hyperthyroidism or moderate T_3 hyperthyroidism. The risk of late-onset hypothyroidism should be anticipated with annual follow-up. Serum TRAb may increase transiently after radioiodine administration; peaking 3 to 5 months after irradiation, an effect to take into consideration in women of childbearing age as well as in adolescents [13].

Thyroid Surgery

Thyroidectomy, total or near-total according to the recent recommendations, is to be considered in the case of suspicion of malignant nodule, radioiodine treatment refusal or inapplicability, in the perspective of a future pregnancy, and in severe intolerance to antithyroid drug as well as in the case of severe hyperthyroidism. Thyroidectomy in hyperthyroid patients with Graves' disease requires the prior restoration of euthyroidism with antithyroid drug

to prevent postoperative thyroid crisis and suffocating hematoma. If the 6–12 week antithyroid drug treatment is inapplicable, alternate medical preparation includes the use of intravenous or oral propranolol, iodine as Lugol's solution, and, according to the severity of hyperthyroidism, oral or intravenous methylprednisolone, oral cholestyramine or oral lithium carbonate, and if necessary extracorporeal plasmapheresis [14, 15]. Thyroidectomy requires a highly and specifically trained and experienced anaesthetic, surgical, and nursing team. The two main complications of thyroidectomy, permanent recurrent laryngeal nerve palsy and permanent hypocalcaemia/hypoparathyroidism occur, on the average, in 1.8% and 5.9% of the patients, respectively [16].

Other Clinical Conditions

Presence of a Large Goitre

The schedule of the therapeutic management programme must be precisely defined. It includes: (a) restoration of euthyroidism with antithyroid drugs; (b) if required by the surgical team, preoperative iodine (50–120 mg/day: Lugol's solution or saturated solution of potassium iodide (SSKI), the duration of which should not exceed 10 days; (c) the surgical procedure itself; (d) the immediate postoperative management. Alternative preoperative programmes have been advocated, using only β-blockers with or without iodide. They require tight monitoring and highly experienced medical–surgical teams. Whatever the preparation, surgery on patients with hypervascular goitre has to be carefully planned and is best performed in selected centres.

Children and Adolescents

Medical Treatment

Initial treatment, in this age group, is antithyroid drugs. However, because compliance is difficult to maintain in the long-term, the relapse rate is high so that thyroidectomy or radioiodine administration is often an alternative. Even more than in adults, only MMI or carbimazole should be used in children because of the high risk of propylthiouracil (PTU)-induced severe hepatitis [17]. The initial starting dose of MMI or carbimazole is 0.5–1 mg/kg/day, with a maximal dose of 30 mg per day, dose to be reduced after 2–4 weeks as thyroid hormone levels normalize. TSH becomes detectable usually within 2–4 months. Thyroid function should be assessed every 3–6 weeks in order to prevent hypothyroidism, then every 3 months at lower antithyroid drug dose. Of note, in this age group, 10% of the patients may elicit T_3-predominant Graves' disease with a notably enlarged thyroid gland and elevated TRAb levels [18]. As to the feasibility of the titration and block–replace regimens, in this age range, compliance may be lower with the latter. Side-effect prevalence is very low at MMI dose <10 mg/day, and may be dose-dependent. Less than 30% of children treated with antithyroid drug treatment for 2 years achieve remission [18]. No initial individual predictive factors have been identified. However, the remission rate increases from 20% to 49% as the duration of the antithyroid drug treatment increases from 4 to 10 years [18]. Therefore, long-term 8–10-year antithyroid drug treatment might be carried on in children and adolescents in case of good compliance and drug tolerance before radical treatment is considered.

Radical Treatment

- Radioactive iodine treatment is safe in children and adolescents. Observational data indicate (a) no case of thyroid cancer developed in paediatric patients treated with dose of radioiodine iodine >150 μCi/g; (b) no evidence for an increased risk of non-thyroid cancer; however, it is prudent to avoid radioactive iodine treatment in children below 5 years of age; and (c) no evidence of adverse effects to offspring of children treated with 131I [19]. Radioiodine should be properly used with large enough doses (120–200 μCi/g) to interfere with the replication potential of residual cells. Strict and prolonged follow-up is mandatory to detect subclinical hypothyroidism.
- Surgical treatment is less controversial, especially in the case of a significant goitre, and in children <5 years, provided an experienced paediatric thyroid surgeon is available as the risk of complication is dependent on the surgeon's experience [20]. The preparation to the thyroidectomy is similar to that in adults.

Graves' Orbitopathy

Incidence of orbitopathy, including that of the more severe forms, has decreased in recent years in Western Europe. In recent studies, while it was initially present in 25% of the patients at diagnosis of Graves' disease, Graves' orbitopathy occurred in 13–15% during antithyroid drug treatment, as a mild form in 80% of the cases [21, 22]. In addition to smoking and to long-standing hyperthyroidism, iatrogenic hypothyroidism, and radioactive iodine treatment may trigger or worsen Graves' orbitopathy in patients treated for Graves' disease. In patients with mild or even moderate-to-severe orbitopathy, glucocorticoids prevent the radioactive iodine exacerbation of the orbitopathy [23]. Whether medical or radical treatment of hyperthyroidism is more appropriate in cases of severe or malignant ophthalmopathy remains unsettled [22]. The major point, in this occurrence, is to ensure and maintain a state of stable euthyroidism, even on prolonged antithyroid drug treatment [24].

Graves' Disease and Pregnancy

During pregnancy, hyperthyroidism is deleterious to the mother, the evolution of pregnancy, and the fetus. Graves' disease, after a transient exacerbation of clinical symptoms likely related to the first-trimester peak of hCG, usually tends to spontaneously improve or even remit in the second half of pregnancy. The primary therapeutic objectives are (a) restoration of maternal euthyroidism; (b) avoidance of fetal hypothyroidism; and (c) evaluation of the risk of fetal hyperthyroidism resulting from the transplacental transfer of maternal stimulating TRAb. Radioactive iodine is contraindicated in pregnant women. Contrarily to T_4, antithyroid drugs cross the placenta without limitation, a combination which prohibits the block–replace regimen and requires restricting antithyroid drug dose to the minimum to maintain maternal fT_4 in the upper normal range in order to prevent fetal hypothyroidism. Antithyroid drug treatment can be withdrawn in the majority of the cases near mid-pregnancy. In contrast, in severe forms of Graves' disease, usually with large hypervascular goitre and very high TRAb concentrations, restoration of euthyroidism requires prolonged full-dose antithyroid drug treatment. Tight management usually allows avoiding thyroidectomy during pregnancy, an option which does not protect from the risk of fetal hyperthyroidism [25]. Antithyroid drugs may be teratogenic and birth defects of all types are observed in 2%–3%

of exposed children. The high-risk period encompasses gestational weeks 6–10, the major period of organogenesis. Birth defects are more severe in newborns of CBZ/MMI than PTU treated mothers. Consequently, PTU should be preferred to CBZ/MMI as early as possible in the first trimester of pregnancy, or even prior to conception and patients on CBZ/MMI should be switched to PTU [26].

Fetal/neonatal hyperthyroidism occur in 2–10% of pregnancies in women with active Graves' disease. TRAb level at the beginning of the third trimester is predictive of fetal/neonatal hyperthyroidism. Women who must be screened for TRAb include, in addition to patients with ongoing Graves 'disease, patients previously treated for Graves' disease either by surgery or radioiodine whatever their current thyroid status, and patients with a previous child with neonatal transient hyper- or hypothyroidism. Fetal thyroid status may be assessed indirectly through clinical signs of hyperthyroidism, of low sensitivity/specificity, and by thyroid ultrasonography after the 23–25th week of pregnancy [27]. However, depending independently on the serum concentration of stimulating TRAb and on the dose of antithyroid drug in the mother, fetal thyroid enlargement may reflect either fetal hyper or hypothyroidism the differentiation of which may require, especially when the goitre is large, to determine TSH and thyroid hormone levels in fetal blood through cordocentesis [27]. A team approach, including obstetrician, experienced ultrasonographer, neonatologist, and endocrinologist, is mandatory to monitor fetal development properly in the last trimester, parturition, the neonate thyroid status, and breastfeeding, as well as the risk of postpartum maternal exacerbation of hyperthyroidism. Neonatal hyperthyroidism, although self-limited, may be immediately fatal if unrecognized or poorly managed. Antithyroid drugs, β-blocker, and supportive measures should be started even before the exacerbation of thyrotoxicosis that follows clearance of the maternally transferred antithyroid drugs.

Final Note: Patients' Satisfaction Appraisal

In the context of the availability of three therapeutic strategies, and of the increasing patients' involvement into treatment selection [6], current studies are also devoted to the patients' perception of medical management, satisfaction with the treatment, and overall quality of life. One of the more recent studies in the domain, performed in patients encouraged to participate, following physician recommendation, to the choice of the method of treatment, has shown that the majority of them were satisfied with the treatment received, that the modality of treatment had little impact and, significantly, that patient's preference for a specific treatment may be more important than the treatment type *per se* [28].

Conclusion

It may seem that no significant improvement has been achieved in recent years in the treatment of Graves' disease. Currently, however, optimization of existing therapeutic strategies may offer every patient the most appropriate management strategy. The cost-effectiveness of the treatment and the socioprofessional and psychological aspects of the disease are of increasing importance and must also be taken into account. Ongoing clinical investigations, as well as immunological research, aim at improving the understanding and management efficiency of Graves' disease. There is no doubt that, in the future, new immuno-specific therapeutic approaches will become available.

3.3.10 Graves' Orbitopathy and Dermopathy

Wilmar M. Wiersinga

Clinical Presentation

The many and often disfiguring features of a typical patient with Graves' ophthalmopathy (GO) are obvious at first glance (**Figure 3.3.10.1**). The changed appearance has a profound effect on the emotional and social status of the patient. The various signs and symptoms can be described according to the NO SPECS classification [1] (**Table 3.3.10.1**). Class 1 signs can be present in any patient with thyrotoxicosis regardless of its cause. Upper eyelid retraction causes stare and lid lag on downward gaze (the latter is the well-known von Graefe's sign). Soft tissue involvement (class 2) comprises swelling and redness of eyelids, conjunctiva, and caruncle. Symptoms are a gritty sandy sensation in the eyes, retrobulbar pressure, lacrimation, photophobia, and blurring of vision. Proptosis (class 3) can be quite marked. Upper eyelid retraction by itself may already give the impression of exophthalmos. Extraocular muscle involvement (class 4) may result in aberrant position of the globe, or fixation of the globe in extreme cases. More common is limitation of eye muscle movements in certain directions of gaze, especially in upward gaze; it is usually associated with diplopia. Elevation is most

Figure 3.3.10.1 Bilateral eye disease due to Graves' orbitopathy. Note lid retraction, stare, periorbital swelling, marked proptosis, and exotropia of the left globe (see also Plate 15).

Table 3.3.10.1 Assessment of disease severity in the patient with Graves' orbitopathy (GO)

Severity measures of GO (using the mnemonic NO SPECS)		
NO SPECS class	**Item**	**Method**
0. **N**o signs or symptoms		
1. **O**nly signs, no symptoms	Lid aperture	With ruler in midline in mm
2. **S**oft tissue involvement	Eyelid and conjunctiva swelling and redness	Inspection, comparison with colour pictures[#]
3. **P**roptosis	Exophthalmos	Hertel in mm[‡]
4. **E**xtraocular muscle involvement	Eye muscle motility Diplopia	Impaired elevation, abduction, Depression, and adduction Subjective grading*
5. **C**orneal involvement	Keratitis, ulcer	Fluorescein dye
6. **S**ight loss due to optic nerve involvement	Dysthyroid optic neuropathy (DON)	Visual acuity, colour vision, visual fields, optic disc

[#] colour atlas Dickinson *et al. Clin Endocrinol*, 2001; 55: 283–303
* intermittent diplopia = at awakening or when tired; inconstant diplopia = at extremes of gaze; constant diplopia = in primary or reading position
[‡] upper normal limit 16/17 mm in Asians, 19/21 mm in whites, and 23/24 mm in African Americans (females/males, respectively).

frequently impaired, followed by abduction and depression; adduction is rarely affected. Diplopia will not occur if the vision of one eye is very low (e.g. in amblyopia), or if the impairment of eye muscle motility is strictly symmetrical. Patients may correct for double vision by tilting the head, usually backwards and sideways; the ocular torticollis often leads to neck pain and headache. Positioning of the head in the default position will unmask diplopia. Corneal involvement (class 5) occurs through overexposure of the cornea due to lid lag, lid retraction, and exophthalmos, easily leading to dry eyes and keratitis. Lagophthalmos is often noted first by the patient's partner because of incomplete closure of the eyelids during sleep. Sight loss (class 6) due to optic nerve involvement is the most serious feature, often referred to as dysthyroid optic neuropathy (DON) [2]. Besides the decrease of visual acuity, there may be loss of colour vision and visual field defects. Visual blurring may disappear after blinking (caused by alteration of the tear film on the surface of the cornea due to lacrimation or dry eyes) or after closing one eye (attributable to eye muscle imbalance). Visual blurring that persists is of great concern as it may indicate optic neuropathy.

The frequency of the various eye changes among GO patients is as follows [3]: von Graefe's sign 46%, upper eyelid swelling 62%, proptosis of 21 mm or higher 53%, diplopia 32%, corneal involvement 14%, and optic nerve involvement 3.9%. Predisposing factors for DON are male sex, old age, smoking, and diabetes mellitus [2] (Figure 3.3.10.2). Unilateral GO is observed in about 10%. Eye changes are similar to those in bilateral GO, but unilateral cases are more often euthyroid [4]. Extraocular muscle enlargement in the fellow eye can be detected by CT in about one-half of cases. Progression to bilateral GO is common. Unilateral GO may thus represent an early stage of the disease that already is or will develop shortly into a bilateral disease. Unknown local factors must be involved in the unilateral expression of GO, which essentially is a bilateral and fairly symmetrical eye disease.

Mean age at GO presentation is 48 years, 23% are males, and 40% are current smokers [3]. Diabetes is present in 4%, and glaucoma in 5.6%. Male sex, older age, and smoking are associated with more severe ophthalmopathy. Childhood GO is rare [5]. Clinical manifestations are less severe in paediatric patients: exophthalmos is seen in 75%, but impaired muscle motility only in 11% [6].

Figure 3.3.10.2 Unusual presentation of Graves' orbitopathy as unilateral eye disease. Male sex, advanced age, and heavy smoking all predisposed this patient to the development of severe eye disease; note the absence of exophthalmos in this case of dysthyroid optic neuropathy (see also Plate 16).

Epidemiology

A population-based study in Sweden observed an incidence rate of Graves' hyperthyroidism of 210/million/year and of GO of 42/million/year [7]. Thus, 20% of Graves' hyperthyroid patients have also GO, which is mild in 15% and severe in 5%. Recent

studies in Denmark and Italy confirm that moderate-to-severe GO is present in about 5% of Graves' hyperthyroid patients [8, 9]. GO develops in a few patients before the onset of Graves' hyperthyroidism, but simultaneous onset of GO and Graves' hyperthyroidism occurs in the majority of GO patients. GO sometimes develops after Graves' hyperthyroidism [9, 10]; risk factors are minimal redness or swelling of eyelids or conjunctiva, high TSH-receptor antibodies, long duration of hyperthyroid symptoms, and current smoking [10]. GO occurs in 3% of cases in patients with autoimmune hypothyroidism and in 7–10% in euthyroid patients [3]. The euthyroid and primarily hypothyroid patients have milder and more asymmetrical GO than the hyperthyroid GO patients [11, 12]. It is not unusual that hypothyroid GO patients proceed to Graves' hyperthyroidism, linked to a shift from TSH receptor blocking to stimulating antibodies. Euthyroid GO patients develop hyperthyroidism in due time in about 20%, but it is unknown why others remain euthyroid despite the presence of TSH receptor antibodies.

Smoking greatly increases the risk for GO (odds ratio 7.7, 95% CI 4.3 to 13.7) [13]. A secular trend to a lower incidence rate of GO is reported. The proportion of patients with GO among all referred patients with Graves' hyperthyroidism decreased from 57% in 1960 to 35% in 1990, and to 29% in 2010 [9, 14]. In a European questionnaire study in 1998, 43% of respondents thought GO was decreasing in frequency, in rough agreement with the decline in smoking [15]. It looks the prevalence of severe GO is also declining: DON was present in 30% in 1960 and in 21% in 1990 in a single centre [14], and in 21% in 2000 and in 4% in 2012 in European Group on Graves' Orbitopathy (EUGOGO) centres [3]. GO patients referred in 2012 had less severe and less active GO than those referred in 2000 [3]. Earlier diagnosis and treatment of hyperthyroidism, identification of risks conferred by ^{131}I therapy and postradioiodine hypothyroidism, and focus on the detrimental effects of smoking have likely contributed to this secular decline in the incidence and severity of GO.

Pathogenesis

Mechanistic Explanation of Eye Changes

GO is characterized by enlarged extraocular muscles and increased orbital fat. The increase in tissue volume and the associated rise of retrobulbar pressure can explain the various signs and symptoms. The swollen retrobulbar tissues impair the venous drainage of eyelids and conjunctiva, resulting in oedematous swelling of eyelids and chemosis. Upper and lower eyelid swelling can also be caused by herniation of retrobulbar fat through openings in the orbital septum. The only other outlet for the increased orbital content, in view of the confinement within the bony walls of the orbit, is pushing forward the eyeball, resulting in exophthalmos. The average volume of the orbital cavity is approximately 27 and 24 ml in healthy males and females respectively; corresponding values of extraocular muscle volume are 4.2 and 3.7 ml, and of orbital fat volume 16.1 ml and 14.0 ml [16]. It has been calculated that an increase of 4 ml in muscle or fat will cause a proptosis of 6 mm.

The enlargement of extraocular muscles impairs muscle relaxation, not the ability for muscle contraction. Limited motion of eye muscles is due to impaired relaxation of the antagonist upon contraction of the agonist. Impaired elevation is thus primarily the result of insufficient relaxation of the rectus inferior muscle. Restricted eye muscle motility may cause diplopia. Upper eyelid retraction (due either to an increased adrenergic activity in hyperthyroidism or to swelling of the levator muscle) and proptosis contribute to overexposure of the cornea, which may become dry and inflamed.

Marked swelling of the extraocular muscles in the apex of the orbit (known as apical crowding), close to the entrance of the optic nerve in the optic canal, may damage the optic nerve either via direct pressure or via impairment of the blood supply to the nerve [17]. The resulting DON causes loss of visual functions. The degree of proptosis in patients with optic neuropathy, despite a greater mass of extraocular muscles, is less than in patients without optic neuropathy [2]. This is remarkable because the retrobulbar pressure (in the normal orbit 3.0–4.5 mmHg) is greatly elevated in patients with DON up to values between 17 and 40 mmHg, much higher than the pressure of 9–11 mmHg measured in orbits of patients with exophthalmos but no optic neuropathy [18]. A well-developed tight orbital septum might preclude proptosis, resulting in a very high retrobulbar pressure and DON.

Immunopathogenesis

Orbital fibroblasts (OF) are considered the target cells of the autoimmune attack in GO. For, retrobulbar T cells from GO patients recognize autologous OF (but not eye muscle extracts) in a major histocompatibility complex (MHC) class I restricted manner, and proliferate in response to autologous proteins from OF (but not from orbital myoblasts). Conversely, OF proliferate in response to autologous T cells dependent on MHC class II and CD40-CD40L signalling [19]. OF are stimulated to produce excessive amounts of glycosaminoglycans (GAG), notably hyaluronic acid. GAGs are very hydrophilic compounds and thus attract much water, resulting in oedematous swelling. GAGs accumulate in the endomysial space between muscle fibres. There is no increase in the number of muscle fibres and no ultrastructural damage to the muscle cells themselves (except in very advanced cases when some damage may be seen). An increased number of OF is found in the endomysial space and in the orbital fat. OF not expressing Thy-1 (present in orbital fat but not in extraocular muscles) may differentiate into mature adipocytes, thereby further contributing to volume expansion. Volumetric studies have shown that most GO patients have increased muscle volume at diagnosis, whereas fat expansion seems a rather late phenomenon [20, 21]. Why some patients present with exophthalmos and enlarged orbital fat volume but do not develop increased muscle volume, remains uncomprehended.

Orbital immunocompetent cells consist of T helper ($T_{h)}$ cells, suppressor/cytotoxic T cells, many macrophages, and relatively few B cells. Many of these cells are activated memory cells ($CD45RO^+$), frequently located adjacent to blood vessels. The infiltrating immunocompetent cells produce cytokines capable of remodelling orbital tissues. The cytokine profile in the early stages is predominantly derived from T_h1 cells, whereas cytokines are mostly derived from T_h2 cells in patients with a duration of GO >2 years [22]. The data suggest GO is primarily a T-cell mediated disease.

The *cytokines* induce expression of immunomodulatory proteins on orbital endothelial cells and fibroblasts (such as HLA-DR,

heat shock protein 72 and several adhesion molecules), generating T-cell migration. Cytokine-activated OF synthesize chemoattractants IL-16 and RANTES, perpetuating the immune attack. Macrophages may present antigen to T cells (CD40L) through provision of costimulatory signals and proinflammatory cytokines. Activated T cells bind to $CD40^+$ fibroblasts, inducing proinflammatory compounds (like cytokines, COX2, and PGE2) and excessive production of GAGs. A subset of OF may differentiate into mature adipocytes, which is associated with increased expression of TSH receptors [23]. This brings us to the nature of the autoantigen in the orbit.

The TSH receptor is presently viewed as the major autoantigen in GO. Full-length functional TSH receptors are expressed on OF, in active stages of the disease to a greater extent than in the inactive stages, and directly related to IL-1β [24]. Graves' immunoglobulins and M22 (a TSH receptor stimulating monoclonal antibody) recognize TSH receptors on OF as evident from increased cAMP and hyaluronan production in cell cultures of differentiated human OF [19]. Clinical studies support the role of TSH receptors. The serum concentrations of TSH receptor antibodies (TSHR-Ab) are higher in Graves' patients with GO than in Graves' patients without GO [25], and are directly related to the severity and activity of GO (whereas thyroid peroxidase and thyroglobulin antibodies are not) [26, 27]. The higher the level of TSHR-Ab, the higher the risk of an unfavourable course of the eye changes [28]. The level of TSHR-Ab fall after thyroidectomy or treatment with antithyroid drugs, but increase by 100% in the first six months after radioactive iodine therapy coinciding with development or worsening of GO after ^{131}I therapy in about 15% [29, 30]. Finally, genetic immunization against the TSH receptor A-subunit plasmid have produced the first experimental animal model of GO [31–35]; within the inherent restrictions of the model (the mouse has no bony orbit), the model mimics rather well the human condition.

Another autoantigen might be the IGF-1 receptor (IGF-1R). IGF-1R are indeed upregulated on OF GO patients, but serum IGF-1 and IGF-binding proteins in GO are normal. The stimulating effect of Graves' IgG on hyaluronan secretion by cultured OF is attenuated by IGF-1R blocking antibodies, suggesting Graves IgG could contain IGF-1R stimulating antibodies [36]. IGF-1R-Ab were found in 14% of GO patients and in 11% of controls [37]. The presence of IGF-1R-Ab was not related to activity or severity of GO nor to TSHR-Ab. IGF-1R-Ab failed to stimulate IGF-1R autophosphorylation, and inhibited IGF-1 induced signalling. Thus, there is no evidence for the existence of IGF-1R stimulating antibodies in GO patients. Further studies suggest crosstalk between TSH receptors and IGF-1 receptors [38, 39]. TSH and IGF-1 synergistically increase hyaluronan secretion by OF; the effect of TSHR stimulating antibodies can be blocked only partially by IGF-1R antagonists but completely by TSHR antagonists [40]. Serum immunoglobulins isolated from GO patients are unable to autophosphorylate IGF-1R, and do not directly activate IGF-1R [41, 42]. The observed crosstalks might be explained from overlap between post-receptor pathways: TSHR signalling via PLC/PI-3K/Akt and IGF-1R signalling via PI-3K/Akt result in the same end-product (**Figure 3.3.10.3**) [43]. Crosstalk and the putative role of

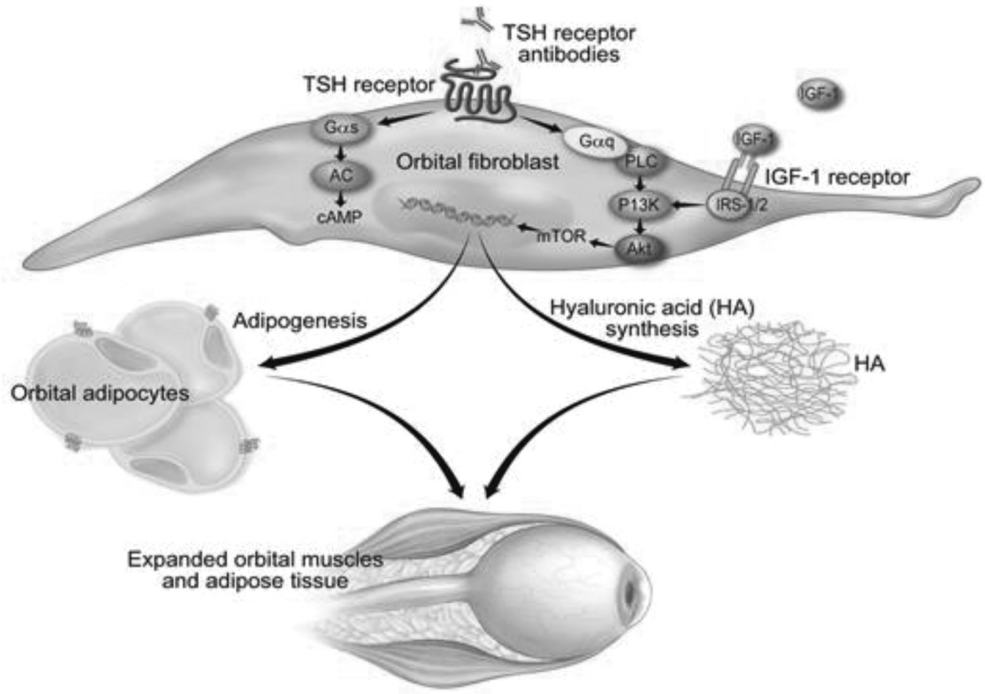

Figure 3.3.10.3 Role of the TSH receptor in the immunopathogenesis of GO. Ligation of the TSH receptor on orbital fibroblasts with TSHR-Ab activates post-receptor signalling via the adenylyl cyclase/cAMP pathway and the phospholipase C/ phosphoinositide-3-kinase/Akt pathway. The latter overlaps with the post-receptor signalling pathway of the IGF-1 receptor. The end result is excessive secretion of hyaluronic acid by OF, and differentiation of a subset of into mature adipocytes (adipogenesis), causing enlarged extraocular muscles and increased orbital fat.

various classes of TSHR-Ab is an area of active research. The IGF-1R is thus not a primary autoantigen in GO, as evident also from the failure of genetic immunization with IGF-1R to produce an animal model of GO [31].

Fibrocytes are bone-marrow derived cells from the monocyte lineage, expressing CD45, CD34, CXCR4, collagen 1, functional TSHR, and Tg. Circulating fibrocytes are highly abundant in GO patients, and seem to infiltrate orbital connective tissue where they might transition to CD34+ OF [44]. Teprotumumab, a human monoclonal IGF-1R blocking antibody, attenuates the actions of both IGF-1 and TSH in fibrocytes; specifically, it blocks the induction of proinflammatory cytokines by TSH [45].

Many questions remain unanswered. It is difficult to explain why most patients with Graves' hyperthyroidism, despite high titres of TSHR-Ab, do not develop GO. This could be related to genetic and environmental factors. GO is more prevalent in white patients than in Asian patients [46]. There is, however, no difference in the frequency of particular polymorphisms in susceptibility genes for Graves' disease (*HLA, CTLA4, PTPN22, CD40, FRCL3, TSHR*) between Graves' hyperthyroid patients with and without GO [47]. Smoking increases greatly the risk of GO [13]. Exposure of OF *in vitro* to cigarette smoke extract dose-dependently increases adipogenesis and hyaluronan production [48].

Natural History

GO has a tendency towards spontaneous improvement. There have been few studies on the natural history of the eye disease. The most extensive ones were carried out in the 1940s and 1950s by Rundle [49] (Figure 3.3.10.4). He describes a stage of ingravescence,

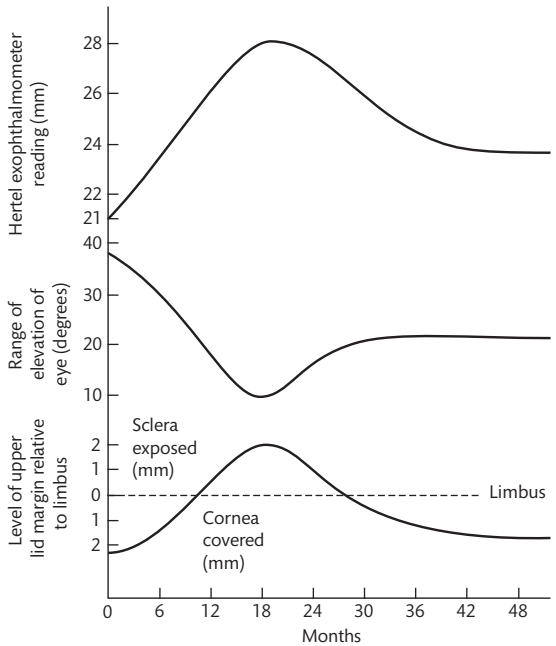

Figure 3.3.10.4 Rundle's curves depicting the natural history of GO, characterized by an initial dynamic phase of ingravescence and remission, followed by the static endstage.

Reproduced with permission from Rundle FF. Management of exophthalmos and related ocular changes in Graves' disease. *Metabolism*, 1957; 6: 36–47. with permission from Elsevier.

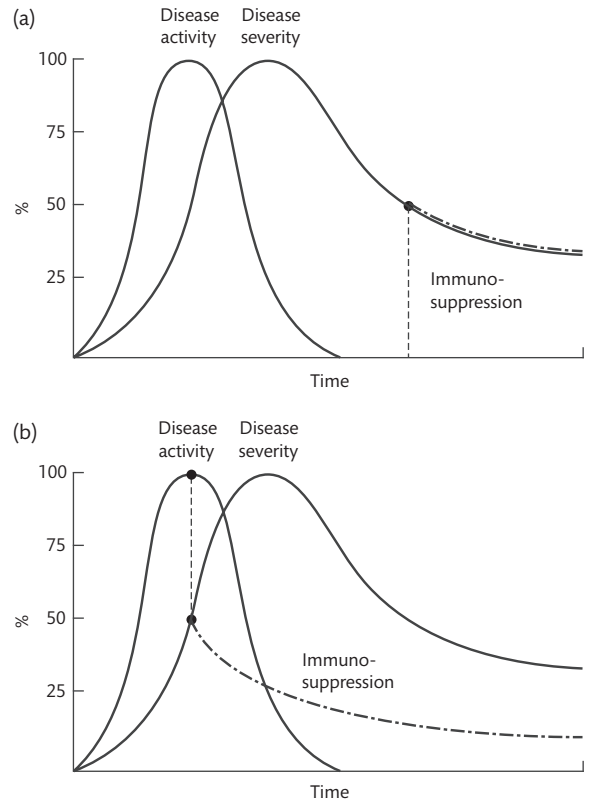

Figure 3.3.10.5 Schematic outcome of immunosuppressive treatment in GO patients as a function of disease activity. The natural history of GO activity and severity is depicted by two separate curves. Immunosuppression is administered at one-half maximal disease severity. The response to treatment is zero when given at zero disease activity like in (a), but a substantial response can be expected when given at peak disease activity like in panel (b).

characterized by the development of exophthalmos (by 0.5 mm monthly, up to an average extent of 2–5 mm) and limitation of elevation; 4–5 degrees elevation is lost for each millimetre of protrusion. Thereafter a stage of remission occurs, which is slower and less complete than ingravescence. Recovery from restricted eye muscle motility precedes that from proptosis. This dynamic phase is succeeded by a static phase, in which exophthalmos and eye muscle disturbance remain unchanged in 75% of patients. The time period in which the stable endstage is reached varies considerably between patients, ranging from several months up to 5 years. Recent studies confirm these early observations: during a 1-year follow-up in patients whose ophthalmopathy did not require immediate treatment, substantial improvement occurred in 22%, slight improvement occurred in 42%, the disease remained stable in 22%, and the disease progressed in 14% [50].

The few histological studies support Rundle's observations. In the early active stage of the disease there is a lymphocytic infiltrate, oedema, and activated fibroblasts; in the end stages there is fibrosis. The data imply that the natural history of GO can also be described according to the activity of the eye disease, next to Rundle's curves on the severity of the eye disease [51] (Figure 3.3.10.5). Assessment of the activity of GO may influence the management plan. Immunosuppression is unlikely to be effective when given

in the fibrotic inactive endstage of the disease, but might be of much benefit in the early active stage with ongoing inflammation. Likewise, the results of eye muscle and lid surgery might be lost when performed in the active stage.

Diagnosis and Differential Diagnosis

The initial work-up is aimed not only to reach a correct diagnosis of GO but also to allow the delineation of a personalized treatment plan [52]. It should contain the following four assessments:

Assessment of Thyroid Function

Restoration and maintenance of a normal thyroid function is relevant because the eye changes are more severe in patients who still have an abnormal thyroid function [53]. Serum concentrations of TSHR-Ab are usually high in GO, and their presence support the diagnosis of GO (quite relevant in patients presenting without hyperthyroidism).

Assessment of GO Severity

The NO SPECS system is a useful memory aid in the examination of disease severity (Table 3.3.10.1). Quantitative measurements are preferred whenever possible. Lid aperture is measured with the ruler centred on the pupil while the facial muscles are relaxed and gaze is directed straight ahead. The degree of soft tissue swelling is difficult to assess objectively, but using a comparative photographic colour atlas is very helpful in this respect [54]. Significant exophthalmos may develop without proptosis readings exceeding the upper normal limit. Comparison with pictures of the patient before the onset of GO are helpful in this respect. Motility disturbances are recognized by asking the patient to move the eyes upwards, downwards, and from side to side, observing impaired elevation, depression, abduction, or adduction. Diplopia is also graded subjectively. More objective measurements can be done by ophthalmologists; most relevant is the field of single binocular vision [55]. Stippling of the cornea can be seen by split lamp and application of dyes; ulceration, clouding, necrosis, and perforation occur in severe cases. Visual acuity is measured using the Snellen chart; the use of a pinhole corrects for refraction disorders and sight loss due to keratitis. Further investigation is warranted if optic nerve involvement is suspected (e.g. in patients complaining of persistent blurred vision or greyish vision). In patients with DON, decreased visual acuity is present in 80%, reduced colour vision in 77%, visual field defects in 71%, afferent pupillary defect (Marcus Gunn's phenomenon) in 45%, optic disc oedema in 56%, and disc pallor in 4% [2]. Choroidal folds, caused by impression of the globe by enlarged retrobulbar tissues, are rare.

Assessment of GO Activity

In some patients, such as the one depicted in Figure 3.3.10.2, one glance is sufficient to conclude the eye disease is in the active phase. However, if it is not self-evident whether GO is active or inactive, an assessment of disease activity by the CAS (clinical activity score) provides guidance in selecting the most appropriate treatment (Figure 3.3.10.6). The CAS is based on the classical signs of inflammation (Table 3.3.10.2). A CAS of <3 is compatible with inactive GO, and CAS ≥3 has fair predictive value for improvement of GO upon immunosuppressive treatment [56]. There have been other

Figure 3.3.10.6 Active versus inactive GO. (a) Note periorbital swelling caused by oedema, redness of eyelids, redness of conjunctiva, and chemosis in a patient with active eye disease. (b) Periorbital swelling in a patient with inactive eye disease due to fat prolapse through the orbital septum and/or fibrotic degeneration; redness and chemosis are absent.

methods for assessing GO activity, like orbital A-mode echography measuring echogenicity in extraocular muscles, orbital ^{111}In-labelled octreotide scintigraphy measuring orbital/occipital skull uptake ratio, and orbital MRI measuring (e.g. T_2-relaxation time). Each of these methods have their own specific drawbacks, and have not become popular although their predictive values for the outcome of immunosuppression are reasonable. A short duration of GO (less than 18 months) is likely to be associated with still active disease [57]. Maybe the combination of GO duration, CAS, and orbital MRI provides the most accurate method for assessing disease activity.

Assessment of Quality of Life

Eye changes adversely affect a patient's self-image and daily functioning. The overall health-related quality of life (QoL) of patients with moderate-to-severe GO is lower than for patients with other chronic conditions such as diabetes mellitus, emphysema, or heart failure [58]. A disease-specific QoL questionnaire has been developed, the GO-QoL, which has been thoroughly validated [59, 60]. The GO-QoL contains eight questions about problems with visual functioning and eight questions about the psychosocial consequences of changed appearance (Table 3.3.10.3). The answers are summarized to one score for visual functioning and one score for appearance. The GO-QoL might be useful not only in evaluation of treatment, but also in reconciling priorities of the patient and of the physician in delineating a management plan. The psychosocial burden imposed by GO is considerable, and support by mental

Table 3.3.10.2 Assessment of disease activity in the patient with Graves' orbitopathy (GO)

Activity measures of GO (using the clinical activity score, CAS)		
Inflammatory sign	**Item**	**Score**
Pain (dolor)	Spontaneous retrobulbar pain Pain on up-, side-, or downgaze	1 1
Redness (rubor)	Redness of the eyelids Redness of the conjunctiva	1 1
Swelling (tumour)	Swelling of the eyelids Swelling of the caruncle and/or plica Chemosis	1 1 1
Maximum CAS score (assessed momently)		7
Impaired function (functio leasa)	Increase in proptosis ≥2 mm in 1–3 months Decrease of ≥8^0 in eye muscle motility in any direction in 1–3 months Decrease in visual acuity of >1 line on the Snellen chart (using pinhole) in 1–3 months	1 1 1
Maximum CAS score (assessed over time)		10

healthcare professionals might be needed. The sequelae of GO are indeed substantial: 45% of patients are restricted in their daily activities, 36% are on sick leave, 28% are disabled, 5% went into early retirement, and 3% lost their jobs, all because of GO [61]. The recent ETA/EUGOGO guidelines for the management of GO state: 'We recommend a patient-focussed approach of patients with GO, which encompasses the effects of disease and its treatment on QoL and psychosocial well-being. Use of GO-QoL, a disease-specific and well validated tool, is recommended in routine clinical practice' [62]. The GO-QoL is available in 18 languages and can be downloaded for free from the EUGOGO website (https://www.eugogo.eu).

Orbital Imaging

The degree of swelling of extraocular muscles and orbital fat can be evaluated using CT scans or MRI. Coronal sections are preferred in view of the pear-shaped orbit with its axis directing backwards and medially (Figure 3.3.10.7) [2]. The bony structures are best evaluated by CT scan and are of relevance in case of surgical decompression. MRI has the advantage of providing an activity parameter in addition to imaging. The muscles in GO are swollen typically at the belly, leaving the tendons uninvolved. For unknown reasons the inferior and medial rectal muscles are most frequently enlarged, followed by the superior rectus; the lateral rectus muscle is least affected. The extraocular muscles originate in Zinn's annulus, which surrounds the optic canal and thus the optic nerve. Muscle swelling at this location (apical crowding) and intracranial fat prolapse are risk factors for optic neuropathy [2]. Orbital imaging is not necessary in most GO patients. Indications for orbital imaging are: (1) suspicion on DON (apical crowding?); (2) unilateral GO (GO is unilateral in about 10% of cases, but GO is the most prevalent cause (15%) of unilateral exophthalmos); (3) euthyroid or hypothyroid GO; (4) before surgical orbital

Table 3.3.10.3 Assessment of quality of life in the patient with Graves' orbitopathy (GO)

Quality of life measures of GO (using the disease-specific GO-QoL)	
Visual functioning During the past week, because of GO, to what extent were you limited in …?	*Appearance* During the past week, because of GO, do you feel that …?

decompression (bony structures are best evaluated by CT); (5) uncertainty about the diagnosis of GO.

Differential Diagnosis

None of the eye signs is pathognomonic for GO. Lid retraction can be due to non-Graves' thyrotoxicosis, contralateral ptosis, or cocaine use. Diplopia is common in myasthenia gravis, and bilateral proptosis can be caused by orbital fat accumulation (Cushing's syndrome, obesity), lithium therapy, liver cirrhosis, Wegner's granulomatosis, arteriovenous malformations, lymphoma, metastatic tumours, or severe myopia (pseudoproptosis).

Proptosis, motility disturbances, and optic nerve compression can be caused by the ill-defined disease entity of orbital pseudotumour, an idiopathic non-specific unilateral focal or diffuse fibroinflammatory orbital lesion [63]. The clinical presentation is characterized by acute or subacute signs of inflammation (pain, redness, oedema) and mass effects; imaging shows a focal or diffuse mass which is poorly demarcated. Orbital myositis is, after GO, the second most common cause of extraocular muscle enlargement, due to non-specific inflammation. The cardinal clinical feature is acute orbital pain exacerbating on eye movements. The disease is bilateral in 50% of patients. One or more muscles may be enlarged and, in contrast to GO, involve the muscle tendons. Orbital pseudotumour and orbital myositis respond quickly to corticosteroids, but recurrences occur in 50%. IgG4-related orbitopathy is a recently described condition characterized by lymphoplasmacytic infiltration and tissue fibrosis, which may mimic GO [64].

Management

Management of GO requires close consultation between the patient, the endocrinologist, and the eye physician, but in this respect notable differences in the delivery of care exist. Combined thyroid–eye clinics are most appropriate to delineate the treatment plan best suited for a particular patient. The timing and mode of thyroid treatment, immunosuppressive treatment, and surgical treatment should be coordinated in a multidisciplinary approach. The patient should be reassured of the possibilities for improvement of eye changes, both functionally and cosmetically, but at the same time be informed that it may require 1–2 years before full rehabilitation is reached. In this respect the experience of other patients with GO can be quite informative, and contact with patient self-help groups is very useful. It is recommended that all GO patients except mildest cases, are referred to specialized clinics or to combined thyroid/eye clinics [62]. Such a policy is likely to improve the quality of care delivered to GO patients [65]. Specific guidelines for the management of GO have been published [62] (Figure 3.3.10.8).

General Measures

About 40% of GO patients are current smokers [3]. The advice to stop smoking should be given repeatedly, and smoking cessation programmes should be offered. Patients should be confronted with the evidence that a/ smokers have more severe GO than non-smokers, b/ risk of worsening of GO after ^{131}I therapy is 4× greater in smokers than in non-smokers, c/ outcome of immunosuppression is less good in smokers than in non-smokers. Passive smoking may also be a risk for developing GO [66].

Simple measures that may be helpful in any stage of the disease are: (1) artificial tears to reduce surface symptoms and protect the epithelium; (2) sunglasses to reduce photophobia but also to comfort patients who are self-conscious of their appearance; (3) lubricant ointments to protect against exposure keratopathy during sleep; (4) prisms to improve diplopia. Botulinum toxin A injections may provide temporary control of eyelid retraction.

Thyroid Treatment

GO is more severe in patients who still have an abnormal thyroid function despite antithyroid treatment; it improves slightly after thyroid function has returned to normal [67]. Restoration and maintenance of euthyroidism is thus relevant for the eyes. Prolonged treatment with **antithyroid drugs** (ATD) (preferably in combination with thyroxine, the so-called block and replace regimen) until full rehabilitation of GO is obtained, is a feasible option. When GO has become inactive and needs no further treatment, ATD are discontinued; if Graves' hyperthyroidism recurs, it can be treated with ^{131}I without adverse effects on the eyes [68, 69]. A large longitudinal cohort study from Australia suggests preference for ATD: the odds for GO are 86% less in hyperthyroid patients using ATD than in those not using ATD (OR 0.14, CI 0.06–0.34) [70].

Iodine-131 therapy of Graves' hyperthyroidism is associated with a relative risk of 4.23 (CI 2.04–8.77) for progression of GO when compared to treatment with antithyroid drugs [30]. This conclusion is based on three large randomized clinical trials. Risk factors are pretreatment serum T3 >5 nmol/L, pre-existent active GO, high TSHR-Ab, and smoking. High TSH levels after ^{131}I therapy also constitute a risk for GO and should be avoided. The eye changes usually occur within 6 months after radioactive iodine, and are mostly transient and mild in nature. They can be prevented by steroids which should be applied in patients with one or more risk factors [71]. Uncertainty exists about the most appropriate dosage schedule: oral prednisone 0.2 mg/kg per day given for 6 weeks might be as effective as 0.3–0.5 mg/kg per day given for 3 months [62]. A causal relationship between ^{131}I therapy and the eye changes is plausible in view of

the radiation-induced release of thyroid antigens, T-cell activation, and immediate and significant rise in serum TSHR-Ab [29, 30].

Total thyroidectomy has been advocated in GO in order to remove all thyroid antigens and thyroid-directed T lymphocytes. This approach is logical assuming cross-reactivity between thyroid and orbital antigens is involved in the immunopathogenesis of GO, although orbital autoimmunity may proceed independently once the eye disease is well established. The implication is that thyroidectomy should be done early in the course of the disease. In a case–control study, development or worsening of eye changes after near-total thyroidectomy occurred in 3.3%, exactly the same as in carefully matched patients treated with ATD [72]. Another study found no difference in the course of GO between subtotal and total thyroidectomy [73]. A randomized trial in GO found total thyroid ablation (total thyroidectomy + ^{131}I ablation) associated with a slightly better outcome at 9 months than total thyroidectomy alone, but improvement was limited to lid aperture and proptosis and was of minor clinical relevance [74]. A longitudinal study using a large database of a US managed care network, observed that surgical thyroidectomy was associated with a 74% decreased hazard for GO (HR 0.26, CI 0.12–0.51) compared with ^{131}I therapy alone [75]. If confirmed, it would make total thyroidectomy an attractive option for treatment of Graves' hyperthyroidism when GO is very mild or still absent.

Eye Treatment

Management of eye changes in GO depends on disease severity and disease activity, as clearly shown in the algorithm of Figure 3.3.10.8 [62]. Mild GO is characterized by lid retraction <2 mm, mild soft tissue involvement, proptosis <3 mm above upper normal limit, absent or intermittent diplopia, absent corneal exposure, and normal optic nerve status. Moderate-to-severe GO is defined by lid retraction ≥2 mm, moderate-to-severe soft tissue involvement, proptosis ≥3 mm above upper normal limit, inconstant or constant diplopia, mild punctuate keratopathy, and normal optic nerve status, and very severe sight-threatening GO by corneal breakdown or DON. When evaluating GO severity and activity, it can be helpful to have a look at the QO-QoL results. It could facilitate discussion with the patient on the most disturbing features, and to identify patients in need of further counselling. Counselling may reduce anxiety, provide reassurance, and help in developing better coping strategies.

Treatment of Mild GO

Spontaneous improvement occurs in about 30% of patients with mild GO after 1 year. A 'wait-and-see' policy is therefore justified [62]. An alternative is treatment with sodium selenite 100 μg twice daily for 6 months: it improves eye manifestations (in 61% of Se and 36% of placebo treated patients) and QoL, and prevents progression to more severe GO (which occurred in 7% upon Se and in 26% upon placebo treatment) (Figure 3.3.10.9) [76]. Antioxidant actions of selenium in OF provide a basis for these favourable effects [77]. The results were obtained in European countries with relatively low selenium intake. It is unknown if selenium would have the same beneficial effect in countries like the United States which are selenium sufficient. Sometimes the eye changes despite being labelled as mild, have such a negative impact on a patient's life that more invasive intervention (e.g. steroids) is warranted. Retrobulbar irradiation in mild GO has a response rate of 50–60%, twice as high as that of sham irradiation, but it does not prevent progress to more severe ophthalmopathy that occurs in about 15% [78].

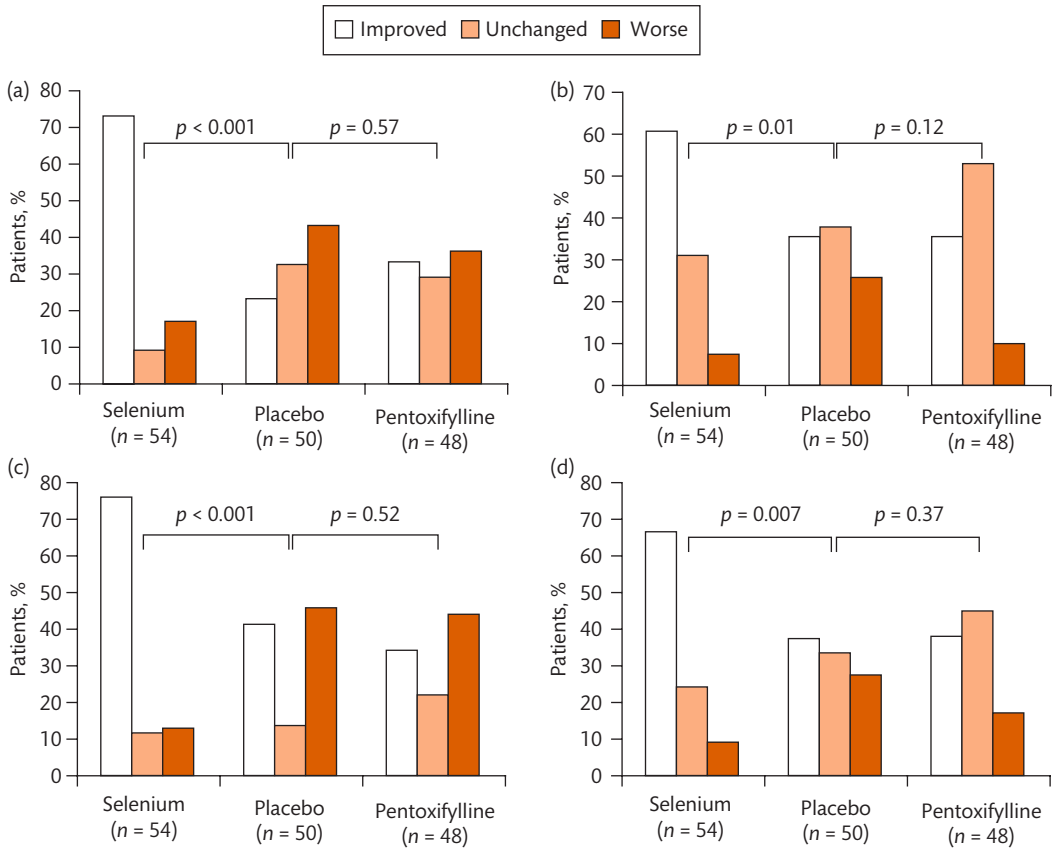

Figure 3.3.10.9 Results of a RCT in patients with mild Graves' orbitopathy comparing a six-month course of selenium or pentoxifylline with placebo on GO-QoL scores (a and b) and a composite score reflecting overall eye evaluation (c and d) at 6 months (a and c) and at 12 months (b and d).

Treatment of Moderate-to-Severe GO

Immunosuppressive treatment modalities are indicated in active moderate-to-severe GO. Glucocorticoids are better than placebo [79], and for long considered the mainstay of immunosuppression in GO. Steroids are effective for the relief of orbital pain and restoring visual acuity; their effectiveness is moderate for improvement of soft tissue involvement and extraocular muscle dysfunction, and limited for reduction of proptosis. Many patients still require rehabilitative surgery after a course of steroids. The main accomplishment of immunosuppression thus seems to be inactivation of the eye disease, thereby permitting earlier corrective surgery.

Intravenous methylprednisolone pulses (IVMP) have a higher response rate than oral prednisone (74–88% vs. 51–63%) and fewer side effects (17–56% vs. 51–85%), rendering IVMP presently the treatment of choice [62, 80]. Dose-finding studies indicate a cumulative dose of 4.5 g IVMP is appropriate for most patients, administered as follows: 500 mg i.v. once weekly for 6 weeks, followed by 250 mg i.v. once weekly for another 6 weeks [81]. Lower doses (2.25 g) are less effective, whereas higher doses (750 mg once weekly for 6 weeks followed by 500 mg once weekly for another 6 weeks, cumulative dose 7.5 g) are more effective at the expense of more side effects, and should be reserved for worst cases. IVMP have been associated with significant cardiovascular and cerebrovascular morbidity and hepatic toxicity, leading to a few sporadic fatalities. These serious events occurred if IVMP was administered in high single doses of ≥1000 mg, in cumulative doses of >8 gram, and/or as repeat infusions on consecutive days [82]. It is therefore recommended that IVMP should not exceed a cumulative dose of >8 g, and should not be given in patients with recent viral hepatitis, significant liver dysfunction, and severe cardiovascular morbidity or psychiatric disorders [62]. Severe hypertension, inadequately managed diabetes, and glaucoma are other contraindications. IVMP therapy should be monitored by regular measurements of blood pressure, blood glucose, and liver function tests. Efficacy of IVMP can be slightly enhanced by coadministration of mycophenolate (one 360 mg tablet twice daily for 24 weeks) [83]. Whereas the combination of oral prednisone and radiotherapy is more effective than oral prednisone alone [62], it is unsettled if addition of radiotherapy to IVMP provides extra benefit.

If eye changes worsen after discontinuation of glucocorticoids, shared decision-making is recommended to select a second-line therapy. This could be another course of IVMP if the cumulative dose of 8 g is not exceeded, oral prednisone (20 mg/day) in combination with either cyclosporine or orbital irradiation, or rituximab [62]. The combination of oral prednisone and cyclosporine is effective in about 60% of patients who had not responded adequately to steroids [84, 85]. The rationale of retrobulbar irradiation is the radiosensitivity of lymphocytes and fibroblasts. A dose of 20 Gy per

orbit fractionated in ten daily doses of 2 Gy over a 2-week period is commonly used [86]. Improvement is seen in about 50–60% of patients, predominantly in soft tissue involvement and eye muscle ductions [78, 87, 88]. A transient increase of conjunctival irritation is seen in 15% of patients. Radiation-induced retinopathy is extremely rare. Long-term follow-up studies did not detect serious complications after 21 years [89], but there exists a theoretical risk of about 0.5% for radiation-induced cancer. Therefore it is prudent to avoid radiotherapy in patients under 35 years of age.

Rituximab (RTX) is an anti-CD20 monoclonal antibody which effectively causes B-cell depletion. In a dose of 1 gram repeated once after two weeks, it is remarkable effective in open case series [90]. However, two randomized controlled trials (RCT) in active moderate-to-severe GO had discrepant outcomes. The first, conducted in the Mayo Clinics, found RTX not better than placebo [91]. The second, performed in Italy, found RTX slightly better than IVMP [92]. Sample size in both trials was very modest, and some differences in patient characteristics and trial execution are noted [93]. Nevertheless, it remains difficult to reconcile the difference in outcomes. It seems too early to accept RTX as an alternative for IVMP, but also too early to dismiss RTX as a disease-modifying drug. Side effects of RTX occur in about 30%; notable is the risk of the cytokine-release syndrome with development of DON.

Other treatment modalities (like azathioprine, ciamexone, pentoxifylline, or acupuncture) have shown no benefit in RCT, but intravenous immunoglobulins can be effective. Somatostatin analogues (octreotide and lanreotide) have little effect. A few case reports mention favourable effects of anti-TNFα antibodies (etanercept and infliximab) and especially of anti-IL6-receptor antibodies (tocilizumab), but these agents have not been tested in RCT [94]. Of considerable interest is teprotumumab, a monoclonal antibody inhibitor of IGF-1 receptors. In a placebo-controlled RCT it had great efficacy in reducing CAS, reducing exophthalmos, and improving diplopia and GO-QoL scores [95]. Its potential to reduce exophthalmos is remarkable, and could be greater than that of IVMP. However, to displace IVMP as first-line treatment, teprotumumab should be compared directly to IVMP in a RCT.

Treatment of Very Severe (Sight-Threatening) GO

There is only one RCT in DON, which, although its sample size is limited, indicates IVMP have a better outcome than immediate surgical decompression [96]. The applied IVMP scheme was 1000 mg daily, given as a 60-min intravenous infusion, on three successive days in week 1 and repeated in week 2. If visual functions have not improved after 2 weeks, we do an urgent surgical decompression. If improved, we continue with oral prednisone (40 mg/day for 2 weeks, 30 mg/day for 4 weeks, 20 mg/day for 4 weeks, and then tapering to zero dose by 2.5 mg/week).

Rehabilitative Surgery

Once GO has become inactive, rehabilitative surgery can be carried out to improve visual functions and appearance. Most orbital surgeons require stable eye disease for 6 months before surgery. Orbital decompression, achieved by removal of part of the bony orbital wall, is very effective in reducing exophthalmos. The more walls are removed, the greater the reduction in proptosis. Careful fat removal during bony decompression is increasingly done. Photographs of how the patient looked before the onset of GO are helpful in determining the required extent of proptosis reduction. Transeyelid or transconjunctival incisions leave a barely visible scar. Postoperative *de novo* or worsening of diplopia occurs in 10–30% of patients. Corrective eye muscle surgery for diplopia should therefore be done after decompressive surgery. Single binocular vision can be obtained in about 80% of patients, but more than one surgical session is often required to reach this goal. Lastly, eyelid surgery can be performed in order to correct upper or lower eyelid retraction; blepharoplasty can reduce any remaining eyelid swelling.

Graves' Dermopathy

Graves' dermopathy or pretibial myxoedema occurs usually in the pretibial area, but can occasionally occur at other sites subject to local mechanical pressure. The most frequent form (49%) is non-pitting oedema with violet discolouration and induration of the skin and prominent hair follicles, so that the lesions have the appearance and texture of orange peel (*peau d'orange*). Other clinical forms are plaques (27%), nodules (18%), and elephantiasis (5%) [97]. Graves' dermopathy occurs almost always in conjunction with GO and high serum concentrations of TSHR-Ab. It is observed in 4% of GO patients, and develops mostly about 1 year after the onset of GO. The postulated pathogenesis is remarkably similar to that of GO: cytokine-induced glycosaminoglycan production by dermal fibroblasts, upregulated TSH receptor expression on dermal fibroblasts, and a contributory role of local trauma and mechanical pressure [98].

The natural course of Graves' dermopathy is not well known. One-half of patients do not require any therapy; such cases may go slowly into complete remission (50% within 17 years). If treatment is necessary because of functional or cosmetic complaints, nighttime occlusive dressings of 0.05–0.1% triamcinolone acetonide in a cream base induce partial remissions in one-third of patients. Usually a trial of 4–10 weeks is needed, followed by intermittent maintenance therapy. The use of compressive bandages or stockings during the day provides additional benefit. Treatment of coexistent GO with systemic glucocorticoids or biologicals can cause regression of the skin lesions as well.

3.3.11 Management of Toxic Multinodular Goitre and Toxic Adenoma

Dagmar Führer and Holger Jäschke

Definition

Toxic adenoma (TA) and toxic multinodular goitre (TMNG) represent the clinically important presentations of thyroid autonomy. Thyroid autonomy is a condition where thyrocytes produce thyroid

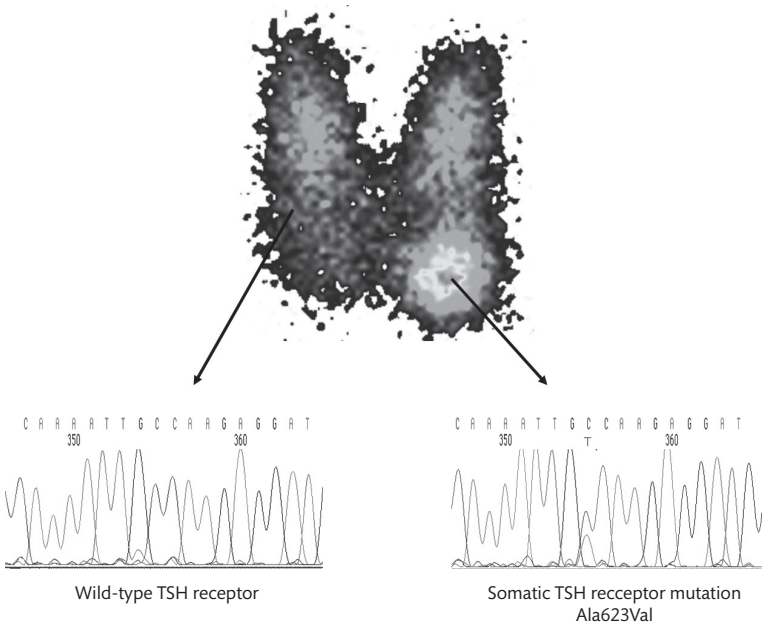

Figure 3.3.11.1 Scintiscan of uninodular goitre shows a circumscribed area of increased ^{99m}Tc-uptake in the left lobe ('hot nodule'). DNA was extracted from the toxic adenoma and surrounding normal thyroid tissue and exon 10 of the TSHR was amplified by polymerase chain reaction (PCR). Sequencing of the PCR products showed the presence of a heterozygous point mutation (GCC→GTC) resulting in an amino acid exchange (Val→Ala) in the toxic adenoma (right panel), whereas only the wild-type TSHR was present in the normal thyroid tissue (left panel). The mutation causes a constitutive activation of the TSHR, which leads to thyrotoxicosis and thyroid growth.

hormones independently of thyrotropin (TSH) and in absence of TSH receptor stimulating antibodies (TSAb).

Toxic adenoma (TA) is a clinical term referring to a solitary autonomously functioning thyroid nodule. The autonomous properties of TA are best shown by radioiodine or ^{99m}Tc imaging. The classic appearance of TA is a local and focal increase in tracer uptake with suppressed uptake in the surrounding extranodular thyroid tissue ('hot' nodule, Figure 3.3.11.1).

Toxic multinodular goitre (TMNG) is a heterogeneous disorder characterized by the presence of autonomously functioning thyroid nodules in an enlarged thyroid gland with or without additional nodules. These additional nodules can show normal or decreased tracer uptake (cold nodules) on scintiscan. TMNG constitutes the most frequent form of thyroid autonomy.

Epidemiology and Pathogenesis

The prevalence of thyroid autonomy is inversely correlated with iodine intake. Thus, thyroid autonomy is a common finding in iodine deficient areas, where it accounts for up to 60% of cases of thyrotoxicosis (TMNG: ~50%; TA: ~10%), but is rare (5–10%) in regions with iodine sufficiency [1, 2]. Specifically, in areas with iodine deficiencies the incidence of TMNG is 18 cases per 100 000 per year. In contrast, an incidence of 1.5 cases per 100 000 per year was determined in regions with high iodine supply [2, 3]. For TA the prevalence is 3.6 vs. 1.6 cases per 100 000 per year in regions with low and high iodine supply, respectively [2, 3]. In a Swedish area with stable iodine supply incidence rates for TMNG of 4.3 and for TA of 1.8 per 100 000 cases per year have been reported [2, 4]. Several studies have suggested that TMNG originates from euthyroid goitres and microscopic autonomous foci have been demonstrated in up to 40% of euthyroid goitres in iodine deficient areas [1]. Correction of iodine deficiency in a population results in decrease of thyroid autonomy and this has been impressively shown, for example, in Switzerland where a doubling in iodine salt content resulted in a 73% reduction of TMNG [5, 6]. Moreover, the prevalence of thyroid autonomy correlates with thyroid nodularity and increases with age as shown in a Danish population study evaluating the epidemiology of subtypes of hyperthyroidism [7]. In this study the most prevalent form of hyperthyroidism in individuals <50 years was Graves' disease. With advancing age, the incidence of TMNG and TA increased and outnumbered the cases of Graves' disease.

Thyrotoxicosis is rare disorder in children. In a Danish nationwide study, the incidence was 1.58/100 000 persons per year and about 96% of cases account for Graves' disease and less than 3% of cases were toxic nodular goitre or TA [8].

Somatic mutations of the G-protein coupled TSH receptor (TSHR; 50–75% http://www.uni-leipzig.de/innere/TSHR) or less frequently the Gs alpha protein subunit (5–10%) have been identified in TA and TMNG and represent the predominant molecular cause of thyroid autonomy. These mutations cause constitutive activation of the cAMP pathway, which stimulates TSH-independent thyroid hormone production and thyroid growth (Krohn 2005 PMID: 15615818, Parma 1993 PMID: 8413627). Recently, a specific mutation in the gene for a histone methyltransferase called **enhancer of zest homolog 1** (*EZH1*) (*c*.1712A>G; p.Gln571Arg) was identified in 27% (25 of 94) of adult TA. Surprisingly, the mutation was neither found in papillary or follicular thyroid carcinoma nor in 29 TA from children. This suggests that paediatric TA constitute a different group

or that the EZH1 variant may be acquired later during progression of the tumour. In contrast to TSHR or Gs alpha mutations, which constitutively activate the cAMP pathway, the EZH1 mutation exerts its effect via hypermethylation of histone H3 and consequently to the repression of gene transcription [9].

Clinical Features and Diagnosis

Clinical features of thyroid autonomy may be related to hyperthyroidism and/or compression signs due to the nodule and TMNG [10].

Clinical presentation of overt hyperthyroidism, defined by suppressed TSH with elevated fT_4 and/or fT_3, varies with age. While classic hyperthyroid features such as tremor, sweating, and hyperkinesis can be found in the younger patients, thyrotoxicosis is often oligosymptomatic in older people. In this population, atrial fibrillation, congestive heart failure, and anorexia may prevail. Subclinical hyperthyroidism is based exclusively on the biochemical determination of thyroid function and is defined by low or suppressed TSH with normal fT_4 and fT_3 levels. It is more commonly observed in older patients and is more than 'just' a low TSH status, since it confers increased risk for atrial fibrillation and contributes in postmenopausal women to reduced bone density [11].

In addition, a history of possible iodine contamination (contrast media, amiodarone) should be obtained. In the European Study Group of Hyperthyroidism iodine contamination was found in 36.8% of patients from iodine deficient areas with first diagnosis of hyperthyroidism. Severity of iodine deficiency, autonomous thyroid cell mass, and older age have been proposed as risk factors for the development of iodine induced hyperthyroidism, which responds less well to antithyroid drug treatment and poses the patient at risk for a life-threatening thyroid storm [12].

Alternatively, a patient may present with a lump or disfigurement of the neck, intolerance of tight necklaces, or increase in collar size. Moreover, dysphagia or breathing difficulties due to local oesophageal or tracheal compression may be present, particularly with TMNG.

Unusually, in some patients there may be a family history of thyroid autonomy and a characteristic course of frequent relapses of hyperthyroidism following thyrostatic therapy or partial thyroidectomy. Depending on the age of onset (neonatal to adulthood) these patients may present with a diffusely enlarged goitre or a TMNG. The underlying cause of this condition is an activating germline mutation in the *TSHR* gene, which can be confirmed through molecular diagnostics from a peripheral blood sample. Patients with an activating TSHR germline mutation require definite treatment in form of total thyroidectomy or an ablative dose of radioiodine to prevent further relapses. Genetic counselling is also mandatory as the condition is autosomal dominantly inherited [13].

Diagnosis of TA and TMNG is based on clinical examination, thyroid function tests, thyroid ultrasound and scintiscanning [10]:

- Examination of the neck will reveal the degree of thyroid enlargement and nodularity of the gland. A history of a recently enlarging nodule and cervical lymph node enlargement should be noted because of concern of a developing malignancy at this site. In addition, clinical evidence of lymph node enlargement and tracheal deviation and/or compression should be sought.
- Standard thyroid function tests (TSH and free thyroid hormones fT_4 and fT_3) will confirm overt or subclinical hyperthyroidism, but depending on the autonomous cell mass, euthyroidism may still prevail.
- Localization, size, and number of thyroid nodule(s) as well as goitre volume can be determined by ultrasound using a 7.5 or 9 MHz linear scanner. In addition, presence or absence of cervical lymph node enlargement should be noted.
- Increased ^{99m}Tc or radionucleotide uptake in the nodule(s) concomitant with a decreased uptake in the surrounding extranodular thyroid tissue is the typical finding on scintiscanning (**Figure 3.3.11.1**). If thyroid autonomy is suspected in a patient with a (still) euthyroid nodule, a 'suppression' scan can be performed, after administration of thyroid hormones (e.g. 75 µg levothyroxine/d for 2 weeks followed by 150 µg/d for 2 weeks). Thereby non-autonomous tissue will be suppressed and thyroid autonomy unmasked.

Measurement of thyroid autoantibodies is not routinely performed in thyroid autonomy. However, in iodine deficient areas distinction between Graves' disease and TMNG can be difficult if extrathyroidal manifestations of autoimmune thyroid disease are absent and ultrasound shows presence of thyroid nodules (~27–34%). In this scenario measurement of TSAb is helpful to establish the correct diagnosis. Urinary iodine excretion can be measured in case of suspected iodine contamination. Computer tomography or magnetic resonance imaging are not routinely indicated for diagnosis of thyroid autonomy but may be used for presurgical planning in cases of large and partly intrathoracic TMNG.

Treatment of TMNG and TA

The management of patients with thyroid autonomy (TMNG and TA) will to some extent depend on the patient's age, the severity of hyperthyroidism, the size of the thyroid gland and concomitant other medical illness [11, 14–16].

Antithyroid medication (ATD) is the first-line of treatment in all patients with overt hyperthyroidism. Depending on the type of antithyroid drug, an initial dosage of 10–20 mg/d methimazole, 15–30 mg/d carbimazole is recommended. Higher dosages are associated with more frequent adverse effects and will only result in marginally faster resolution of thyrotoxicosis. β-blockers are helpful for symptom relief, until the patient is euthyroid.

A trial of low dose antithyroid medication (5–10 mg methimazole/d) may be justified in selected patients with symptomatic subclinical hyperthyroidism (i.e. atrial fibrillation; alternatively, β-blocking agents can be used) [11]. Monitoring of thyroid function and ATD side effects, in particular full blood count and liver function tests are mandatory [11, 15].

Due to the underlying molecular defect there is no spontaneous resolution of thyroid autonomy and definite treatment is indicated once thyroid autonomy becomes clinically manifest. Elderly patients with severe non-thyroidal illness may be an exception from this rule.

Table 3.3.11.1 Treatment of TMNG and TA

Modality	Advantages	Disadvantages
Surgery	Effective	Hospitalization
	Simple operation	Anaesthesia
	Rapid euthyroidism	Side effects (vocal cords, Hypoparathyroidism)
Radioiodine	Outpatient therapy	Time to cure possible hypothyroidism in long term
Antithyroid drugs	Rapid euthyroidism	Relapse on stopping
	Not destructive	Side effects (skin, liver, bone marrow)
Local ablative treatment practised	Outpatient procedure	Not widely
(e.g. Laser ablation, radiofrequency, percutaneous ethanol injections)	Effective	Several treatment sessions required Side effects (vocal cord, pain)

However, benefits and risks of such 'long-term' ATD have to be considered against the nowadays very low risk of definite treatment.

Two different ablative treatment options are widely available for TA and TMNG and comprise thyroid surgery and radioiodine treatment.

The purpose of thyroid surgery is to cure hyperthyroidism by removing all autonomously functioning thyroid tissue and other macroscopically visible nodular thyroid tissue [10, 17]. Thus the extent of surgery will vary depending on preoperative ultrasound findings and intraoperative morphological inspection. Hemithyroidectomy is usually adequate for TA, if no further nodules are detectable, while in case of TMNG a subtotal, near-total, or total thyroidectomy is performed. Advantages of surgery are a fast ablation of hyperthyroidism and the immediate relief of compression symptoms. Disadvantages of surgery are thyroid-specific side effects (i.e. vocal cord paralysis and permanent hypoparathyroidism), which should be less than 1% with an experienced endocrine surgeon. Evidently, the rate of postoperative hypothyroidism will vary with the extent of thyroid resection and in case of a near-total or total thyroidectomy requires start of efficient thyroid hormone replacement therapy (1.6–1.8 μg levothyroxine/kg body weight), aiming for a normal range TSH value after surgery.

Surgery is usually recommended in large TMNG (>100 ml) and is indicated in case of suspicion of thyroid cancer. In addition, surgery is also advocated in patients with overt hyperthyroidism and adverse side effects of ATD, or as an early emergency procedure in patients with a thyroid storm [12, 18].

Radioiodine therapy is also highly effective for ablation of hyperthyroidism and reduction of TA or TMNG volume [10, 14, 15, 19]. Different protocols have been suggested for ^{131}I therapy in benign thyroid disease. Some investigators prefer to administer a standard dose (e.g. 370–740 MBq/thyroid gland) while others apply a certain ^{131}I activity/gram thyroid tissue. The success rate of an individually dosed ^{131}I therapy has been reported to range between 85% and 100% in TA and reaches up to 90% in TMNG. An average thyroid and/or nodule volume reduction of ~40% can be anticipated. Advantages of radioiodine are its simple and outpatient-based applicability. Disadvantages are the 'time to euthyroidism' period (6 weeks to >3 months), during which ATD has to be continued and thyroid function monitored at 3- to 6-week intervals. Radioiodine treatment is contraindicated in pregnancy and contraception is advocated for at least 6 months after receiving ^{131}I therapy.

Postradioiodine hypothyroidism in TMNG and TA usually develops insidiously and depends on the extent of TSH suppression prior to ^{131}I therapy and the protocol applied. In one study the incidence of hypothyroidism was 3% at 1 year, 31% at 8 years, and 64% at 24 years follow-up after radioiodine treatment. These data emphasize the requirement of long-term monitoring of thyroid function in all patients receiving ^{131}I therapy.

For the treatment of TMNG and TA non-surgical ultrasound-guided ablation techniques have been explored. These ablation modalities include ethanol injection therapy (PEIT), radiofrequency ablation (RFA) and laser therapy and were studied by a limited number of centres mainly in Europe and South Korea [20–23]. In experienced hands, these methods have been shown to eliminate autonomy in a tissue and to decrease the size of a nodule with very few complications, except for pain and local discomfort. Since these techniques are not widely available they might be reserved for further trials and for patients for whom no other treatment option is feasible or for those who decline traditional option. However, treatment of hyperfunctioning nodules remains best treated with radioiodine due to better control of hyperthyroidism long-term and with fewer side effects [24].

A summary of the advantages and disadvantages of the different treatment modalities for TA and TMNG is shown in Table 3.3.11.1.

Follow-up

The long-term management of patients with TA and TMNG is directed at the detection and adequate treatment of thyroid dysfunction (TSH-level), detection of novel nodular thyroid disease (palpation and ultrasonography) and in case of surgery, detection and treatment of postsurgical hypoparathyroidism (serum calcium). In case of ^{131}I therapy, long-term follow-up for development of hypothyroidism is mandatory (e.g. at an annual rate). Thyroxine with or without iodine is often administered after thyroid surgery to prevent recurrent goitre/thyroid nodules. Although large randomized trials are lacking to provide definite evidence that postoperative thyroxine administration is beneficial, unless the patient is hypothyroid, this treatment strategy is inferred by studies treating goitre/nodules with levothyroxine. In addition, in iodine deficient areas iodine supplementation may be appropriate to prevent further nodular thyroid disease.

3.3.12 Management of Thyrotoxicosis Without Hyperthyroidism

Wilmar M. Wiersinga

Introduction

Thyrotoxicosis without hyperthyroidism originates either from the thyroid gland as a result of destructive lesions or from extrathyroidal sources (Box 3.3.12.1). In contrast, thyrotoxicosis with hyperthyroidism refers to conditions like Graves' hyperthyroidism and toxic nodular goitre in which there is increased biosynthesis of thyroid hormones in the thyroid gland. Radioiodine uptake in the neck and thyroid vascularity at ultrasonography are low in thyrotoxicosis without hyperthyroidism, but high in thyrotoxicosis with hyperthyroidism. Cytokine-, iodine-, and amiodarone-induced thyrotoxicosis manifest themselves either as thyrotoxicosis without hyperthyroidism, or as thyrotoxicosis with hyperthyroidism in which thyroidal radioiodine uptake is preserved. Both types are discussed in this chapter.

Box 3.3.12.1 Thyrotoxicosis without hyperthyroidism

1 Destructive thyroiditis
- Subacute thyroiditis of De Quervain
- Painless or silent thyroiditis
- Postpartum thyroiditis
- Radiation-induced thyroiditis
- Cytokine-induced thyroiditis
- Checkpoint inhibitor-induced thyroiditis

2 Iodine-induced thyrotoxicosis
3 Amiodarone-induced thyrotoxicosis
4 Thyrotoxicosis of extrathyroidal origin
- Factitious thyrotoxicosis (excess of exogenous thyroid hormone, Hamburger thyrotoxicosis)
- Struma ovarii
- Functional metastases of differentiated thyroid carcinoma

Thyrotoxicosis Due to Destructive Thyroiditis

The inflammatory reaction in destructive thyroiditis disrupts the normal architecture of the thyroid gland, causing release of preformed T_4 and T_3 stored in the colloid. The colloid contains more T_4 than T_3, explaining the lower serum T_3/T_4 ratio in thyrotoxic patients without hyperthyroidism as compared to thyrotoxic patients with hyperthyroidism. Leakage of the iodine-rich contents of the colloid into the bloodstream expands the iodide pool in the circulation; administered radioiodine will be diluted in the expanded iodide pool, which in conjunction with damage to the thyrocytes causes a low thyroidal radioiodine uptake. The efficacy of treatment with radioiodine or antithyroid drugs is consequently very low.

Subacute, painless, and postpartum thyroiditis run a self-limited course, in which the inflammation gradually subsides under restoration of the normal thyroid architecture (see Chapter 3.2.6). Thyrotoxicosis associated with thyroiditis is usually mild, lasting for only a few weeks, and either no treatment or treatment with a β-adrenoceptor antagonist is sufficient. Short-term salicylates, or glucocorticoids in more resistant cases, may be required to relieve neck pain in subacute thyroiditis. The thyrotoxic phase may be followed by a hypothyroid phase in any type of thyroiditis and can last for 1–4 months. Thyroxine treatment may be warranted in symptomatic patients, but should be withdrawn after 6 months because most patients will spontaneously regain euthyroidism. Postpartum thyroiditis is very likely to recur after a subsequent pregnancy. Permanent hypothyroidism develops in about one-third of patients with silent or postpartum thyroiditis.

Radiation-induced thyroiditis may occur after treatment with large doses of ^{131}I. It develops in the first 2 weeks, and is characterized by neck and ear pain, painful swallowing, thyroid swelling, and tenderness. Thyrotoxicosis is mild and transient, resolving spontaneously within a week or two, and not requiring any specific treatment besides salicylates for mild pain. Glucocorticoids (e.g. 30 mg prednisone daily) may be given for severe pain or swelling, tapering the dose when the complaints have disappeared.

Cytokine-induced thyroiditis has been observed after the administration of interleukin-2, interferon-α (IFNα), or granulocyte-macrophage colony stimulating factor. The clinical picture may resemble that of destructive thyroiditis: transient thyrotoxicosis developing after a few weeks to months, followed by a hypothyroid phase which may be transient as well. Radioiodine thyroid uptake is low and a small non-tender goitre is sometimes present. However, it is not uncommon that the hypothyroid phase is permanent, or develops much later without preceding thyrotoxicosis. In patients treated with IFNα for chronic hepatitis C, *de novo* occurrence of thyroid antibodies is observed in 10–14% [1–3]. Thyroid function disorders develop in 15%, due to autoimmune hypothyroidism (*c.*50%), Graves' hyperthyroidism (*c.*25%), or destructive thyroiditis (*c.*25%); however, only a small minority needs treatment as spontaneous recovery is the rule rather than the exception. These abnormalities have a median date of onset 17 weeks after starting treatment, but can occur at any time. Risk factors are female sex and pre-existent thyroid antibodies, but IFNα dosage or efficacy are not. It is recommended to measure thyroid-stimulating hormone (TSH) and TPO-Ab before treatment, and to monitor TSH during treatment (e.g. every 3 months). IFNα-induced Graves' disease does not resolve spontaneously after discontinuation of IFNα, and thyroid ablation with ^{131}I or surgery is preferred. IFNα-induced destructive thyroiditis is mostly mild or subclinical and resolves spontaneously, although permanent hypothyroidism develops in less than 5% of cases. IFNα treatment can usually be continued, except in very severe cases. Corticosteroids are generally contraindicated in patients with hepatitis C. Rechallenge with IFNα may result in recurrent destructive thyroiditis.

Immunotherapy with **checkpoint inhibitors** (like the CTLA4-inhibitor ipilimumab, and the PD-1 inhibitors nivolumab and pembrolizumab) improves survival in a number of cancers but may induce various endocrinopathies, including thyroid function disorders and destructive thyroiditis resembling those induced by interferon-α [4].

Trauma of the thyroid gland may rarely result in transient thyrotoxicosis associated with a low radioiodine thyroid uptake. Infiltration of the thyroid gland with malignant lymphoma or cancer metastases may cause thyrotoxicosis associated with low radioiodine thyroid uptake in exceptional cases, due to invasion and disruption of thyroid follicles.

Iodide-Induced Thyrotoxicosis

Exposure to pharmacological quantities of iodine may cause occasionally iodide-induced thyrotoxicosis (IIT), also called Jod-Basedow [5–8]. IIT is more prevalent in iodine-deficient areas than in iodine-sufficient areas. Risk factors are old age, nodular goitre, and low TSH. In case of underlying thyroid disease (like in patients with multinodular goitre or latent Graves' disease and subclinical hyperthyroidism), thyroidal radioiodine uptake may be normal or even high. In contrast, in patients without underlying thyroid disease, ITT is caused by the cytotoxic effect of iodine excess on thyrocytes resulting in destructive thyroiditis, and radioiodine uptake will be low. IIT usually resolves spontaneously within 6 months, often after a hypothyroid phase. The efficacy of antithyroid drugs is impaired by the presence of iodine excess, and ß-blockers or no treatment at all may suffice.

Many drugs contain huge quantities of iodine, such as kelp tablets, certain expectorants, and iodinated contrast agents. The risk

for developing IIT is 0.3% in unselected people after coronary angiography in iodine-deficient areas [9]. In patients with an autonomous thyroid function before coronary angiography, treatment with 20 mg thiamazole and/or 900 mg sodium perchlorate, starting the day before angiography and continued for 2 weeks, was not very effective in preventing IIT [10, 11]. Close monitoring of high-risk patients rather than prophylaxis is thus recommended, with prescription of β-adrenoceptor antagonists if thyrotoxicosis occurs [12].

Amiodarone-Induced Thyrotoxicosis

One tablet of 200 mg amiodarone contains 74.4 mg iodine of which 10% is released *in vivo* during biotransformation of the drug. A maintenance dose of 300 mg amiodarone daily results in a 40-fold rise of plasma inorganic iodide and urinary iodide excretion [13]. The iodine excess may induce thyrotoxicosis in patients with underlying thyroid disease, referred to as amiodarone-induced thyrotoxicosis (AIT) type 1. Amiodarone and especially its main metabolite desethylamiodarone have a potent cytotoxic effect on thyrocytes causing destructive thyroiditis [14, 15]; it may give rise to a destructive type of thyrotoxicosis, referred to as AIT type 2. The analogy with IIT is obvious, but the molar concentrations required for the cytotoxic effect of amiodarone are about three times lower than for potassium iodide [14].

Epidemiology and screening. Whereas amiodarone-induced hypothyroidism (AIH) is most prevalent in iodine-sufficient regions, AIT is more prevalent in iodine-deficient areas. A prospective study in the Netherlands, a country with an average daily iodine intake of 150 μg, demonstrated development of AIH in 6% and of AIT in 8% of patients starting amiodarone [16]. It means one out of every five to six patients taking amiodarone will develop overt thyroid dysfunction. It is striking that no new cases of AIH develop after 2 years on amiodarone therapy, whereas new cases of AIT continue to occur with continuation of amiodarone. The incidence rate/100 person-years in France and the Netherlands is 4.6 and 1.9 for AIH, respectively, and 1.6 and 1.6 for AIT [16, 17]. The high incidence and the potential danger of worsening of heart disease upon occurrence of AIH or AIT [18] call for thyroid monitoring. It is therefore recommended to measure TSH and TPO-Ab at baseline, and TSH every 6 months thereafter [19, 20]. A normal serum TSH during follow-up, however, does not guarantee that AIT will not develop in the interval to the next visit in view of the unpredictable and often sudden onset of AIT [21]. Furthermore, the finding of a suppressed TSH during follow-up does not necessarily mean AIT that has to be treated, because in one-half of these cases TSH returns spontaneously to normal values [21, 22]. AIT can develop up to 12 months after discontinuation of amiodarone, related to the very long terminal half-life of the drug.

Diagnosis. AIT can be asymptomatic. Recurrence of cardiac arrhythmias, which previously had been controlled, may suggest the diagnosis. Symptoms can be unexplained weight loss (50%), heavy sweating (42%), palpitations (37%), hyperkinesia (29%), muscle weakness (27%), heat intolerance (24%), overall weakness (12%), and diarrhoea (12%) [23]. The biochemical diagnosis of AIT is based on a suppressed TSH in combination with an elevated free T_4. T_3 can be elevated or normal (related to the strong inhibition of T_4 deiodination into T_3 by amiodarone), and cases of T_4 toxicosis do occur. The fT3 to fT_4 ratio in AIT (like in IIT and subacute thyroiditis) is thus much lower than in Graves' hyperthyroidism.

Distinction between AIT subtypes is considered to be useful because management of types 1 and 2 is different (Table 3.3.12.1) [24]. However, none of the proposed methods accurately discriminates between both subtypes. Serum interleukin-6 was originally advocated as a good discriminator (being much higher in type 2 than in type 1), but subsequent studies have been unable to confirm its value. Thyroidal radioiodine uptake is low or absent in type 2, but can also be low in type 1, and in one study did not differ at all between both types. Colour flow Doppler sonography can be useful, revealing a patchy pattern of thyroid vascularity to a markedly increased blood flow in type 1 and an absent blood flow in type 2 [25]. The latest tool has been the ^{99m}Tc-sestamibi scan, showing mostly increased MIBI retention in type 1 and no uptake in type 2 [26]. It should be admitted that sometimes distinction between type 1 and type 2 AIT fails, and mixed cases do occur in about 10–15% [22].

Treatment. Guidelines for the management of AIT have been published by the European Thyroid Association (Figure 3.3.12.1)

Table 3.3.12.1 Characteristics of amiodarone-induced thyrotoxicosis types 1 and 2

	Type 1	Type 2
Underlying thyroid abnormality	Yes	No
Pathogenesis	Iodide-induced thyrotoxicosis	Destructive thyrotoxicosis
Physical examination	Usually nodular or diffuse goitre	Occasionally small diffuse firm goitre
Thyroid antibodies	Can be present	Mostly absent
Thyroid ultrasound	Diffuse or nodular goitre	Heterogeneous pattern
Doppler sonography	Normal or increased blood flow	Decreased blood flow
Thyroidal radioiodine uptake	Low or normal	Low or absent
^{99m}Tc-sestamibi scan	Clear thyroid retention	No thyroid uptake
Spontaneous remission	Unlikely	Likely
Preferred drug treatment	$NaClO_4$ + methimazole	Glucocorticoids
Amiodarone medication	Discontinue if possible	Can be continued
Subsequent hypothyroidism	Unlikely	Possible

[24]. Amiodarone should be stopped in AIT type 1. Older studies indicate most patients with AIT type 1 are still thyrotoxic 6–9 months after discontinuation of amiodarone; in contrast, many patients with AIT type 2 are cured spontaneously in 3–5 months, in line with the self-limiting nature of AIT type 2 [22]. A recent prospective controlled trial has indeed demonstrated the feasibility of continuation of amiodarone in AIT type 2 [27].

AIT type 1 should be treated with rather high doses of antithyroid drugs (40–60 mg methimazole daily) because the ambient iodine excess renders the thyroid gland less sensitive to methimazole. One may opt to co-administer sodium perchlorate, which by acute inhibition of thyroidal iodide uptake decreases intrathyroidal iodide thereby increasing the efficacy of methimazole [24]. The recommended dose is 500 mg sodium perchlorate twice daily for a restricted period of time (12 weeks). Using this schedule, dreaded side effects of $NaClO_4$ like agranulocytosis have not been encountered.

AIT type 2 should be treated with oral prednisone in a starting dose of 30 mg daily, and tapering when fT_4 and/or TSH have been normalized (which occurs after a median time of 30 and 90 days, respectively) [28]. Time to restore euthyroidism was much longer after iopanoic acid therapy compared to prednisone in an RCT (221 vs. 40 days, respectively) [29]. Time to euthyroidism is little affected if amiodarone is continued [27]. $KClO_4$ inhibits the cytotoxic effect of amiodarone on thyrocytes *in vitro*, but adding the drug to steroids did not improve outcome [15, 27]. It may not always be necessary to treat mild cases of AIT type 2 in view of its self-limiting nature. In this context one should be reminded that slightly increased fT_4 levels up to 25 pmol/L in the presence of a normal TSH are not unusual during amiodarone treatment, caused by a decreased T_4 metabolic clearance rate induced by amiodarone. Smaller thyroid volumes and modest increases of fT_4 are predictors of a fast response to steroids in AIT type 2 [28], and may help in choosing an expectant or active policy.

In mixed/indefinite AIT, one can start with methimazole ± perchlorate, and add glucocorticoids if there is no improvement in 4–6 weeks. Alternatively, one can start immediately with triple therapy. AIT sometimes has a rather severe course, and fatal cases do occur. In very severe cases and in patients resistant to medical therapy, one should not wait too long to perform total thyroidectomy. Despite compromised cardiac function, the surgery has a rather low mortality and morbidity [30–33]. Total thyroidectomy improves cardiac function and mortality, especially in those with ejection fraction <40% preoperatively [32]. ^{131}I therapy may sometimes be feasible despite the iodine excess, by applying high doses [34, 35]. rhTSH prior to ^{131}I therapy is not recommended in AIT type 1 [24].

When euthyroidism has been restored in AIT type 1, definitive thyroid treatment with thyroidectomy or radioiodine is recommended [24, 36]. When AIT type 2 has been cured and amiodarone needs to be restarted, prophylactic thyroid ablation is not recommended. If amiodarone had been continued in AIT type 2, recurrent AIT may occur in 6–18%; recurrences are apparently less severe and more easy to handle [27, 37, 38].

Prognosis. Patients with AIT have more major adverse cardiovascular events than patients who remain euthyroid (32% vs. 11%, P <0.001) [18]. Mortality is also higher in AIT patients with severe left ventricle dysfunction (31% at ejection fraction <50% vs. 14% at ejection fraction >50%) [39]. Permanent hypothyroidism develops in 17% of cured AIT type 2 patients, occurring at 10 months (range 6–24) after reaching euthyroidism [27, 40].

Thyrotoxicosis of Extrathyroidal Origin

Factitious thyrotoxicosis is due to ingestion of excess thyroid hormone [41]. The hormone can be ingested unintentionally in diet pills and in ground beef contaminated with bovine thyroid tissue, or intentionally by people (mostly women) with psychiatric disturbances and by children as an accident [42, 43]. Characteristic features are thyrotoxicosis associated with a low thyroidal radioiodine uptake, normal urinary iodine excretion, no goitre, and no thyroid antibodies. Strong evidence for the existence of factitious thyrotoxicosis is the finding of a low serum thyroglobulin. The disease will resolve spontaneously after the ingestion of excess thyroid hormone is stopped. Thyrotoxicosis due to the ingestion of a well-cooked 227-g hamburger prepared from contaminated ground beef, disappears within 1 month. Symptomatic treatment with propranolol may be necessary. Acute thyroxine intoxication may benefit from gastric lavage; plasmapheresis has been recommended in life-threatening situations. Discrepancy is often noted between modest clinical toxicity and very high thyroid hormone concentrations in serum.

Struma ovarii is an ovarian tumour with thyroid tissue as an important constituent. These tumours are often part of a mature teratoma, and harbour thyroid cancer in under 10% of instances [44]. They are mostly unilateral, occurring in less than 1% of all ovarian tumours. The highest incidence is in the fourth to sixth decade. Thyrotoxicosis develops in 5–15%, especially in tumours bigger than 30 mm in size. Radioiodine uptake is low in the neck and high in the abdomen at the side of the lesion in classic cases, but the presence of a goitre (with some uptake in the neck) is not uncommon. Treatment is by surgical removal of the tumour [45].

Functional metastases of differentiated thyroid cancer are a rare cause of thyrotoxicosis due to a large bulk of tumour. Treatment is primarily by radioiodine [46].

3.4

Hypothyroidism

3.4.1 Clinical Assessment and Systemic Manifestations of Hypothyroidism

Massimo Tonacchera and Luca Chiovato

Introduction

Hypothyroidism may affect people of both sexes and all ages. The clinical expression of thyroid hormone deficiency varies considerably between individuals. It is influenced mainly by the age of the patient and the rate at which hypothyroidism develops although being largely independent of its cause. Most adult patients complain of a slowing of physical and mental activity.

Hypothyroidism is a graded phenomenon, ranging from very mild cases, in which biochemical abnormalities (see Chapter 3.4.4, 'Subclinical Hypothyroidism') are present but the individual hardly notices symptoms and signs of thyroid hormone deficiency, to very severe cases in which the danger exists of sliding down into a life-threatening myxoedema coma.

Organ System Manifestations of Hypothyroidism

Cutaneous Manifestations and Changes in the Connective Tissues

The cutaneous changes observed in hypothyroidism belong to the most classic and frequent findings of the disease (Table 3.4.1.1) [1]. Although other important symptoms and signs of hypothyroidism may be present, changes in the skin may be the most important factor for seeking medical attention [1]. In over 80% of patients with primary hypothyroidism, the epidermis is dry, rough, cool, and covered with fine superficial scales. This is an expression of decreased cutaneous metabolism, reduced secretion of sweat and sebaceous glands, vasoconstriction, thinning of the epidermis, and hyperkeratosis of the stratum corneum. The skin may have a finely wrinkled, parchment-like character. Unusual coldness of the arms and legs is sometimes a subject of complaint. The palms are cool and dry. Subcutaneous fat may be increased, with the formation of definite fat pads, especially above the clavicles, but is conspicuously absent in the more advanced form of the disease (myxoedematous cachexia). The hands and feet have a broad appearance, due to thickening of subcutaneous tissue.

Table 3.4.1.1 Cutaneous signs and symptoms of hypothyroidism

Cutaneous manifestation	Frequency (%)
Cold intolerance	50–95
Nail abnormality	90
Thickening and dryness of hair and skin	80–90
Oedema of hands, face, and eyelids	70–85
Change in shape of face	70
Malar flush	50
Non-pitting oedema	30
Alopecia	30–40
Pallor	25–60
Decreased sweat secretion	10–70

The diffuse pallor and pale waxy surface colour can be attributed to two mechanisms. First vasoconstriction occurs and second the excess fluid and mucopolysaccharides in the dermis may compress small vessels to create blanching as well as interference with the transmission of colour from the deeper vessels. Anaemia may also contribute to pallor. Yellowish discolouration of the skin, most notably of the palms, soles, and nasolabial folds, occurs in patients with long-standing hypothyroidism and is caused by elevation of serum and tissue carotene concentrations. The face is puffy, pale, and expressionless at rest (Figure 3.4.1.1). The skin of the face is also parchment-like. In spite of the swelling, it may be traced with fine wrinkles, particularly in pituitary myxoedema. The swelling sometimes gives it a round or moonlike appearance. The palpebral fissure maybe narrowed because of blepharoptosis, due to diminished tone of the sympathetic nervous fibres to Müller's elevator palpebral

Figure 3.4.1.1 A patient with hypothyroidism.

superior muscle. The modest measurable exophthalmos seen in some patients with myxoedema is presumably related to accumulation of the same mucous oedema in the orbit as is seen elsewhere.

The tongue is usually large, and some patients will complain of this problem. The tongue is smooth if pernicious anaemia coexists. The voice is husky, low-pitched, and coarse due to the enlargement of the tongue and thickening of the pharyngeal and laryngeal mucous membranes. The speech is deliberate and slow, and there may be difficulty in articulation.

There are other, less common, cutaneous findings seen in adult hypothyroid patients. Six patients have been reported in literature of an acquired palmoplantar keratoderma, verrucous in character, and predominantly affecting the plantar surface [2]. An additional reported cutaneous finding specifically linked to atrophic thyroiditis is dermatitis herpetiformis, a gluten-sensitive skin disease characterized by blisters on the elbows, buttock, and knees [3].

Hair Follicles and Nails

The hair is dry, dull, and coarse, growing slowly, becoming sparse, and falling out readily. Loss of scalp, genital, and beard hair may also occur. Hair may be lost from the temporal aspects of the eyebrows (Queen Anne's sign). However, this sign is not uncommon in elderly euthyroid women and occurs in association with several types of cutaneous disease, including atopic dermatitis, seborrhoeic dermatitis, and lupus erythematosus. In men, the beard becomes sparse, and its rate of growth becomes greatly retarded. The scalp is dry and scaly. The nails, through retardation of growth, become thickened and brittle, striated both in transverse and longitudinal grooves, and show frequent deformities.

Dermal Changes

The dermal pathological findings in patients with hypothyroidism are clinically manifested by the non-pitting swelling, most marked around the eyes and hands, that is myxoedema. This is due to an abnormal accumulation of salts, mucopolysaccharides, and protein in the interstitial spaces of the skin [4]. Histopathological examination of the skin reveals that the connective tissue fibres are separated by an increased amount of metachromatically staining, periodic acid-Schiff-positive mucinous material [1]. This material consists of protein complexed with two mucopolysaccharides, hyaluronic acid and chondroitin sulphate B [1]. An increase in the synthesis and accumulation of glycosaminoglycans leads to an excess of these normal intercellular substances.

The glycosaminoglycans are polymers of D-glucuronic acid and *N*-acetyl-D-glucosamine, forming hyaluronic acid, or of L-hyaluronic acid and *N*-acetyl-D-galactosamine sulphate, forming chondroitin sulphate B. They exist free and in ionic or covalent linkage to proteins. These mucoproteins comprise part of the normal non-fibrillar intercellular matrix, the ground substance holding cells together. Due to its strong water binding capacity, accumulated hyaluronic acid may also contribute to the peculiar non-pitting quality of myxoedema. Capillary permeability is augmented in hypothyroidism with increased accumulation of sodium, water, and proteins.

Cardiovascular Changes

Lack of thyroid hormones causes multiple alterations in the cardiovascular system [5]. The most frequent changes in hypothyroid patients are increased systemic vascular resistance, diastolic dysfunction, reduced systolic function, and decreased cardiac preload [5]. Bradycardia, cardiomegaly, and low voltage complexes on the electrocardiogram (ECG) are well-known features (**Box 3.4.1.1**). The decrease in pulse rate approximately parallels the decrease in the body's metabolic rate. Myocardial contractility is reduced. The cardiac output at rest is decreased because of reduction in both stroke volume and heart rate, reflecting loss of the inotropic and chronotropic effects of thyroid hormones [5]. The mechanism responsible for the impaired ventricular performance is multifactorial. The actions of thyroid hormone on the hearth are mediated by genomic and non-genomic mechanisms targeted to membrane proteins, cytoskeletal components, and organelles. The genomic actions are mediated by nuclear receptors alpha and beta [5]. In animal models, low thyroid hormone concentrations alter the expression of myocyte-specific genes and the distribution of the heavy-chain isoforms of sarcomeric myosin and of the calcium-regulating proteins [6]. Alterations in myocyte calcium uptake and release are responsible for the change in the inotropic state [6]. Peripheral vascular resistance at rest is increased, and blood volume is reduced. These haemodynamic alterations cause narrowing of pulse pressure, prolongation of circulation time, and decreased blood flow to the tissues. In most tissues the decrease in blood flow is proportional to the decrease in oxygen consumption, so the arteriovenous oxygen difference remains normal or may be slightly increased. Slow peripheral circulation, and therefore more complete extraction of

Box 3.4.1.1 Cardiovascular signs and symptoms in hypothyroidism

- Symptoms
  - Dyspnoea
  - Decreased exercise tolerance
  - Angina
- Signs
  - Low pulse rate
  - Increased systemic vascular resistance
  - Diastolic hypertension
  - Cardiomegaly
  - Pericardial effusion
  - Peripheral non-pitting oedema
  - Low voltage ECG, non-specific ST-T changes

oxygen, as well as anaemia, may be responsible for the increased arteriovenous oxygen difference. Myocardial oxygen consumption is decreased, usually more than blood supply to the myocardium, so that angina is infrequent [5]. In some patients a reduction in cardiac output greater than the decline in oxygen consumption indicates specific cardiac damage from the myxoedema [5].

The haemodynamic alterations at rest resemble those of congestive heart failure, but cardiac output increases and peripheral vascular resistance decreases normally in response to exercise unless the hypothyroid state is severe [5]. The non-pitting oedema observed in hypothyroid patients is due to an increase in protein distribution in the extravascular extracellular space resulting from increased capillary permeability.

Venous pressure is normal, but peripheral resistance is increased. The mechanism responsible for the increase in systemic vascular resistance is not known. Triiodothyronine (T_3) may act as a vasodilator and in its absence vascular resistance may rise [5, 7]. Arterial blood pressure is often mildly increased. Hypertension is present in 10–20% of patients with hypothyroidism [5, 7]. Diastolic hypertension is usually restored to normal after treatment [7]. Three factors can contribute to systemic hypertension, increased peripheral resistance, increased arterial stiffness, and endothelial dysfunction [7–9].

Few symptoms referable to the cardiovascular system are referred in patients with hypothyroidism. Exertional dyspnoea and exercise intolerance are probably due to skeletal muscle dysfunction. There has been much discussion as to whether the hypercholesterolaemia that accompanies primary hypothyroidism accelerates the development of coronary atherosclerosis. An increased risk for atherosclerosis is supported by autopsy and epidemiological studies in patients with thyroid hormone deficiency and may be, in part, explained by the hypercholesterolaemia and marked increase in low-density lipoprotein (LDL) [8]. Moreover, diastolic hypertension, increased arterial stiffness and endothelial dysfunction, altered coagulability, and increased levels of C-reactive protein may further contribute to the increased cardiovascular risk (8, 9). Most autopsied myxoedematous individuals have severe atherosclerosis, but they are also usually 60 years of age or more. Occasionally angina pectoris is encountered in myxoedema [5]. Sometimes angina or angina-like pain is present before treatment. This generally indicates the presence of significant coronary artery disease since there is inadequate myocardial oxygenation despite reduced cardiac output and oxygen utilization. Angina may also appear for the first time after treatment has been initiated, indicating that coronary flow is inadequate for resumption of normal cardiac function [7]. The presence of a structural lesion must be strongly suspected.

On physical examination certain findings can suggest hypothyroidism. The heart rate is lowered, the pulse pressure is narrowed, and the carotid upstroke and left ventricular apical impulse are diminished [5]. The heart sounds are diminished in intensity; this finding is due largely to effusion into the pericardial sac of fluid rich in protein and glycosaminoglycans.

The combination of a large heart, associated with typical haemodynamic and electrocardiographic alterations, and the serum enzyme changes (creatine kinase, aspartate aminotransferase, and lactate dehydrogenase may be increased) has been termed myxoedema heart. This term was introduced by Zondek in 1918 [10]. It embraced dilatation of the left and right sides of the heart, a slow indolent heart action with normal blood pressure, and lowering of the P and T waves of the electrocardiogram. Zondek found that after treatment with thyroid hormone there was a return of the dilated heart to near normal size, a more rapid pulse without change in blood pressure, and gradual return of the P and T waves to normal. Microscopic examination discloses myxoedematous changes of the myocardial fibres. The myocardium is pale and flabby. Histopathological examination of the myocardium reveals interstitial oedema and swelling of the muscle fibres with loss of striations. The cause of the cardiac enlargement has been disputed. It is not due to hypertrophy alone, since it would not disappear so rapidly with treatment. One factor may be a decrease in contractility of the heart muscle; this would require a lengthening of muscle fibres in order to perform the required work.

In myxoedema, when the heart does not return to a normal size under thyroid hormone administration, hypertrophy due to some other disease is present as a complication. The slow and progressive return to normal size under treatment requires between 3 weeks and 10 months for completion. This decrease in size, like the progressive elevation of the T waves, is of diagnostic value.

Electrocardiographic Changes

Electrocardiographic changes include sinus bradycardia, prolongation of the P–R interval, low amplitude of the P wave and QRS complex, alterations of the ST segment, and flattened or inverted T waves. Although suggestive of myocardial ischaemia, these waveform changes often disappear during thyroxine (T_4) treatment. Pericardial effusion is probably responsible for the low amplitude. Rarely, complete heart block may be present, but this disappears when the hypothyroidism is treated. In hypothyroidism, the atrial pacemaker function is normal and atrial ectopy is rare, but ventricular premature beats and occasionally ventricular tachycardia may occur. The syndrome of *torsades de pointes* with a long Q–T interval and ventricular tachycardia can occur with hypothyroidism, and resolve with T_4 treatment alone.

Systolic Time Intervals and Echographic Findings

Systolic time intervals are altered, the pre-ejection period is prolonged, and the ratio of pre-ejection period to left ventricular ejection time is increased. Some patients have been reported to have asymmetrical hypertrophy of the intraventricular septum by echocardiography that resolves with T_4 treatment [11], but a recent study failed to show septal hypertrophy in any hypothyroid patient studied. Pericardial effusion occurs in one-third to one-half of patients with overt hypothyroidism. The effusion is more common and their volume is greater in patients with long-standing severe disease. Cardiac tamponade is very rare. More sophisticated techniques have been used to assess systolic and diastolic function and myocardial texture, such as cardiac MRI, tissue Doppler imaging [12], and ultrasonic myocardial textural analysis [12]. By using magnetic resonance spectroscopy, an early cardiac bioenergetics impairment was demonstrated in patients with subclinical hypothyroidism which was reversible after L-thyroxine therapy [13].

Laboratory Tests

The serum levels of creatine kinase, aspartate aminotransferase, and lactate dehydrogenase may be increased. Serum creatine kinase activity is high in as many as 30% of patients. Whereas the increase may reflect myocardial necrosis, in most patients the isoenzyme

distribution indicates its origin from the skeletal rather than cardiac muscle. Prolongation of the half-life of creatine kinase in the circulation contributes to the elevated serum concentration.

Respiratory Changes

Respiratory troubles are rarely a serious complaint in hypothyroid patients. However, hypothyroidism may cause respiratory problems through: (1) depression of the respiratory centre in the brain; (2) disturbed neural conduction and/or neuromuscular transmission to the respiratory muscles (due to hypothyroid neuropathy); (3) diseased respiratory muscle function (due to hypothyroid myopathy); and (4) changes in the alveolar-capillary membranes and the surfactant lining the alveoli, leading to impaired gas exchange. Fatigue and dyspnoea on exertion are frequent symptoms. Dyspnoea is a frequent complaint of myxoedematous patients, but is also a common symptom among well people. Congestive heart failure of separate origin, pleural effusion, anaemia, obesity, or pulmonary disease may be responsible.

Some information on pulmonary function in hypothyroidism is available [14]. Wilson and Bedell [14] found a normal vital capacity and arterial PCO_2 and $_pO_2$ in 16 hypothyroid patients. They also found a decreased maximal breathing capacity, decreased diffusion capacity, and decreased ventilatory response to carbon dioxide. Decreased ventilatory drive is present in about one-third of hypothyroid patients, and the response to hypoxia returns rapidly within a week after beginning therapy. Summarizing the few studies, there is little abnormality of resting pulmonary function in most non-obese patients with hypothyroidism [15–16]. Some patients may exhibit a decreased vital capacity, probably due to muscular weakness. Overall oxygen transfer may be slightly decreased, as evidenced by a decreased $_pO_2$, possibly due to a decreased diffusing capacity for carbon monoxide. An increase in ventilation perfusion mismatching or an opening of anatomical shunts may also contribute to these modifications.

The severity of hypothyroidism parallels the incidence of impaired ventilatory drive [17, 18]. Patients with myxoedema may develop carbon dioxide retention, and carbon dioxide narcosis may be a cause of myxoedema coma. Hypothyroidism-induced breathing disorders during sleep, particularly sleep apnoea syndromes *(OSAS)*, have been described [19]. Obstructive sleep apnoea has been documented in hypothyroidism in about 30% of patients and is reversible with treatment [19, 20]. Hypothyroidism may predispose to upper airway obstruction by several mechanisms: increased size of the tongue and other pharyngeal skeletal muscles; a slow and sustained pharyngeal muscle contraction pattern; or diminished neural output of the respiratory centre. After LT4 replacement therapy, apnoea periods, oxygen desaturation events, and snoring usually improve [16]. Myxoedematous patients are more subject to respiratory infections. Pleural effusions usually are evident only on radiological examination.

Gastrointestinal Changes

The gastrointestinal manifestations of hypothyroidism are listed in Box 3.4.1.2. Poor appetite can be a leading symptom in hypothyroid patients. Anorexia can be interpreted as the reflection of a lowered food requirement. Although two-thirds of patients have reported weight gain, it is of modest degree and due largely to retention of fluid by hydrophilic glycoprotein deposits in the tissues.

Box 3.4.1.2 Gastrointestinal manifestations of hypothyroidism

- Symptoms
  - Anorexia
  - Gaseous distension
  - Constipation
  - Prolonged gastric emptying
- Signs
  - Prolonged intestinal transit time
  - Ascites
  - Elevated liver enzymes
  - Gallbladder hypotonia

True obesity is not a feature of hypothyroidism. Younger patients with iatrogenic hypothyroidism secondary to treatment for thyrotoxicosis commonly gain weight because of decreased physical activity coupled with unchanged food intake.

Constipation is commonly present and is the result of a lowered food intake and decreased peristaltic activity. The latter may lead to faecal impaction and may mimic mechanical ileus when accompanied by colicky pains. Spontaneous hypothyroidism most often afflicts older people, who may discount the significance of an insidious decrease of bowel movements [21]. Severe constipation that is unresponsive to treatment may, therefore, be a prominent finding at the time of diagnosis. Gastric emptying and intestinal transit time are prolonged [21, 22]. Gaseous distension may be a troublesome symptom; it responds slowly to thyroid treatment. In most patients, intestinal absorption is normal. Although the rates of absorption for many substances are decreased [21, 22], the total amount absorbed may be normal or even increased because the decreased bowel motility may allow more time for absorption. Occasional malabsorption has been attributed to myxoedema of the intestinal mucosa or altered intestinal motility. Galactose and glucose tolerance curves show a delayed rise to a lower peak than normal and a delayed return to baseline.

Ascites in the absence of another cause is unusual in hypothyroidism, but it can occur in association with pleural and pericardial effusion [22]. Myxoedema ascites consists of a yellow and gelatinous peritoneal exudate. It has been related to congestive heart failure, enhanced capillary permeability, or inappropriate secretion of antidiuretic hormone.

Atrophy of the gastric [23] and intestinal mucosa and myxoedematous infiltration of the bowel wall may be present at histological examination. Immune gastritis is often observed in hypothyroid patients [23] with autoimmune thyroiditis. As many as 50% of patients with autoimmune hypothyroidism have achlorhydria, 25% have circulating antibodies directed against the gastric parietal cells or intrinsic factor, and 10% have pernicious anaemia caused by impaired absorption of vitamin B_{12}.

A history of overt hypothyroidism has been associated with small intestinal bacterial overgrowth (SIBO), which is a clinical condition caused by an increased level of microorganisms exceeding the presence of more than 106 colony-forming units/ml within the small intestine. SIBO is considered a malabsorption syndrome [24].

Symptoms or signs of disturbed liver or exocrine pancreatic function are usually not encountered, but biochemical tests may suggest disease. Non-alcoholic fatty liver disease (NAFLD) is also frequently observed in hypothyroidism [25]. The association of liver disease and hypothyroidism is suggestive of a multisystem autoimmune

disease affecting both the liver (e.g. chronic active hepatitis or primary biliary cirrhosis) and the thyroid. Structural liver damage is unusual in hypothyroidism. Serum glutamic-oxaloacetic transaminase, lactate dehydrogenase, and creatine phosphokinase levels are elevated in patients with hypothyroidism [26]. The enzymes return to normal over 2–4 weeks during treatment. Urinary amylase levels may be increased. Gallbladder motility is decreased, and the gallbladder may appear distended on radiographic examination; hypothyroidism increases the risk of gallstones due to a reduced gallbladder motility and bilirubin excretion and increased serum cholesterol [22].

Cerebral and Neurological Changes

Thyroid hormone is essential for the development of the central nervous system. Deficiency in fetal life or at birth causes hypoplasia of cortical neurons with poor development of cellular processes, retarded myelination, and reduced vascularity. Deficiency of thyroid hormone beginning in adult life causes less severe manifestations that usually respond to treatment with thyroid hormone. Recent studies using ^{32}P nuclear magnetic resonance spectroscopy of the frontal lobe of adult hypothyroid patients report reversible alterations in phosphate metabolism, suggesting impairment of mitochondrial metabolism [27]. Cerebral blood flow is reduced in hypothyroidism, but cerebral oxygen consumption is usually normal [28]. This finding is in accord with the observation that the oxygen consumption of isolated brain tissue *in vitro*, unlike that of most other tissues, is not stimulated by the administration of thyroid hormones. In severe cases, decreased cerebral blood flow may lead to cerebral hypoxia. These and other findings indicate that the adult human brain is a thyroid hormone-responsive organ. Hypothyroidism may induce neurological abnormalities at an early stage of the disease [29]. It has been shown [29] that peripheral and central neuropathy develops in patients of hypothyroidism at an early stage of disease and the electrophysiological investigations of such patients can help in timely detection and treatment of neurological disorders that occur due to thyroid hormone deficiency.

Box 3.4.1.3 lists the numerous symptoms suggesting either neurological or psychiatric disorders in patients with moderate to severe hypothyroidism. In adult and elderly patients, mental changes may go unrecognized because of their slow development and because they may mimic cerebral atherosclerosis. However, an unusual complacency, fatigue, and pronounced somnolence or even lethargy together with a prolonged reaction time should suggest the possibility of hypothyroidism. Special attention is required for patients who need an increasing amount of sleep (over 12–14 h/day). They may lapse into stupor or even coma, and develop convulsions. This may be the beginning of myxoedema coma, a rare but very serious condition, the extreme expression of severe hypothyroidism. All intellectual functions, including speech, are slowed. There is loss of initiative, and slow wittedness and memory defects are common; in a study [30] working memory was impaired in hypothyroidism. Dementia in elderly patients may be mistaken for senile dementia. Memory is undoubtedly impaired, and attention and the desire to think are reduced. The emotional level seems definitely low, and irritability is decreased. Except in the terminal stage, reasoning power is preserved. Cognitive tests of patients with moderate to severe hypothyroidism indicate difficulties in performing calculations, recent memory loss, reduced attention span, and slow reaction time [31, 32]. In a metanalysis the association between subclinical hypothyroidism (sHT) and cognitive impairment has been shown only in individuals younger than 75 years of age and those with higher thyroid-stimulating hormone (TSH) concentrations [33].

Headaches are frequent.

In a minority of patients, nervousness and apprehension are present. Psychiatric disorders are common and are usually of the paranoid or depressive type and may induce agitation (myxoedema madness). Depression is so often associated with hypothyroidism [31] that thyroid function tests should be performed in the evaluation of any patient presenting with this symptom [33]. Central 5-hydroxytryptamine activity is reduced in hypothyroid patients, and T_3 supplementation might increase the efficacy of antidepressant drugs. At times, this manifestation of hypothyroidism is more severe than are many of the other clinical manifestations of the disease. Because hypothyroidism is so readily treated, it is an especially important cause to eliminate.

In rare cases of long-standing hypothyroidism cerebellar ataxia with or without intention tremor has been found. Jellinek and Kelly [34] described a series of myxoedematous patients with ataxia, intention tremor, nystagmus, and dysdiadochokinesia. Ataxia has been noted in 8% of a large series of hypothyroid patients [35]. Patients may have intention tremor, nystagmus, and an inability to make rapid alternating movements. The cause of this syndrome is not apparent, but myxoedematous infiltrates of glycogen and mucinous material have been found in the cerebellum. There may be foci of degeneration and an increase in glial tissue. These symptoms show a prompt and definite decrease after replacement therapy with thyroid hormone.

Sensory phenomena are common. Numbness and tingling of the extremities are frequent. Mononeuropathies occur in hypothyroidism, as attested to by the high incidence of carpal tunnel syndrome (compression of the median nerve at the wrist) [36]. Nocturnal paraesthesia and pain in the median nerve distribution in one or both hands is a common manifestation of this condition. Paraesthesia or lancing pain in the legs are manifestations of lower extremity peripheral neuropathy. A study of 39 patients with primary hypothyroidism found complaints of polyneuropathy in 64%, findings of polyneuropathy in 33%, and a definite diagnosis by electrophysiological criteria in 72% [36]. A metachromatic infiltrate has

Box 3.4.1.3 Neurologic and psychiatric manifestations in hypothyroidism

- Neurologic symptoms or signs
  - Somnolence, lethargy
  - Slow speech
  - Impaired cognitive functions
  - Headache
  - Paraesthesias
  - Cerebellar ataxia
  - Deafness
  - Vertigo
  - Delayed relaxation of deep tendon reflexes
- Psychiatric syndromes
  - Depression
  - Bipolar disorders
  - Affective psychosis

been found in the lateral femoral cutaneous nerve and sural nerve, together with axon cylinder degeneration.

The tendon reflexes are slow, especially during the relaxation phase, producing the characteristic 'hung-up' reflexes: this phenomenon is due to a decrease in the rate of muscle contraction and relaxation, rather than a delay in nerve conduction. The presence of extensor plantar responses or diminished vibration sense should alert the physician to the possibility of coexisting pernicious anaemia with combined system disease.

Electroencephalographic changes include slow α-wave activity and general loss of amplitude. The concentration of protein in the cerebrospinal fluid is often increased, but cerebrospinal pressure is normal.

Deafness is a very characteristic and troublesome symptom of hypothyroidism. It may be due to both conduction or nerve impairment and usually responds very well to treatment. Vestibular abnormalities have also been demonstrated. Serous otitis media is not uncommon. Two-thirds of patients complain of dizziness, vertigo, or occasionally tinnitus: these problems suggest damage to the eighth nerve or labyrinth, or possibly to the cerebellum. Whatever type of deafness is present, there is marked improvement after thyroid treatment. Acquired hearing loss in association with adult-onset hypothyroidism should be distinguished from the sensorineural deafness of Pendred's syndrome. In the latter, treatment of hypothyroidism does not correct the hearing defect.

Night blindness is not uncommon. It is caused by a deficiency in the pigment retinene, which is required for the adaptation to dark.

Musculoskeletal Changes

Muscles

In patients with hypothyroidism, disordered muscle function often is the predominating feature of the clinical syndrome. Generalized muscular hypertrophy, accompanied by easy fatigue and slowness of movements, occurs in some myxoedematous children or adults. It has been referred to as the Kocher–Debré–Sémélaigne syndrome in children [37] and as Hoffmann's syndrome in adults. These patients do not have the classic electromyography findings of myotonia. The myopathy of hypothyroidism in some patients is associated with weakness even though the muscles are hypertrophied. The typical patient presents with firm large well-developed muscles, like those of an athlete. The entire musculature is affected to some extent, but the most obvious enlargement is in the arms and legs.

Muscle symptoms such as myalgia, muscle weakness, stiffness, cramps, and easy fatigability are very prevalent in hypothyroid patients [38, 39]. The symptoms are aggravated by exposure to cold. They are also prominent during the rapid onset of hypothyroidism after surgery or ^{131}I treatment. Impairment of mitochondrial oxidative metabolism provides a biochemical substrate for these complaints.

Reflex contraction and relaxation time is prolonged, mainly because of the intrinsic alterations in muscle contractility. Nerve conduction time may also be prolonged. Delayed reflex relaxation is characteristic and has been developed into a diagnostic test of thyroid function. The rate-limiting step in muscle relaxation is the reuptake of calcium by the sarcoplasmic reticulum. In skeletal muscle, this process is dependent on the content of Ca^{2+}-ATPase. Recent studies have indicated that Ca^{2+}-ATPase activity of the fast twitch variety (SERCA1) is markedly reduced in hypothyroidism [40] with impairment of calcium reuptake as a consequence. This occurs at a transcriptional level, since thyroid hormone response elements have been identified in the 5′ flanking region of the SERCA1 Ca^{2+}-ATPase gene. The reduction in Ca^{2+}-ATPase would explain the delayed relaxation of the deep tendon reflexes. On histopathological examination the muscles appear pale and swollen. The muscle fibres may show swelling, loss of normal striation, and mucinous deposits.

Skeletal System: Calcium and Phosphorus Metabolism

In the adult skeleton, thyroid hormone deficiency decreases recruitment, maturation, and activity of bone cells, leading to decreased remodelling, which is especially reflected in the impaired function of the osteoclasts [41]. Bone mass may be normal or slightly increased; however hypothyroid patients show a two-to threefold increased risk fracture [42]. In some patients, fracture may occur before bone mass reaches levels compatible with osteoporosis, reflecting an impairment of bone quality [41]. Recent data suggest that high TSH levels may be linked to the risk of osteoporotic fractures only in young and middle-aged men, while in postmenopausal women, the long term risk of hip and other osteoporotic fractures is strongly related to the cumulative duration of LT4 overtreatment [43].

Urinary excretion of calcium is decreased as is the glomerular filtration rate, whereas faecal excretion of calcium and both urinary and faecal excretion of phosphorus are variable. The concentrations of calcium and phosphorus in serum are usually normal, but calcium may be slightly elevated. Serum alkaline phosphatase levels are often decreased, as are serum osteocalcin levels. Because the levels of parathyroid hormone are often slightly increased, some degree of resistance to its action may be present. Serum concentrations of 1,25-dihydroxycholecalciferol are also increased.

Joints

At the clinical level, patients with hypothyroidism often complain of articular and muscular pain and stiffness of the extremities. These symptoms may suggest rheumatoid arthritis or also polymyalgia rheumatica or primary myositis. Patients may exhibit joint effusions involving the knees and small joints of the hands and feet. In 5–10% of patients with carpal tunnel syndrome, primary hypothyroidism may be the cause due to the accumulation of the hygroscopic glycosaminoglycan in the interstitial space with compression of the median nerve.

Changes in Kidney Function

Clinically significant disturbances of kidney function, and hence of water and electrolyte metabolism, are uncommon in hypothyroidism. Renal blood flow and glomerular filtration rate can be reduced [44]. Because of the moderate extent of these reductions and the hypothyroidism-induced decreased metabolism, renal failure does not usually occur. Factors contributing to the decrease in renal blood flow are a decrease in cardiac output, a decrease in plasma volume, and a narrowing of renal blood vessels through enlargement of endothelial and mesangial cells and thickening of the glomerular basement membrane.

Laboratory examinations may reveal a slight increase of serum creatinine and uric acid [44]. Urine flow is reduced, and delay in the excretion of a water load may result in reversal of the normal diurnal pattern of urine excretion. The delay in water excretion appears to be due to decreased volume delivery to the distal diluting

segment of the nephron resulting from diminished renal perfusion and inappropriate secretion of vasopressin [44]. Since urinary hydroxycorticoid excretion is decreased, the adrenals might be responsible for delayed water excretion. Other evidence suggests that the tissue supply of adrenal cortical hormones is usually normal in myxoedema. The ability to concentrate urine may be slightly impaired. Occasionally, minimal proteinuria is seen. This condition could be due to congestive heart failure or to the increased capillary transudation of protein typical of hypothyroidism.

The total body sodium content is increased [45]. The excessive sodium is presumably bound to extracellular mucopolysaccharides. In spite of reduced renal blood flow and blood volume, the sodium retention is probably not a reflection of altered renal function. In fact, salt loads are usually excreted readily and serum sodium concentrations tend to be low [45], in contrast to other clinical situations associated with sodium retention, such as congestive heart failure. No consistent changes in plasma potassium levels have been reported. Total magnesium levels may be elevated and the bound fraction and urinary excretion are reduced. Plasma homocysteine concentrations are increased in hypothyroidism, related to lower folate levels and a lower creatinine clearance in thyroid hormone deficiency [46].

Haematological Changes

Erythrocytes

Anaemia is present in up to two-thirds of hypothyroid children and adolescents, and in about one-third of adults with hypothyroidism [47]. Anaemia is usually mild. Anaemia in hypothyroidism may be a normochromic and normocytic anaemia due to the diminished oxygen requirements and decreased production of erythropoietin [47] or may result from a specific depression of marrow that lacks thyroid hormone [47]. The bone marrow generally shows mild hypoplasia with an increase in fatty marrow. The anaemia may be macrocytic, sometimes from deficiency of vitamin B_{12}. Folate deficiency from malabsorption or dietary inadequacy may also cause macrocytic anaemia. The frequent menorrhagia and the defective absorption of iron resulting from achlorhydria may contribute to a microcytic hypochromic anaemia [47].

Leucocytes and Thrombocytes

Granulocyte, lymphocyte, and platelet counts are usually normal in hypothyroidism. Leucopenia might indicate associated vitamin B_{12} or folic acid deficiency. Mean platelet volume can be decreased. The erythrocyte sedimentation rate (ESR) may be elevated in uncomplicated hypothyroidism.

Haemostasis

Hypothyroid patients may have bleeding symptoms such as easy bruising, menorrhagia, or prolonged bleeding after tooth extraction. The most frequent defects in haemostasis are prolonged bleeding time, decreased platelet adhesiveness, and low plasma concentrations of factor VIII and von Willebrand's factor (acquired von Willebrand syndrome type 1) [48]. This coagulopathy should be taken into account when planning invasive procedures in hypothyroid patients. The mild or moderate acquired von Willebrand syndrome is reversible after restoration of euthyroidism. There are also data suggesting existence of a hypercoagulation and hypofibrinolytic state, particularly in subclinical hypothyroidism [48].

Changes in the Reproductive Tract

In both sexes thyroid hormone influences sexual development and reproductive function. Infantile hypothyroidism leads to sexual immaturity and juvenile hypothyroidism causes a delay in the onset of puberty followed by anovulatory cycles. Paradoxically, primary hypothyroidism may also cause precocious sexual development and galactorrhoea [49].

In adult men, hypothyroidism may lead to impotence, lack of libido, and, rarely, to testicular tubular involution. The testicles are histologically immature if hypothyroidism preceded puberty and show tubular involution if its onset was after puberty [50]. In adult hypothyroid men, semen analysis is usually normal. Delayed ejaculation, hypoactive sexual desire, and erectile dysfunction have been described [51]. In adult women, severe hypothyroidism may be associated with diminished libido and failure of ovulation [52, 53]. In general, hypothyroid women complain of menorrhagia and, occasionally, oligo- and amenorrhoea. Plasma gonadotropins are usually in the normal range in primary hypothyroidism and the pulsatile gonadotropin release in the follicular phase is normal [52], but the ovulatory surge may not happen. Secretion of progesterone is inadequate, and endometrial proliferation persists, resulting in excessive and irregular breakthrough menstrual bleeding. The anovulation is reflected in the frequent finding of a proliferative endometrium. These changes may be due to a deficient secretion of luteinizing hormone. Mild to moderate hyperprolactinaemia is a frequent finding in hypothyroid women, with or without galactorrhoea. It is attributed to the stimulatory effect of increased thyrotropin-releasing hormone on prolactin secretion. Fertility is reduced, and spontaneous abortion may result, although many pregnancies are successful.

The total concentrations of both testosterone and oestradiol in serum are decreased, predominantly due to a diminution in the concentration of the carrier sex hormone-binding globulin. Because of the concomitant increase in the unbound fraction of sex steroids, their absolute free concentration remains normal. The metabolism of testosterone is shifted towards aetiocholanolone rather than androsterone. With respect to oestradiol and oestrone, hypothyroidism favours metabolism of these steroids via 16α-hydroxylation with the result that formation of oestriol is increased.

The literature contains many reports of pregnancy in untreated hypothyroid women [53, 54]. Euthyroid neonates born to hypothyroid mothers during pregnancy have been reported to achieve a lower IQ later in life [55]. When treatment has been started during pregnancy, generally a normal child is produced [53], but abortion is frequent in women with myxoedema. Pregnancy-induced hypertension is 2–3 times more common in hypothyroid women. Low birthweight is secondary to premature delivery for gestational hypertension. The incidence of various congenital abnormalities may be increased, but recent studies do not report an increased risk of fetal death or congenital anomalies with proper treatment [53, 56].

Other Endocrine Glands

Pituitary Function

Hypothyroidism can affect the secretion of all pituitary hormones. The effect of hypothyroidism on the secretion of vasopressin, follicle-stimulating hormone, and luteinizing hormone are discussed

in other sections. Hypothyroidism decreases growth hormone secretion and hypothyroid children have a dramatic retardation of growth [57]. Retarded growth caused by hypothyroidism appears to result from deficient secretion of growth hormone as well as from impaired action of growth hormone. Many hypothyroid children have subnormal serum growth hormone response to insulin-induced hypoglycaemia. Growth hormone secretion is decreased in hypothyroidism related to an increase in hypothalamic somatostatinergic tone [57], and results in low serum insulin-like growth factor (IGF)-1 concentrations [57]. Serum IGF-2, IGFBP1, and IGFBP3 also fall, whereas IGFBP2 rises; these changes are reversible upon treatment [57].

Thyrotropic hyperplasia caused by primary hypothyroidism may result in sellar enlargement, particularly when the condition has remained untreated for a long time [58]. Rarely, such hyperplasia may give rise to a pituitary macroadenoma that shrinks after thyroxine replacement [59]. Patients with severe hypothyroidism may have an increase in serum prolactin level that correlates with the level of serum TSH, and some patients develop galactorrhoea. Since thyroid hormone decreases the mRNA for preprothyrotropin-releasing hormone in the paraventricular nuclei, hypothyroidism may lead to increased thyrotropin-releasing hormone secretion, unopposed by thyroid hormones, with consequent hyperprolactinaemia.

Adrenal Cortex

Patients with primary hypothyroidism have subtle abnormalities of pituitary–adrenal function that may be correlated with the severity and duration of hypothyroidism [60]. Cortisol secretion and the rate of turnover are decreased in patients with hypothyroidism. The net result is that serum cortisol concentrations and urinary cortisol excretion are normal. Hepatic clearance of cortisol and adrenal androgens 17-hydroxycorticosteroids and 17-ketosteroids are decreased. This slowing is principally due to a decrease in the rate of cortisol oxidation as a result of reduced 11-hydroxysteroid dehydrogenase activity [60]. Conjugation with glucuronic acid in the liver is normal. The turnover rate of aldosterone is also decreased in hypothyroidism [61]. The decrease in hepatic clearance causes an increase in its plasma half-life. The reduced rate of clearance of aldosterone is balanced by a lower secretion rate. The serum concentration of aldosterone is normal and there is no clinical evidence of hyperaldosteronism. Angiotensinogen production in the liver is reduced, as is plasma renin activity. These subtle modifications are not responsible for alterations in sodium and potassium homeostasis.

The adrenal response to adrenocorticotropic hormone (ACTH) is normal or reduced. In long-standing hypothyroidism, a significant reduction in cortisol secretion after ACTH has been documented in primary adrenal cell culture and it was recently confirmed also in humans [62]. Pituitary–adrenal responses to the metyrapone test have been variable. Normal but delayed peak response, impaired response, or even lack of response has been reported. Grossly impaired responses to the stimulation with lysine-8-vasopressin and a delayed increase in serum cortisol levels after insulin-induced hypoglycaemia have also been observed. Whether steroid production can be augmented sufficiently in times of stress is not clear, but the provocative test results suggest that these patients usually have a mildly impaired hypothalamic–pituitary–adrenal axis.

Metabolic Changes

Energy Metabolism

The decrease in energy metabolism and heat production is reflected in the low basal metabolic rate, decreased appetite, cold intolerance, and slightly low basal body temperature. Measurement of the resting energy expenditure is rarely performed nowadays. In patients with complete athyreosis it falls to between 35% and 45% below normal. In Addison's disease, the basal metabolic rate may fall to 25% or 30% below normal, and in hypopituitarism to 50% below normal.

Thyroid hormones are involved in the regulation of energy balance in mammals, acting not only in the periphery but also in brain areas involved in the regulation of food intake and energy expenditure [63].

The effect of hypothyroidism on appetite and energy intake is not precisely known, but energy expenditure decreases leading to a slight net gain in energy stores. An increase in adipose tissue mass results in an increase of serum leptin, which mediates a decrease in energy intake while energy disposal increases, eventually leading to a reduction in adipose tissue mass. In adult rats methimazole induced hypothyroidism impairs hypothalamic leptin signalling and the anorectic response to the peripheral administration of leptin. These findings suggest that thyroid hormones are essential for the effect of leptin on food intake. A large number of studies have investigated the relationship between thyroid dysfunction and circulating levels of leptin, but results have been conflicting [64].

Protein Metabolism

Both the synthesis and the degradation of proteins are decreased, the latter especially so, with the result that nitrogen balance is usually slightly positive. Despite both a decrease in the rate of albumin synthesis and degradation, the total exchangeable albumin pool increases in myxoedema [65]. The albumin is distributed in a much larger volume, suggesting enhanced permeability of capillary walls. The synthesis of thyroid hormone-responsive proteins is clearly reduced in the hypothyroid state, whereas that of proteins such as TSH or glycosaminoglycans may be increased under the same circumstances.

Comparative studies of protein translation by hepatic ribosomes from T_3-treated hypothyroid rats show that the mRNAs from some proteins are increased and others are decreased. Most of these proteins have not been identified. Treatment of myxoedema is accompanied by a marked but temporary negative nitrogen balance, reflecting the mobilization of extracellular protein [65]. In a later phase there is an increase in urinary potassium and phosphorus together with nitrogen in amounts suggesting that cellular protein is also being metabolized.

Carbohydrate Metabolism

In hypothyroidism, absorption of glucose from the gastrointestinal tract is slowed and peripheral glucose assimilation is retarded for impairment of insulin-mediated translocation of glucose transporter 4. At the same time, glycerol release from adipose tissue is slowed, and the availability of amino acids and glycerol for gluconeogenesis is decreased. The oral glucose tolerance curve is characteristically flat, and the insulin response to glucose is delayed. Degradation of insulin is slow, so the sensitivity to exogenous insulin may be increased. Despite the easily demonstrable abnormalities

Box 3.4.1.4 Changes in serum lipids in hypothyroidism

- Total cholesterol—increase
- LDL cholesterol—increase
- HDL2 cholesterol—modest increase
- HDL3 cholesterol—no change
- Triglycerides—no change or modest increase

in carbohydrate metabolism in hypothyroidism, clinical manifestations of these abnormalities are seldom conspicuous. Although hypoglycaemia is sometimes listed as a manifestation of hypothyroidism, it is rarely a sign of isolated hormone deficiency, and the presence of hypoglycaemia in a patient with hypothyroidism should suggest the presence of hypopituitarism. The occurrence of hypothyroidism in a patient with insulin-dependent diabetes mellitus may result in a diminution in exogenous insulin requirement and a greater risk of developing hypoglycaemia.

Lipid Metabolism

Thyroid hormones have multiple effects on the regulation of lipid synthesis, absorption, and metabolism. Therefore, overt and subclinical hypothyroidism significantly affects the lipids profile and promotes cardiovascular disease [25].

A variety of abnormalities in plasma lipid concentrations occur in hypothyroidism (Box 3.4.1.4). Plasma free fatty acid concentrations are normal, plasma concentrations of triglycerides, phospholipids, and LDL cholesterol are well elevated [25, 66]. Biosynthesis of fatty acids and lipolysis are reduced. The changes bear, in general, a reciprocal relationship to the level of thyroid activity.

The increased serum cholesterol may represent an alteration in the substrate steady-state level caused by a transient proportionally greater retardation in degradation than in synthesis [25, 66]. The increase of serum cholesterol is largely accounted for by an increase of LDL cholesterol, which is cleared less efficiently from the circulation due to a decreased T_3-dependent gene expressing the hepatic LDL receptor [25, 66]. Interestingly, the LDL particles of hypothyroid patients are also susceptible to increased oxidizability [25, 66]. The increase of high-density lipoprotein (HDL) 2 but not of HDL3 cholesterol is due to a diminished activity of cholesterol ester transfer protein [66] and hepatic lipase (which is involved in the conversion of HDL2 to HDL3). The modest increase of serum triglycerides seen in certain cases has been related to a decreased lipoprotein lipase activity in post-heparin plasma. Lipoprotein(a) is increased in hypothyroidism in some but not all studies. A recent study evaluating lipid profile and TSH levels in a large Spanish population including euthyroid and hypothyroid individuals identified a serum TSH cut-off of 2.57 mU/L for detecting significant differences in circulating lipid levels [67].

Clinical Aspects of Hypothyroidism at Different Ages

Infantile and Juvenile Hypothyroidism

Hypothyroidism in newborn infants results in mental and physical impairment unless treatment is initiated within weeks after birth. Hypothyroidism in children is mainly characterized by retarded growth and impaired mental performances. Infantile hypothyroidism leads to sexual immaturity; juvenile hypothyroidism causes a delay in the onset of puberty followed by anovulatory cycles in girls. Rarely precocious puberty may occur [49].

Thyroid hormone is essential for normal growth and maturation of the skeleton [41]. Deficient thyroid hormone production *in utero* and in the neonate retards growth and delays skeletal maturation. Deficiency in early life leads both to a delay in the development of and an abnormal stippled appearance of the epiphyseal centres of ossification (epiphyseal dysgenesis). Before puberty, thyroid hormones also play an important role in the maturation of bone. Impairment of linear growth leads to dwarfism in which the limbs are disproportionately short in relation to the trunk [41]. Bone age is retarded in hypothyroid children [41].

Hypothyroidism in Adults

In adults, the clinical manifestations of hypothyroidism, though they may be profound, are reversible [68]. The development of spontaneous hypothyroidism is usually slow and many patients seek medical attention for variable and non-specific symptoms [68]. In contrast, patients who develop hypothyroidism rapidly (when replacement therapy is discontinued in a patient with primary hypothyroidism, or after surgical removal of the gland) have more symptoms. In such patients, manifestations of overt hypothyroidism are present by 6 weeks. Older patients tend to have fewer symptoms and signs of hypothyroidism than do young adults.

In adults, common features of hypothyroidism include easy fatigability, tiredness, coldness, weight gain, constipation, menstrual irregularities, and muscle cramps. Drowsiness and slowing of intellectual and motor activity is often referred. Sensitivity to cold is suggested by the use of more blankets on the bed. Women frequently complain of hair loss, brittle nails, and dry skin. Periorbital puffiness may be present. Stiffness and aching of muscles may be attributed to rheumatism. Constipation may occur. Numbness and tingling of the extremities are frequent. Physical findings include a cool, dry skin, puffy face and hands, hoarse husky voice, and slow reflexes.

In a recent study [68] in overt autoimmune hypothyroidism, 94% of women and 91% of men reported at least one of the hypothyroidism-associated symptoms, with tiredness as the most common symptom followed by dry skin and shortness of breath. In contrast, women free of thyroid disease self-reported at least one hypothyroidism-associated symptom considerably more often than men [68].

Hypothyroidism in Older People

Hypothyroidism in older people is often atypical and elusive and lacks the classic clinical features present in younger patients [69]. This is due to a combination of factors including the insidious onset, the ambiguity of several signs and symptoms (fatigue, weakness, cold intolerance, dry skin, hair loss, constipation, poor appetite, depression and/or mental deterioration, hearing loss, cardiomegaly, congestive heart failure) which may be attributed to normal ageing, and to the frequent coexistence of several age-associated diseases.

The most relevant clinical findings that lead one to suspect hypothyroidism in older people are an unexplained increase in serum cholesterol, constipation, congestive heart failure (particularly when it presents as restrictive cardiomyopathy), and macrocytic anaemia (as a consequence of folate deficiency or coexistent autoimmune

gastritis and pernicious anaemia). Other common clinical features encountered in elderly hypothyroid patients include neurological signs (syncope, seizures, impaired cerebellar function, carpal tunnel syndrome) and vague arthritic complaints. Due to the frequent involvement of the cardiovascular system, the presenting symptoms of hypothyroidism in elderly patients include dyspnoea in more than 50% and chest pain in up to one-quarter. A significant minority of elderly hypothyroid patients may paradoxically lose weight as a consequence of reduced appetite. Neuropsychiatric symptoms are often prominent and depression occurs in up to 60% of patients; psychoses are rare. Dementia may be found in elderly hypothyroid patients but it is rarely the direct consequence of thyroid failure, although a few patients show marked improvement of intellectual function after correction of hypothyroidism. In a recent population-based study of hypothyroidism, the power of symptom presence in predicting overt hypothyroidism in both young and older subjects was investigated [69]. Hypothyroid symptom score is a good discriminating tool to identify hypothyroidism in young patients but fails to identify hypothyroidism in older people [69].

In a multicentre, double-blind, randomized, placebo-controlled, parallel-group trial involving old hypothyroid patients with persisting subclinical hypothyroidism [70], treatment with L-thyroxine had no consistent beneficial effect on thyroid related symptoms. Besides L-thyroxine treatment yielded no significant beneficial effects on a range of secondary outcome measures [70].

Elderly patients are more susceptible to myxoedema coma, a rare but serious complication of hypothyroidism. It generally occurs in the winter months, in hospitalized patients, and can be precipitated by intercurrent non-thyroidal illness, use of drugs, exposure to cold, and stress. Progressive deterioration of mental status to stupor and coma, localized neurological signs, marked hypothermia (which may not be present in patients with systemic infections), hyponatraemia, and hypoglycaemia are the hallmarks of myxoedema coma. The mortality of clearly hypothermic myxoedema coma is very high (over 80%), unless vigorous supportive therapy and thyroid hormone replacement are given immediately.

Clinical Aspects of Hypothyroidism due to Different Aetiologies

Primary Hypothyroidism

Primary hypothyroidism in adults results mainly from autoimmune thyroiditis, it is more common in women than in men, and occurs between the ages of 40 and 60 years [71]. In these patients, clinical features of hypothyroidism may be accompanied by the typical goitre of Hashimoto's thyroiditis. When present, the goitre is usually firm in consistency, generally moderate in size, and often lobulated; well-defined nodules are unusual. Both lobes are enlarged, but the gland may be asymmetrical. Adjacent structures, such as the trachea, oesophagus, and recurrent laryngeal nerves may be compressed but this is a rare occurrence. Goitre develops gradually over many years. Rarely, the thyroid enlarges rapidly and may be accompanied by pain and tenderness. In other cases of hypothyroidism due to autoimmune thyroiditis the gland is atrophied. Infiltrative ophthalmopathy similar to that of Graves' disease occurs in a small proportion of patients.

Other organ-specific autoimmune diseases such as insulin-dependent diabetes mellitus, Addison's disease, premature ovarian failure, hypoparathyroidism, myasthenia gravis, and coeliac disease may coexist [72]. Patients with primary hypothyroidism may also complain of vitiligo and alopecia. Primary autoimmune hypothyroidism may be present as a component of either the type I or type II polyglandular autoimmune syndrome. The specific association of primary hypothyroidism and primary adrenal cortical insufficiency is known as Schmidt's syndrome [72]. The type I syndrome consists of at least two of the triad of Addison's disease, hypoparathyroidism, and chronic mucocutaneous candidiasis; other autoimmune disorders, such as alopecia, chronic autoimmune thyroiditis, and malabsorption syndrome, may also be present. Autoimmune thyroid disease is reported in 10–12% of these patients. Type I polyglandular autoimmune syndrome generally presents in childhood, whereas the type II syndrome is more common and usually presents in adult life. Addison's disease, Hashimoto's thyroiditis, and type 1 diabetes are the most common endocrine deficiencies found in these patients, although gonadal failure, pernicious anaemia, and vitiligo are observed in a significant percentage.

Rarely a combination of primary and pituitary hypothyroidism with or without ACTH deficiency occurs, presumably also on an autoimmune basis. Thus, other glands may be affected with increased frequency in patients with autoimmune hypothyroidism.

Postablative Hypothyroidism

A common cause of hypothyroidism in adults is the type following total thyroidectomy for thyroid carcinoma or near-total thyroidectomy for euthyroid or toxic multinodular goitre or Graves' disease. Hypothyroidism following radioiodine treatment for Graves' hyperthyroidism is also frequent, and is currently regarded as a common outcome of ^{131} I treatment rather than a complication [73].

Overt hypothyroidism in patients who have received ^{131} I is often preceded by subclinical hypothyroidism, which may become apparent within 2–4 months after ^{131} I therapy. The early onset of hypothyroidism may cause distinct symptoms in the previously thyrotoxic patient who received ^{131} I or surgery. These patients may develop muscle cramps, often in large muscle groups (trapezius, latissimus dorsi, or the proximal muscles of the extremities).

Central Hypothyroidism

The clinical picture of central hypothyroidism varies depending on the severity of thyroid failure, the extent of the associated hormone deficiencies, the age of the patients, and the nature of the underlying lesion. Central hypothyroidism is due to TSH deficiency caused by either hypothalamic or pituitary disease [74]. The differentiation of secondary from primary hypothyroidism is important for the institution of the proper therapy. The clinical features of central hypothyroidism are similar to those of primary hypothyroidism, although generally less pronounced. The skin is pale and cool, but not as coarse and dry as in primary hypothyroidism. Periorbital and peripheral oedema are uncommon in patients with central hypothyroidism. Loss of axillary, pubic, and facial hair and thinning of the lateral eyebrows are more pronounced. The tongue is not enlarged, and hoarseness of the voice is not prominent as in primary hypothyroidism. The heart tends to be small, and blood pressure is low. Atrophic breasts and amenorrhoea are found in women.

Table 3.4.1.2 Sensitivity and specificity of the 14 symptoms and signs of hypothyroidism and analysis of their positive and negative predictive values

Symptoms and signs	Sensitivity (%)	Specificity (%)	Positive predictive value (%)	Negative predictive value (%)
Ankle reflex	77	93	92	80
Dry skin	76	64	68	73
Cold intolerance	64	65	65	64
Coarse skin	60	81	76	67
Puffiness	60	96	94	71
Pulse rate	58	42	50	50
Sweating	54	86	79	65
Weight increase	54	77	70	63
Paraesthesia	52	82	75	63
Cold skin	50	80	71	61
Constipation	48	85	76	62
Slow movements	36	99	96	61
Hoarseness	34	87	73	57
Hearing	22	97	90	53

Body weight is more likely to be reduced than increased. Defects in growth hormone and gonadotropin secretion usually precede TSH insufficiency, and in most cases ACTH secretion is the last to be affected. Growth failure with delayed skeletal maturation results from growth hormone deficiency in children. Hypoglycaemia may occur. Gonadotropin insufficiency results in impotence, loss of libido, diminished beard growth, amenorrhoea, infertility, and atrophy of the breasts in women. ACTH deficiency leads to weakness, postural hypotension, and depigmentation of the areole and of other normally pigmented areas of the skin. Symptoms and signs that arise directly from the hypothalamic or pituitary lesion may precede, accompany, and even obscure manifestations of pituitary failure. The manifestations of a sellar mass include headache and symptoms secondary to compression of adjacent structures with visual field disturbances and ophthalmoplegia.

Diagnostic Accuracy

Several attempts have been made to develop a clinical score system, based on the most frequent symptoms and signs of hypothyroidism, that could accurately predict the diagnosis of thyroid

Table 3.4.1.3 Scoring of symptoms and signs of hypothyroidism

	On the basis of	Score	
		Present	Absent
Symptoms			
Diminished sweating	Sweating in a warm room or on a hot summer day	1	0
Hoarseness	Speaking voice, singing voice	1	0
Paraesthesia	Subjective sensation	1	0
Dry skin	Dryness of skin, noticed spontaneously, requiring treatment	1	0
Constipation	Bowel habit, use of laxative	1	
Impairment of hearing	Progressive impairment of hearing	1	0
Weight increase	Recorded weight increase, tightness of clothes	1	0
Physical signs			
Slow movements	Observe patient removing his/her clothes	1	0
Delayed ankle reflex	Observe the relaxation of the reflex	1	0
Coarse skin	Examine hands, forearms, elbows for roughness and thickening of skin	1	0
Periorbital puffiness	This should obscure the curve of the malar bone	1	0
Cold skin	Compare temperature of patient's hands with examiner's	1	0

For clinical judgement, add 1 point to the sum of symptoms and signs present in women younger than 55 years. Hypothyroid, more than 5 points; euthyroid, less than 3 points; intermediate, 3–5 points.

failure in individual patients. In the 1960s, Billewicz *et al.* [75] described a diagnostic index that scored the presence or absence of various signs and symptoms of hypothyroidism. However, at that time, modern laboratory thyroid function tests were not available to validate the diagnostic accuracy of such a score [65]. Recently a convenient clinical score has been proposed by Zulewski *et al.* [76] that is both easy to perform and sensitive for individual assessment of the severity of thyroid failure. The frequencies of the 14 more common symptoms and signs of overt hypothyroidism are shown in Table 3.4.1.2. The most common features in hypothyroid patients were prolonged ankle reflex (77%) and complaints about dry skin (76%). A reduced pulse rate and cold intolerance were recorded with a high frequency in euthyroid controls and were, therefore, excluded from this score. The sensitivity and specificity of each symptom and sign of hypothyroidism and the analysis of their positive and negative predictive values are shown in Table 3.4.1.2. Table 3.4.1.3 shows the scoring system of symptoms and signs of hypothyroidism. Because a correlation analysis revealed a significant correlation of these scores with age, a simple age correcting factor was defined by adding 1 point to the sum of symptoms and signs in women younger than 55 years. According to this analysis, the following diagnostic ranges for the clinical judgement with the age-corrected score were defined: hypothyroid, more than 5 points; euthyroid, 0–2; intermediate, 3–5 points [76].

3.4.2 Causes and Laboratory Investigation of Hypothyroidism

Ferruccio Santini

Introduction

Hypothyroidism is the clinical state that develops as a result of the lack of action of thyroid hormones on target tissues [1]. Hypothyroidism is usually due to impaired hormone secretion by the thyroid, resulting in reduced concentrations of serum thyroxine (T_4) and triiodothyronine (T_3). The term primary hypothyroidism is applied to define the thyroid failure deriving from inherited or acquired causes that act directly on the thyroid gland by reducing the amount of functioning thyroid tissue or by inhibiting thyroid hormone production. The term central hypothyroidism is used when pituitary or hypothalamic abnormalities result in an insufficient stimulation of an otherwise normal thyroid gland. Both primary and central hypothyroidism may be transient, depending on the nature and the extent of the causal agent. Hypothyroidism following a minor loss of thyroid tissue can be recovered by compensatory hyperplasia of the residual gland. Similarly, hypothyroidism subsides when an exogenous inhibitor of thyroid function is removed.

Peripheral hypothyroidism may arise as a result of excessive thyroid hormone degradation due to anomalous overexpression of type 3 iodothyronine deiodinase in some neoplastic tissues, while loss of protein-bound thyroid hormones in patients with nephrotic syndrome may unravel or deteriorate a pre-existing thyroid dysfunction. Peripheral hypothyroidism may also occur as a consequence of tissue resistance to thyroid hormones due to a mutation in the thyroid hormone receptor or in the molecules involved in membrane transport and intracellular metabolism of thyroid hormones. Reduced sensitivity to thyroid hormones is a heterogeneous clinical entity with most patients appearing to be clinically euthyroid while some of them have symptoms of thyrotoxicosis and others display selected signs of hypothyroidism or neurodevelopment abnormalities, depending on the specific gene responsible for the disease. The variability in clinical manifestations depends on the severity of the hormonal resistance, the relative degree of hyposensitivity to thyroid hormone in different tissues, and the coexistence of associated genetic defects (see Chapter 3.4.8).

Primary Hypothyroidism

A list of the causes of primary hypothyroidism is given in Box 3.4.2.1. Autoimmune thyroiditis is the most common cause of spontaneous hypothyroidism in areas with adequate iodine intake. Iatrogenic hypothyroidism is responsible for many hypothyroid patients in these regions and inborn errors of thyroid hormone synthesis, goitrogens, and other destructive processes of the thyroid gland account for a few cases. Iodine deficiency is crucial in the pathogenesis of endemic cretinism and of adult hypothyroidism in areas in which an efficient iodine prophylaxis has not been undertaken.

Autoimmune Thyroiditis

Autoimmune thyroiditis includes a spectrum of diseases that are distinguished for their clinical course, the degree of thyroid dysfunction, and the changes of thyroid size. All these variants recognize an immune-mediated pathogenesis and usually present with high titres of circulating antithyroid antibodies. As in most organ-specific autoimmune reactions, the aetiology of autoimmune thyroiditis is still unknown but is somehow linked to genetic and environmental factors, and is influenced by the gender and the age (see Chapter 3.2.6).

Chronic Thyroiditis

Chronic thyroiditis is the most common among the autoimmune thyroiditis. Historically, two clinical variants of the disease are described. A goitrous variant (Hashimoto's thyroiditis), characterized by heavy lymphocytic infiltration and thyroid enlargement, and an atrophic variant (primary myxoedema) with progressive fibrosis and reduction of thyroid size. In clinical practice, a clear distinction between the two forms is not always possible. In the initial stage of the disease the two variants commonly do not present distinctive features. Moreover, atrophy may be a destructive end result of goitrous thyroiditis with the thyroid gland showing near complete replacement with fibrosis. When overt hypothyroidism has occurred, thyroid volume shows a unimodal distribution, with thyroid atrophy and goitre being extremes within the distribution

Box 3.4.2.1 Causes of primary hypothyroidism

- Autoimmune thyroiditis
  - Chronic thyroiditis
    - Hashimoto's thyroiditis
    - Atrophic thyroiditis
  - Postpartum thyroiditis
  - Graves' disease (spontaneous late evolution)
- Subacute thyroiditis
- Riedel's thyroiditis
- Iatrogenic
  - Thyroidectomy
  - ^{131}I therapy for hyperthyroidism
  - External radiotherapy
  - Excessive iodine
  - Drugs
    - Thionamides
    - Amiodarone
    - Lithium
    - Tyrosine kinase inhibitors
    - Immune checkpoint inhibitors
    - Others
- Severe iodine deficiency
- Natural goitrogens
- Thalassaemia major
- Congenital abnormalities
  - Thyroid dysgenesis
    - Agenesis
    - Ectopic gland
    - Hypoplasia
- Inherited defects in thyroid hormone biosynthesis
  - Iodide transport defect
  - Organification defect
  - Pendred's syndrome
  - Iodotyrosine deiodinase defect
  - Thyroglobulin defect
  - TSH-receptor defect
  - Gs-protein defects
- Transient neonatal hypothyroidism
  - Iodine deficiency or excess
  - Administration of antithyroid agents to the mother
  - Maternal TSH-blocking antibody.

[2]. Overall, these observations suggest that the two variants do not represent separate disorders.

Thyroid failure usually develops very slowly and, as thyroid function fades, the resulting increase in serum thyroid-stimulating hormone (TSH) limits the decline in thyroid secretion. Thus overt hypothyroidism is commonly preceded by a variable period of time in which elevated TSH is the only hormonal abnormality (subclinical hypothyroidism) [3, 4]. The transition from euthyroidism to hypothyroidism may pass unrecognized and initial symptoms may be attributed to ageing, menopause, or other chronic concomitant diseases [5]. Thus, it is not uncommon that chronic thyroiditis is diagnosed when clinical manifestations of thyroid failure become severe or complications of hypothyroidism have occurred. The circumstances leading to early diagnosis of the disease include family history for autoimmune thyroid diseases, appearance of goitre, blood testing for screening of autoimmune diseases in patients with polyglandular autoimmunity, routine diagnostic protocols for patients with menstrual dysfunction, or hyperlipidaemia.

Occasionally hypothyroidism may be due to TSH-receptor blocking antibodies preventing thyroid cell stimulation by TSH. TSH-receptor blocking antibodies are more frequent in atrophic thyroiditis than in goitrous thyroiditis [6]. Hypothyroidism may be reversible if the TSH-receptor blocking antibody titre declines and enough thyroid tissue remains for thyroid hormone synthesis. Graves' hyperthyroidism may develop in hypothyroid patients with chronic thyroiditis because of a change in the nature of TSH-receptor antibodies from blocking to stimulating [7].

In some instances, the disease may be preceded by a transient phase of thyrotoxicosis (hashitoxicosis) due to the discharge of preformed thyroid hormones, as a result of an unusually intense inflammatory process. The gland is tender and sometimes painful, resembling subacute thyroiditis. Hypothyroidism usually develops in a short time and may be permanent, especially in patients with elevated thyroid peroxidase antibody.

Features of thyroid-associated ophthalmopathy may occur in patients with chronic thyroiditis and hypothyroidism. This condition is termed 'hypothyroid Graves' disease' and may be the endstage of Graves' disease after spontaneous remission of hyperthyroidism or may represent a distinct entity with pathogenetic mechanisms common to Graves' disease, involving thyroid-stimulating antibody [8].

Focal thyroiditis is characterized by spotty collections of mononuclear cells within thyroid tissue, and minimal changes in follicular epithelium or stromal fibrosis. Most patients with focal thyroiditis are euthyroid and only 10–20% have subclinical hypothyroidism [9]. The disease may be suspected at ultrasound examination in patients with circulating thyroid autoantibodies, or may be a histological occurrence in surgical or autopsy specimens. In the presence of circulating thyroid autoantibodies, focal thyroiditis may represent the earliest stage of chronic autoimmune thyroiditis, whereas the clinical significance of non-specific isolated lymphocytic infiltration in patients without circulating autoantibodies has still to be clarified.

Juvenile thyroiditis (autoimmune thyroiditis in childhood and adolescence) is described as a separate entity because follicular oxyphilia is usually mild or absent, goitre is soft, and thyroid antibody titres are not as high as in adults. Fine-needle aspiration biopsy is sometimes required to establish the diagnosis. Spontaneous resolution is relatively common, but hypothyroidism may develop during the course of the disease [10].

Postpartum Thyroiditis

Pregnancy is known to influence the clinical course of various autoimmune disorders, including autoimmune thyroid disease. Typically, amelioration during pregnancy is followed by aggravation after delivery. This phenomenon is thought to depend on the physiological need of inhibiting maternal immune reactions that might cause rejection of the fetus. Thus, thyroid peroxidase antibodies, thyroglobulin antibodies, and TSH-receptor antibody titres decrease or may even disappear during pregnancy. Following delivery, a rebound of autoimmune processes occurs and may result in destructive thyroiditis with release of preformed thyroid hormones and transient thyrotoxicosis, followed by a transient hypothyroid phase. Persistent hypothyroidism may develop in a minority of women. This clinical entity is named postpartum thyroiditis and occurs in 5–9% of unselected postpartum women [11] (see Chapter 3.4.6).

Graves' Disease

Spontaneous hypothyroidism may develop during the course of Graves' disease whenever destructive processes of thyroiditis predominate over thyroid-stimulating events (burnt out Graves' disease). This may occur after long-term remission of hyperthyroidism associated with disappearance of TSH-receptor stimulating antibodies, or following prolonged therapy with antithyroid drugs [12]. TSH-receptor blocking antibodies may also appear and neutralize TSH-receptor stimulating antibodies, leading to hypothyroidism.

Subacute Thyroiditis

Subacute thyroiditis is an inflammatory disease of viral origin [13]. Although the disease is relatively uncommon it must be suspected any time a patient presents with anterior neck pain. Recovery is complete in most patients but in rare cases (1–5%) epithelial loss is severe, resulting in permanent hypothyroidism (see Chapter 3.2.7).

Riedel's Thyroiditis

Riedel's thyroiditis is an extremely rare chronic disease of unknown aetiology, characterized by progressive fibrosis of the thyroid and surrounding tissues [14]. Hypothyroidism develops when fibrosclerosis has involved most of the gland (see Chapter 3.2.7).

Iatrogenic Hypothyroidism

Thyroid ablation for therapeutic purposes is a common cause of primary hypothyroidism in the adult. Thyroid failure is an obvious consequence of total or subtotal thyroidectomy for thyroid cancer, goitre, or Graves' disease, but clinical hypothyroidism does not develop as long as substitutive therapy is started shortly after surgery. Similarly, ^{131}I therapy for Graves' disease is directed to destroy thyroid tissue. However, the success rate of radioiodine therapy and the time of onset of hypothyroidism are not fully predictable; they depend on several factors including the dose of radiation delivered, the size of the goitre, and the underlying autoimmune phenomena [15]. Drug-induced hypothyroidism is also common. Excessive inhibition of thyroid hormone synthesis commonly occurs during therapy for hyperthyroidism with antithyroid agents. Furthermore, primary hypothyroidism may develop as a side effect of several drugs administered for different purposes.

Postoperative Hypothyroidism

Total thyroidectomy is performed for thyroid cancer, Graves' disease, and large diffuse or multinodular goitres, occasionally also harbouring Hashimoto's thyroiditis. However, hypothyroidism does not develop as long as L-thyroxine replacement therapy is started soon after thyroidectomy. In the past, patients with thyroid cancer had to discontinue thyroid hormone therapy before ^{131}I scanning and therapy. The availability of recombinant human TSH has greatly reduced the need for thyroid hormone withdrawal before radioiodine administration (see Chapter 3.5.6).

The frequency of hypothyroidism after subtotal thyroidectomy varies depending on the mass of remaining tissue and the degree of its autonomous function. A small thyroid residue may be sufficient for maintenance of the euthyroid state in Graves' disease. On the other hand, a large residue of a multinodular or Hashimoto's goitre may not be enough for adequate thyroid hormone secretion. Partial thyroidectomy or lobectomy for multinodular goitres or solitary nodules are usually not associated with permanent hypothyroidism, although L-thyroxine is usually administered to prevent relapse of the goitre.

Post-Irradiation Hypothyroidism

Among different radioactive isotopes of iodine, ^{131}I is the agent of choice in the treatment of thyroid hyperfunction. After oral administration, radioiodine is completely absorbed, rapidly concentrated, oxidized, and organified by thyroid follicular cells. The biological effects of radioiodine include necrosis of follicular cells, shorter survival and impaired replication of undestroyed cells, and vascular occlusion, leading to atrophy and fibrosis of thyroidal tissue.

The goal of radioiodine therapy for hyperthyroidism is to destroy sufficient thyroid tissue to cure the hyperthyroidism with one dose of ^{131}I. This dose is calculated on the basis of thyroid size and uptake of ^{131}I. Because of radiation safety restrictions, in some centres small repeated doses of radioiodine are administered. In other centres standard fixed doses are given. Small glands are destroyed more readily by radioiodine than larger ones, and toxic adenoma or toxic multinodular goitre are usually more radioresistant than Graves' glands. Radioiodine has a delayed effect and several months may be required for the complete control of hyperthyroidism.

In the case of Graves' disease, the goal of radioiodine should be to destroy as much thyroid tissue as possible [16]. This strategy has been adopted because residual tissue, necessary to ensure euthyroidism, is responsible for the relapse of hyperthyroidism in a large proportion of patients. A strict control of thyroid function is required during the first 6–12 months following ^{131}I therapy for Graves' disease to avoid the appearance of symptoms of hypothyroidism, which may be rapidly progressive and severe. Early post-radioiodine hypothyroidism may be transient, and hyperthyroidism may relapse during L-thyroxine replacement therapy.

Radioiodine-induced hypothyroidism is less frequent after treatment for toxic adenoma or multinodular goitre because non-functioning thyroid tissue should not receive the radioisotope. Yet, hypothyroidism may develop whenever TSH is not completely suppressed at the time ^{131}I is administered. Furthermore, a small degree of iodine uptake is maintained in normal thyroid cells even in the absence of TSH stimulation, and this may be the cause of hypothyroidism many years after radioiodine administration.

External irradiation to the neck for non-thyroidal neoplasias (lymphomas, tumours of the head and neck, spinal tumours, or metastases) may produce hypothyroidism in up to 50% of patients [17]. Thyroid failure may develop after a variable interval, depending on the dose of radiation that has been administered. Hypothyroidism after total body irradiation for acute leukaemia or aplastic anaemia has also been reported [18]. An increased risk of hypothyroidism has been found in breast cancer patients treated with radiation, since a portion of the thyroid gland may be included in the treatment fields [19].

Drug-Induced Hypothyroidism

Transient hypothyroidism is common in the course of medical treatment for hyperthyroidism with thionamides, and quickly subsides with adjustment of the dose. Excess iodide, such as in disinfectants, radiographic contrast agents, and seaweed-containing preparations, may precipitate hypothyroidism in autoimmune chronic thyroiditis, due to failure of the thyroid to escape from the

Wolff–Chaikoff effect. Animal studies suggest that excessive iodide increases the incidence of thyroid autoimmunity but evidence in humans is controversial. Amiodarone is an antiarrhythmic agent containing about 37 mg iodine per 100 mg drug. Amiodarone may produce hypothyroidism by the excess iodine released with metabolism of the drug. As in other cases of excess iodine administration, an underlying autoimmune thyroid disease is a prerequisite. Amiodarone may also induce destructive thyroiditis in an otherwise normal thyroid gland. The prevalence of overt hypothyroidism may be as high as 5% of amiodarone-treated patients, with no clear association between the occurrence of hypothyroidism and the dose of the drug. Substitutive L-T_4 can be administered with no need to discontinue amiodarone, if the antiarrhythmic drug is essential for the underlying cardiac disease. Mild (subclinical) hypothyroidism is more common and does not necessarily progress to overt hypothyroidism. Treatment of mild hypothyroidism may be avoided in patients at high risk of cardiovascular events [20].

Lithium inhibits thyroid hormone synthesis and secretion, and lithium therapy for psychiatric disorders is associated with an increased risk of hypothyroidism, with a hazard ratio of 2.31 [21]. The risk is increased in patients with positive antithyroid antibodies or with minor thyroid abnormalities, which reduce the ability of the thyroid gland to override the inhibitory effects of lithium. Goitre is also common in lithium-treated patients, even when serum thyroid hormones and TSH are within normal limits. If hypothyroidism appears, LT4 therapy should be initiated and lithium therapy may be continued.

Tyrosine kinase inhibitors are newly developed drugs approved for the treatment of several tumours. The first observation of hypothyroidism after sunitinib treatment has been reported in 2006 [22]. Since then several studies have been published and have confirmed that various tyrosine kinase inhibitors can affect thyroid function tests through different physiopathological mechanisms impairing thyroid function or thyroid hormone metabolism [23].

Targeted manipulation of immune checkpoints by monoclonal antibodies against molecules that are critical for immune regulation, has been recently introduced as an effective anticancer therapy for its ability to enhance the immune responses against malignant cells. Triggering of autoimmunity due to disruption of immunological tolerance to self-antigens may induce immune-related adverse events, with primary hypothyroidism scoring among the most frequent, usually associated with appearance of thyroid autoantibodies [24].

Several other drugs have been reported to be capable of inducing primary hypothyroidism [25]. Treatment with interferon-α or interleukin-2 may produce hypothyroidism, thyrotoxicosis, or the biphasic pattern of silent thyroiditis. Pre-existent thyroid autoimmunity increases the risk of thyroid dysfunction during treatment with these agents. Other medications occasionally reported to induce hypothyroidism include tricyclic antidepressants, selective serotonin reuptake inhibitors, rifampin, sulphonamides, sulphonylureas, ethionamide, *p*-aminosalicylic acid, phenylbutazone, and nicardipine, but the antithyroid potential of these drugs is weak and an underlying thyroid abnormality or concurrent iodine deficiency are usually associated.

Severe Iodine Deficiency and Natural Goitrogens

Environmental iodine deficiency is common in many areas throughout the world, particularly in inland mountainous areas. Goitre is the most common disorder due to iodine deficiency and its prevalence is inversely related to the median iodine intake of the population. Endemic goitre is usually not associated with hypothyroidism. However, the pattern of circulating thyroid hormones in the population from areas of severe iodine deficiency differs from that found in iodine-sufficient areas [26]. The mean serum T_4 is reduced while serum T_3 is unchanged or increased and an inverse correlation between serum TSH and T_4 is found. The low iodine content within the thyroid gland and the increased TSH stimulation lead to preferential secretion of T_3, which is far more potent than T_4 in terms of metabolic responses. Thus, the relative increase in T_3 secretion enables a patient to maintain the euthyroid status in spite of reduced availability of iodide.

Cretinism is the result of an insufficient supply of thyroid hormones to fetal tissues and is due to severe iodine deficiency in both the mother and the fetus during early stages of gestation [27]. Fetal hypothyroidism is not compensated by transplacental passage of maternal T_4 and is responsible for severe physical and neurological damage.

Adult hypothyroidism may occur in rural populations living in areas of severe iodine deficiency where isolation prevents access to iodine-rich foodstuff. In this case, hypothyroidism is rapidly reversed by iodine supplementation. Consumption of food containing antithyroid agents, such as thiocyanate in cassava meal and flavonoids in a variety of plants, may aggravate the effects of dietary iodine deficiency and add to the development of goitre and hypothyroidism. Phloroglucinol, a potent antithyroid compound contained in some species of seaweeds, may play an additional role to that of iodine excess in the development of iodine-induced hypothyroidism.

Acquired hypothyroidism has been described in children on chronic parenteral nutrition as a consequence of the lack of iodine in delivered nutrients [28]. More recently, attention has been focused on environmental endocrine disrupters (pesticides and industrial pollutants) as a possible cause of thyroid imbalance, but their effects on human thyroid function have not been fully elucidated (see also Chapter 3.2.2) [29].

Thalassaemia Major

A high prevalence of primary hypothyroidism has been described in patients with thalassaemia major. The incidence and severity of thyroidal dysfunction appears related to the degree of iron overload. Hypothyroidism may be reversible if intensive chelation therapy is timely started [30].

Congenital Abnormalities

Congenital hypothyroidism is detected in about 1/2000 neonates, its prevalence being increased over the years mainly due to lowering of TSH cut-offs for primary screening of the disease [31]. Primary congenital hypothyroidism accounts for most affected children, whereas central congenital hypothyroidism is rare. In a small proportion of detected cases a transient dysfunction occurs, which recover in the following months. Screening programmes for early detection of congenital hypothyroidism are active in developed countries, but many affected newborns worldwide remain unrecognized and the burden of the disease is still a relevant public health challenge [32] (see Chapter 3.4.7).

Both the fetus and the neonate are particularly sensitive to the block of thyroid function induced by excess iodide since the immature gland is not able to escape from the Wolff–Chaikoff effect [33]. Iodide-induced transient hypothyroidism is most common in

premature infants and in low-birthweight babies, and has occurred more in relatively iodine-deficient areas of Europe [34], than in iodine-sufficient North America.

Transient fetal–neonatal hypothyroidism and goitre may develop in babies born to hyperthyroid mothers with Graves' disease treated with excessive doses of propylthiouracil or methimazole. Both hypothyroidism and goitre resolve spontaneously with the clearance of the drug from the circulation of the neonate. TSH-receptor blocking antibodies may be present in patients with autoimmune hypothyroidism; the antibodies compete with TSH and inhibit the biological effects of TSH on thyroid cell function and growth [6]. These antibodies have been found mainly in patients with autoimmune atrophic thyroiditis, and contribute to the development of thyroid failure and atrophy. The maternal TSH-receptor antibody responsible for thyroid failure in the neonate inhibits TSH binding to its receptor and therefore blocks the effect of TSH on adenylate cyclase stimulation, iodine uptake, and thyroid cell growth [35]. Delayed thyroid development due to the transplacental transfer of potent TSH-receptor blocking antibodies has been described [36]. TSH-receptor blocking antibody may also occur in women with Graves' disease and be transmitted to the fetus. Although thyroid-stimulating antibodies usually predominate in these patients, transient hypothyroidism is possible in the offspring of women with Graves' disease due to very high TSH-blocking antibody titres and relatively low concentrations of thyroid-stimulating antibody. Because TSH-induced growth is blocked, these infants do not have a goitre.

Central Hypothyroidism

Central hypothyroidism is the consequence of anatomical or functional disorders of the pituitary or the hypothalamus [37]. Several of the causes reported in **Box 3.4.2.2** may affect both the pituitary and the hypothalamus, and in many instances the main anatomical site of the dysfunction cannot be identified. Thus, the former terms of secondary hypothyroidism (of pituitary origin) and tertiary hypothyroidism (of hypothalamic origin) are no longer recommended. Central hypothyroidism is rarely isolated, being part of a generalized disorder involving the secretion of other pituitary hormones. Permanent central hypothyroidism is rare, its prevalence ranging from 1:20 000 to 1:80 000 in the general population. However, transient functional abnormalities of TSH secretion are relatively common, and often pass unrecognized due to rapid recovery of the normal thyroid hormone balance.

Pituitary adenomas represent the most common cause of central hypothyroidism. Reduced secretion of TSH is usually a consequence of mechanical compression of non-tumorous cells and of adenohypophyseal blood vessels by the adenoma. The pituitary stalk and the hypothalamus may also be involved by suprasellar extension of the tumour. The tumour may be non-functioning or secrete other hormones. Thus, the resulting syndrome will depend on the extent of hypopituitarism and on the particular hormone secreted by the adenoma. A sudden enlargement of pituitary adenomas may occur as a result of haemorrhage within the tumour, leading to pituitary apoplexy.

Several other causes may produce central hypothyroidism, by acting at the hypothalamic or pituitary level. Primary extrasellar brain tumours or metastatic tumours originating from other sites may produce a variable degree of hypopituitarism, depending on the location and the extension of their mass. Among brain tumours, craniopharyngiomas should be suspected when central hypothyroidism is diagnosed in young people. Craniopharyngiomas are usually extrasellar but they may extend inferiorly causing destruction of the bony margins of the sella. Pituitary infarction may develop postpartum following excessive blood loss during delivery (Sheehan's syndrome), or in patients with severe shock or during systemic anticoagulation therapy. Various degrees of pituitary insufficiency may be observed in these cases. Traumatic head injuries can lead to central hypothyroidism because of hypothalamic or pituitary infarction or haemorrhage. Iatrogenic causes of central hypothyroidism include external radiation and surgery for pituitary or brain tumours. The empty sella syndrome is caused by a defect of the sellar diaphragm leading to cisternal herniation within the pituitary fossa and flattening of the pituitary. Hypopituitarism develops

Box 3.4.2.2 Causes of central hypothyroidism

- Pituitary dysplasia
- Congenital malformations of the hypothalamus
- Inherited diseases
  - Combined pituitary hormone abnormalities: pituitary transcription factor defects; immunoglobulin superfamily gene 1 mutations
  - Isolated CH: TSHβ-subunit; thyrotropin-releasing hormone receptor (TRHR) mutations
- Transient central hypothyroidism
  - Recovery from prolonged thyrotoxicosis
  - Severe non-thyroidal illnesses
  - Drugs
    - Somatostatin analogues
    - Glucocorticoids
    - Dopamine
    - Bexarotene

slowly along with expansion of the cisternal herniation caused by transmission of cerebrospinal fluid pressure. Hypothalamic or pituitary lesions may derive from any of the infectious or granulomatous diseases listed in Box 3.4.2.2.

Autoimmune (primary) hypophysitis is an increasingly recognized disease that can cause central hypothyroidism, isolated or associated with other tropin defects, in up to 45% of the cases. However, when an appropriate treatment with immunosuppressive drugs is started, TSH deficiency can considerably improve with no need of hormone replacement therapy with L-thyroxine in the long term [38]. Another emerging disorder, first described in 2003, is hypophysitis secondary to checkpoint inhibitors immunotherapy [39]. In this condition, observed in approximately 10% of cancer patients treated, various degrees of hypopituitarism, including isolated central hypothyroidism, have been described.

A high prevalence of hypothyroidism following traumatic brain injury or subarachnoid haemorrhage has been demonstrated, although TSH deficiency is less common than growth hormone, luteinizing hormone/follicle-stimulating hormone, and adrenocorticotropic hormone deficiencies [40]. Pituitary aplasia or hypoplasia is a rare congenital defect, usually associated with other severe malformations. In most instances these patients die shortly after birth.

Genetic abnormalities in TSH synthesis may cause central hypothyroidism characterized by inherited isolated TSH deficiency. A number of mutations in genes involved in pituitary function have been described, leading to isolated central hypothyroidism or combined pituitary hormone defects, with variable clinical phenotypes and degrees of severity [41]. In some patients no demonstrable pathology can be found to explain TSH deficiency, and the term idiopathic central hypothyroidism is still applied.

Transient impairment of TSH secretion is commonly observed and may depend on a variety of causes, including the use of several drugs (see Box 3.4.2.2). The recognition of these conditions is essential to avoid unnecessary and expensive diagnostic procedures. In most instances, replacement therapy is not necessary or is contraindicated.

Laboratory Investigation of Hypothyroidism

The diagnosis of hypothyroidism and of its cause requires the evaluation of several clinical, laboratory, and instrumental parameters to manage the patient properly (Table 3.4.2.1).

Hormonal Evaluation

A small decrease in thyroid secretion may produce only minor changes in serum concentrations of thyroid hormones that remain within the normal range. The most sensitive index of a reduction in serum thyroid hormone concentration is serum TSH because of a decrease in feedback inhibition of pituitary TSH secretion. Thus, elevated serum TSH is the earliest laboratory abnormality in patients with primary hypothyroidism.

The combination of normal thyroid hormones and elevated TSH has been long defined as subclinical hypothyroidism. However, this term may be misleading because it suggests the absence of symptoms and signs of hypothyroidism, whereas they may be present if thyroid hormone deficiency does actually exist [42]. Indeed, an isolated increase in serum TSH may arise as a consequence of mild thyroid failure due to a recognized pathogenic event in an otherwise normal thyroid gland (most commonly autoimmune thyroiditis), and in this case grading of hypothyroidism based on biochemical criteria should be preferred. Differently, a slight TSH elevation may depend on inherited defects that produce a minor impairment of TSH action on thyroid cells, leading to isolated hyperthyrotropinaemia and an apparent euthyroid state [43]. A mild increase in serum TSH can also be observed in obese subjects, which is secondary to the obesity state and is reversible after weight loss [44]. Distinction among these conditions is important to decide on the opportunity of starting the replacement therapy.

With the progression of thyroid dysfunction, serum levels of T_4 fall below the normal limit while serum T_3 may still be normal. This is because high TSH levels induce preferential secretion of T_3 by residual thyroid tissue.

The lack of TSH response to reduced thyroid hormone levels complicates the diagnosis of central hypothyroidism, and the finding of low serum T_4 is a prerequisite for the diagnosis of this condition. Usually in central hypothyroidism, basal serum TSH concentrations are inappropriately low with respect to reduced serum thyroid hormones. Yet, in some instances serum TSH may be slightly elevated due to secretion of immunoreactive but biologically inactive TSH [45].

Assays for measurement of total thyroid hormones in serum are gradually being replaced by methods that determine the free (unbound) fraction of T_4 and T_3 [46]. Although measurement of free T_4 and free T_3 concentrations is more cumbersome as compared to that for total T_4 and T_3, free T_4 and free T_3 determinations are preferred because free thyroid hormones are those capable of entering

Table 3.4.2.1 Differential diagnosis of hypothyroidism

	Primary	Central	Resistance to thyroid hormone	Non-thyroidal illness
Symptoms of hypothyroidism	Present	Present	Occasionally present	Absent
Thyroid volume	↑, N,↓	N,↓	↑	N
TSH	↑	N, ↓, (↑)	N, ↑	N, ↓, (↑)

the cell and therefore represent the biologically active hormone. Indeed, the concentrations of total thyroid hormones may be elevated or reduced in spite of normal free fractions, due to changes in the concentrations of serum transport protein (see Chapter 3.1.2). Current free thyroid hormone immunoassays are valuable in most clinical instances but more accurate methodologies may be required in selected cases [47].

The initial assessment of thyroid function may be accomplished by testing of TSH first, followed by reflex testing for free T_4 if TSH is outside the reference range. The implementation of appropriate TSH reference ranges is essential to achieve optimal effects on case detection [48]. However, it must be emphasized that TSH alone is not reliable for the detection of central hypothyroidism and may be misleading in other clinical settings, including treated hyperthyroidism and hypothyroidism before stabilization of the hormonal equilibrium, combined therapy with T_4 and T_3, and non-thyroidal illness.

Measurement of the serum TSH response to thyrotropin-releasing hormone (TRH) (200–500 μg intravenously) may be useful in selected patients with a borderline to low value of T_4 and borderline to high or borderline to low values of basal TSH, to identify subclinical primary or central hypothyroidism, respectively [49]. An exaggerated response will be observed in primary hypothyroidism whereas in central hypothyroidism the serum response of TSH may be reduced or abnormally prolonged. The TRH test may be useful also to measure the increase in serum T_3 levels following the rise in serum TSH. In people with normal thyroid function, serum T_3 increases 30–100% above the baseline value 120–180 min after the injection of 200 μg TRH. In central hypothyroidism, the T_3 response may be impaired or absent in spite of a normal peak of TSH, indicating secretion of biologically inactive TSH. Evaluation of the nocturnal surge of TSH in samples taken every 30 min from 11.00 p.m. to 2.00 a.m. may be useful to confirm the diagnosis of central hypothyroidism. At variance with people with normal thyroid function, the TSH surge is blunted or absent in central hypothyroid patients [50].

A transient phase of central hypothyroidism may occur in patients with non-thyroidal illness, particularly hospitalized patients with medical or psychiatric illnesses. In these cases, repeated hormonal measurements are useful since values usually become normal as patients recover from that illness.

Other *In Vitro* Tests

Antithyroglobulin and antithyroperoxidase antibodies are sensitive markers of thyroid autoimmunity [51]. Thus, if present, they may contribute to the diagnosis of autoimmune thyroiditis, often preceding the appearance of thyroid dysfunction, represent a prognostic index for the development of postpartum thyroiditis, and help to predict the outcome of iodine- or drug-induced hypothyroidism. Antithyroperoxidase antibodies and, less frequently, antithyroglobulin antibodies are observed in most patients with chronic autoimmune thyroiditis but hypothyroid patients with serum negative Hashimoto's disease have also been reported, who display a milder clinical picture compared with classic Hashimoto's thyroiditis [52]. Screening for antithyroperoxidase and antithyroglobulin antibodies in patients with non-thyroidal autoimmune diseases may be helpful for early recognition of concurrent autoimmune thyroid diseases, in the context of polyglandular autoimmune syndromes [53].

TSH-receptor antibodies can either have stimulating activity (thyroid-stimulating antibody), as in Graves' disease, or block the receptor (TSH-receptor blocking antibody) preventing TSH stimulation of the follicular cell. TSH-receptor blocking antibodies are highly specific for autoimmune thyroiditis. They are found in up to 30% of patients with chronic autoimmune thyroiditis and can produce or add to the development of hypothyroidism by blocking the thyroid response to TSH [6]. Hypothyroidism produced by TSH-receptor blocking antibodies can spontaneously remit following disappearance of antibody from serum. Assays for TSH-receptor antibodies measure the ability of a patient's IgG to inhibit the binding of ^{125}I-TSH to its receptor in thyroid membrane preparations. Radioreceptor assays are now easy to perform, inexpensive, and provide reliable results but do not distinguish thyroid-stimulating antibodies from TSH-receptor blocking antibodies. For this purpose, methods that assess the capacity of IgG to stimulate or to prevent TSH-induced cAMP production in thyroid preparations are necessary.

Endogenous antibodies against thyroid hormones may develop in patients with autoimmune thyroiditis [54]. These antibodies usually have no clinical relevance, but may interfere on assays for serum total and free T_4 and T_3, producing artefactual results depending on the technique used to measure the hormones. The presence of T_4 or T_3 antibodies should always be suspected in autoimmune patients with unexpected results of thyroid hormone assays. These antibodies can be detected easily by immunoprecipitation of radiolabelled T_4 or T_3 with the patient's serum.

Thyroglobulin is present at low concentrations in serum of people with normal thyroid function, and is elevated in all states associated with enlargement, hyperfunction, or injury of the thyroid gland. Measurement of serum thyroglobulin has no meaning for the diagnosis or the management of hypothyroidism, but may be useful to estimate the amount of residual thyroid tissue after surgery or other thyroid destructive events. Furthermore, detectable serum thyroglobulin in congenital hypothyroidism excludes thyroid agenesis. Increased levels of serum thyroglobulin in iodine deficiency have also been observed [55]. Antithyroglobulin antibodies in serum interfere with measurement of thyroglobulin and therefore this test should not be performed in such patients.

Measurement of urinary iodide provides information about the daily iodide intake in epidemiological studies [56]. The demonstration of elevated concentrations of urinary iodide in a hypothyroid patient may be useful if exposure to excessive iodide is suspected.

Thyroid Imaging in Hypothyroidism

Ultrasonography

Thyroid ultrasonography may be helpful in determining the cause of hypothyroidism by providing important information on location, size, structure, and vascularity of the gland. In autoimmune thyroiditis a gross inhomogeneity and low echogenicity characterize the echo pattern of the gland. Areas of apparently normal tissue of variable size may be observed, whereas true nodules reflect a different aetiology and should raise the possibility of coexisting nodular goitre, adenomas, or malignancies. A diffuse low thyroid echogenicity is indicative of diffuse autoimmune involvement of

the gland and is associated with or may predict the development of hypothyroidism [57]. Studies using colour flow Doppler show a variable degree of vascularity in goitrous autoimmune thyroiditis, whereas vascularity is decreased in the atrophic variant of the disease. In subacute thyroiditis the gland is usually enlarged and presents large hypoechoic areas with poorly defined boundaries, mainly within the painful lobe. A large diffuse or multinodular goitre can be documented by ultrasonography in hypothyroidism with inherited defects in thyroid hormone biosynthesis. No evidence of thyroidal tissue in its appropriate location and the demonstration of an ectopic gland are helpful in the diagnosis of congenital hypothyroidism due to thyroid dysgenesis.

In Vivo Isotopic Tests

Thyroid scintiscan may be helpful in the evaluation of hypothyroid patients to indicate the location of functioning thyroid tissue and to provide an estimation of overall thyroid size, although in this regard better evidence is usually obtained by thyroid ultrasonography. Occasionally scintiscan may reveal ectopic thyroid tissue not discernible by other means (e.g. lingual thyroid). Thyroid scintiscan can also be used to reveal substernal thyroid tissue when hypothyroidism is associated with a large goitre.

Radioiodine uptake is expressed as the percentage of radioactivity that is trapped by the thyroid at a given time after administration of a tracer quantity of inorganic radioiodine. Early radioiodine uptake measurements (3–6 h) provide information on the rates of transport and organification of iodide within the gland, whereas 24- and 48-h radioiodine uptake measurement reflects the rate of release of radioiodine from thyroidal tissue. It is also a way of estimating the extrathyroidal pool of iodide, being low to absent after intake of excess iodide but increased in iodine deficiency. An exception is represented by amiodarone-induced hypothyroidism in which radioiodine uptake is preserved despite iodine excess [58]. Radioiodine uptake is increased if hypothyroidism is caused by defective synthesis of thyroid hormones since TSH stimulates all steps in hormone synthesis capable of response. In chronic autoimmune thyroiditis values of the radioiodine uptake depend on the amount of residual functioning thyroid tissue and the serum concentration of TSH. Radioiodine uptake may be normal or even increased during the initial phase of chronic thyroiditis, whereas it tends to decrease as the disease progresses. Very low values of the radioiodine uptake are characteristic of the early phase of destructive thyroiditis (e.g. subacute thyroiditis) which is usually associated with thyrotoxicosis caused by follicular disruption. In these cases, return of radioiodine uptake to within the normal range may be helpful to indicate recovery of thyroid function. Radioiodine uptake measurement, which is obviously reduced in postablative hypothyroidism, may be used occasionally to estimate the amount of residual thyroid tissue after thyroidectomy or radioactive treatment.

3.4.3 Myxoedema Coma

Leonard Wartofsky, Dorina Ylli, and Joanna Klubo-Gwiezdzinska

Introduction

Myxoedema coma is the extreme expression of severe hypothyroidism and fortunately is quite rare. The first reported case appears to have been in 1879 by Ord from St Thomas's Hospital, London. Two other patients who died in a hypothyroid coma were reported in 1888 in the proceedings of the Clinical Society of London [1]. The next cases in the literature appeared in 1953 [2, 3] and some 500 cases have since been reported. Epidemiological data indicate an incidence rate of 0.22–1.08/1 000 000 per year [4, 5]. The most common presentation of the syndrome is in hospitalized elderly women with long-standing hypothyroidism, with 80% of cases occurring in women over 60 years of age. However, myxoedema coma occurs in younger patients as well, with 36 documented cases occurring during pregnancy [6, 7] and a few cases occurring in the paediatric age group [8–11]. In spite of early diagnosis and treatment, the mortality rate may be as high as 30–60% [5].

Clinical Presentation and Precipitating Events

Patients with myxoedema coma generally present in the winter months, suggesting that external cold may be an aggravating factor. The precipitating events vary from the most frequent including pulmonary infections, congestive heart failure, and cerebrovascular accidents (**Box 3.4.3.1**) to the more unusual such as in subclinical hypothyroidism or consumption of large amounts of raw bok choy [12, 13]. The comatose and hypoventilating patient is also at risk for pulmonary infection or aspiration pneumonia as a secondary event. Similarly, other abnormalities frequently accompanying myxoedema coma, such as hypoglycaemia, hypercalcaemia, hyponatraemia, hypercapnia, and hypoxaemia, may be either precipitating factors or secondary consequences. In hospitalized patients, drugs such as anaesthetics, narcotics, sedatives, antidepressants, and tranquillizers may depress respiratory drive and thereby either cause or compound the deterioration of the hypothyroid patient into coma. Also, drugs that could impair thyroid function such as amiodarone, lithium and tyrosine kinase inhibitors might precipitate myxoedema coma [14, 15].

Box 3.4.3.1 Myxoedema coma: precipitating factors

- Cerebrovascular accidents
- Drugs
- Anaesthetics
  - Sedatives
  - Tranquillizers
  - Narcotics
  - Amiodarone
  - Lithium carbonate
  - Tyrosine kinase inhibitors
- Hypothermia
- Congestive heart failure
- Infections
- Trauma
- Gastrointestinal bleeding
- Metabolic disturbances compounding obtundation
  - Acidosis
  - Hypoglycaemia
  - Hyponatraemia
  - Hypercapnia

Hypothermia (often profound to 80 °F (26.7 °C)) and unconsciousness constitute two of the cardinal features of myxoedema coma. The syndrome will typically present in a patient who develops an infection or other systemic disease superimposed upon previously undiagnosed hypothyroidism. Sometimes a history of antecedent thyroid disease, thyroidectomy, treatment with radioactive iodine, or thyroxine (T_4) replacement therapy that was discontinued for no apparent reason can be elicited. Other clues to the presence of underlying thyroid disease may be seen on examination of the neck, such as a surgical thyroidectomy scar, goitre, or even the absence of palpable thyroid tissue as may occur in chronic Hashimoto's thyroiditis. A pituitary or hypothalamic basis for hypothyroidism is encountered in less than 10–15% of patients. In two large series [16, 17] that identified 12–14 patients with myxoedema coma, the findings on presentation included hypoxaemia in 36–80%, hypotension 50%, hypercapnia in 36–54%, bradycardia in 36%, and hypothermia with a temperature below 94°F (34.4°C) in 50–88%. Fifty per cent (50%) of patients died despite treatment with thyroid hormone. A dreaded aspect of the usual clinical course is progression into respiratory failure and CO_2 retention which is heralded by hypoventilation with lethargy progressing to stupor and then coma. Because of the delayed metabolism of drugs in

hypothyroidism, the deterioration may be hastened by the use of sedative, hypnotics, or narcotics.

Cardiovascular Manifestations

In myxoedema coma, typical findings of hypothyroid heart disease may include bradycardia, decreased quality and intensity of the heart sounds, enlarged cardiac silhouette, and minor electrocardiographic (ECG) abnormalities such as varying degrees of block, low voltage, flattened or inverted T waves, and prolonged Q–T interval which can result in *torsades de pointe* ventricular tachycardia [18]. Myocardial infarction should be ruled out by the usual diagnostic procedures. The lactate dehydrogenase isoenzyme pattern in severe hypothyroidism may mimic that of myocardial infarction [19], and creatine kinase levels also are elevated [20, 21]. Moreover, aggressive or injudicious triiodothyronine (T_3) or T_4 replacement may increase the risk of myocardial infarction (see next). The enlarged cardiac silhouette may be due, in part, to ventricular dilatation or a pericardial effusion which can be confirmed by echocardiography. This fluid is rich in mucopolysaccharide and tends to accumulate slowly over time, only rarely causing cardiac tamponade.

Cardiac contractility is impaired, leading to reduced stroke volume and cardiac output, but congestive heart failure is rare. T_4 replacement therapy will slowly reverse the abnormalities in left ventricular function; although the pericardial effusion may also gradually diminish, reduced cardiac output with hypotension secondary to the effusion must be borne in mind. Patients should be admitted to an intensive care unit because of the propensity for shock and potentially fatal arrhythmias. Hypotension may occur in spite of increases in total body water and extracellular fluid volume because of reduction in intravascular volume. Although blood pressure may be normalized with T_4 replacement, severe hypotension or shock may supervene acutely before the T_4 effect is seen, necessitating the use of pressor drugs.

Respiratory System

The mechanism for hypoventilation in profound myxoedema is a combination of a depressed hypoxic respiratory drive and a depressed ventilatory response to hypercapnia [22]. CO_2 narcosis results from the reduction in alveolar ventilation with the hypoventilation compounded by impairment in respiratory muscle function ultimately leading to coma. The central factor in the pathophysiology of coma appears to be a depressed ventilatory response to CO_2 [23–25]. When present, obesity may impair the bellows action of the chest. Improvement in the response to CO_2 after T_4 therapy has been seen in some [23, 25, 26] but not all [22] studies. Irrespective of the underlying pathophysiology, the mechanical function of the chest in myxoedema coma usually is reduced sufficiently to require mechanically assisted ventilation. Tidal volume may be reduced by other factors such as pleural effusion or ascites. Upper airway partial obstruction may also play a role, caused by oedema or swelling of the tongue, or laryngeal obstruction due to marked oedema of the vocal cords. Hypothyroid patients may be predisposed to increased airway hyper-responsiveness and chronic inflammation [27]. Even with appropriate and adequate therapy, the complexity of the pathophysiology of respiratory failure means that ultimate recovery may be prolonged.

Gastrointestinal Manifestations

The gastrointestinal tract in myxoedema may be marked by mucopolysaccharide infiltration and oedema of the muscularis and neuropathic changes leading to impaired peristalsis, obstipation, and potential paralytic ileus [28]. Given the risks of anaesthesia in the profoundly hypothyroid patient, surgical intervention can be temporized for apparent obstruction by conservative management with decompression until the therapeutic response to thyroid hormone might occur. Initially, parenteral administration of T_4 or triiodothyronine (T_3) may be preferable because absorption of oral medications could be impaired due to the gastric atony often present in myxoedema coma. Ascites has been documented in 51 cases [29] and gastrointestinal bleeding can occur secondary to a coagulopathy.

Renal and Electrolyte Manifestations

Alterations in mineral metabolism and renal clearance in severe hypothyroidism may include decreases in plasma volume, serum sodium, and osmolality, glomerular filtration rate, and renal plasma flow, and increases in total body water, urine sodium, and urine osmolality. Atony of the urinary bladder with retention of large residual urine volumes is commonly seen. High creatine kinase levels are typical of hypothyroidism, but unusually high values may be a clue to underlying rhabdomyolysis. Increased serum antidiuretic hormone levels [30] and impaired water diuresis caused by reduced delivery of water to the distal nephron [31] are likely to account for the hyponatraemia. Depending upon its duration and severity, hyponatraemia will add to altered mental status, and when severe may be largely responsible for precipitating the comatose state. T_4 treatment promotes water diuresis resulting in an increase in serum sodium and a decrease in oedema and total body water.

Neuropsychiatric Manifestations

Although coma is the predominant clinical presentation in myxoedema coma, a history of disorientation, depression, paranoia, or hallucinations ('myxoedema madness') may often be elicited. Other findings present either just before entering the comatose state or early during recovery include cerebellar signs, such as poorly coordinated purposeful movements of the hands and feet, ataxia, adiadochokinesia, poor memory and recall, or even frank amnesia. Abnormal findings on electroencephalography are few and include low amplitude and a decreased rate of α -wave activity. Status epilepticus has been described [32] and up to 25% of patients with myxoedema coma may experience minor to major seizures possibly related to hyponatraemia, hypoglycaemia, or hypoxaemia due to reduced cerebrovascular perfusion from low cardiac output and atherosclerotic vessels in elderly patients. T_4 treatment will generally lead to improved perfusion.

Haematological Manifestations

A microcytic anaemia may be seen secondary to gastrointestinal haemorrhage, or a macrocytic anaemia due to vitamin B_{12}deficiency which may also worsen the neurological state. Granulocytopaenia with a decreased cell-mediated immunological response may contribute to a higher risk of severe infection. In contrast to the tendency to thrombosis seen in mild hypothyroidism, severe hypothyroidism is associated with a higher risk of bleeding due to coagulopathy related to an acquired von Willebrand's syndrome (type 1) and decreases in factors V, VII, VIII, IX, and X [33]. The von Willebrand syndrome is reversible with T_4 therapy [34]. Another cause of bleeding may be disseminated intravascular coagulation associated with sepsis.

Hypothermia

The first clinical clue to the diagnosis of myxoedema coma may be hypothermia which occurs in approximately 75% of patients and may be dramatic (below 80°F (26.7°C)), with temperatures of less than 90°F (32.2°C) being associated with the worst prognosis. Because patients with myxoedema and infection may not mount a febrile response, a diagnosis of profound hypothyroidism should be entertained in any unconscious patient with a known infection but no fever. In view of the latter and because undiscovered infection might lead inexorably to vascular collapse and death, some authors have advocated the routine use of antibiotics in patients with myxoedema coma. Underlying hypoglycaemia may further compound the decrement in body temperature. With T_4 therapy, the hypothermia gradually improves in parallel with the fall in serum thyroid-stimulating hormone (TSH) and increments in serum T_4 and T_3 levels.

Diagnosis

The typical patient presenting with myxoedema coma is a woman in the later decades of her life who may have a history of thyroid disease and who is admitted to hospital during the winter months, possibly with pneumonitis. Physical findings could include bradycardia, macroglossia, hoarseness, delayed reflexes, dry skin, general cachexia, hypotension, hypoventilation, and hypothermia, commonly without shivering. Even though specific diagnostic criteria are not available a diagnostic scoring system has been proposed. Based upon the presence of thermoregulatory and central nervous system dysfunction, gastrointestinal findings, precipitating events, cardiovascular dysfunction, and metabolic alterations, the scoring system has reached a sensitivity of 100% and specificity of 80% (Table 3.4.3.1) [17]. According to the score achieved, the patient would be classified as either highly suggestive, suggestive, or unlikely to have myxoedema coma. Another objective screening tool was proposed based on heart rate, temperature, Glasgow coma scale, TSH, free thyroxine, and precipitating events which was associated with a sensitivity and specificity of approximately 80% [35]. Despite the importance that both scoring systems could have in allowing

Table 3.4.3.1 Diagnostic scoring system for myxoedema coma

Thermoregulatory dysfunction (temperature, °C)		**Cardiovascular dysfunction**	
>35	0	Bradycardia	
32–35	10	Absent	0
<32	20	50–59	10
Central nervous system effects		40–49	20
Absent	0	<40	30
Somnolent/lethargic	10	Other EKG changes[a]	10
Obtunded	15	Pericardial/pleural effusions	10
Stupor	20	Pulmonary oedema	15
Coma/seizures	30	Cardiomegaly	15
Gastrointestinal findings		Hypotension	20
Anorexia/abdominal pain/constipation	5	**Metabolic disturbances**	
Decreased intestinal motility	15	Hyponatraemia	10
Paralytic ileus	20	Hypoglycaemia	10
Precipitating event		Hypoxemia	10
Absent	0	Hypercarbia	10
Present	10	Decrease in GFR	10

Abbreviations: EKG, electrocardiogram; GFR, glomerular filtration rate.

A score of 60 or higher is highly suggestive/diagnostic of myxoedema coma; a score of 25 to 59 is suggestive of risk for myxoedema coma, and a score below 25 is unlikely to indicate myxoedema coma.

[a] Other EKG changes: QT prolongation, or low voltage complexes, or bundle branch blocks, or non-specific ST-T changes, or heart blocks.

early diagnosis and initiation of treatment, the limited number of patients in these studies requires additional validation.

Laboratory evaluation may indicate anaemia, hyponatraemia, hypercholesterolaemia, and increased serum lactate dehydrogenase and creatine kinase. On lumbar puncture there is increased pressure and the cerebrospinal fluid will have a high protein content. The electrocardiogram and chest radiograph may demonstrate the characteristic findings described earlier. If hypothyroidism is suspected in a comatose patient, blood should be obtained for thyroid function testing, but treatment should not be delayed awaiting laboratory confirmation of the diagnosis. On the other hand, a correct diagnosis is particularly important because the unnecessary administration of large doses of T_4 or T_3 to an elderly euthyroid patient could induce a fatal arrhythmia or coronary event. In addition to routine thyroid function tests, ancillary studies should be performed to determine whether CO_2 retention, hypoxia, hyponatraemia, or infection are present. Indeed, in many patients the clinical features may be so notable as to render the measurement of thyroid function tests necessary only for confirmation of the diagnosis. The urgency of the diagnosis should be stressed to the laboratory, which often can perform a serum T_4 and TSH determination in 3–4 h. Although an elevated serum TSH concentration is the most important laboratory evidence of the diagnosis, the presence of severe complicating systemic illness or treatment with drugs such as dopamine, dobutamine, or corticosteroids may serve to reduce the elevation in TSH levels [36, 37]. Furthermore, an association between the use of catecholamines and higher mortality has been reported [5]. There may also be a pituitary cause for the hypothyroidism, in which case an increased TSH would not be found. Until the presence of pituitary disease is ruled out, corticosteroid therapy is recommended in addition to T_4.

Treatment

Myxoedema coma is a true medical emergency, and treatment must be instituted in a critical care setting with modern electronic monitoring equipment as soon as the diagnosis is made in view of the extremely high mortality anticipated in these patients when treatment is delayed. As outlined here, a multifaceted approach is required because of the multiple metabolic derangements derived from, or affecting, several organ systems which may be contributing to the comatose state.

Ventilatory Support

The patient's comatose state is perpetuated by hypoventilation with CO_2 retention and respiratory acidosis. Appropriate diagnostic and therapeutic measures must be instituted for any suspicious infiltrate seen on chest radiographs. The high mortality rate is often related to inexorable respiratory failure, and hence maintenance of an adequate airway and prevention of hypoxaemia is the single most important supportive measure required to avoid a disastrous outcome. Mechanical ventilation is usually required during the first 36–48 h, particularly if the hypoventilation is related in part to drug-related respiratory depression. Although the patient may become alert by the second or third day of treatment, it may be necessary to continue assisted ventilation for as long as 2–3 weeks in some patients.

Intubation may be necessary initially or with worsening of hypoxaemia or hypercarbia, and arterial blood gases need to be monitored regularly until the patient is fully recovered. The hypercapnia may be rapidly relieved with mechanical ventilation, but the hypoxia may tend to persist possibly due to shunting in non-aerated lung areas [38]. Moreover, the physician should guard against extubating the patient prematurely; some case reports have cited the danger of relapse, and it should not be attempted until the patient is fully conscious.

Hyponatraemia

Total body sodium is believed to be normal to increased, but it is the impaired excretion of water that causes hyponatraemia. Low serum sodium may cause a semicomatose state or seizures even in euthyroid patients, and the very severe hyponatraemia (105–120 mmol/L) in profound myxoedema is likely to contribute substantially to the coma in these patients. With such severe hyponatraemia, it may be appropriate to administer a small amount of hypertonic saline (50–100 ml 3% sodium chloride), enough to increase sodium concentration by about 2 mmol/L early in the course of treatment, and this can be followed by an intravenous bolus dose of 40–120 mg furosemide to promote a water diuresis [39]. A small quick increase in the serum sodium concentration (2–4 mmol/L) is effective in acute hyponatraemia because even a slight reduction in brain swelling results in a substantial decrease in intracerebral pressure [40]. On the other hand, too rapid correction of hyponatraemia can cause a very dangerous complication, the osmotic demyelination syndrome. In patients with chronic hyponatraemia this complication is avoided by limiting the sodium correction to less than 10–12 mmol/L in 24 h and to less than 18 mmol/L in 48 h.

After achieving a sodium level of more than 120 mmol/L, no further hypertonic saline infusion should be required, and restriction of fluids may be all that is necessary to correct hyponatraemia, especially if it is mild (120–130 mmol/L). Because of the likelihood of decreased cardiac reserve, therapy with saline or other intravenous fluids must be approached cautiously. If hypoglycaemia is present, dextrose in 0.5 N sodium chloride may be used to correct the low blood glucose. With regard to fluid or saline therapy, careful monitoring of volume status based on clinical parameters and central venous pressure measurements is essential in patients with significant cardiovascular decompensation.

New vasopressin antagonists named vaptans (conivaptan and tolvaptan), have been approved by the Food and Drug Administration (FDA) in the United States for the treatment of patients with euvolaemic and hypervolaemic hyponatraemia. These treatments could be attempted in this clinical setting in view of the high vasopressin levels observed in myxoedema coma. Conivaptan current dosing recommendations are a 20-mg loading dose to be infused over 30 min followed by a 20 mg/day continuous infusion for up to 4 days. Tolvaptan is administered orally in a starting dose of 15 mg the first day followed by titration up to 30 mg and 60 mg at 24 hours if necessary. During the active phase of correction with tolvaptan, fluid restriction is not recommended in order to reduce the risk of overcorrection. With both therapies, serum [Na+]

concentration should be measured frequently during the active phase of correction of the hyponatraemia at a minimum of every 6–8 hours. No data are available on the use of vaptans in severe hyponatraemia (<115 mmol/L) in hypothyroid patients, or whether sole therapy with vaptans without hypertonic saline would be effective [40, 41].

Hypothermia

Restoration of body temperature to normal will require administration of T_4 or T_3. Blankets or increasing room temperature can be used to keep the patient warm until the thyroid hormone effect is achieved, but caution must be exercised in the use of more vigorous electric warming blankets. Too aggressive warming may cause peripheral vasodilatation, a precipitous fall in peripheral vascular resistance with increased peripheral blood flow, and increased oxygen consumption, which may then lead to hypotension or shock.

Hypotension

Hypotension should also be corrected after treatment with T_4; this may take several days, and the hypotensive patient may require additional therapy. Fluids may be administered cautiously as 5–10% glucose in 0.5 N sodium chloride initially, or as isotonic normal saline if hyponatraemia is present. It is wise to administer hydrocortisone (100 mg intravenously every 8 h) until the hypotension is corrected. Pressors are only very rarely required, and the possibility of an adverse cardiac event needs to be kept in mind, especially in patients with suspected underlying ischaemic heart disease. An agent such as dopamine might be employed to maintain coronary blood flow, but patients should be weaned off the pressor as soon as possible. The physician must weigh the risk of a pressor-induced ischaemic event against the known high mortality of poorly managed hypotension in myxoedema coma.

Corticosteroids

A rising urea nitrogen, hypotension, hypothermia, hypoglycaemia, hyponatraemia, and hyperkalaemia may signal the coexistence of adrenal insufficiency. Indeed, decreased adrenal reserve has been found in 5–10% of patients on the basis of either hypopituitarism or primary adrenal failure accompanying Hashimoto's disease (Schmidt's syndrome). Otherwise, plasma total and free cortisol levels and the adrenal response to adrenocorticotropic hormone (ACTH) infusion should be normal in hypothyroidism or myxoedema coma. However, ACTH reserve or the ACTH response to stress may be impaired in myxoedema coma. There should be no reluctance to administer short-term corticosteroids until the patient is stable and the integrity of the pituitary–adrenal axis can be determined. On theoretical grounds, one should also administer corticosteroids when first instituting thyroid hormone therapy, in view of the potential risk of precipitating acute adrenal insufficiency due to the accelerated metabolism of cortisol that follows T_4 therapy. The typical dosage of hydrocortisone is 50–100 mg every 6–8 h during the first 7–10 days with tapering of the dosage thereafter based upon clinical response and any plans for further diagnostic evaluation.

Thyroid Hormone Therapy

One of the most controversial aspects of the management of myxoedema coma is which thyroid hormone medication to give and how to give it (dose, frequency, and route of administration). Because of the relative rarity of this condition, the paucity of reported treatment results, and the difficulties inherent in performing a controlled investigation, the optimum treatment remains uncertain, and several approaches will be discussed. Some of the differences of opinion relate to whether to administer T_4 and rely on the patient to convert it to the more active T_3, or to give T_3 itself. One must balance the need for quickly attaining physiologically effective thyroid hormone levels against the risk of precipitating a fatal tachyarrhythmia or myocardial infarction. T_4 provides a steady smooth onset of action with a lower risk of adverse effects.

Parenteral preparations of either T_4 or T_3 are available for intravenous administration. Although oral forms of either T_3 or T_4 can be given by nasogastric tube in the comatose patient, this route is fraught with risks of aspiration and uncertain absorption, particularly in the presence of gastric atony or ileus.

Parenteral preparations of T_4 may be available in ampoules of 100 and 500 μg. A loading dose of 200–400 μg of levothyroxine may be given intravenously. After this initial 'loading' dose, a maintenance dose of 1.6 μg/kg body weight, reduced to 75% if being intravenously administered, can be given thereafter. This method may be attended by increases in serum T_4 to within the normal range within 24 h and by significant decrements in serum TSH. After clinical improvement the patient may be switched to oral therapy. Larger doses of T_4 probably have no advantage and may, in fact, be more dangerous [42]. Due to its conversion from T_4, a progressive increase in serum T_3 is seen after 300–600 μg doses of T_4, as has been described by Ridgway *et al.* [42].

The approach to therapy employing an initial large intravenous bolus dose of T_4 followed by maintenance therapy has been considered optimal [41, 42], but other evidence suggests improved outcomes with lower doses of thyroid hormone [43]. This was also indicated in a prospective trial in which patients were randomized to receive either a 500-μg loading dose of intravenous T_4 followed by a 100-μg daily maintenance dose, or only the maintenance dose [44, 45]. The overall mortality rate was 36.4% with a lower mortality rate in the high-dose group (17%) versus the low dose group (60%). Although suggestive, the difference was not statistically significant. Factors associated with a worse outcome included a decreased level of consciousness, lower Glasgow coma score, and increased severity of illness on entry as determined by an APACHE II score of more than 20.

T_4 treatment has been generally considered effective, but there is one important drawback to total reliance on T_3 generation from T_4. The rate of conversion of T_4 to T_3 is reduced in many systemic illnesses (the euthyroid sick or low T_3 syndrome) [37] and hence T_3 generation may be reduced in myxoedema coma as a consequence of any associated illness [39]. Theoretically then, one might administer

T_4, see increases in serum T_4 levels confirming adequate absorption, but fail to witness any significant fall in TSH or dramatic clinical improvement. As a consequence, small supplements of T_3 should be given along with T_4 during the initial few days of treatment, especially if obvious associated illness is present. Irrespective of the type of treatment selected, all patients should have continuous ECG monitoring with reduction in thyroid hormone dosage should arrhythmias or ischaemic changes be detected.

T_3 is available for intravenous use (Triostat) in 1 ml vials containing 10 μg/ml. When therapy is approached with T_3 alone, it may be given as a 10–20 μg bolus followed by 5–10 μg every 4 h for the first 24 h, dropping to 5–10 μg every 6 h for days 2–3, by which time oral administration should be feasible. T_3 has a much quicker onset of action than T_4 and increases in body temperature and oxygen consumption may occur 2–3 h after intravenous T_3, compared to 8–14 h after intravenous T_4. A patient with profound secondary myxoedema believed due to postpartum pituitary necrosis has been reported who presented with cardiogenic shock which responded to T_3 but not T_4 therapy [44]. Because of the high mortality rate in myxoedema coma, advocates for T_3 therapy argue that the more rapid onset of action could make the difference between life and death. But the benefits of the more rapid onset of action need to be weighed against the greater risk of complications. As a consequence, it is difficult to justify the high risk/benefit ratio of a regimen that uses rapid replacement with relatively large doses of intravenous T_3 alone. Such treatment would be marked by large and unpredictable fluctuations in serum T_3 levels, and high serum T_3 levels during treatment with thyroid hormone have been associated with fatal outcomes [45].

A more conservative but seemingly rational course of management is to provide combined therapy with both T_4 and T_3. Rather than administer 300–500 μg T_4 intravenously initially, a dose of 4 μg/kg lean body weight (or about 200–300 μg) is given, and an additional 100 μg is given 24 hours later. By the third day, the dose is reduced to a daily maintenance dose of 50 μg, which can be given by mouth as soon as the patient is conscious. Simultaneously with the initial dose of T_4, a bolus of 5–20 μg T_3 is given and intravenous T_3 is continued at a dosage of 2.5–10 μg every 8–12 hours until the patient is conscious and taking maintenance T_4 [46]. Sensitivity to thyroid hormone in terms of cardiac risk varies, depending on age, cardiac medications, and the presence of underlying hypoxaemia, coronary artery disease, congestive failure, and electrolyte imbalance. Clinical improvement has been seen with even a single dose of only 2.5 μg T_3 [47]. It is wise to monitor the patient for any untoward effects of therapy before administering each dose of thyroid hormone.

Myxoedema Coma and Emergent Surgery

Clearly, given their fragile clinical state, non-emergent surgery should be deferred in a patient with myxoedema coma. However, in the patient with myxoedema coma requiring emergent surgery, the same general management principles prevail [48] with particular attention to careful monitoring of intraoperative and postoperative respiratory and cardiovascular status. Postoperatively, close monitoring for maintenance of the airway is essential.

General Supportive Measures

In addition to the specific therapies outlined, other treatments will be indicated as in the management of any other elderly patient with multisystemic problems. This might include the treatment of underlying problems such as infectious processes, congestive heart failure, diabetes, or hypertension. The dosage of specific medications (e.g. digoxin for congestive heart failure) may need to be modified based on their altered distribution and slowed metabolism in myxoedema. Even with this vigorous therapy, the prognosis for myxoedema coma remains grim, and patients with severe hypothermia and hypotension seem to do the worst. Several prognostic factors may be associated with a fatal outcome [43, 45, 49, 50] and include: older age, persistent hypothermia or bradycardia, lower degree of consciousness by Glasgow coma scale, multiorgan impairment indicated by an APACHE II score of more than 20, or SOFA score ≥6, and use of catecholamines [5]. The most common causes of death are respiratory failure, sepsis, and gastrointestinal bleeding. Early diagnosis and prompt treatment, with meticulous attention to the details of management during the first 48 hours, remain critical for the avoidance of a fatal outcome.

3.4.4 Subclinical Hypothyroidism

Bijay Vaidya and Chantal Daumerie

Introduction

Subclinical hypothyroidism is biochemically defined as a raised serum thyrotropin (TSH) level together with serum free thyroxine (fT_4) and free tri-iodothyronine (fT_3) levels within the population reference range [1]. It is also referred to as compensated hypothyroidism or mild thyroid failure. Although the term 'subclinical' suggests the absence of symptoms, some patients with subclinical hypothyroidism have vague non-specific symptoms of hypothyroidism. However, the diagnosis of subclinical hypothyroidism cannot be made based on clinical features alone and laboratory thyroid function tests are required for the diagnosis. The risk of long-term complications of subclinical hypothyroidism depends upon the degree of TSH elevation and the age of the patient, with younger adults showing an increased risk of cardiovascular and cerebrovascular morbidities. The paucity of well conducted large randomized controlled trials in subclinical hypothyroidism means its management remains controversial, and there is a wide variation in the routine clinical practice [2].

This chapter reviews the diagnosis, long-term complications, and management of subclinical hypothyroidism in non-pregnant adults.

How Common is Subclinical Hypothyroidism?

In population-based studies, the prevalence of subclinical hypothyroidism ranges from 4 to 15%, with higher prevalence associated with advancing age, female sex, and suboptimal iodine status of the population [3, 4]. It affects about 10% women in perimenopausal age, and more than 20% women aged 75 years or above [5]. The apparent variation in the prevalence rate of subclinical hypothyroidism in different studies reflects the differences in the demographic characteristics of the study populations and the upper limits of the reference range used for TSH measurements.

Causes of Subclinical Hypothyroidism

The commonest cause of subclinical hypothyroidism, like overt hypothyroidism, is autoimmune thyroiditis (Hashimoto's disease or autoimmune atrophic thyroiditis). Other causes include previous thyroid surgery, radioiodine treatment, drugs, inadequate dose of levothyroxine for overt hypothyroidism, thyroiditis (subacute, painless, or postpartum), and radiotherapy involving head and neck (Box 3.4.4.1). Rarely, it is associated with loss-of-function mutations in the TSH receptor gene [6]. Although severe iodine deficiency can cause both subclinical and overt hypothyroidism, chronic excess iodine intake, for example, following inadequately monitored universal salt iodization, is a recognized risk factor for subclinical hypothyroidism [7]. In addition, long-term occupational exposure to pesticides has also been shown to be associated with subclinical hypothyroidism [8]. In contrast, smoking is associated with a reduced risk of subclinical hypothyroidism [9].

Box 3.4.4.1 Causes of subclinical hypothyroidism

- Chronic autoimmune thyroiditis (Hashimoto's disease or autoimmune atrophic thyroiditis)
- Iatrogenic (partial thyroidectomy, radioiodine therapy, external radiotherapy involving head and neck)
- Thyroiditis (subacute, painless, or postpartum)
- Drugs (iodine, amiodarone, lithium, interferon-alpha, interleukin 2, tyrosine kinase inhibitors, checkpoint inhibitor immunotherapy)
- Suboptimal levothyroxine replacement for overt hypothyroidism
- Chronic excessive iodine intake
- Occupational exposure to pesticides
- Thyroid infiltration (sarcoidosis, lymphoma, haemochromatosis, amyloidosis)
- Loss-of-function mutations in the TSH receptor gene

Diagnosis of Subclinical Hypothyroidism

Symptoms and Signs

Few patients with subclinical hypothyroidism present with classical symptoms and signs of hypothyroidism. In the Colorado thyroid disease prevalence study, more patients with subclinical hypothyroidism than euthyroid individuals reported multiple symptoms, such as dry skin, poor memory, slow thinking, muscle weakness, constipation, and tiredness [5]. However, the association was weak with low sensitivities (3–28%) and positive predictive values (8–12%) for the individual symptoms, such that only a minority of patients with subclinical hypothyroidism had the symptoms while many of the individuals with these symptoms had normal thyroid function. Similarly, another case–control study found that patients with subclinical hypothyroidism and euthyroid controls have similar frequencies of symptoms of hypothyroidism, except tiredness which was more prevalent in patients with subclinical hypothyroidism [10].

Laboratory Investigations

The diagnosis of subclinical hypothyroidism is based on laboratory thyroid function tests: a serum TSH level above the laboratory reference range together with a normal serum fT_4 level is suggestive of the diagnosis. A serum TSH level of 4.5–5 mU/L is widely accepted as the upper limit of the reference range, although there is a considerable debate whether this should be set lower at 2.5 mU/L [11].

Several physiological and demographic factors affect serum TSH levels that may influence the interpretation of laboratory thyroid function tests. First, the presence of a diurnal variation in TSH secretion with peak levels at night and trough levels in the afternoon means that the timing of the blood test may affect the TSH result [12]. Second, TSH levels progressively rise with age, possibly reflecting an adaption of the hypothalamus-pituitary-thyroid axis to ageing, and therefore some experts advocate the use of age specific TSH reference ranges [13]. Third, ethnicity influences serum TSH; for example, the levels tend to be higher in Caucasians than in Blacks or Hispanics [4]. Finally, an individual's TSH levels over time fluctuate within a much narrower range than the population reference range [14]. This suggests that each individual has their own TSH set point, and any deviation from that set point may be abnormal for the individual even if the level is within the population reference range.

It is also important to distinguish subclinical hypothyroidism from other conditions associated with a raised serum TSH and normal fT_4 (Table 3.4.4.1). The presence of heterophile or human anti-animal antibodies can result in spuriously high serum TSH by interfering TSH assay [15]. Macro-TSH (a biologically inert large molecular complex of TSH and immunoglobulin G) is another cause of spurious elevation of serum TSH, and accounts for about 1.5% cases of apparent subclinical hypothyroidism [16]. Patients recovering from non-thyroidal illness and thyroiditis (subacute, painless, or postpartum) often show transient rise in TSH levels. Likewise, patients with untreated Addison's disease may have a raised TSH, which normalizes after glucocorticoid replacement. Patients on levothyroxine replacement for overt hypothyroidism frequently have raised TSH due to inadequate dose, non-concordance, malabsorption, and concomitant use of drugs impairing levothyroxine absorption (e.g. iron, calcium, and cholestyramine) or increasing levothyroxine clearance (e.g. phenytoin, phenobarbital, and rifampicin). Resistance to thyroid hormone due to mutations in the thyroid hormone receptor β gene is often associated with raised TSH with variable levels of fT_4. However, most patients with this condition will have fT_4 above or towards the upper end of the reference range; in contrast, fT_4 levels tend to be towards the lower half of the reference range in subclinical hypothyroidism. Furthermore, as resistance to thyroid hormone is an autosomal dominant condition, first degree relatives of the patient may show similar thyroid function test abnormalities.

In patients with subclinical hypothyroidism, the presence of thyroid peroxidase antibodies (TPO-Ab) not only confirms autoimmunity as the aetiology, but also provides a prognostic value for predicting progression to overt hypothyroidism. Thyroid ultrasound may show hypoechogenicity or heterogeneous echogenicity in autoimmune thyroid disease leading to subclinical hypothyroidism; however, a routine thyroid ultrasound is unnecessary in the diagnostic work-up of subclinical hypothyroidism.

Natural History of Subclinical Hypothyroidism

Without intervention, a small percentage of patients with subclinical hypothyroidism will progress to overt hypothyroidism, and the risk of progression is higher in patients with TPO-Ab. In the Whickham follow-up study, 2.6% TPO-Ab negative patients with subclinical hypothyroidism progressed to overt hypothyroidism each year as compared to 4.3% TPO-Ab positive patients [3]. Apart from TPO-Ab, TSH level also predicts the likelihood of progression. In a longitudinal study, patients with TSH 10.0–14.9 mU/L had a 10-fold higher incidence of progression to overt hypothyroidism, as compared to those with TSH 5.0–9.9 mU/L [17]. However, it is noteworthy that thyroid function recovers spontaneously over time in about 40% patients with subclinical hypothyroidism [17, 18]. Patients with lower baseline TSH levels are more likely to recover spontaneously.

Long-Term Complications of Subclinical Hypothyroidism

Cardiovascular Disease

Several epidemiological studies have examined for an association between subclinical hypothyroidism and the risk of cardiovascular outcomes. They have shown conflicting results due to differences in the demographic characteristics of patient populations, the study designs, and the TSH cut-off levels to define subclinical hypothyroidism. However, there is emerging evidence that patient age and TSH level have a major influence on the association. A meta-analysis of observational studies found a significant association between subclinical hypothyroidism and cardiovascular mortality in younger adult patients aged below 65 years (odds ratio (OR) 1.37; 95% confidence interval (CI) 1.04–1.79) but the association was not seen in older patients [19]. In fact, in very elderly patients above the age of 85 years, subclinical hypothyroidism has been shown to be associated

Table 3.4.4.1 Conditions simulating subclinical hypothyroidism with a raised TSH and normal free T_4

Conditions	Characteristic features
Assay interference (including heterophile antibodies and macro-TSH)	Laboratory results inconsistent with clinical status
Non-thyroidal illness	Recent acute illness
Thyroiditis (subacute, painless, or postpartum)	Recent viral illness, neck tenderness (subacute thyroiditis); childbirth in the last 6 months (postpartum thyroiditis)
Non-concordance with levothyroxine treatment	History of intermittently missing levothyroxine tablets
Addison's disease	Clinical features of adrenal insufficiency (e.g. fatigue, low blood pressure, postural hypotension, weight loss), skin pigmentation, worsening of symptoms after starting levothyroxine
Resistance to thyroid hormone (due to mutations in the thyroid hormone receptor β gene)	Often asymptomatic, presence of similar thyroid function test results in first degree relatives

with a decreased risk of cardiovascular and all-cause mortality [20]. In another meta-analysis, which included more than 50 000 participants from 11 prospective cohorts, increasing TSH level in subclinical hypothyroidism was associated with a higher risk of fatal and non-fatal coronary heart disease events [21]. This association was most striking in patients with TSH levels of 10 mU/L or above, with hazard ratios of 1.89 (95% CI 1.28–2.8) for non-fatal coronary heart disease events and 1.58 (95% CI 1.1–2.27) for coronary heart disease deaths. In a meta-analysis of six prospective observational studies with over 25 000 participants, subclinical hypothyroidism was associated with a significantly higher risk of heart failure in patients with TSH levels of 10 mU/L or above (hazard ratio 1.86; 95% CI 1.27–2.72) [22]. In addition, patients with pre-existing heart failure may have a poorer prognosis in the presence of coexisting subclinical hypothyroidism [23]. Finally, subclinical hypothyroidism has also been shown to be associated with several functional cardiovascular anomalies, including left ventricular diastolic dysfunction, reduced resting and exertional systolic function, increased vascular resistance, arterial stiffness, and endothelial dysfunction [24–26].

Cerebrovascular Disease

Like cardiovascular disease, the risk of cerebrovascular disease is increased in younger adult patients with subclinical hypothyroidism. A meta-analysis of 17 observational studies, which included over 47 000 participants, failed to demonstrate a significant increase in the risk of cerebrovascular events or fatal stroke in patients with subclinical hypothyroidism in the whole cohort [27]. However, in younger patients under the age of 65 years, subclinical hypothyroidism was significantly associated with an increased risk of fatal stroke (HR 2.29; 95% CI 1.41–3.74).

Adverse Metabolic Characteristics

Many observational studies have shown associations between subclinical hypothyroidism and several adverse metabolic parameters, which may partly explain the increased cardiovascular and cerebrovascular risk in younger patients with subclinical hypothyroidism. A meta-analysis of 16 observational studies, which included over 40 000 participants, found significantly increased levels of serum total cholesterol, low-density lipoprotein cholesterol and total triglyceride in patients with subclinical hypothyroidism as compared to euthyroid individuals although there was no difference in serum high-density lipoprotein cholesterol levels between the two groups [28]. The risk of adverse lipid profile increases with an increasing TSH level. In addition, there appears to be a gender-related difference in the relationship between subclinical hypothyroidism and adverse lipid profile, with a more pronounced effect in women [29]. Apart from dyslipidaemia, a meta-analysis found an association between subclinical hypothyroidism and increased risks of type 2 diabetes (OR 1.93, 95% CI 1.66–2.24) and its complications, including diabetic nephropathy (OR 1.74, 95% CI 1.34–2.28), diabetic retinopathy (OR 1.42, 95% CI 1.21–1.67), peripheral vascular disease (OR 1.85, 95% CI 1.35–2.54) and peripheral neuropathy (OR 1.87, 95% CI 1.06–3.28) [30]. Furthermore, subclinical hypothyroidism has been shown to be associated with a higher levels of plasma homocysteine (a risk factor for atherosclerosis) and insulin resistance as measured by homeostatic index of insulin resistance (HOMA-IR) [31]. Finally, a meta-analysis has also shown an association between subclinical hypothyroidism and non-alcoholic steatohepatitis (OR 1.63, 95% CI 1.19–2.24) [32].

Impaired Cognitive Function

Several studies have assessed for an association between subclinical hypothyroidism and impaired cognitive function showing inconsistent results. Two meta-analyses found no significant association between subclinical hypothyroidism and decline in cognitive function, as measured by Mini-Mental State Examination (MMSE) score [33, 34]. However, another meta-analysis has suggested that subclinical hypothyroidism is associated with an increased risk of impaired cognitive function and dementia in younger patients aged less than 75 years, particularly in those with higher TSH levels [35]. These observations suggest more research is needed to conclude whether subclinical hypothyroidism increases the risk of cognitive decline.

Bone Loss, Osteoporotic Fractures, and Frailty

Although optimum thyroid function is important for bone health, subclinical hypothyroidism has not been shown to be associated with an increased risk of bone loss [36] or osteoporotic fractures [37, 38]. Likewise, subclinical hypothyroidism is not associated with an increased risk of frailty in elderly populations [39, 40].

Mood, Mental Health, and Well-Being

Some studies have suggested that subclinical hypothyroidism is associated with poor neuropsychological function, mood, and quality of life [41, 42]. However, the association remains uncertain as other studies have failed to confirm these observations [43, 44].

In summary, subclinical hypothyroidism is associated with a higher risk of cardiovascular and cerebrovascular disease in younger adult patients (below the age of 65 years), particularly in those with TSH levels of 10 mU/L or above. This association may be partly explained by an increased prevalence of dyslipidaemia, type 2 diabetes, and other adverse metabolic characteristics in patients with subclinical hypothyroidism. In contrast, there is no convincing evidence to support the association between subclinical hypothyroidism and impaired cognitive function, osteoporosis, frailty, poor neuropsychological function, or reduced quality of life.

Management of Subclinical Hypothyroidism

Efficacy of Levothyroxine Treatment

The potential benefits of treating subclinical hypothyroidism include improvement in symptoms and quality of life, stopping progression to overt hypothyroidism and prevention of long-term complications. A previous systematic review of randomized controlled trials failed to demonstrate a benefit of levothyroxine treatment over placebo to improve symptoms or health-related quality of life in subclinical hypothyroidism [45]. However, a subsequent randomized controlled trial found an improvement in tiredness with levothyroxine treatment [46]. A recent randomized double-blind placebo-controlled trial of levothyroxine treatment in elderly patients (aged 65 years or above) failed to show an improvement in thyroid specific quality of life with the treatment in subclinical hypothyroidism [47]. Furthermore, another randomized controlled trial in elderly patients (above the age of 65 years) found no benefit of levothyroxine in subclinical hypothyroidism to improve cognitive function [48].

There is some evidence to show improvement in lipid profile, features on echocardiography and cardiac magnetic resonance imaging, and arterial stiffness with levothyroxine replacement in subclinical hypothyroidism [45, 46, 49]. However, at present, there are no large scale randomized controlled trials to show that levothyroxine treatment improves cardiovascular or cerebrovascular morbidity and mortality in subclinical hypothyroidism. Interestingly, a large observational study based on the UK general practice research database has found a reduction in fatal and non-fatal coronary heart disease events with levothyroxine in younger patients (aged between 40 and 70 years) with subclinical hypothyroidism, but not in older patients above the age of 70 years [50]. In contrast, a large cohort study based on the Danish national registries showed no evidence of reduction in myocardial infarction, cardiovascular deaths, or all-cause mortality with levothyroxine treatment in patients with subclinical hypothyroidism, although all-cause mortality was reduced in patients under the age of 65 years [51].

Potential Risks of Levothyroxine Treatment

Levothyroxine is considered a safe treatment in subclinical hypothyroidism provided that thyroid function is monitored regularly to avoid both overtreatment and undertreatment. Patients with subclinical hypothyroidism are prone to overtreatment with levothyroxine resulting in TSH suppression [52], which is associated with an increased risk of atrial fibrillation and osteoporosis, particularly in elderly patients [53, 54].

Recommendations from the International Guidelines

In the absence of randomized controlled trial evidence to show benefit of levothyroxine replacement in improving quality of life and long-term cardiovascular and cerebrovascular complications, the management of subclinical hypothyroidism remains controversial. However, because of the association between subclinical hypothyroidism and long-term cardiovascular morbidity and mortality, particularly in young patients and those with high TSH levels, the current guidelines from the American Thyroid Association/the American Association of Clinical Endocrinologists [55] and the European Thyroid Association [56] recommend levothyroxine treatment in subclinical hypothyroidism if TSH is 10 mU/L or above. The European guidelines take a more cautious approach in treating subclinical hypothyroidism in older patients above the age of 70 years and recommend treatment if TSH is 10 mU/L or above in the presence of clear symptoms of hypothyroidism or in the presence of high vascular risk [56].

Managing Subclinical Hypothyroidism in Routine Clinical Practice

An algorithm for management of non-pregnant adult patients under the age of 65 years with subclinical hypothyroidism is shown in Figure 3.4.4.1. In new patients with elevated serum TSH and normal fT_4, other potential causes (such as, assay interference) should be considered and excluded (Table 3.4.4.1). Thyroid function tests

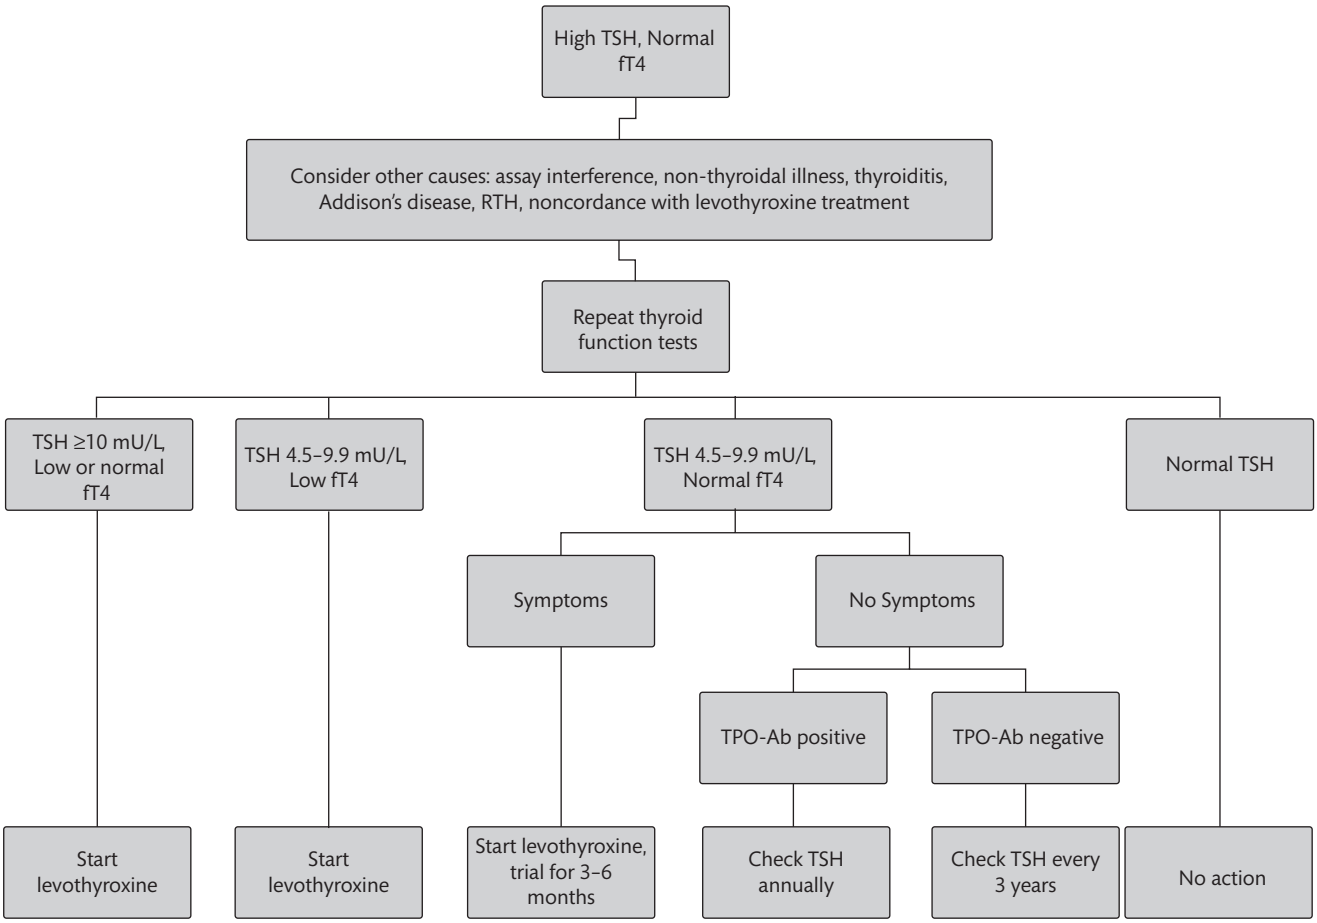

Figure 3.4.4.1 Algorithm for management of subclinical hypothyroidism in non-pregnant young adults. Please see the text for the management in elderly patients (>65 years age).

Abbreviations: fT_4, free thyroxine; RTH, resistance to thyroid hormone; TPO-Ab, thyroid peroxidase antibodies; TSH, thyroid-stimulating hormone.

should be repeated in 2–3 months, as thyroid function in patients with transient thyroiditis and non-thyroidal illness usually returns to normal without intervention. In patients with persistent subclinical hypothyroidism, treatment with levothyroxine should be considered if TSH is 10 mU/L or higher. In young adult patients with TSH <10 mU/L, levothyroxine treatment could be prescribed after evaluation case by case and discussion with the patient. For example, a trial of levothyroxine for 3–6 months should be considered in the presence of non-specific symptoms to assess symptomatic benefit, especially in the presence of TPO-Ab. In elderly patients (above the age of 65 years) with subclinical hypothyroidism, levothyroxine replacement is indicated in the presence of TSH above 10 mU/L and clear symptoms [56]. In cases of non-treatment, thyroid function should be monitored annually in presence of TPO-Ab and every 3 years in absence of TPO-Ab.

If the decision is made to treat subclinical hypothyroidism, levothyroxine is the treatment of choice. In young patients without known coronary heart disease, levothyroxine should be started on a dose based on bodyweight, at around 1.5 μg/kg/day [56]. In patients starting levothyroxine, TSH should be checked every 6–8 weeks adjusting the dose of levothyroxine until TSH is in the reference range. After that, thyroid function tests should be performed annually to keep thyroid function normal. In elderly patients and those with coronary heart disease, levothyroxine should be started on a smaller dose (e.g. 25 μg/day) and the dose increment should be more gradual.

There is no evidence to support the use of liothyronine, combination of liothyronine and levothyroxine, or desiccated thyroid extract in subclinical hypothyroidism [55, 56]. In autoimmune thyroid disease, selenium supplement can reduce titres of thyroid antibodies but does not affect thyroid hormone levels [57]. Therefore, it is not recommended as a treatment for subclinical hypothyroidism due to autoimmune thyroid disease [55, 56].

Conclusions

The current uncertainties about the management of subclinical hypothyroidism and the associated variability in the clinical practice reflect the lack of high-quality evidence. Clearly, there is an urgent need for well-designed large randomized controlled trials to investigate whether levothyroxine reduces the risk of cardiovascular and cerebrovascular events and improves quality of life in young adults with subclinical hypothyroidism. Even when a decision is made to treat subclinical hypothyroidism with levothyroxine, the optimal TSH target remains uncertain, particularly for elderly patients. It is hoped that future studies will inform optimum TSH targets for patients of different ages treated with levothyroxine.

3.4.5 Syndromes of Resistance to Thyroid Hormone

Carla Moran, Mark Gurnell, and Krishna Chatterjee

Introduction

Thyroid hormones (TH—thyroxine, T_4; triiodothyronine, T_3) regulate many physiological processes in virtually every type of tissue. The diverse effects of TH include regulation of growth, control of basal metabolic rate, cardiac chronotropic and inotropic effects, and functional differentiation of the central nervous system. The synthesis of TH is controlled by hypothalamic thyrotropin-releasing hormone (TRH) and pituitary thyroid-stimulating hormone (TSH), and in turn, T_4 and T_3 regulate TRH and TSH production as part of a negative feedback loop.

The regulation of physiological processes by TH are mediated by changes in expression of specific target genes in different tissues. Thus, the feedback effects of TH on TSH production are mediated by inhibition of hypothalamic TRH and pituitary TSHα and β subunit gene expression. Nuclear thyroid hormone receptors (TRα1, TRβ1, TRβ2), encoded by different genes (*THRA, THRB*), mediate canonical TH action to regulate transcription of target genes in a hormone-dependent manner. TRα1 is most highly expressed in the central nervous system, bone, intestine, skeletal & cardiac muscle; TRβ1 is the predominant receptor subtype in liver and kidney; the TRβ2 isoform is most highly expressed in the pituitary and hypothalamus but is also found in the inner ear and retina. TRα2, a variant protein which is unable to bind thyroid hormone, is widely expressed but its biological function is not understood [1].

Unliganded TRs recruit a multiprotein complex, containing corepressors (CoR, e.g. nuclear receptor corepressor, NCoR; silencing mediator of retinoic acid and thyroid hormone receptor, SMRT) and histone deacetylase (HDAC), to inhibit basal gene transcription; hormone (T_3) occupancy of TRs promotes dissociation of the corepressor complex and relief of target gene repression, followed by recruitment of coactivators (e.g. steroid receptor coactivator 1 (SRC-1), cAMP response element-binding protein (CREB)-binding protein (CBP)), which mediate target gene activation [2] (Figure 3.4.5.1).

Thyroid hormone action is also regulated at other levels. Monocarboxylate transporter 8 (MCT8), a membrane protein, mediates cellular thyroid hormone uptake, particularly in the central nervous system (CNS). Intracellularly, a family of deiodinase enzymes (DIOs) mediate hormone metabolism: type 1 deiodinase (DIO1) in peripheral tissues is responsible for T_3 generation; type 2 deiodinase (DIO2) mediates T_4 to T_3 conversion in the CNS, including pituitary and hypothalamus; type 3 deiodinase (DIO3) catabolizes T_4 and T_3 to inactive metabolites (Figure 3.4.5.1).

The first syndrome of resistance to thyroid hormone (RTH), described in 1967 and characterized by elevated circulating TH, non-suppressed TSH and variable resistance to hormone action in target tissues, is mediated by defects in TRβ. However, recognition that other disorders, due to defective TH transport, intracellular metabolism of TH, or hormone action via TRα, are also characterized by tissue resistance, has led to a broader definition of RTH, encompassing all disorders that can interfere with the biological action of TH secreted in normal or excessive amounts [3].

Allan-Herndon-Dudley Syndrome—A Disorder of Thyroid Hormone Transport

Clinical Features

In 1944, a large family with X-linked intellectual disability was described by Allan, Herndon, and Dudley, with this and subsequent similar cases being designated an eponymous (Allan-Herndon-Dudley) syndrome (AHDS). Many decades later AHDS patients were noted to have abnormal thyroid function tests.

Patients with AHDS are usually born at term from uncomplicated pregnancy with normal birthweight. Generalized muscular hypotonia is a feature in early neonatal life, with persistent truncal hypotonia being associated with poor head control; peripherally, hypotonia progresses into spasticity with hyperreflexia, clonus, and extensor plantar responses. Poor motor development usually precludes ability of patients to sit, stand, or walk; cognitive impairment (IQ <40) limits speech severely, but patients retain awareness of surroundings with smiling and crying; hearing and vision are typically unaffected. Epilepsy, ranging from absence to tonic-clonic seizures, occurs in 25% of cases. Involuntary movements (dystonic, choreoathetoid, ballismus), sometimes occurring in paroxysms triggered by external stimuli, are a further characteristic. Progressive microcephaly is associated with reduced head circumference. Brain MRI in early life (<2 years) shows reduced myelination but this normalizes by 4 years of age, distinguishing this disorder from other hypomyelinating leukodystrophies (e.g.

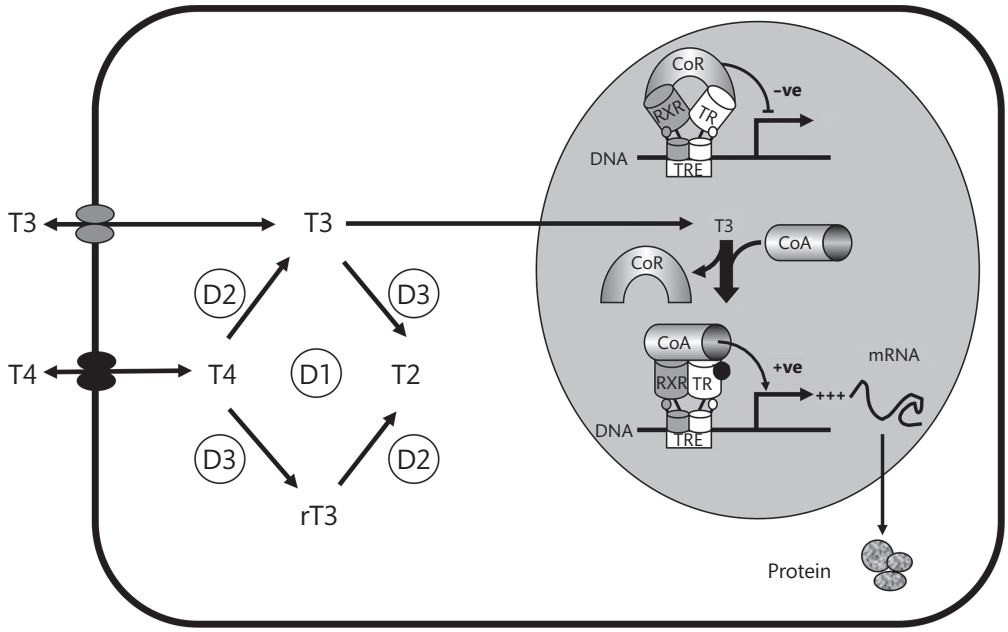

Figure 3.4.5.1 Schematic outline of thyroid hormone uptake, metabolism, and regulation of target gene transcription via binding to the nuclear receptor TR (positively regulated target gene shown). Transporters are required for the passage of T_3 and T_4 across the plasma membrane. The deiodinases (D1–3) catalyse conversion of T_4 to T_3 (D1, D2) or inactivation of T_4 to reverse T_3 (rT_3) and T_3 to T_2 (D_3). In the absence of ligand, TR binds to target gene response elements (TREs) as either a homodimer (not shown) or heterodimer with the retinoid X receptor (RXR). Basal gene transcription is inhibited by recruitment of a corepressor complex (CoR). The deacetylation of core histones in chromatin reduces access to general transcription factors resulting in transcriptional repression. Following addition of T_3, TR homodimers dissociate, whereas the heterodimer-DNA complex is stable. The corepressor complex is released, enabling recruitment of coactivator proteins (CoA). The intrinsic histone acetylase activity of the latter results in remodelling of chromatin leading to transcriptional activation.

Pelizaeus–Merzbacher disease) [4]. Although linear growth is preserved, body weight is usually extremely low in AHDS patients despite gastrostomy feeding to overcome swallowing difficulties; proximal muscle wasting is an added contributory factor [5–8]. Somatic features include elongated myopathic facies and a tented upper lip due to hypotonia. Some patients exhibit a milder neurological phenotype, walking with ataxic gait and being capable of dysarthric speech [9, 10].

AHDS patients exhibit reduced circulating free T_4, raised free T_3, normal or mildly elevated TSH, and subnormal reverse T_3 levels; consequently, circulating T_3/rT_3 ratios are raised. Serum levels of sex hormone-binding globulin (SHBG), a hepatic marker of thyroid action, are markedly elevated; in addition, ammonemia and raised lactic acid levels, signifying a catabolic state, has been documented [8, 11]. These biochemical features support the notion of a relative hyperthyroid state in peripheral tissues of MCT8-deficient patients.

Molecular Genetics and Pathogenesis

Consistent with the male-limited nature of the disorder, AHDS is due to defects in the monocarboxylate transporter 8 (*MCT8, SLC16A2*) gene located on chromosome Xq13.2 [12, 13]. Over 70 different *MCT8* mutations (deletions, frameshift/premature stop, missense) have been identified in ~100 families from diverse ethnic backgrounds, with complete penetrance in males and occurring *de novo* in ~25% of cases. When expressed in cells the majority of MCT8 mutants exhibit complete loss-of-function, with failure of TH transport; however, some missense mutants show residual transport capacity, which may correlate with a milder clinical phenotype in patients [10, 14]. Female carriers are fertile with normal neurocognitive and thyroid function, but in rare cases it is possible that skewed X-inactivation leading to MCT8 deficiency could mediate a phenotype.

MCT8 is expressed in many tissues, including brain, liver, kidney, heart, thyroid and placenta; in murine brain MCT8 is found predominantly in neurons and coexpressed with DIO_3 which catabolizes T_3, whereas DIO_2 mediating T_4 to T_3 conversion is largely expressed in adjacent astrocytes and glial cells; accordingly, one theory is that MCT8-mediated neuronal uptake of T_3, generated by surrounding, DIO_2-containing, astrocytes, maintains euthyroid status of the CNS [5]. Alternatively, a study using patient-derived stem cells has suggested that the key defect is loss of MCT8-mediated T3 transport across the endothelial blood-brain barrier [15].

Management

General supportive measures include use of braces or baclofen to prevent joint contractures; gastrostomy feeding to prevent aspiration and catabolic weight loss; counteracting dystonia with anticholinergic agents or L-DOPA; reducing hypersalivation with glycopyrrolate or scopolamine; and anticonvulsants to treat seizure activity.

Specific treatment approaches include normalization of TH levels with a 'block and replace' combination of propylthiouracil and T4. Treatment of older AHDS patients has targeted increased body weight and reduced heart rate [10].

An alternative approach involves administration of a thyroid hormone analogue whose CNS uptake is MCT8-independent. Diiodothyropropionic acid (DITPA) has been used in four, younger, AHDS patients, with normalization of circulating TH levels, weight gain, and reduction in heart rate [16]. 3,5,3'-triiodothyroacetic acid (TRIAC), another TH analogue, has been trialled in AHDS patients (ClinicalTrials.gov NCT02060474), with preliminary results showing normalization of fT_3 levels and alleviation of peripheral hyperthyroidism [17].

Selenoprotein Deficiency–A Disorder of Thyroid Hormone Metabolism

Selenium, a trace element that is essential for human health, is incorporated as selenocysteine (Sec) into 25 different human proteins, including the deiodinase enzymes. A complex molecular mechanism mediates Sec incorporation into proteins during their biosynthesis (Figure 3.4.5.2); consequently, genetic defects in this pathway result in a multisystem disorder due to deficiency of diverse selenoproteins, with lack of deiodinase activities mediating abnormal thyroid function.

Clinical Features

Many cases have presented in childhood due to growth retardation with raised circulating fT_4, normal to low fT_3, and raised reverse T_3 levels, reflecting deficiency of all three deiodinase enzymes [13, 18].

Muscle weakness due to progressive rigid spine muscular dystrophy, affecting axial and proximal limb muscles with raised creatine kinase (CK) levels and fatty infiltration on MRI scan, is attributable to deficiency of selenoprotein N which is enriched in skeletal muscle. Male azoospermic infertility reflects loss of specific selenoproteins (e.g. mitochondrial GPx4, thioredoxin-glutathione reductase, selenoprotein V) required for spermatogenesis [18].

Lack of antioxidant selenoenzymes results in cellular accumulation of hydrogen peroxide and reactive oxygen species (ROS), mediating with oxidative DNA damage and peroxidation of membrane lipids. Clinical consequences of raised cellular ROS include skin photosensitivity, sensorineural hearing loss which worsens with age and increased total body adipose tissue mass, but associated paradoxically with preserved or enhanced systemic insulin sensitivity [18]. We have documented significant, progressive dilatation of the ascending aorta due to cystic medial degeneration requiring cardiac surgery in older patients [19].

Additional age-dependent phenotypes such as neurodegeneration, premature ageing or neoplasia may emerge, but have not been described hitherto.

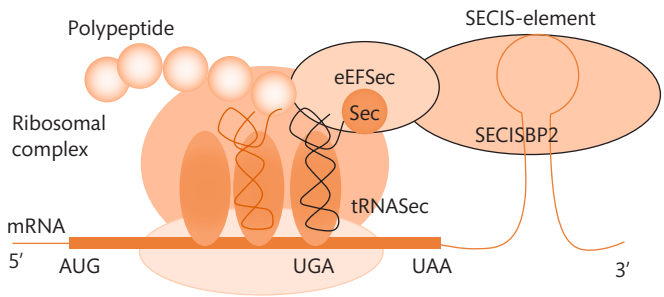

Figure 3.4.5.2 Mechanism of selenoprotein biosynthesis. The 3′-untranslated region of selenoprotein mRNAs contains a stem-loop RNA structure (SECIS element) which interacts with a protein complex that includes SECIS binding protein 2 (SECISBP2) and Sec-specific elongation factor (eEFSec), to enable ribosomal recruitment of selenocysteyl-transfer RNA (tRNASec) to the UGA codon and incorporation of selenocysteine (Sec) into the nascent polypeptide. Failure of this mechanism results in miscoding of the UGA as a stop codon, terminating protein synthesis.

Molecular Genetics

To date, 13 individuals from 11 families, with compound heterozygous or homozygous *SECISBP2* defects have been described; residual production of functional SBP2 protein likely preserves some selenoprotein synthesis and precludes the disorder being embryonic lethal, as occurs in *secisbp2* knockout mice [18, 20, 21]. As SBP2 is differentially rate-limiting for Sec incorporation into different proteins, a hierarchy of selenoprotein synthesis preserves production of essential, cellular housekeeping selenoproteins (e.g. thioredoxin reductases) at the expense of other factors (e.g. deiodinases) that are dispensable for survival.

In one patient, a homozygous mutation in *TRU-TCA1-1*, affecting synthesis and posttranscriptional modification of selenocysteine transfer ribonucleic acid (RNA), has been described [22].

Mutations in *SEPSECS*, an enzyme mediating synthesis of tRNAsec, are associated with cerebrocerebellar atrophy and a profound neurological phenotype due to disruption of selenoprotein synthesis in the CNS, but are not associated with a thyroid biochemical phenotype [21].

Management

Oral selenium supplementation raises circulating selenium levels but with no effect on circulating selenoprotein or TH levels [23]. T_3 treatment can improve growth in childhood [18]; antioxidant (vitamin E) administration reduces cellular lipid peroxidation but other clinical effects have not been determined [24].

Resistance to Thyroid Hormone Beta

Resistance to thyroid hormone action in the hypothalamic–pituitary–thyroid axis is the hallmark of RTHβ, with inappropriate pituitary TSH secretion driving T_4 and T_3 production, to establish a new equilibrium with high circulating TH, together with non-suppressed TSH levels. RTHβ was first described in 1967 in two siblings with high circulating TH levels who were clinically euthyroid and exhibited other features (deaf-mutism, stippled femoral epiphyses, winging of scapulae, pectus carinatum, short stature, and dysmorphic facies) which are unique to this kindred, in which the disorder was recessively inherited [25, 26].

The prevalence of RTHβ is approximately 1 in 40 000 and several hundred cases (from more than 250 families) have been described [27]. The disorder is usually dominantly inherited and associated with variable clinical features. Many patients are either asymptomatic or have non-specific symptoms and a goitre, prompting testing of thyroid function, which suggests the diagnosis. In such individuals, classified as exhibiting generalized resistance (GRTH), the high thyroid hormone levels are thought to compensate for ubiquitous

tissue resistance, resulting in a euthyroid state. In contrast, a subset of individuals with the same TH abnormalities exhibit thyrotoxic clinical features: in adults these can include weight loss, tremor, palpitations, insomnia, and heat intolerance; in children failure to thrive, accelerated growth, and hyperkinetic behaviour have also been noted. When the latter clinical entity was first described, patients were thought to have 'selective' or predominant pituitary resistance to thyroid hormone action (PRTH), with preservation of normal responses to TH in peripheral tissues [28].

However, comparison of characteristics of individuals classified as GRTH or PRTH indicates significant overlap between these entities, with no differences in age, sex ratio, frequency of goitre, or levels of free T_4, free T_3, or TSH between patients with the two types of RTHβ. Significantly, features such as tachycardia, hyperkinetic behaviour, and anxiety have been documented in individuals with GRTH. Conversely, serum SHBG—a hepatic marker of thyroid hormone action—is normal in patients with PRTH, suggesting that tissue resistance is not solely confined to the pituitary–thyroid axis in this group [29]. Indeed, in some RTHβ cases, hypothyroid features such as growth retardation, delayed dentition, or bone age in childhood or hypercholesterolaemia in adults, may coexist with thyrotoxic symptoms in the same individual. Nevertheless, the absence or presence of overt thyrotoxic symptoms, signifying either GRTH or PRTH phenotypes, respectively, is a clinical distinction which remains useful in guiding management of the disorder [27].

Clinical Features

Goitre

Palpable goitre is present in up to 65% of individuals—especially adult women. Fewer children with RTHβ born to affected mothers exhibit thyroid enlargement (35%) compared to offspring born of unaffected mothers (87%), suggesting that maternal hyperthyroxinaemia may protect against goitre formation [30]. Increased biological activity of circulating TSH may account for goitre and marked hyperthyroxinaemia in some RTHβ patients with normal immunoreactive TSH levels [31]. A multinodular thyroid gland can develop, particularly following previous goitre surgery, but thyroid cancer is rare and most likely represents coincidental micropapillary carcinoma [32].

Cardiovascular System

In a large cohort of children and adults with RTHβ, resting heart rate was significantly raised with some indices of cardiac systolic and diastolic function (e.g. stroke volume, cardiac output), suggesting a 'partially hyperthyroid' cardiac phenotype. Atrial fibrillation is commoner in older RTHβ patients [33], but they do not exhibit the hypercoagulable state associated with conventional hyperthyroidism.

Skeletal Abnormalities

Childhood short stature (height <5th centile) has been noted in 18% and delayed bone age (more than two standard deviations) in 29% in RTHβ, but final adult height is not usually affected [30, 34]. In adults, we have measured bone mineral density in approximately 80 subjects with RTHβ and documented a reduction at both femoral neck (mean Z score –0.71) and lumbar spine (mean Z score –0.73), but with normal bone turnover markers (Gurnell, Chatterjee and Beck-Peccoz, unpublished observations).

Metabolic

Resting energy expenditure (REE) is substantially increased in adults and children with RTHβ, due to mitochondrial uncoupling in skeletal muscle [35]. Increased energy expenditure is accompanied by hunger, reduced satiety, and raised energy intake, with hyperphagia being particularly evident in childhood [35].

Central Nervous System

A history of attention-deficit hyperactivity disorder (ADHD) in childhood was more frequent (75%) in RTHβ patients compared to their unaffected relatives (15%) [36], but screening for RTHβ in ADHD cohorts is negative. Children and adults with RTHβ exhibit problems with language development, manifested by poor reading skills and problems with articulation [37]. Frank intellectual disability (IQ less than 60) is quite uncommon but 30% of patients show mild learning disability (IQ less than 85) [30].

Hearing and Vision

Significant hearing loss has been documented in 21% of RTHβ cases [38]: in most, audiometry indicated a conductive defect, probably related to an increased recurrent ear infections in childhood; abnormal otoacoustic emissions, suggestive of cochlear dysfunction, were also documented in those with hearing deficit [38]. Defective colour vision has been documented in homozygous RTHβ [25]; abnormal photoreceptor electroretinography in heterozygous RTHβ [39] is not associated with overt colour visual dysfunction.

Other Associated Disorders

RTHβ cases with coexistent autoimmune hypothyroidism or Graves' disease have been recorded and the increased prevalence of thyroid autoantibodies found in a large RTHβ cohort suggests possible predisposition to thyroid autoimmunity [40]. Inappropriate thyroid ablation in RTHβ results in pituitary thyrotrope hyperplasia [41], and a small number of RTHβ cases with coexisting pituitary adenomas have also been described. Recurrent otitis media and upper respiratory tract infections are more frequent in RTHβ (30). A higher miscarriage rate and neonatal growth retardation has been documented in unaffected offspring of mothers with RTHβ, suggesting that intrauterine exposure to elevated TH could be detrimental [42].

Differential Diagnosis

Concordance of elevated free thyroid hormone levels when measured in different immunoassays or by equilibrium dialysis makes artefactual hyperthyroxinaemia due to assay interference from familial dysalbuminaemic hyperthyroxinaemia (FDH) or anti-iodothyronine antibodies less likely. Likewise, linear fall in TSH levels following serial dilution of serum or its adequate recovery following polyethylene glycol (PEG) precipitation can exclude interference with TSH measurement. Other causes of hyperthyroxinaemia (neonatal period, systemic illness, drugs) are excluded by recognition of the abnormal clinical context or documenting subsequent normalization of thyroid function following recovery or drug withdrawal [43].

The main differential diagnosis of RTHβ is from a TSH-secreting pituitary tumour (TSHoma), but many factors can make this

distinction difficult. There are no differences in age, gender, fT_4, fT_3, or TSH levels between the two disorders. MRI scan may show an obvious macroadenoma but fail to visualize small microadenomas; the recognized occurrence of pituitary 'incidentalomas' in RTHβ can confound diagnosis. Circulating pituitary α-subunit levels can be normal in micro TSHomas; serum SHBG levels are elevated in TSHoma but can be normal with tumours cosecreting growth hormone. Abnormal thyroid function tests (TFTs) in first-degree relatives are highly suggestive of RTHβ but are also a feature of FDH which is dominantly inherited; conversely, normal TFTs in family members does not exclude RTHβ as the disorder does occur sporadically [43]. With most TSHomas, administration of long-acting somatostatin analogue normalizes TH levels whereas fT_4 and fT_3 levels remain unchanged in RTHβ cases [44]; inhibition of tracer uptake with functional pituitary imaging following somatostatin analogue administration can be invaluable in diagnosis of TSHoma [45].

Molecular Genetics

Following cloning of TRs, RTHβ was shown to be tightly linked to the *THRB* locus. In keeping with the dominant inheritance of RTHβ, affected individuals are heterozygous for *THRB* mutations, which occur *de novo* in approximately 10% of sporadic cases. Over 150 different defects (missense, frameshift/premature stop, in-frame deletions) have been recorded, localizing to three mutation clusters within the hormone-binding domain of the receptor [27] (Figure 3.4.5.3).

THRB mutations have been identified in both GRTH and PRTH, indicating that these clinical entities represent different phenotypic manifestations of a single genetic disorder. Nevertheless, certain TRβ mutations (e.g. R338W/L, R383C/H, R429Q) may be particularly associated with a PRTH phenotype [27].

Nine cases of homozygous or hemizygous RTHβ have been described, associated with a severe clinical phenotype encompassing marked elevation of TH levels, dysmorphic features, audiovisual abnormalities with a propensity to developing life-threatening cardiac failure [46, 47].

In ~10% of cases, biochemical evidence of RTHβ is not associated with a *THRB* defect—so-called non-TRβ RTH. Possible explanations include somatic mosaicism with occurrence of TRβ mutations whose expression is restricted so as to be undetectable in peripheral blood leucocyte DNA [48] or non-receptor mechanisms (e.g. cofactor gene defects) whereby thyroid hormone action is disrupted to produce the RTHβ phenotype [27].

Properties of Mutant Receptors

In keeping with their location in the hormone-binding domain, the ability of TRβ mutants to bind T_3 and recruit coactivator is reduced, impairing their ability to regulate target gene transcription.

In the first documented family with RTHβ, both affected siblings were homozygous for complete deletion of *THRB*. Significantly, their heterozygous parents, with deletion of one *THRB* allele, were completely normal with no evidence of thyroid dysfunction [27]. Thus, TRβ haploinsufficiency is insufficient to mediate RTH; furthermore, TRβ mutants in heterozygous RTHβ are not simply functionally impaired but also capable of inhibiting the action of their wild-type counterparts in a 'dominant negative' manner [49] (Figure 3.4.5.4).

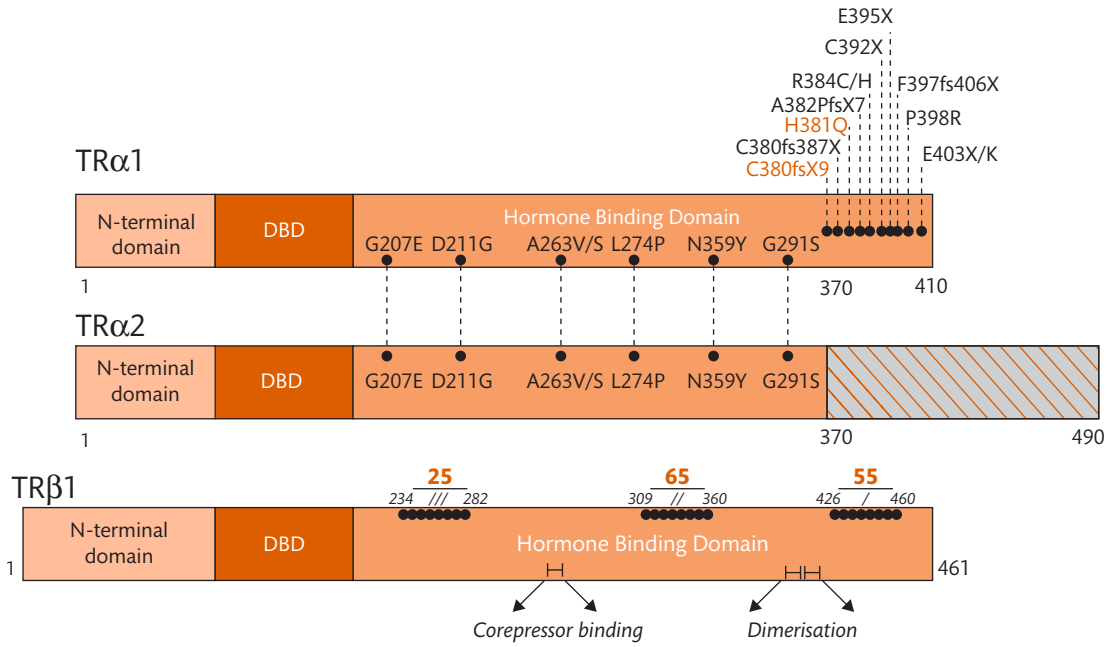

Figure 3.4.5.3 Schematic alignment of TRα1, TRα2 and TRβ1 showing functional regions (N-terminal, DNA-binding domain (DBD), hormone-binding domains); the divergent carboxyterminus of TRα2 is cross-hatched. The location of published (black) and unpublished (orange) RTHα mutations, involving either TRα1 alone or both TRα1 and α2 proteins, is superimposed. Three regions (aminoacids 234 to 282, 309 to 360 and 426 to 460) of TRβ1 within which RTHβ mutations cluster are depicted. The number of different mutations described hitherto within each cluster (orange) is superimposed. No RTHβ mutations have been recorded in regions of the hormone-binding domain that are important for corepressor binding or dimerization with RXR.

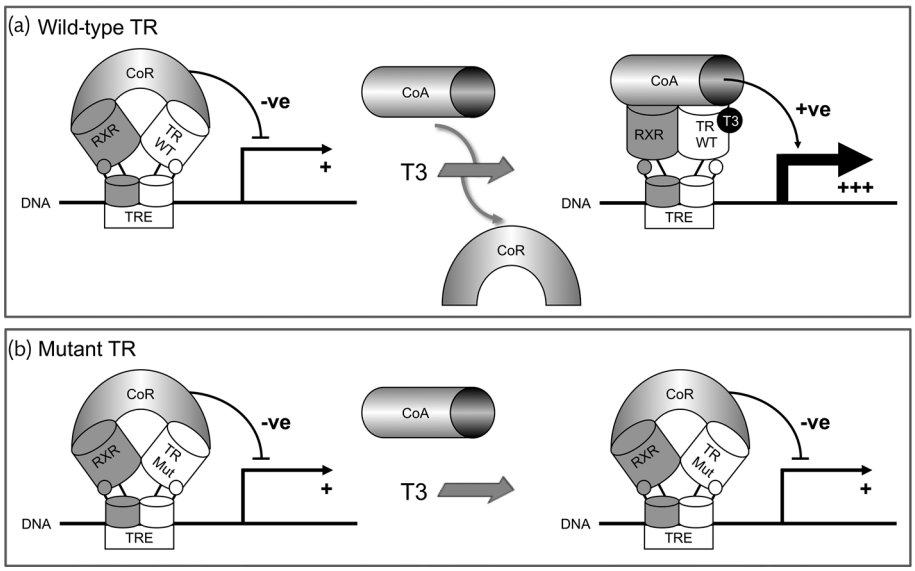

Figure 3.4.5.4 Possible mechanism for dominant negative inhibition by TRβ or TRα mutants. The upper panel (a) depicts wild-type (WT) TR action on target genes. The unliganded RXR-TR heterodimer recruits a corepressor complex (CoR) to silence basal gene transcription. Receptor occupancy by ligand (T_3), promotes corepressor dissociation followed by binding of a coactivator complex (CoA) which leads to target gene activation. The lower panel (b) shows mutant receptor action. In comparison to wild-type TR, the primary defect in mutant receptors is impaired hormone-dependent corepressor release or coactivator recruitment. For most receptor mutants, this functional alteration is a consequence of reduced hormone binding. However, a subset exhibits intrinsic enhanced binding to corepressor or impaired recruitment of coactivator, with preserved hormone binding. Constitutive occupancy of thyroid response elements (TREs) by mutant receptor-corepressor complexes results in inhibition of target gene expression.

Pathogenesis of Variable Tissue Resistance

The ability to exert a dominant negative effect within the hypothalamic–pituitary–thyroid axis is a key property of mutant receptors in RTHβ, generating abnormal TFTs that are the hallmark of the disorder. For some RTHβ mutants, their functional impairment *in vitro* correlates with the degree of axis resistance *in vivo*, quantified by the magnitude of elevation in circulating free T_4 levels.

Variable tissue resistance is partly mediated by differing tissue distributions of TR subtypes. Thus, TRβ-expressing tissues (hypothalamus, pituitary, liver) exhibit hormone resistance, exemplified by non-suppressed TSH and normal SHBG levels in patients; conversely, cardiac hyperthyroidism and raised metabolic rate seen in RTHβ represent features of sensitivity of TRα-expressing myocardium and skeletal muscle to elevated TH. Differences in relative expression of wild-type versus mutant TRβ in tissues or variable dominant negative inhibitory potency of TRβ mutants in different target gene contexts are further variables which may influence the degree of hormone resistance [27].

Management

The management of RTHβ is complex, as variable resistance makes it difficult to maintain euthyroidism in all tissues. In most individuals, the receptor defect is compensated by high circulating thyroid hormone levels, leading to a clinically euthyroid state. Inappropriate thyroid ablation with surgery or radioiodine is commonly unsuccessful, with recrudescence of goitre and disruption of the pituitary–thyroid axis, rendering the RTHβ patient hypothyroid unless levothyroxine (L-T_4) is administered in supraphysiologic dosage.

Conversely, reduction in thyroid hormone levels may be of benefit in the management of patients with thyrotoxic symptoms. However, conventional antithyroid drug administration results in marked elevation of TSH levels with consequent further thyroid enlargement and pituitary thyrotrope hyperplasia, with a risk of autonomous tumour formation. 3,5,3'-triiodothyroacetic acid (TRIAC), a TH analogue which acts centrally to inhibit TSH secretion thereby reducing thyroid hormone levels, yet is devoid of peripheral thyromimetic activity, has been shown to be beneficial in both childhood and adult cases [50]. A daily dose of 1.4–4.5 mg is used, with one study suggesting that twice-daily administration inhibits TSH secretion more effectively [51]. Given spontaneous variation in thyrotoxic symptoms in RTHβ, periodic cessation of TRIAC therapy and re-evaluation of the clinical status of the patient is advisable. The use of TRIAC in one pregnancy controlled maternal thyrotoxic symptoms but may have induced fetal goitre [52]. Use of antithyroid drugs in combination with TRIAC may be of value in homozygous RTHβ associated with cardiac hyperthyroidism [47]. Thyroid ablation followed by thyroxine replacement in subphysiological dosage could also be used in RTHβ associated with life-threatening, thyrotoxic cardiac failure.

TRIAC treatment is not always successful and dextro-thyroxine (D-T4) is another agent which has been shown to be effective in some cases [53]. Bromocriptine or octreotide have been used in RTHβ but, unlike TSHomas, pituitary TSH secretion escapes from their inhibitory effects [54, 55].

The treatment of RTHβ with thyrotoxic manifestations (for example, failure to thrive) in childhood also requires careful monitoring to ensure that any reduction in thyroid hormone levels is not associated with growth retardation or adverse neurological sequelae. Indeed, control of cardiac and peripheral sympathetic overactivity with β-blockade may be the safest course in this context. One study showed that L-T3 therapy improved hyperactivity in nine children with ADHD, including three individuals who were unresponsive to methylphenidate [56].

Dyslipidaemia should be managed with statin therapy if associated cardiac risk factors suggest benefit; in future, TRβ-selective thyromimetics may prove a more targeted therapeutic option [57]. If reduced bone mineral density is identified, usual lifestyle measures (weight bearing exercise, calcium and vitamin D supplementation) can be advised. Whether bisphosphonate therapy is beneficial in RTHβ remains unknown.

During pregnancy, normal fetal growth and heart rate in the third trimester may provide reassurance that significant fetal thyrotoxicosis is not present. In women with RTHβ and a history of recurrent miscarriage, antithyroid drug treatment in early pregnancy could be considered [58].

Resistance to Thyroid Hormone Alpha

TRβ and TRα proteins are highly homologous, with 80% aminoacid identity within their hormone-binding domains favouring the existence of individuals with resistance to thyroid hormone due to defective TRα (RTHα). Indeed, transgenic mice harbouring mutant TRα are viable and exhibit recognizable phenotypes but associated with normal TH levels [59], likely accounting for delayed identification of the first human RTHα case in 2012 [60].

Clinical Features

Interestingly, some features of congenital hypothyroidism, such as umbilical hernia, macroglossia, poor feeding and hoarse cry, are reported in RTHα patients at birth [61, 62]. The majority of patients exhibit delayed growth, which can be predominantly lower segmental; many have macrocephaly and facial dysmorphic features including broad facies, hypertelorism, a flattened nasal bridge, enlarged tongue, thick lips [63, 64]. Older children and adults have an excessive number of skin tags and moles [60–62].

Neurocognitive

Developmental milestones (motor, speech) in childhood are almost uniformly delayed. Dyspraxia, slow and dysarthric speech, and ataxic gait are also common. IQ is variably reduced, being markedly subnormal in a few cases, but with other patients achieving third level qualifications [64–66]. Autism spectrum disorder is associated with one case [67]. In severe RTHα cases, MRI has documented cortical microencephaly, reduced cerebellar volume and white matter tract density [65].

Gastrointestinal

Constipation is common and variable, but was sufficiently severe in one case to warrant consideration of surgical intervention prior to diagnosis of RTHα [60].

Cardiovascular

Many patients are bradycardic with some indices of cardiac function being within the hypothyroid range [61].

Metabolic and Endocrine

Resting energy expenditure is reduced, likely reflecting relative hypothyroidism of skeletal muscle and myocardium [60–62, 66]. No reproductive abnormalities have been identified to date, with both maternal and paternal transmission of the disorder being documented [62, 64, 68].

Biochemical Features

TFTs are marginally deranged, with the most consistent abnormality being low or low-normal free T_4 with high or high-normal T_3, resulting in a low T_4/T_3 ratio. Reverse T_3 levels are subnormal in some cases [63]. Mild anaemia and raised muscle CK levels are observed frequently [60–62, 64, 66, 69]. Dyslipidaemia has been recorded in both children and adults [61, 69].

Skeletal

Radiographic features in childhood include delayed fusion of fontanelles and excessively serpiginous (Wormian bone) skull sutures, femoral epiphyseal dysgenesis, delayed dentition, and bone maturation [60, 64, 70]. In adulthood, features include a thickened skull vault, cortical hyperostosis, and increased bone mineral density [60, 68].

Differential Diagnosis

RTHα should be considered in any child with growth retardation or delayed development; the presence of features such as macrocephaly, constipation, anaemia, skeletal dysplasia, or raised muscle CK levels further raises suspicion, reducing the threshold for genetic testing. Low free T_4 and high free T_3 levels are also features of MCT8 deficiency or dyshormonogenetic hypothyroidism (due to iodine deficiency and/or a genetic cause), but these conditions can be distinguished clinically from RTHα (Table 3.4.5.1).

Molecular Genetics

Nineteen different heterozygous *THRA* mutations (frameshift/premature stop, missense) inherited from either parent or occurring *de novo* have been recorded in 30 cases (Figure 3.4.5.3). Frameshift/premature stop TRα1 mutants exhibit either markedly reduced hormone binding and impaired regulation of target genes [60, 61, 68] and are associated with a severe clinical phenotype [60, 61, 69]. Analogous to TRβ mutants in RTHβ, TRα1 mutants inhibit the function of their wild-type receptor counterparts in a dominant negative manner [60, 68, 69], via a mechanism involving constitutive mutant TRα1-corepressor interaction, with failure of normal dissociation of CoR from TRs in the presence of thyroid hormone [60, 61] (Figure 3.4.5.3).

Several RTHα cases involve *THRA* mutations which affect both TRα1 and TRα2 subtypes [62, 66, 70–72] (Figure 3.4.5.3). When studied in the TRα2 subtype background, these mutations exert no gain or loss-of-function, which correlates with absence of any discernible additional clinical phenotype attributable to mutant TRα2, in these patients [62, 66, 70, 71]. In a single case, unusual phenotypic

Table 3.4.5.1 Comparison of biochemical and clinical features in syndromes of resistance to thyroid hormone

Disorder	Resistance to thyroid hormone beta (RTHβ)	Resistance to thyroid hormone alpha (RTHα)	Allan-Herndon-Dudley syndrome	Selenoprotein deficiency*
Gene (S)	*THRB*	*THRA*	*MCT8*	*SBP2; TRU-TCA 1-1*
Free T4	Raised	Low-normal or Low	Normal or low	Raised
Free T3	Raised	High-normal or High	Raised	Normal or Low
TSH	Normal (or raised)	Normal (or raised)	Normal (or raised)	Normal (or raised)
Reverse T3	Raised	Low	Low	Raised
Clinical Features	Goitre, hyperthyroid symptoms	Neurodevelopmental retardation, skeletal dysplasia, constipation	Severe mental and psychomotor retardation	Growth retardation, muscular dystrophy, hearing loss, male infertility, aortic dilatation

* Low plasma selenium levels are also characteristic of these disorders.

features (micrognathia, clavicular agenesis, syndactyly of digits, chronic diarrhoea) may not be related to the *THRA* defect [73].

The clinical phenotype in patients with missense TRα1 mutations is variable and likely correlates with the severity of the underlying receptor defect. Thus, a mild phenotype (mild developmental and pubertal delay, subtle facial abnormalities, normal stature, normal schooling) and favourable response to thyroxine therapy was recorded in a patient with a missense TRα1 mutation (A263V) exhibiting partial, T3-reversible, loss-of-function *in vitro*; in contrast, a severe phenotype (marked developmental and growth retardation, dysmorphic facial features, special schooling), refractory to thyroxine therapy, was seen in another patient harbouring a missense TRα1 mutation (L274P) with severe, virtually irreversible, dysfunction *in vitro* [66] with similar correlations of phenotype with genotype-phenotype being reported in other cases [70].

Given the prevalence (~1 in 40 000) of RTHβ due to over 150 different *THRB* mutations and marked homology of TRα and TRβ subtypes (with equivalent receptor defects being recorded in RTHα and RTHβ), it is highly likely that RTHα is more common than currently ascertained. Such underdiagnosis may reflect lack of a clear-cut, diagnostic biochemical signature, or a variable phenotype in this disorder.

Pathogenesis

Skeletal abnormalities (delayed fontanelle closure and dentition, femoral epiphyseal dysgenesis, Wormian skull sutures) and dysmorphic features (coarse facies, macroglossia, flattened nasal bridge) in RTHα are recognized features of untreated congenital or childhood hypothyroidism. Likewise, constipation due to reduced colonic motility is a recognized symptom of hypothyroidism and can be complicated by colonic dilatation or ileus [63].

Thyroid hormone abnormalities in RTHα are attributable to altered TH metabolism, rather than biosynthesis: increased hepatic DIO1 expression (seen in transgenic mice harbouring mutant TRα1), likely mediates enhanced T_4 to T_3 conversion, resulting in elevated free T_3 and low free T_4 levels; diminished DIO3 activity (a TRα1-regulated deiodinase) may contribute to reduced conversion of T_4 to rT_3 and also predispose patients to developing skin tags, as inhibition of this enzyme enhances keratinocyte proliferation in mice [63]. TRα mutations affect the balance between proliferation and differentiation of erythroid progenitor cells *in vitro*, possibly accounting for the mild anaemia seen in RTHα patients [74]. Idiopathic epilepsy seen in RTHα cases [61, 62] may not be coincidental; increased susceptibility to seizures following photic or audiogenic stimulation and aberrant GABAergic inhibitory interneuron development have been recorded in TRα mutant mice [63].

Treatment

Thyroxine therapy of RTHα is beneficial, improving growth, well-being, basal metabolic rate, and lowering elevated low-density lipoprotein (LDL) cholesterol and CK levels [60–62, 66, 69, 71, 72]; in turn, these metabolic changes may limit excessive weight gain in patients. In the childhood patient first described [60], 7 years of thyroxine therapy have been clearly beneficial, improving lower segment length and total height, alleviating constipation (with improved colonic contractile activity), and enhancing well-being (Moran & Chatterjee, unpublished observations). Addition of growth hormone to thyroxine therapy in childhood does not result in further improvement in growth [69]. Commencement of thyroxine in early childhood may have ameliorated the phenotype in cases harbouring mutant TRα1 whose dysfunction is reversible at higher TH levels [62]. In adult life, these individuals report that thyroxine therapy improves dyspraxia, constipation and enhances social interaction (Moran & Chatterjee, unpublished observations). In virtually all cases thyroxine treatment does not improve anaemia.

Following thyroxine therapy TSH levels fall quickly and remain suppressed, with elevation of fT_3 to supraphysiologic levels; serum SHBG rises further from high-normal baseline levels [60, 72] and in one case, biochemical markers of bone turnover became progressively elevated [61]; conversely, cardiac parameters, REE and muscle CK levels are less responsive to thyroxine treatment [61, 62]. These observations suggest preserved sensitivity and possible propensity to TH toxicity of TRβ-containing tissues (e.g. liver) but relative thyroid hormone resistance in TRα1-expressing organs (e.g. heart, skeletal muscle). Accordingly, ideal future therapies would selectively activate mutant or residual normal TRα1 function to overcome resistance in TRα-expressing tissues.

With current circulating abnormal parameters in RTHα being non-specific and insensitive, future identification of RTHα-specific biomarkers would be invaluable: better diagnosis of the disorder with earlier commencement of thyroxine therapy may improve outcome; specific biomarkers may also guide treatment, correlating with overcoming hormone resistance in TRα-expressing tissues and helping avoid TH toxicity in TRβ-containing organs.

3.4.6 Treatment of Hypothyroidism

Birte Nygaard

Indications of Initiating Therapy

Hypothyroidism can be divided into clinical/overt hypothyroidism and subclinical/mild hypothyroidism (SCH) [1] (see Chapter 3.4.4.)

Overt hypothyroidism is defined as having increased serum thyroid-stimulating hormone (TSH) combined with serum-free thyroxine (fT_4) less than lower reference value. Serum TSH of more than 10 mU/L will, in most patients, represent overt hypothyroidism.

Biochemical Measurements

Measurement of serum fT_4 and not just serum TSH is necessary to discriminate between SCH and overt hypothyroidism due to individual TSH setpoints [2], and repeated measurement must be applied, as a single slight increased serum TSH could represent transient fluctuation in serum TSH [3].

Initiating Therapy

L-T_4 is available in most countries as tablets of 25, 50, and 100 μg. It has a half-life of 7 days, and should be given as a single daily dose.

Practice varies slightly from centre to centre and between countries. A dose of L-T_4 app 1.6 μg/kg/day is recommended as a final dose. Some centres recommend in younger to middle-aged patients with no history of cardiac disease to start directly on this dose while other centres recommend a stepwise increase (i.e. 50 μg, increased to 100 μg, and then to 125–150 μg at intervals of 2–3 weeks). After approximately 3 months of therapy, minor adjustment can be made to stabilize the serum concentrations of TSH within reference values.

In older patients and patients with a known cardiovascular disease a stepwise increase is recommended to avoid a sudden increase in metabolic rate in a patient with long-standing severe hypothyroidism which may unmask previously unrecognized ischaemic heart disease risking angina, myocardial infarction, dysrhythmia, or even sudden death. In these patients, the recommendations are to begin with 25 μg of L-T_4 daily with increments of 25 μg daily every 3–4 weeks.

Patients begin to feel better within weeks of L-T_4 treatment with a minor reduction in body weight, rarely more than 10% caused by fluid loss, whereas maximal improvement can't be evaluated before the thyroid parameters have been stable for several months.

Not Reaching the Treatment Goal

Most hypothyroid patients treated according to the aforementioned guidelines feel they return to normal health without complaints. However, persistent symptoms such as tiredness, depression, lack of energy, decreased cognitive function, weight increase, and musculoskeletal symptoms are described in 25% of L-T_4 treated hypothyroid patients compared to 15–20% in controls without thyroid disease [4, 5].

At the same time, an increased risk of getting/having a diagnose of psychiatric disease *hazard ratio* (HR) 1.5 (95% confidence-interval (CI): 1.12–2.04) [6] and an increased need for a disability pension HR 2.24 (95% CI: 1.73–2.89) is described [7].

Several explanations for this have been suggested [8]: autoimmunity by itself; comorbidity (known as well as unknown); dysregulation /low compliance; non-specific symptoms—not related to thyroid disease; *and* a possible subgroup needing a supplement of T_3.

Ensuring Compliance

Once the correct dose of L-T_4 has been established, the tradition of good practice has been to evaluate the patient and measure serum

TSH concentrations annually. However, several studies have demonstrated [9, 10] that almost 50% of patients treated with long-term L-T_4 have serum TSH out of reference range and compliance to L-T_4 treatment seems to be a major determinant factor to reach the target TSH levels in hypothyroid patients [9]. A combination of both raised serum fT_4 and TSH concentrations is most likely due to overenthusiastic tablet-taking for a few days before a clinic visit by a patient who was previously taking L-T_4 sporadically.

If compliance is suspected to be the problem, a week dosage box is recommended, and the patients can be instructed to take a missing L-T_4 tablet, when the patients realize that it has been forgotten. If access to the pharmacy databases is possible, an evaluation of the number of tablets, bought by the patients, can give a reasonable overview of the exact taken dose.

It is recommended to take L-T_4 before breakfast on an empty stomach. However, L-T_4 can be taken at *any* time of day and in patients with variations in thyroid function parameters better compliance and by this more stable parameter can often be obtained by changing the schedule as mornings often are busy, especially for women having small children. Taken at bedtime, is associated with higher thyroid hormone concentrations and lower serum TSH concentrations compared to the same dose taken in the morning, probably due to greater gastrointestinal uptake of L-T_4 during the night [11].

Weekly administration of seven times the daily dose of L-T_4 may be of benefit in *very* poorly compliant patients [12, 13], but there is little or no experience of its efficacy and safety.

Other Reasons for Variation in Thyroid Parameters

Malabsorption due to coeliac disease, small intestinal bacterial overgrowth with Helicobacter pylori or other bacteria's can be the explanation for the need of unexpected high doses of L-T_4 [14].

Pseudo malabsorption due to drug and food interference could also be the reason for dysregulation (see Table 3.4.6.1). If feasible L-T_4 intake should be separated from potential interfering drugs if these induce changes in serum TSH. This can, however, lead to decreased compliance—therefore a simpler approach should be recommended as standard and there is no need to for taking L-T_4 separately from food in most patients.

Different Formulations of L-T4

There are numerous manufacturers of L-T_4 preparations and divergence in bioequivalence can be present. An overall recommendation is to prescribe the same preparation for each prescription refill in each patient. When changes from one brand to another are made, it is important to check the thyroid function parameters to ensure that the dose is correct [15].

Liquid L-T_4 and soft gel capsules have higher bioavailability than the tablet L-T_4 in in hypothyroid patients with gastric disorders, malabsorption, or drug interference [16].

Effect of Altering L-T4 Dose on Quality of Life (QoL)

It has been discussed whether small changes within the normal thyroid function reference range could optimize QoL. In a new randomized controlled trial (RCT) on 138 L-T_4 treated patients with stable serum TSH were randomized to have either lower, unchanged, or higher L-T_4 dose. The mean TSH levels were 1.85 ± 0.25, 3.93 ± 0.38, and 9.49 ± 0.80 mU/L (P <0.001), respectively, in the three arms. However, these changes did not affect QoL significantly [17].

Other Treatments of Hypothyroidism

Combinations of L-T_4 and L-T_3

It has been assumed that all the necessary T_3 could be derived from peripheral mono-deiodination of orally administered L-T_4. Nevertheless, data has pointed towards a possible need for supplementary T_3 to fully restore the balance between TSH, TRH, thyroid hormones, deiodinase, and metabolism. Data show a 15–20% lower serum fT_3/fT_4 ratio given a stabile serum TSH after thyroidectomy than before in a prospective study on 50 euthyroid patients before and after total thyroidectomy for a benign nodular goitre, or thyroid cancer [18], and when comparing thyroidectomized patients to euthyroid control having similar serum TSH [19] (see Figure 3.4.6.1).

In accordance with this a study in rats have demonstrated a downregulation of the deiodinase enzyme leading to a downregulation of serum T3 as a respond to higher levels of serum fT_4 [20].

In thyroidectomized rats it has been demonstrated, that it is only possible to restore normal concentrations of fT_3 in all tissues, when normal serum concentrations of fT_3, fT_4, and TSH are maintained, by giving a combination of L-T_4 as well as L-T_3, and not just L-T_4 [21]. Although the relative importance of thyroidal T_3 secretion versus extrathyroidal T_3 generation from T_4 is different in rats compared to humans with a molar ratio of T_4 to T_3 in thyroidal secretion in 5.7:1 in rats and 14:1 in humans [22] these findings could suggest that the treatment modality with L-T_4 alone might be inadequate.

This theory was supported in a small human study in 1999 showing that a combination of L-T_4 and L-T_3 induced significant improvements in mood and neuropsychological function, compared to giving a higher dose of L-T_4 alone [23]. Hereafter several

Table 3.4.6.1 Interaction between fT_4 and drugs

Decreased intestinal absorption of fT_4	Increased clearance	Increased binding to TBG	fT_4 changes effect of medicine
PPI Ferrous sulphate Calcium carbonate Cholestyramine Aluminium hydroxide Cimetidine Sucralfate Magnesium Zinc fibres Caffeine Iodine Selenium	Phenytoin Carbamazepine Phenobarbital Rifampicin Sertraline (exact mechanism is not clear)	Oestrogen	*Increased effect* Warfarin Amitriptyline *Decreased effect* Propranolol

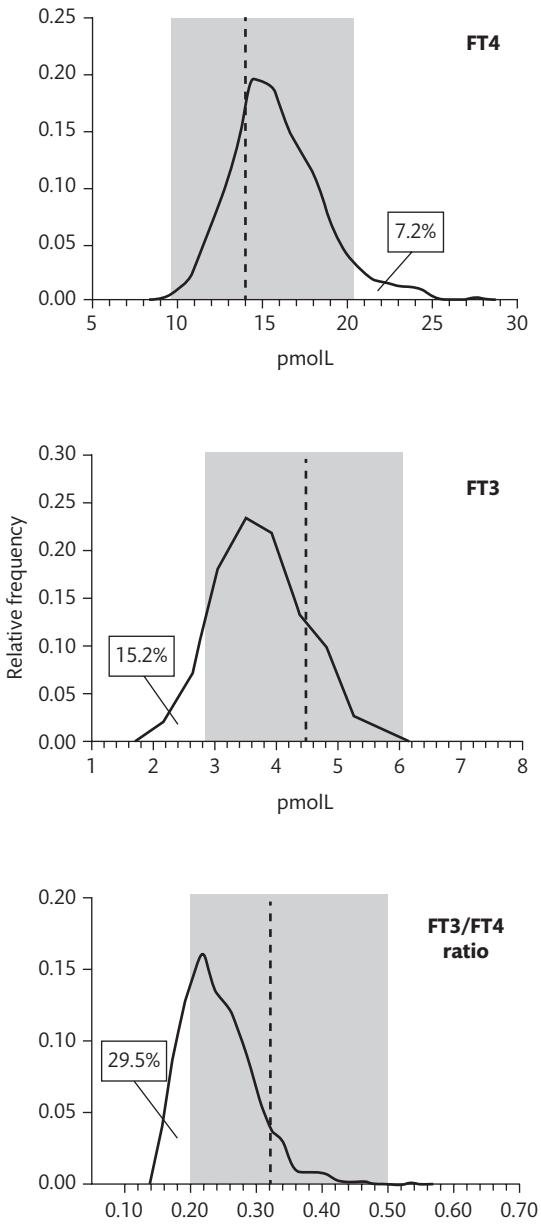

Figure 3.4.6.1 Free thyroid hormones and fT_3/ fT_4 ratio frequency distribution. fT_3 and fT_4 serum levels and fT_3/fT_4 ratio distribution in 1811 athyreotic patients under levothyroxine (L-T_4) monotherapy. Shaded areas indicate the normal range (2.5–97.5 percentiles) calculated in 3875 euthyroid controls. Vertical dotted lines indicate the median of the normal values. Percentages indicate the patients with values under or above the normal values.

Reproduced with permission from Gullo D, Latina A, Frasca F, Le Moli R, Pellegriti G, Vigneri R. Levothyroxine monotherapy cannot guarantee euthyroidism in all athyreotic patients. *PLoS One*. 2011;6(8):e22552. Copyright © 2011 Gullo D et al.

studies were initiated to confirm these results. A meta-analysis in 2006 of data from more than 1000 unselected patients from 11 trials could not confirm these results [24]. However, the included studies in the meta-analysis were heterogeneous, including unselected patients for example patients with SCH.

A minor study in a highly selected patient group with Hashimoto' disease and overt hypothyroidism (serum TSH>20 mU/L at the time of diagnosis) as well as persistent symptoms despite a stable L-T_4 dose and serum TSH with in normal range confirmed the original data with significant effects in 7 out of 11 quality of life scores and preference for L-T_3/L-T_4 combination therapy in 49% compared to L-T_4 monotherapy in 15% ($P = 0.002$) [25].

A calculation of patient preferences was published in the European Thyroid Association (ETA) guidelines from 2012. In 5 RCT crossover studies (228 patients), patients were asked which medication they preferred: 27% preferred L-T_4, 25% had no preference, and 48% preferred L-T_4/L-T_3 combination [8].

A possible decrease in bodyweight has been suggested at being the explanation for preference of combination therapy [26], however a new study on 23 patients shifted from L-T_4 monotherapy to L-T_4/L-T_3 combination therapy did not show any correlation between changes in bodyweight and changes in QoL [27].

A suggested explanation for a possible need for a T_3 substitution as well as T_4 has been related to a change in the feedback in the hypothalamic–pituitary–thyroid axis induced by high dose of T_4 and a possible relative inactivation of deiodinase 2 and hereby lower values of T_3. Based on this theory a suggestion of using serum T_3 as a simple maker of decreased QoL has been brought up [20, 28]. However clinical data on patients changes from L-T_4 monotherapy to L-T_4/L-T_3 combination therapy have not showed a correlation between changes in serum values of T_3 and increase in QoL [25, 27, 29].

Another possible suggested explanation is polymorphisms in the deiodinase 2 gene (D2–92 Ala) or to the cellular membrane transporter (MCT10) [30, 31] and by this a potential decrease in the transportation of thyroid hormone from plasma to the intracellular space and a decreased deiodination of T_4 to T_3. However, extended research is needed to explore the exact effect of these polymorphisms.

A request of L-T_4/L-T_3 combination therapy from patients with persistent symptoms is often brought forward with reference to patient's platforms on the social medias on the internet [32, 33].

It has been described that 5–10% of patients treated with hypothyroidism do have decreased QoL [4, 5], however, it is important to recognize that in these studies the same symptoms were present in app 15% of the controls. Therefore, it is pertinent to evaluate the specific symptoms in these patients and to discuss with the patient if any other explanations could be present; such as symptoms of menopause, stress, or depression, and to eliminate other specific disease that potentially could explain the symptoms.

The European Thyroid Association recommends in a guideline from 2012 **not** to use L-T_4/L-T_3 combination therapy as a standard treatment but suggest the following algorithm [8]:

- L-T_4 + L-T_3 combination therapy might be considered as an experimental approach in compliant L-T_4-treated hypothyroid patients who have persistent complaints despite serum TSH values within the reference range, provided they have previously given support to deal with the chronic nature of their disease and associated autoimmune diseases have been ruled out.
- T_4 + T_3 combination therapy is not recommended in pregnant women and in patients with cardiac arrhythmias.
- It is suggested that L-T_4 + L-T_3 combination therapy is discontinued if no improvement is experienced after 3 months. The L-T_4/L-T_3 ratio should be between 13:1 and 20:1 by weight (a suggestion for a calculation of the T_3 dose were made in the ETA guideline Table 3.4.6.2 [8]).

Table 3.4.6.2 A method for calculating L-T_4 and L-T_3 dosages for T_4 + T_3 combination therapy

T4 monotherapy = dose x #	Dose *x* = 100 µg L-T_4	Dose *x* = 150 µg L-T_4	Dose *x* = 200 µg L-T_4
T4 + T3 combination therapy			
L-T_3 dose *y* = *x*: 20	L-T_3 dose 5 µg	L-T_3 dose 7.5 µg	L-T_3 dose 10 µg
L-T_4 dose *z* = *x*–3y	L-T_4 dose 85 µg *	L-T_4 dose 127.5 µg *	L-T_4 dose 170 µg *
L-T_4: L-T_3 dose ratio	17: 1	17: 1	17: 1

Dose *x* = daily L-T4 dose that normalized serum TSH during T4 monotherapy; * dose could be round off to 87.5 µg, 125 µg and 175 µg, respectively, for convenience reasons (i.e. availability of L-T4 tablets of 25 µg but not of 10 µg).

Animal Thyroid Extracts

Extracts from animal thyroid glands were first used successfully in the treatment of hypothyroidism in 1892 and this was the only drug until the 1960s. The product had standardization problems and when the synthetic L-T_4 became available in the 1960s, as a more stable drug with the ability to normalize serum values of fT_4 as well as fT_3, this became the drug of choice. From time to time, thyroid extracts have enjoyed a renaissance as a 'more natural thyroid hormone product', usually among practitioners on the more 'alternative' part of medicine, and often used in a high dose inducing SCH to overt hyperthyroidism.

A single RCT is present comparing L-T_4 treatment to thyroid extract from pigs. A preference for thyroid extract was described in 49% vs. 19% in L-T_4, but no difference was found in symptom scores or neurocognitive function [34].

Risks Related to Thyroid Hormone Replacement Treatment

The potential risk when treating with thyroid hormones is overtreatment inducing overt or subclinical hyperthyroidism. Population studies have verified an association between suppressed serum TSH and the following:

- Atrial fibrillation, relative risk (RR): 1.16 (95% CI: 0.99–1.36) increasing with age to 1.41 (95% KI: 1.25–1.59) [35].
- Overall dead, RR 1.23 (95% KI: 1.16–1.30) [35].
- Osteoporosis with a hip fracture hazard ratio (HR) 1.16 (95% CI: 1.07–1.26) [36].
- Dementia, RR: 2–3 [37].

There are no studies comparing risks of suppressed serum TSH when treating with L-T_4 monotherapy, L-T_4+ L-T_3 combination therapy, animal thyroid extract, or when suppressed serum TSH are caused by Graves' disease or nodular goitre, but the effect must be expected to be a class effect of thyroid hormones and hereby a suppressed serum TSH is a potential risk whether it is caused by any thyroid hormone given or by endogenous produced thyroid hormone as in Graves' or nodular goitre.

Treatment During Pregnancy

Most patients require an increase of 30–50% daily in L-T_4 dosage within the first months of pregnancy. The principal reason for this change in L-T_4 requirement is the increase in the serum concentration of thyroxine-binding globulin in pregnancy, which results in decreased serum concentrations of fT_3 and fT_4. These decreases cannot be compensated for by increased thyroidal secretion due to lack of functioning thyroid tissue.

In hypothyroid pregnant—or patients planning to become pregnant a serum TSH <2.5 mU/L is recommended. As minor studies have described an increased risk of abortion and preterm delivery in patients with serum TSH is between 2.5 and 4 mU/L and presence of TPO-Ab treatment is also recommended in these patients [38].

Temporary Hypothyroidism

Most patients with primary hypothyroidism require lifelong L-T_4 therapy. However, hypothyroidism may be transient and even short-term treatment may be unnecessary.

Transient hypothyroidism is seen in the recovery phase of subacute (De Quervain's), painless, and postpartum thyroiditis, if excess iodine or iodine-containing drugs such as amiodarone or lithium have been applied; presence of TSH-receptor blocking antibodies; inhibition of synthesis or release of thyroid hormone by immune modulating therapy such as interferon and other cytokines; thyroiditis induces by tyrosine kinase inhibitors; blockage of receptors for vascular endothelial growth factor; and central hypothyroidism by anti-CTLA4 or anti-PD-1 antibody drugs [39].

Unnecessary Thyroid Hormone Therapy

Obesity often link to a question of a need of thyroid hormone. Weight loss after initiating L-T_4, in even severe hypothyroidism are modest, and weight reduction can only be obtained if supraphysiological doses of L-T_4 or L-T_3 are given [15].

Depression: Although a relationship between thyroid function at depression has been assumed for many years, the exact relationship is still poorly defined, and a historical suggested effect of thyroid hormone (primarily T_3) in euthyroid depressed patients are not recommended due to low evidence and risk of subclinical hyperthyroidism [40].

Non-thyroid illness: Thyroid hormone therapy in patients with low levels of thyroid hormones due to non-thyroid illness has been investigated in patients in intensive care units, and no evidence for treatment with T_4 or T_3 are present in general. A question on a possible effect in a subgroup of patients with severe prolonged illness is still questioned [41].

Heart failure: In a small study in patients New York Heart Association (NYHA) class III or heart failure demonstrated a beneficial effect from short-term intravenous L-T_3 therapy [42], however, this effect could not be confirmed in a trial of long-term T_3 therapy [43].

Unspecific symptoms: Occasionally, patients query treatment with thyroid hormone for non-specific symptoms such as tiredness—although normal values of serum TSH as well as T_4 are present. In an RCT in patients with non-specific symptoms L-T_4 100 µg did not improve cognitive function and psychological well-being [44]. In these cases, other conditions or diseases must be considered and thyroid hormone therapy cannot be recommended.

Patients with previously initiated thyroid hormone therapy based on unclear indications or with a single measurement of a slightly elevated serum TSH is recommended to assess the continued need for L-T_4, treatment by stopped for 4 weeks if the serum TSH concentration is normal, or for 6 weeks if it is undetectable, to allow recovery of the suppressed TSH. Measurement of serum T_4 and TSH concentrations at this stage will determine whether the patient is truly hypothyroid.

Thyroid Lumps

3.5.1 Pathogenesis of Non-Toxic Goitre

Dagmar Führer and Holger Jäschke

Definition

Nodular goitre can be divided into solitary nodular and multinodular thyroid disease and constitutes a complex thyroid disorder with heterogeneous, morphological, functional and pathogenetic properties [1]. Histologically, thyroid nodules are distinguished by morphological criteria according to the World Health Organization (WHO) classification [2]. On functional grounds, nodules are classified as either 'cold', 'normal', or 'hot' depending whether they show decreased, normal, or increased uptake of radioactive nuclides such as technetium on scintiscan. In contrast to solitary nodular thyroid disease, which has a more uniform clinical, pathological, and molecular picture, multinodular goitre (MNG) usually comprises a mixed group of nodular entities (i.e. one usually finds a combination of hyperfunctional, hypofunctional, or normally functioning thyroid lesions within the same thyroid gland). The overall balance of functional properties of individual thyroid nodules within an MNG ultimately determines the functional status in the individual patient, which may be euthyroid, subclinical hyperthyroid, or overt hyperthyroid. On the molecular level, thyroid nodules within goitre may represent polyclonal lesions or true monoclonal thyroid neoplasia.

The Role of Environmental Factors

The development of nodular goitre is influenced by extrinsic factors interacting with intrinsic factors and constitutional parameters of gender and age [1, 2].

The most important trigger for nodular (and diffuse) goitre is iodine deficiency [3]. There is a direct correlation between goitre prevalence and iodine deficiency and *vice versa* between correction of iodine deficiency and regression of goitre incidence. This indicates that iodine supply or intake has to be adjusted adequately to reduce the burden of thyroid goitre development in a population.

Iodine deficiency was common in Germany until the early 1990s. Introduction of iodized salt into food industries resulted in a marked improvement in nutritional iodine supply as reflected by an increased urinary iodine excretion (median 72 µg iodine/L urine in 1994 to 125 µg iodine/L urine in 2003). Also, the percentage of private households covered with sufficient iodized salt increased from less than 10% to 66% between 1990 and 2002 [4].

In 1994 the prevalence of diffuse goitre was 21% in the age group of 18–30 years and 33% in the age group of 46–65 years. In the Papillon study of 2002 investigating 96 000 German employees an impressive reduction in goitre frequency to 6% in the group of 18–30-year-olds and to 26% in the group of 46–65-year-old participants was found [5]. The epidemiological study SHIP-0, has underscored that with a decrease in overall-goitre prevalence due to improved iodine supply, thyroid nodules now tend to occur in normal size rather than enlarged thyroid glands [6]. This may be explained by the thyroid inherent disposition to develop focal hyperplasia as discussed next.

Table 3.5.1.1 Gender and age dependent upper reference values for normal thyroid volume

Men	25 ml
Women	18 ml
13–14 yr	8–10 ml
3–4 yr	3 ml
Newborn	0.8–1.5 ml

Table 3.5.1.2 Histological diagnosis of goitre

Pathology	Thyroid function	Comment
Diffuse goitre	Euthyroid	
Nodular goitre (uni- or multinodular)	Euthyroid-hyperthyroid	May concur with autoimmune disease in regions with endemic goitre
Thyroid cancer	Euthyroid	May be present in an NTG and/or autoimmune disease
Autoimmune thyroid disease	Euthyroid, hypo-, or hyperthyroid	
Thyroiditis	Variable	
Defect in thyroid hormone synthesis	Hypothyroid-euthyroid	
Thyroid hormone resistance	Euthyroid	End organ dependent function
Acromegaly	Euthyroid	IGF-1 dependent
Drugs (Lithium, antithyroid drugs)	Euthyroid-hypothyroid	
TSHoma	Hyperthyroid	TSH dependent

Recently, two German studies in children (KiGGS) [7] and adults (DEGS) [8] showed results that the iodine status may not be sufficient. In both surveys about 25–30% of the individuals were below the estimated average requirement for iodine. This was also supported by comparing results from the SHIP-0 (1997–2001) [6] and SHIP-TREND (2008–2012) [9] study in an adult population of Northeast Germany. The median urinary excretion levels significantly decreased from 123µg/L to 112µg/L between 2000 and 2010. These data clearly indicated that informative advertising of iodine prophylaxis needs to be intensified to maintain and still to improve iodine status.

Various other goitrogenic factors are known and are relevant to thyroid disease in situations with coexisting iodine deficiency. First, metabolites of various nutrients (e.g. cabbage, cauliflower, and broccoli) may interfere with iodine uptake. Second, industrial pollutants, including resorcinol and phthalic acid, are known to be goitrogenic. Third, deficiencies of selenium, iron, and vitamin A may exacerbate the pathogenic effects of iodine deficiency [10].

Other risk factors for nodular goitre have been suggested, whereby a possibly distinct impact on the prevalence of thyroid nodules occurring in a normal sized or enlarged thyroid gland is less clear [1, 2]. Smoking has been proposed as a risk factor for goitre and nodules were also found with higher prevalence in goitres of smokers compared with non-smokers. The impact of smoking on thyroid disease is most likely due to increased thiocyanate levels in smokers exerting a competitive inhibitory effect on iodide uptake. In line with this, the association is more pronounced in areas with iodine deficiency [11].

Radiation is another environmental risk factor not only for thyroid malignancy but also for benign nodular thyroid disease. An increased prevalence of thyroid nodules disease has been associated with exposure to radio nuclear fallouts and therapeutic external radiation.

Nodular thyroid disease and goitre are more frequent (2.5- to 7-fold) in women and it seems that this prevalence appears after puberty. The determined gender difference is more pronounced in areas of long-standing iodine deficiency compared with regions of iodine sufficiency. However, the precise reasons for this observation remain to be clarified [12]. A growth promoting effect of oestrogens has been described *in vitro* and oestradiol has been suggested to amplify growth factor-dependent signalling in normal thyroid cells and thyroid tumours [11]. However, pregnancy-related thyroid enlargement appears to be mostly related to iodine deficiency and in one German study [13] increased MNG prevalence with parity was only observed in women who had not taken iodine supplementation during an earlier pregnancy.

Several studies suggest that thyroid volume is also significantly correlated with body mass index. In agreement with this, a recent study has shown that in obese women, weight loss of more than 10% may result in a significant decrease in thyroid volume [14]. Lastly, because of the cumulative impact of external risk factors on the thyroid gland, the prevalence of thyroid nodular disease increases with age.

For example, a study (DanThyr) from a borderline iodine-deficient area in Denmark demonstrated the relationship of nodular goitre development in ageing women [15]. The survey of 4242 women showed a goitre incidence of 18% with participants aged 20–39 years exhibiting higher prevalence for solitary thyroid nodules than for MNG. The prevalence of these two entities is similar in the fourth decade of life but shifts to MNG after 50 years of age.

Genetic Disposition

Thyroid nodules (and goitre) also occur in individuals without exposure to iodine deficiency, and not all individuals in an iodine-deficient region develop goitre. A familial clustering for nodular goitre is well documented and family and twin pair studies in endemic and non-endemic goitre regions have underscored a genetic predisposition for goitre development [1, 2]. For example, twin studies show a concordance rate of 80% for monozygotic twins and of 42% for dizygotic twins in endemic and of 40–50% and 13% in non-endemic regions, respectively, strongly suggesting interplay between genetic and environmental factors. On the basis of twin studies, the contribution of genetic susceptibility to goitre

development has been calculated to be 39% in endemic regions and 82% in a non-endemic area [10].

Genetic defects in enzymes involved in thyroid hormone synthesis (e.g. thyroglobulin (TG), thyroperoxidase (TPO), sodium-iodide symporter (NIS) typically result in hypothyroid goitres, but in some rare cases genetic variations in the TG, TPO, and NIS gene have also been reported in association with (diffuse or) nodular euthyroid goitre. Furthermore, alterations in the pendrin gene account for the syndromic occurrence of euthyroid nodular goitre and congenital sensorineural hearing loss.

Since these monogenetic defects are exceptionally rare, linkage studies have been performed to identify susceptibility loci for non-toxic goitre (NTG) on a broader scale [16]. A locus on chromosome 14 (termed MNG-1 locus) has been identified in a Canadian and a German study and was found to cosegregate with familial NTG. In an Italian pedigree with euthyroid goitre an X-linked autosomal pattern of inheritance with a putative genetic defect in the Xp22 region was suggested (termed MNG-2 locus) [17]. Moreover, in a study by the European Thyroid Association working group on the 'Genetics of euthyroid goitre' 18 extended Danish, German, and Slovakian families were analysed in a genome-wide scan. Further putative candidate loci for NTG were identified on chromosomes 3p, 2q, 7q, and 8p emphasizing the genetic heterogeneity of euthyroid goitre.

The first association of germline *DICER1* mutations with NTG was shown 2011. DICER1 is an important enzyme in the maturation of microribonucleic acid (RNA), which have substantial impact in gene expression at the posttranscriptional level. The *DICER1* gene is located in the MNG-1 locus and loss-of-function mutations were identified in 33 members of five families [18]. Besides NTG, mutations in *DICER1* are associated with several benign and malignant tumours (e.g. pleuropulmonary blastoma, cystic nephroma, and ovarian Sertoli-Leydig cell tumour) [19]. The incidence of multinodular goitre in individuals with *DICER1* mutations by age 20 years is 32% in females and 13% in males and also the risk of developing thyroid cancer is increased [20]. Thus, for the majority of euthyroid goitres, a complex, multifactorial pathogenesis including interactions between various environmental factors, gender-specific components, and the genetic background has to be assumed.

Molecular Processes Involved in Nodule Formation

Development of nodular goitre most likely proceeds in two phases, that involve global activation of thyroid epithelial cell proliferation (e.g. as the result of iodine deficiency or other goitrogenic stimuli) leading to hyperplasia and a focal increase of thyroid epithelial cell proliferation causing thyroid nodules. So far, the most common stimulus for focal proliferation is a somatic mutation.

Two driving pathogenetic events have to be considered (Figure 3.5.1.1) [1]: first, iodine deficiency causing an increase in thyroid cell numbers (true hyperplasia) as observed in animal models. Second, H_2O_2 production and free radical formation, which occurs physiologically during thyroid hormone synthesis, may damage genomic DNA. Thus in a mouse model, the spontaneous mutation rate in the naive thyroid gland has been found to be almost ten times higher than in other organs [21, 22].

Both processes provide a mutagenic milieu, in which the likelihood of somatic mutations is increased. Whether these somatic mutations lead to thyroid nodular disease critically depends on the affected gene and most likely the environmental selection factors (e.g. iodine deficiency; Figure 3.5.1.2). A proof of principle for this concept is the evolution of a toxic adenoma from a somatic thyroid-stimulating hormone (TSH) receptor mutation ([1]; also see Chapter 3.3.11). Other examples include the origin of papillary thyroid cancer based on *BRAF* mutations or RET/PTC rearrangements. These somatic mutations have been found already in microscopic lesions of thyroid autonomy and papillary microcarcinoma,

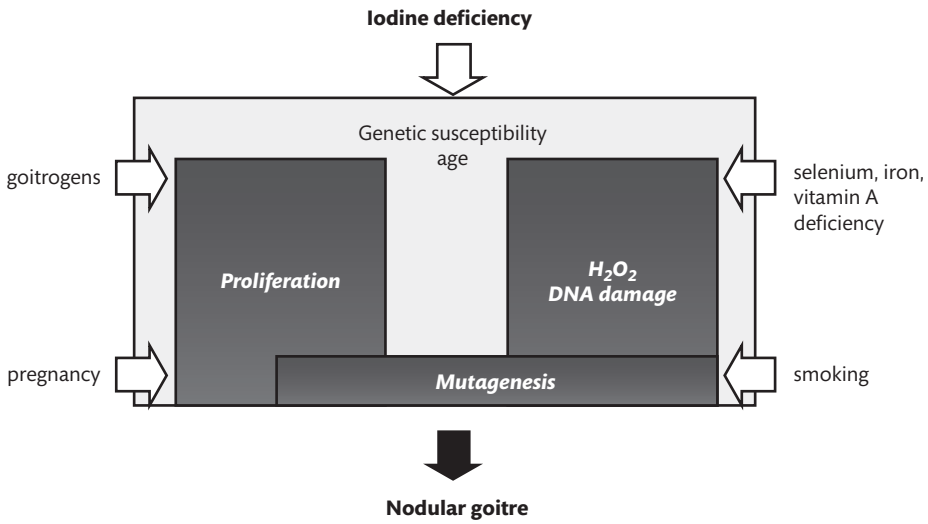

Figure 3.5.1.1 Interaction of extrinsic and intrinsic factors contributing to the development of nodular goitre.

Note that the pathogenic influence of several goitrogenous components (e.g. selenium deficiency, pregnancy) will be aggravated with coexisting iodine deficiency. The two elementary molecular pathomechanism are increased cell proliferation, leading to hyperplasia/goitre and in addition with oxidative stress leading to increased mutagenesis and nodule formation.

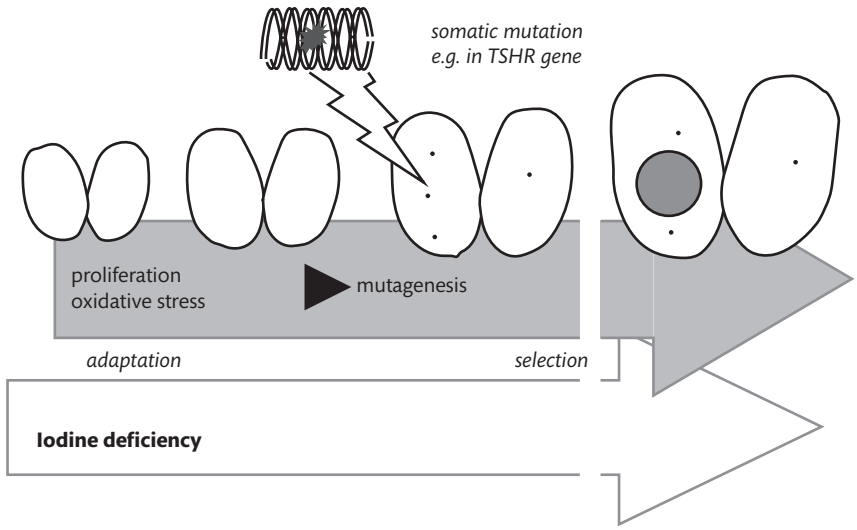

Figure 3.5.1.2 Pathogenesis of nodular goitre in an iodide deficiency environment. According to current concepts the development of nodular goitre proceeds in two phases, that involve: (1) adaptive increase in thyroid epithelial cell proliferation and function, providing a mutagenic milieu with increased likelihood for occurrence of somatic mutations; and (2) clone expansion to a macroscopic thyroid nodule by growth advantage of cell clone with somatic mutation and propagation in persisting iodine deficiency.

respectively. Besides the driving mutation, increased growth factor production and auto- and paracrine action of secreted growth factors (e.g. IGF-1) has been found in monoclonal thyroid tumours and may further propel nodule development.

The development of polyclonal thyroid lesions in an NTG is less clear and putatively is linked to exogenous factors (e.g. intrathyroidal production of growth factors such as IGF-1), which act on the naturally functional and morphological heterogeneous thyroid follicles [11].

Natural Course of Disease

From the epidemiological data discussed earlier, one might expect an inherent progressive course of nodular thyroid disease. Studies aimed at accurate assessment of the nodules by ultrasonography differ in terms of follow-up period, definition of growth, type of thyroid lesion and the background, in which they are conducted. Moreover, the interobserver variability of long-term studies of nodule volumes is not known. With these caveats in mind, the following observations have been reported [1, 2]: in iodine-sufficient areas, nodule 'growth' has been reported in 35% of US patients over a follow-up period of 4.9 to 5.6 years. On long-term follow-up over 15 years in an area of iodine sufficiency, only one-third of benign nodules showed growth as assessed by palpation and ultrasonography compared with the majority of nodules, which remained unchanged or even showed a decrease in size. In Germany, a mean 3-year follow-up of 109 consecutive patients showed a steady and significant (30% volume) increase in nodular size in 50% of patients. In a Danish study, only four (8%) of 45 cold nodules in an area of borderline iodine deficiency showed a change in size (5 mm in diameter), of which only one nodule actually increased and three nodules shrank over a follow-up period of 2 years [23]. Nodule growth was also determined in a 5-year follow-up study from two areas in Italy with mild to moderate iodine deficiency [24]. Significant nodule growth occurred in 153 of 992 patients (15.3%), shrinkage was observed in 13.1% of cases whereas the majority of nodules (69%) exhibited no change in size over the investigated time period. However, nodule growth was significantly linked to patients with multinodular glands [24]. Thus, in an iodine-deficient and -sufficient setting a variable portion, but most likely not all, of nodules will grow, and the speed of growth is highly heterogeneous.

3.5.2 Management of Non-Toxic Multinodular Goitre

Hans Graf and Gilberto Paz-Filho

Introduction

Multinodular goitre (MNG) is characterized by the progressive nodular enlargement of the thyroid gland, without underlying inflammation, autoimmune thyroid disease, and malignancy. It is the result of the interaction between genetic susceptibility, hormonal, and environmental aspects, being iodine deficiency the most important factor. Patients with MNG usually present multinodular enlarged thyroid glands, and its natural history is characterized initially with a diffuse thyroid growth, followed by nodule formation, and frequently with the progression to nodule autonomy, subclinical hyperthyroidism, and eventually overt hyperthyroidism denominated toxic MNG (TMNG). In TMNG, hyperfunctioning nodules secrete thyroid hormones independent of TSH stimulation [1].

The clinical features of MNG varies from an asymptomatic patient to a critical patient with upper airway compression and respiratory insufficiency. The diagnostic work-up includes thyroid function tests, imaging studies such as thyroid ultrasound (US), computed tomography (CT), and magnetic resonance imaging (MRI), cytological evaluation of nodular samples obtained through US guided fine-needle aspiration (US-FNAB), and assessment of radioactive iodine uptake (RAIU) [2].

The management of a patient with MNG is based upon the clinical presentation and the patient´s preference, which involves surgery or radioiodine therapy in most cases. Radioactive iodine (^{131}I) is a safe and effective therapy introduced more than three decades ago for the treatment of MNG, leading to significant thyroid volume

(TV) reduction. Its efficacy can be enhanced by strategies leading to the elevation of TSH levels [3].

Clinical Manifestations

The clinical manifestations observed in patients with MNG are very heterogeneous. Patients with smaller goitres and with normal thyroid function are usually asymptomatic. However, the gradual increase in size may determine compressive symptoms, such as cough, respiratory distress, difficulty in swallowing, and the feeling of a lump in the throat. Asymptomatic subclinical hyperthyroidism or overt hyperthyroidism may develop, particularly in older patients, as a result from the overproduction of thyroid hormones due to the onset of thyroid autonomy [4].

In young patients with small and diffuse goitres, with normal thyroid function, observation alone can be recommended. Conversely, patients with large goitres may develop compressive symptoms, determined not only by the size of the goitre, but also by its possible substernal extension. The most widely used classification defines substernal goitre as the one that has >50% of the total bulk of the thyroid gland into the mediastinum. The prevalence of intrathoracic goitres, with substernal or mediastinal extension, ranges between 2.6% and 30.4% [5, 6]. A maximal tracheal diameter of <8–10 mm can cause exertional dyspnoea, and when the diameter is smaller than 5 mm, dyspnoea at rest and stridor may occur [7].

Patients with large goitres may present the Pemberton's sign, the reversible facial congestion triggered by the elevation of both arms. In those patients, that movement leads to dislocation of the goitre into the upper thoracic inlet, compressing the subclavian and jugular vein [8]. Airway compression may occur if there is a sudden increase in TV due to thyroid haemorrhage or upper respiratory tract infections contributing to a decrease in tracheal lumen [9]. The close relationship of the thyroid gland with the recurrent laryngeal nerves may determine unilateral or bilateral vocal cord paralysis. Similarly, compression of the cervical sympathetic chain may elicit paralysis of the phrenic nerve, which can be asymptomatic or present with dyspnoea, or Horner's syndrome, characterized by ptosis, miosis and decreased sweating of the face on the same side [10].

As the MNG progresses, the increase of TV and nodularity leads to subclinical or overt hyperthyroidism in many cases, particularly in older patients, as a consequence of the autonomous overproduction of thyroid hormones [11].

Diagnostic Evaluation

Anamnesis and Physical Examination

Detailed anamnesis and physical examination are essential in the diagnostic evaluation of a patient with MNG. One source of concern is the presence of malignancy, which incidence is the same in uninodular goitre [12]. However, a systematic review and meta-analysis suggests a slightly higher risk of malignancy in solitary nodules, compared to MNG [13]. Features suggesting benign disease include factors such as family history of benign thyroid nodule or goitre and symptoms of hypothyroidism or hyperthyroidism [1].

In the physical examination, smaller goitres may be visible only when the patient is asked to swallow or drink a glass of water. Younger patients tend to have smaller goitres, with few nodules, and without intrathoracic extension. Malignant nodules are usually firm, irregular, and fixed to adjacent tissues. Fortunately, thyroid nodules are generally benign colloid nodules, just around 5% of nodules are carcinomas [12]. Goitres with intrathoracic extension cannot be fully evaluated by palpation and their presence can be identified through the Pemberton's manoeuvre.

Laboratorial Investigation

The initial laboratory investigation of MNG is based on the measurement of serum thyrotropin (TSH). Normal TSH levels indicate euthyroidism, and further laboratory investigation is not necessary [11]. Abnormally low TSH levels suggest thyroid hyperfunction, and must be followed by measurements of serum free T_4 to assess the presence of subclinical or overt hyperthyroidism. T_3 measurements may be useful in situations of difficult interpretation, such as T_3 thyrotoxicosis. A recent panel of the American Thyroid Association (ATA) could not recommend either for or against routine measurement of serum calcitonin in patients with thyroid nodules [12]. In MNG, neither calcitonin or thyroglobulin measurements are recommended, and if measured, calcitonin levels must be interpreted with caution since it has low positive predictive value and can lead to unnecessary surgery. To exclude autoimmune hyperthyroidism or hypothyroidism it is valuable to measure thyroid antibodies as thyroid-stimulating antibodies, antithyroglobulin (ATG) and antithyroid peroxidase antibodies (ATPO).

Imaging

Thyroid US should be the first fundamental imaging test [12, 14]. It is relatively inexpensive, easy to perform, and can be used to guide fine-needle aspiration biopsies (FNAB-US). It provides an estimative of TV and characterizes suspicious thyroid nodules. US may assess not only the baseline characteristics of the thyroid nodules, but is also used to follow those nodules [1, 14].

However, the usefulness of US is very limited in cases of intrathoracic MNG, since the US waves cannot penetrate bone. In these cases, CT or MRI are invaluable tools that fully characterize TV, extension, and compressive effects over the trachea. In addition, CT and MRI can determine the cross-sectional area of the trachea, a useful measure of tracheal compression. When performing these diagnostic imaging tests, it is crucial not to administer iodinated contrast agents, which impair future therapeutic or diagnostic approaches with radioiodine, and can also induce thyrotoxicosis.

CT scan is the preoperative gold-standard exam for intrathoracic goitres, and can be used to categorize goitres into three grades of retrosternal extension: above the aortic arch, between the aortic arch and the pericardium, and below the right atrium. Both CT and MRI allow the estimation of planimetric volumes, especially useful in cases of irregularly enlarged goitres [2, 15] (Figure 3.5.2.1).

Positron emission tomography (PET) with 18-fluoro-deoxyglucose (FDG) is not useful in for the diagnostic work-up, as it does not

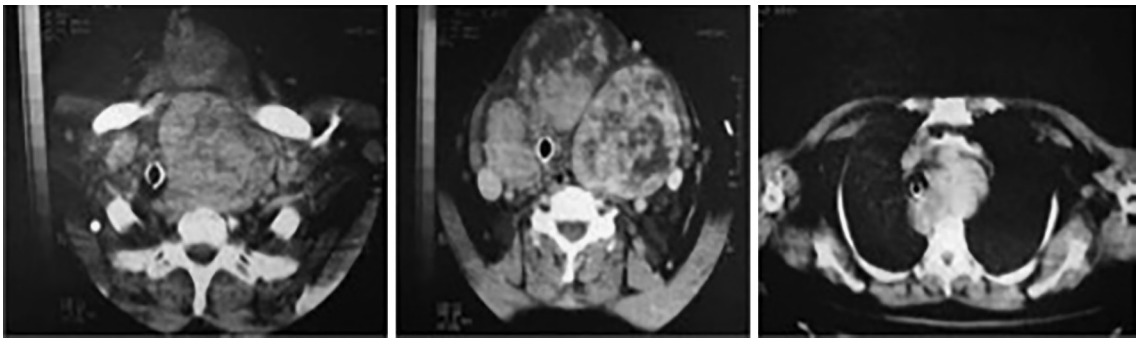

Figure 3.5.2.1 CT scan of a 13 × 15 × 19 cm substernal goitre causing tracheal deviation and acute respiratory failure. Morbid obesity and upper respiratory tract infection were contributing factors for the acute respiratory failure.

Adapted with permission from Ioannidis O, Dalampini E, Chatzopoulos S, *et al*. Acute respiratory failure caused by neglected giant substernal nontoxic goiter. *Arq Bras Endocrinol Metabol* 2011;55:229–32. Copyright © 2011 Ioannidis O, et al.

allow the visualization of the normal thyroid gland, and only shows hypermetabolic thyroid uptake that may be malignant.

Thyroid scintigraphy and RAIU measurements are not recommended in the initial diagnostic evaluation, but they are important for the differential diagnosis of hyperthyroidism in the presence of nodularity. Thyroid scintigraphy also documents the presence of intrathoracic extension of large goitres, and confirms whether intrathoracic masses identified by CT or MRI are of thyroid origin. Goitres with low and heterogeneous uptake are less responsive to radioiodine therapy, and require higher activities of the radioisotope. The use of thyroid scintigraphy and uptake studies was questioned in a study that showed that those tests do not influence diagnosis or treatment outcomes in most cases of hyperthyroidism [16], but it is very important in defining radioactive iodine treatment, especially in patients receiving recombinant human TSH or methimazole for RAIU augmentation [3].

Fine-Needle Aspiration Biopsy (FNAB)

Patients with toxic and non-toxic MNG are at the same risk of malignancy as in patients with single nodules [17]. The recommendations for FNAB in patients with MNG are the same as those for patients with single nodules: the dominant nodule, as well as any sonographically suspicious nodules, should be biopsied [12, 18]. Nodules that are suspicious for malignancy are hypoechoic, have irregular margins, do not have a sonolucent halo, and have intranodular vascularity and microcalcifications [19]. Since the fine-needle capillary (FNC) and the fine-needle aspiration (FNA) techniques provide similar sample adequacy and diagnostic accuracy, either technique can be employed, depending on the operator's personal preferences and experience [20].

Cytopathologic reports should follow the classification proposed at the National Cancer Institute Thyroid Fine-Needle Aspiration State-of-the-Science Conference in Bethesda [21].

Pulmonary Function Tests

Large MNG can lead to tracheal compression and pulmonary function impairment, but this problem is probably overlooked by many clinicians. Pulmonary function studies must include flow-volume loop tracings, which show a reduction of inspiratory capacity. Abnormal results are found even in asymptomatic patients, who can benefit from this evaluation. Improvements in pulmonary function after surgery or radioiodine therapy can be objectively quantified with pulmonary function tests [2].

Management

The management of patients with multinodular goitre is guided by the clinical presentation, professional experience and by the patients' preference: expectant clinical observation, surgery, or radioiodine therapy. Iodine supplementation and suppressive therapy with levothyroxine are not recommended therapeutic options. Nevertheless, surveys involving European [22], American [23], and Latin-American [24] endocrinologists showed that there is no consensus in the management of non-toxic multinodular goitre.

Clinical Observation

Clinical observation is a reasonable approach in the management of patients with non-toxic and asymptomatic benign MNG that do not raise any cosmetic concerns from the patient. In the natural history of many multinodular goitres, thyroid growth is extremely slow, with no significant change in a mean TV over 5 years [25].

For thyroid nodules, the American Thyroid Association (ATA) suggest that monitoring should be conducted according to risk stratification: nodules with high suspicion, low to intermediate suspicion, and low suspicion sonographic pattern should be evaluated every 12, 12–24, and ≥24 months, respectively [12]. If a nodule has been submitted to a repeated US-FNAB with a second benign cytology result, US surveillance for malignancy is no longer indicated [12]. In terms of thyroid dysfunction, a retrospective population study conducted in Scotland found that the percentages of patients with untreated subclinical hyperthyroid patients who remained subclinically hyperthyroid was 81.8% at 2 years, 67.5% at 5 years, and 63.0% at 7 years [26]. In another study evaluating 94 patients with subclinical hyperthyroidism (69 had MNG), the

progression rate from subclinical to overt hyperthyroidism was 8% at 1 year, 16% at 2 years, 21% at 3 years, and 26% at 5 years [27]. Therefore, it is reasonable to adopt a conservative approach based on periodic assessment of the thyroid hormonal status (by measuring serum TSH and free T_4), and on the monitoring of goitre and thyroid nodule sizes by US and CT scans. It is recommended by the ATA that this evaluation be conducted every 6 to 18 months, and the frequency can be reduced if no significant changes are identified over 3–5 years [12].

When clinical observation is chosen as a therapeutic approach, malignancy should first be excluded by FNAB-US. Periodic US surveillance is done to identify potentially malignant nodules that may have been missed by previous US or FNAB-US [28]. If a euthyroid patient with MNG develops subclinical or overt hyperthyroidism, additional tests are recommended, including T_3 or free T_3 measurements and thyroid scintigraphy. If the patient is asymptomatic and has no cosmetic complaints, but is hyperthyroid, therapy with antithyroid drugs, or preferably radioiodine should be employed.

Iodine Supplementation

Despite the knowledge that iodine deficiency is the most important aetiological factor in goitre development, iodine supplementation does not have sufficient therapeutic effect on an established MNG. In a multicentre German study, a 1-year combination of iodine and levothyroxine leading to incomplete TSH suppression reduced thyroid nodule volume compared to either component alone or placebo. In this trial patients were iodine deficient (mean urinary iodine excretion 49.7–59.5 μg/L) and this finding can partially explain the reduction in goitre size [29]. Due to the risk of inducing hyperthyroidism (Jod-Basedow effect), iodine supplementation is not used a therapeutic option in patients with MNG.

Suppressive Therapy with Levothyroxine

As TSH is the most important thyroid growth factor and its suppression by pharmacological doses of levothyroxine (L-T_4) supposedly could inhibit thyroid growth, or even reduce its volume. Several studies have evaluated L-T_4 in patients with diffuse goitre, but few studies have involved euthyroid patients with MNG in a randomized placebo-controlled design [30, 31]. Suppressive therapy is greatly inferior than radioactive iodine (^{131}I) therapy; goitre shrinkage occurred in 7% of patients given suppressive treatment compared to a reduction of 35% in volume in the first year after ^{131}I treatment [32].

Suppressive therapy with LT4 is not recommended as a therapeutic option for MNG due to its low efficacy, the need for continuous treatment, and its adverse effects [33]. Low serum TSH in individuals aged 60 or older is associated with increased mortality from all causes, and, in particular, with increased mortality due to circulatory and cardiovascular diseases [1–4].

Surgery

For most patients with symptomatic multinodular goitres, surgery is the treatment of choice. The optimal treatment is total thyroidectomy, because the recurrence rate is more common (2.5–42%) when a more conservative approach is chosen compared to total thyroidectomy (0–0.3%) [34]. Total thyroidectomy eliminates the risk of recurrence, cures coexisting hyperthyroidism if present, and it is not associated with an increase in surgical risk when performed by experienced surgeons [35]. The higher surgical risks associated with reoperation must be considered—reoperation results in a 3- to 10-fold risk for hypoparathyroidism or permanent vocal cord paralysis [36]. Surgery should be considered in patients whose goitre progressively enlarges or who have evidence of upper airway obstruction despite absence of any symptoms. More recently, minimally invasive thyroidectomy has been evaluated as a technique that is associated with less surgical risks [37]. The complication rate is higher in patients with goitres that extend substernally compared to patients whose goitre is entirely cervical [38].

Total thyroidectomy leads to rapid decompression of vital structures, with resolution of compressive symptoms in 100% of the patients, versus 46% of the patients undergoing radioiodine therapy [39]. However, it is associated with higher costs, requires hospitalization, and poses risks inherent to surgery in general and risks that are specific to thyroidectomy, such as hypoparathyroidism, vocal cord paralysis due to trauma of the laryngeal recurrent nerve, tracheal obstruction due to haemorrhage and tracheomalacia. Hypothyroidism is rather an objective than a complication and occurs virtually in all patients who undergo total thyroidectomy.

After total or near-total thyroidectomy, thyroid hormone replacement can be promptly initiated at 1.5–1.7 μg/kg/day, or 10–15% less in older people. Levothyroxine (L-T_4) replacement should not be used as a prophylactic agent against thyroid regrowth if subtotal thyroidectomy is chosen, since evidence for this is lacking. During the postoperative period, calcium and parathyroid hormone levels should be monitored, and supplementation with calcium and vitamin D should be initiated if necessary. Hypoparathyroidism is observed in up to 4–10% of non-specialized centres [40]. Permanent hypoparathyroidism is defined when calcium and/or calcitriol supplementation is required for more than 6 months after the surgery. Some patients may have permanent hypoparathyroidism despite having normal parathyroid hormone levels [41]. The risk for laryngeal recurrent nerve damage in thyroid surgery is higher in cases of recurrent thyroid cancer, recurrent benign goitre, thyroid cancer, extensive resection, and low surgical experience [42]. More than 50% of patients with vocal cord palsy are asymptomatic, and other diagnostic tools may be useful, such as fibreoptic laryngoscopy, subjective questionnaires, or computerized voice analysis [43]. Surgery is relatively contraindicated in patients with significant comorbidities, when a high-volume thyroid surgeon is not available or during pregnancy. If necessary, it should be performed in the latter portion of the second trimester [44].

Radioactive Iodine

For more than seven decades, radioactive iodine (^{131}I) therapy has been used to treat thyroid diseases, mainly Graves' disease [45]. Radioactive iodine is not only effective for curing hyperthyroid states, but also leads to shrinkage of the thyroid gland. Owing to this effect on the gland volume, ^{131}I has been used for a long time in the treatment of compressive non-toxic nodular goitres. In 1988,

Hegedus *et al.*, using US, demonstrated that ^{131}I treatment of non-toxic MNG leads to significant goitre volume reduction after 1 year of ^{131} administration [46].

Treatment with ^{131}I is an option for patients with contraindications to surgery, for those who reject surgical procedures, and for patients who have had previous surgery or radiation to the neck (making further surgical procedures more difficult) [3]. Pretreatment with methimazole before ^{131}I therapy is indicated to patients with subclinical hyperthyroidism that are at an increased risk for complications due to worsening of hyperthyroidism, including elderly and those with cardiovascular disease or severe hyperthyroidism [11]. Studies employing images such as US, CT, or MRI (for accurate measurements of TV) have confirmed that ^{131}I therapy reduces the volume of MNG by 35–50% within 1 year with further reduction observed after 3–5 years and improvement in obstructive symptoms in most patients [1–3, 47].

The RAIU determines the therapeutic efficacy of radioiodine itself. Low isotope accumulation in inactive and partially suppressed areas around the nodule is a limitation for radioiodine treatment in patients with MNG. Multinodular goitres with low and heterogeneous RAIU requires higher activities, and sometimes repeated administrations of ^{131}I. The improvement in compressive symptoms after therapeutic activities of ^{131}I is accompanied by significant tracheal widening, as measured by CT or MRI [3]. Treatment is usually accomplished by the administration of a single oral dose of radioiodine. An effective administered activity is calculated to deliver 100–150 μCi per gram of thyroid tissue, corrected for 24-hour RAIU [1]. The calculated activity is directly proportional to the TV, and inversely proportional to the radioiodine uptake, aiming at an absorbed thyroid dose of 100 Gy [1, 3].

Activities may range from 15 mCi for small goitres with normal/high RAIU, to 100–150 mCi for large glands with low RAIU and heterogeneous scintigraphic tracer distribution [1]. Higher ^{131}I activities cause considerable irradiation of extrathyroidal organs and tissues [48]. In most cases, patients require hospitalization and isolation [3]. A survey about safety practices among members of major societies of physicians and allied specialists who treat patients with thyroid disorders showed a diversity of responses related to ^{131}I administration, suggesting the importance of a multispecialty collaboration in defining more uniform recommendations for patients receiving ^{131}I treatment [49].

The adverse effects of ^{131}I therapy can be classified as either acute or late effects. Acutely, ^{131}I can cause radiation thyroiditis, characterized by thyroid pain that can present with fever, an increased erythrocyte sedimentation rate, and thyrotoxicosis. This effect is generally mild and self-limited to the first week of treatment. It can be treated with non-steroidal anti-inflammatory drugs or, less frequently, corticosteroids (e.g. 40 mg of prednisone daily) [50]. Radiation-related thyrotoxicosis can be treated with β-blockers. Antithyroid drugs and β-blockers should also be used in patients with TMNG before radioiodine therapy in older people or those with cardiovascular disease, but should be discontinued 3–5 days before radioiodine therapy in order to prevent treatment failure [11].

An acute increase of TV following ^{131}I administration is a theoretical complication, caused by the inflammatory response to ^{131}I. In one study the increase was minimal (approximately 4% after 1 week) [51] and no instances of acute respiratory decompensation are reported in the literature. Prophylactic administration of glucocorticoids may be considered in cases of patients with large goitres and/or very small cross-sectional tracheal areas [3]. The most common late effect of ^{131}I therapy is the development of hypothyroidism with a prevalence of 20% to 60% after 5 to 8 years [52]. Younger patients with small goitres and with circulating ATPO antibodies are more likely to become hypothyroid [3].

On the other hand, autoimmune hyperthyroidism (i.e. Graves' disease) can be triggered by ^{131}I therapy. This complication usually appears 1 to 3 months after therapy, and is characterized by the development of hyperthyroidism with increased RAIU and elevated titres of TSH receptor antibodies (TRAb). It is likely to be caused by the exposure to the immune system to thyroidal antigens following follicular cell destruction. One study showed that there is an estimated 1.1% risk of developing postradioiodine Graves' disease in patients undergoing radioiodine therapy for autonomous thyroid disease, and this rate increases approximately 10-fold when TPO antibody levels are elevated before radioiodine therapy. Approximately 1–2% of patients may also develop increase titres of TRAb, without hyperthyroidism [53].

The risk of cancer development after the administration of ^{131}I should be taken in account. There are no systematic data evaluating the effects of radioiodine treatment for MNG on the development of secondary malignancies; all of the available data are derived from patients with either thyroid cancer or hyperthyroidism. In the Cooperative Thyrotoxicosis Therapy Follow-Up Study, almost 36 000 hyperthyroid patients treated with ^{131}I and other therapeutic alternatives were followed for an average of 8.2 years. There was no evidence of increased risk of total mortality due to cancer or leukaemia in patients treated with ^{131}I. While there was an elevated risk of thyroid cancer mortality in patients with TMNG, the excess number of deaths was small, and may represent an association of thyroid cancer with MNG, rather than a causal relationship, since no excess thyroid cancer mortality was seen in patients with Graves' disease [54]. Absolute contraindications to ^{131}I therapy are pregnancy, lactation, coexisting thyroid cancer on FNAB, the inability to comply with radiation safety requirements, and the desire to become pregnant within 4–6 months.

Due to the usually low and heterogeneous RAIU seen in MNG, many strategies to enhance uptake have been evaluated, such as the use of recombinant human TSH [55] or after the use of methimazole to elevate endogenous TSH [56].

Radioiodine and Recombinant Human TSH (RHTSH)

Recombinant human TSH (rhTSH) significantly increases RAIU, TSH, T_3, and T_4 in patients with MNG [55]. There are important interindividual variations regarding the RAIU increase after rhTSH administration as reported in a study, in which the administration of 0.9 mg rhTSH increased the 24-h thyroid RAIU from 23.0% at baseline to 41.0% [57]. Recombinant human TSH induces thyroid swelling in healthy individuals, in a dose-dependent manner (0.1, 0.3, and 0.9 mg of rhTSH). Fast *et al.* suggest that these adverse effects are probably without clinical significance following doses of rhTSH that are equal to or lower than 0.1 mg [58].

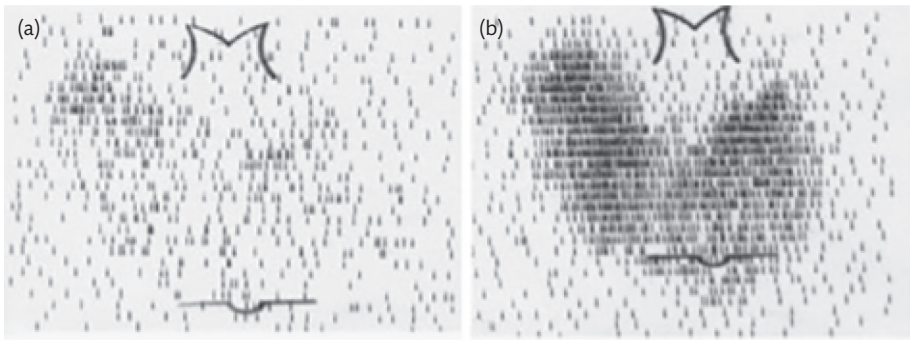

Figure 3.5.2.2 Scintigraphy before (a) and 24hs after the administration of a single dose of 0.1 mg rhTSH (b). Besides making the uptake of ^{131}Imore homogeneous, rhTSH increased the 24-hour uptake from 4.3% to 39%.

Recombinant human TSH is routinely used for diagnostic and therapeutic purposes in patients with differentiated thyroid cancer (DTC). After thyroidectomy, patients with DTC considered with intermediary and high risk by the ATA guidelines [12] receive routinely adjunct ^{131}I for thyroid remnant ablation, and it has been demonstrated that the two existing regimens (rhTSH stimulation vs. thyroid hormone withdrawal) are equally effective for TSH stimulation and thyroid remnant ablation [59].

The administration of a single low dose of rhTSH in patients with MNG significantly enhances and homogenizes thyroid radioiodine uptake [3, 60] (Figure 3.5.2.2).

There is a large interindividual variation in the RAIU increase after the administration of rhTSH. Usually the lower the basal RAIU, the higher the post-rhTSH RAIU [60]. This indicates that individual factors, most of which are yet unidentified, are involved. Much of the variation is explained by differences in the baseline thyroid RAIU, since the effect is highly negatively correlated with this variable [3]. Baseline serum TSH may be a confounding factor, since the increase in RAIU correlates negatively with serum TSH [4]. Since patients with MNG frequently present low serum TSH, radioiodine is only taken up by some 'hot' areas encircled by suppressed thyroid tissue that is inactive on scintigraphy. After RAIU stimulation with rhTSH, these inactive thyroid areas concentrate and amplify the effect of ^{131}I in the gland, with further thyroid reduction. During the last two decades, different rhTSH doses have been utilized: 0.2 mg or more in some studies while 0.1 mg or less in others. Few safety concerns have been observed with the latter doses [61].

In a multicentric randomized controlled study, modified release rhTSH (MRrhTSH) was used to treat patients with MNG [62, 63]. MRrhTSH is an analogue of rhTSH that has the same potency to increase thyroid RAIU, and that determines a lower peak plasma TSH concentration. Potentially, MRrhTSH could reduce the side effects of rhTSH due to its altered pharmacokinetics, with a slightly delayed serum TSH peak after injection, compared to aqueous rhTSH. In this study, the objective was to compare the efficacy and safety of 0.01 and 0.03 mg MRrhTSH as an adjuvant to ^{131}I therapy, vs. ^{131}I alone. TV decreased significantly in all groups after six months: by 23% in patients prestimulated with either placebo or 0.01 mg MRrhTSH, and by 33% in patients prestimulated with 0.03 mg. The smallest cross-sectional area of the trachea increased more in the latter group, without significant difference from the two other groups. The long-term (36 months) results of the same trial demonstrated that patients who received 0.03 mg of MRrhTSH with baseline RAIU <20% achieved a greater reduction in goitre size [63].

Side Effects of rhTSH Use In MNG

Some side effects with the use of rhTSH in MNG can occur [4, 64]. Nielsen *et al.* demonstrated that patients with MNG can report a sensation of thyroid swelling after administration of 0.3 mg rhTSH, but no acute compressive effects have been observed [65]. In this study, patients with a rather small MNG (median volume of 40.0 ml) presented a 24% transient goitre enlargement. Patients with TMNG presented higher increases in thyroid hormone levels after 0.1 mg rhTSH plus ^{131}I, with more side effects [66]. In these cases, safety measures such as the use of β-blockers should be considered.

Currently, the rhTSH adjunct therapy is not indicated for patients with TMNG [4, 11]. Glucocorticoid therapy rarely is necessary in patients receiving ^{131}I for the treatment of MNG [1]. On the other hand, prophylactic glucocorticoid therapy should be considered in patients with critical tracheal narrowing, to prevent thyroid swelling and further respiratory compromise [11]. Painful transient thyroiditis may occur within the first month after treatment, and the development of Graves' disease (with high levels of TSH receptor antibodies) is reported in euthyroid MNG patients with pre-existing TPOAb [67].

The occurrence of hypothyroidism after the use of ^{131}I with or without rhTSH preparation should not be viewed as a complication, rather more as a normal consequence of TV reduction and consequent thyroid hypofunction. The occurrence of hypothyroidism after the use of ^{131}I for MNG usually indicates that goitre shrinkage is occurring. The development of hypothyroidism is common, and depends on the size of the treated goitre, and on the administered rhTSH dose and ^{131}I activity [3, 4]. The optimal rhTSH dose for enhancing ^{131}I therapy in MNG with non-significant side effects is most likely in the range of 0.05–0.1 mg [4].

A recent meta-analysis demonstrated that the administration of rhTSH before radioiodine therapy resulted in a greater reduction in TV than radioiodine therapy alone, and in an increased incidence of hypothyroidism in patients receiving high-dose rhTSH. The authors concluded that low-dose rhTSH before radioiodine therapy was more efficacious than radioiodine therapy alone, when used for treating non-toxic benign thyroid nodules [68].

Use of Methimazole to Enhance RAIU

Recent studies suggest that TSH elevation after the use of methimazole in patients with MNG leads to a rise in the RAIU and an excellent result in goitre volume reduction after ^{131}I activities [56, 69–71]. Albino *et al.* treated nine female patients with MNG with methimazole for 2.8 +/– 0.8 months (10–20 mg, with monthly adjusted doses based on thyroid hormone levels), leading to increases in mean serum TSH to 11.7 +/– 5.4 mU/L, and to increases in mean 24-h RAIU, from median values of 21.3–78.3%. After 1 year of a fixed activity of 1.11 GBq (30 mCi) of ^{131}I, median TV decreased from 97 ml to 56 ml (mean reduction of 46.2%). Eight patients (89%) had initially subclinical hyperthyroidism, which was reversed in all patients after one year. Five patients (56%) developed overt hypothyroidism, and no clinical adverse events were observed [56]. Kyrilli evaluated 22 patients with MNG, with subclinical hyperthyroidism and RAIU <50%. Patients were randomized to receive either a low iodine diet (LID) or methimazole (MTZ, 30 mg/day) [70]. Thiamazole treatment prior to ^{131}I therapy resulted in an average twofold increase in thyroid RAIU and enhanced the efficiency of radioiodine therapy assessed at 12 months.

It is important to mention that the adjunct therapy of MNG with rhTSH and ^{131}I is not approved by the US Food and Drug Administration (FDA) or European Medicines Agency (EMA). Moreover, the cost-effectiveness of the combined rhTSH therapy has not been demonstrated [4].

3.5.3 Management of the Single Thyroid Nodule

Laszlo Hegedüs and Finn N. Bennedbæk

Introduction

The main concern of patients and physicians alike, when dealing with the solitary thyroid nodule, is to diagnose the few cancers (approximately 5%) as rapidly and cost-effectively as possible and to reduce superfluous thyroid surgery. This chapter focuses on the palpably discrete swelling within an otherwise normal gland in the clinically and biochemically euthyroid patient [1, 2]. The toxic nodule is dealt with in Chapter 3.3.11, and thyroid malignancy in Chapters 3.5.4–3.5.7.

Occurrence

The estimated life-time risk of developing a thyroid nodule is between 5% and 10% [1, 2], but factors such as sex (four times more common in women), age (frequency increases with age), regional iodine intake (more prevalent in iodine-deficient areas), and whether the diagnosis is made clinically (palpation), by ultrasonography (US), or at autopsy (5–10 times more prevalent using the last two) are of importance when estimating prevalence [1, 2]. The incidence of clinical disease has been estimated at 0.1% by palpation [1, 2].

Natural History

Very little is known regarding the natural history of thyroid nodules, since data are highly selected and generally concern patients with small nodules without suspicion of malignancy and not causing pressure symptoms or cosmetic complaints. With these restrictions, most nodules appear not to change appreciably over time. The nodules that increase in size are predominantly solid and carry a higher risk of harbouring thyroid carcinoma than those predominantly cystic, being more prone to decrease in size or even disappear.

In most patients, US will identify nodules not evident clinically and, given time, most of these patients will be classified as having multinodular goitre. Therefore, the risk of thyroid malignancy, at the patient level, is independent of whether the nodule is solitary or appears in a multinodular gland [1, 3]. Furthermore, non-palpable nodules have the same risk of malignancy as do US confirmed palpable nodules of the same size [4].

Diagnosis

Clinical Examination

History and physical examination are important and patients with a risk of thyroid carcinoma can be identified (**Box 3.5.3.1**). A positive family history of benign goitre suggests a benign disorder, whereas multiple endocrine neoplasia, medullary thyroid carcinoma, or even papillary or follicular thyroid carcinoma in the family should raise suspicion. Nodules occurring in the young or in the old are especially likely to be cancerous, the risk being higher in men than in women. Head or neck irradiation in childhood leads to clinically evident thyroid abnormality in 10–40% of patients 5–40 years later. Rapid tumour growth (weeks to months)

Box 3.5.3.1 Clinical factors increasing the likelihood of thyroid malignancy in a euthyroid patient with a solitary nodule

- Family history of thyroid malignancy
- Age less than 20 or more than 60 years
- Male sex
- History of head and neck irradiation in infancy, childhood, or adolescence
- Large nodule (greater than 4 cm in diameter) and partially cystic
- Rapid nodule growth
- Pain
- Firm or hard nodule
- Fixation to adjacent structures
- Compression symptoms: dysphagia, dyspnoea, vocal cord paralysis
- Regional lymphadenopathy
- Growth during L-thyroxine therapy

and symptoms of local invasion, such as pain, dysphagia, hoarseness, or dyspnoea, suggests a carcinoma, but only a minority of patients have these symptoms.

The physical examination is important in the work-up and certain signs and symptoms are highly suspicious of thyroid malignancy (Box 3.5.3.1), but inter- and intraobserver variation is alarmingly high [5] and the specificity and sensitivity of the diagnosis of a solitary thyroid nodule is low. Thus, nodules of 10 mm or more can usually be palpated depending on their localization in the neck. However, one-half of the nodules found by US examination escape clinical detection, one-third of which are more than 20 mm in diameter. A hard nodule is not necessarily a carcinoma (chronic thyroiditis), whereas a soft nodule may well be a cystic papillary cancer. In view of this, current guidelines rely on a US-based risk stratification and fine-needle aspiration biopsy (FNA) rather than a physical examination [6, 7].

Laboratory Investigation

The only relevant biochemical test that is routinely needed is serum thyroid-stimulating hormone (TSH) measured with a sensitive assay. Subnormal serum TSH values should lead to determination of free thyroxine (T_4) and free triiodothyronine (T_3). In the presence of normal thyroid hormone levels, a suppressed serum TSH on repeat examination should lead to treatment, especially in older patients (Chapter 3.3.4) [8]. Scintigraphy is recommended and will most likely demonstrate a hot or a toxic nodule (Chapters 3.1.6 and 3.3.11) in such patients, most of whom are euthyroid, including those with thyroid malignancy. It seems that the risk of malignancy in a thyroid nodule increases with serum TSH concentration, within the normal range, at presentation, and thus serves as an additional and independent predictor of malignancy [9]. Hypothyroidism indicates that the patient may have Hashimoto's thyroiditis. Thyroglobulin in serum is positively correlated with thyroid size but has no place in the routine investigation or in the follow-up of benign nodules. Calcitonin is the only clinically relevant biochemical marker of medullary thyroid carcinoma. Routine determination has been suggested by European guidelines [10, 11]. It allows the detection of unsuspected medullary thyroid carcinoma with a frequency of 1 in 200–300 thyroid nodules, with better sensitivity than FNA (11). However, there remains unresolved issues of sensitivity, specificity, assay performance, and cost-effectiveness [10]. Thyroid autoantibodies against thyroid peroxidase cannot differentiate between malignant and benign disease. In our opinion, they should be determined routinely in the work-up to identify patients with possible Hashimoto's thyroiditis. These antibodies are also markers of an increased risk of developing hypo- or hyperthyroidism (Graves' disease) spontaneously or secondary to surgery or radioiodine treatment [12]. TSH-receptor antibodies are rarely present and should not be determined routinely.

Diagnostic Imaging

No method of imaging can differentiate benign from malignant nodules accurately. However, 88% of European thyroidologists use either scintigraphy (66%), ultrasonography (80%), or both (58%) in the evaluation of patients with a clinically solitary thyroid nodule, illustrating that the diagnosis is not always straightforward and that they believe diagnostic imaging gives valuable information (see also Chapters 3.1.6 and 3.1.6.1) [13].

There is no consensus on the use of scintigraphy in the euthyroid patient. Since most have a cold nodule—increasing the risk of thyroid malignancy at least 10-fold—many investigators, mainly in the United States, advocate using FNA as the first step [1, 2]. Imaging, if performed, can be with ^{123}I, ^{131}I, or ^{99m}Tc pertechnetate, the latter being preferred (86%) among European thyroidologists [13], although iodine isotopes should be used if the aim is also to reduce the risk of overlooking malignancy. A clinically dominant nodule that is cold on scintigraphy, should be treated as a solitary cold nodule, the risk of malignancy being the same [1, 3], and FNA should be performed. In case of suppressed serum TSH or overt hyperthyroidism, the risk of malignancy is thought to be much lower as is the need for FNA.

US, often used in Europe (80%) and less so in the United States, allows determination of total thyroid volume, individual nodule evaluation for size, echogenicity, internal content, margin, shape, calcifications, nodule vascularity, elasticity, and regional lymph nodes [7, 13]. Elastography, however, should not replace grey-scale US-investigation, but it may be used as a complementary tool for assessing nodules for FNA, especially due to its high NPV.

Classification of thyroid nodules according to a thyroid imaging reporting and data system (TIRADS) is based on the fact that certain US-features of thyroid nodules are consistently predictive of malignancy and are used as criteria for FNA (see Chapter 3.1.7) [7]. About 50% of the nodules can be classified as benign by US criteria with a risk of false negatives of only 3%. US aids in performing accurate biopsies and is of great help in therapeutic procedures such as cyst punctures, percutaneous ethanol injection and thermal (laser, radiofrequency, microwaves and high-frequency US) therapy of solid as well as cystic nodules [1, 14, 15]. For the objective determination of thyroid or nodule size, whether initially or during follow-up, it is the technique of choice.

Focal ^{18}FDG-PET uptake within a US confirmed thyroid nodule conveys an increased risk of thyroid cancer, and FNA is recommended for those nodules [16]. CT and MRI are generally of little value except in the evaluation of the intrathoracic goitre or in the evaluation and follow-up of malignant thyroid disease.

Ultrasonography and Fine-Needle Aspiration Biopsy

FNA provides the most direct and specific information about a thyroid nodule, and it is used by the majority of clinicians on an outpatient basis [13, 17]. As the cornerstone in the evaluation it is

virtually without complications, inexpensive, and easy to learn to perform (see Figure 3.5.3.1).

Current guidelines for thyroid nodule FNA are recommended for the intermediate and high-risk nodules and is based on the structured and standardized US reporting system (TIRADS) (see Chapter 3.1.7, Box 3.1.7.4) [7]. Pure cysts and entirely spongiform nodules (TIRADS 2) should be considered as benign and therefore FNA is not indicated (unless for therapeutic purposes or in case of compressive symptoms). Oval-shaped, isoechoic, or hyperechoic nodules with smooth margins and no high-risk features (TIRADS 3) should be considered at low risk of malignancy (estimated risk of malignancy: 2–4%) and FNA should usually be performed only for nodules larger than 20 mm. Oval-shaped, mildly hypoechoic nodules with smooth margins and no high-risk features (TIRADS 4) should be considered at intermediate risk of malignancy (estimated risk of malignancy: 6–17%). FNA should usually be performed for nodules larger than 15 mm. Nodules having at least one suspicious US feature (i.e. a non-oval shape, irregular margins, microcalcifications, or marked hypoechogenicity) should be considered at high risk of malignancy, increasing with the number of suspicious features, and FNA should be performed for nodules larger than 10 mm. In this group (TIRADS 5) the risk of malignancy is significantly higher: 26–87%. However, in case of subcentimetric nodules with high-risk US features, FNA or at least active surveillance is recommended [7].

Diagnostically useful FNA specimens are obtained in about 80% of cases. The number of insufficient samples depends on operator experience, number of aspirations, the character of the nodule (cystic/solid), the experience of the cytopathologist, and especially the criteria used for adequacy of a sample. The number of sufficient samples increases if FNA is guided by US. Rebiopsy will typically halve the number of insufficient biopsies. Large-core needle biopsies can be considered when cytopathology expertise is not available. Its limitations include the need for local anaesthesia, local discomfort, and decreasing patient acceptance of repeat biopsies [18].

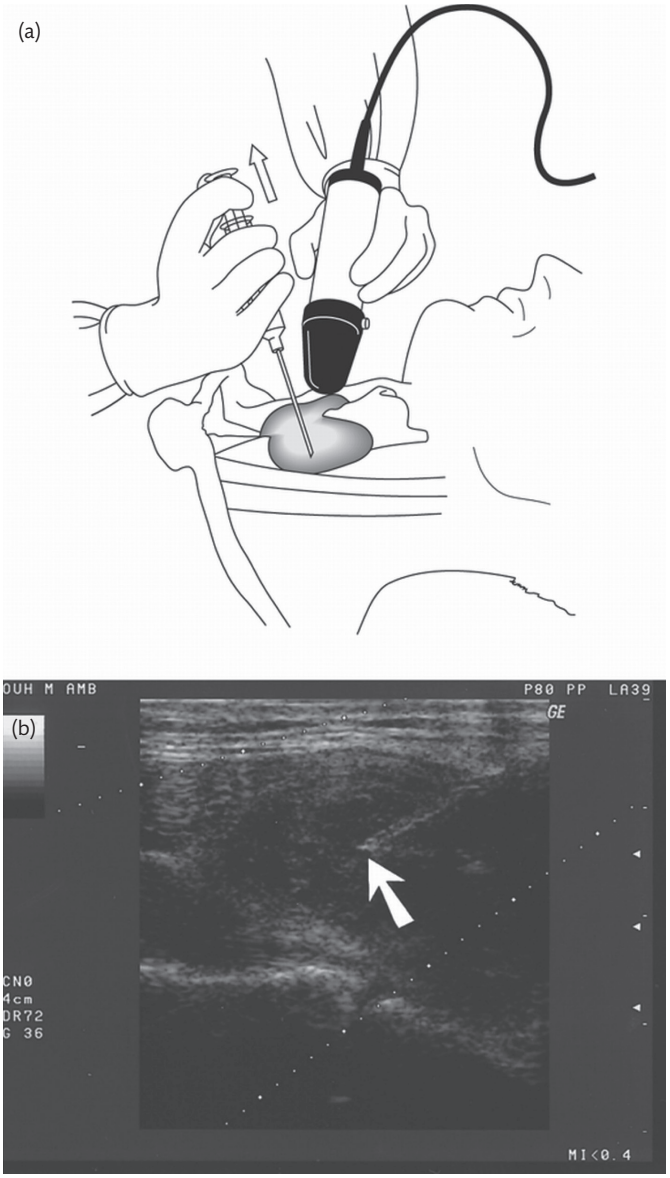

Figure 3.5.3.1 (a) Ultrasound-guided fine-needle aspiration biopsy of a thyroid nodule. The needle is inserted into the nodule. Some use a free-hand technique; others use needle-steering devices. (b) Longitudinal ultrasound scan of the neck showing the needle tract and needle tip (arrow) inside a solid hypoechoic thyroid nodule.

Fine-Needle Aspiration Cytology

There are several cytology classification systems. Here we focus on the Bethesda classification, which is based on five cytological diagnostic categories with a subdivision of the indeterminate category into atypia of undetermined significance/follicular lesion of undetermined significance (AUS/FLUS) and follicular neoplasm/suspicious for a follicular neoplasm (FN/sSFN) (see Table 3.5.3.1) [19].

While non-diagnostic and benign cytologies are characterized by a low estimated risk of malignancy (1–4% and 0–3%, respectively), the risk for the indeterminate group is considerably higher (5–15% and 15–30%, respectively) and as expected very high in the suspicious and malignant group (60–75% and 97–99%, respectively) [6]. In unselected patients undergoing FNA, cytologically benign results are expected in 39–74% of the nodules and 2–16% are cytologically malignant [20]. AUS/FLUS and FN/SFN results were observed in 1–27% and 1–25%, respectively, and cytologically non-diagnostic in 2–24% of FNAs [20]. An intrinsic limitation of thyroid FNA cytology will inevitably result in a number of indeterminate results. Vascular or capsular invasion, which are the criteria distinguishing follicular adenomas or adenomatous nodules from follicular carcinomas (FTCs) and follicular variant papillary thyroid carcinomas (fvPTC), cannot be detected in cytology samples. Thus, a high proportion of patients with FNAs classified as indeterminate will undergo diagnostic, potentially unnecessary, thyroid surgery with possible complications with the ultimate histology revealing only a 20% malignancy rate [6, 11]. Repeat FNA for AUS/FLUS FNA results are thus recommended to increase the chance for a definitive cytological diagnosis.

Accumulating evidence suggests that the limitation of AUS/FLUS and FN/SFN cytology can be compensated for by add-on molecular diagnostic approaches [21–23]. The different molecular diagnostic methodologies can be broadly classified into two categories: 'rule out' malignancy or 'rule in' malignancy approaches (see Chapter 3.5.1). While the former aims to reduce the overtreatment of benign nodules, the latter aims to optimize surgical planning (primary total thyroidectomy vs. a two-staged approach with 'diagnostic' lobectomy and subsequent completion surgery).

Table 3.5.3.1 The Bethesda system for reporting thyroid cytology and corresponding risk of malignancy

Diagnostic category	Estimated risk of malignancy % (range)	Actual risk of malignancy in nodules surgically excised % median (range)
Non-diagnostic or unsatisfactory	1–4	20 (9–32)
Benign	0–3	2.5 (1–10)
Undetermined		14 (6–48)
AUS/FLUS	5–15	
FN/SFN	15–30	25 (14–34)
Suspicious for malignancy	60–75	70 (53–97)
Malignant	97–99	99 (94–100)

AUS/FLUS, atypia of undetermined significance/follicular lesion of undetermined significance; FN/SFN, follicular neoplasm/suspicious for a follicular neoplasm.

Approach to the Patient with a Single Thyroid Nodule

- With the discovery of a thyroid nodule, a complete history and physical examination focusing on the thyroid gland and adjacent cervical lymph nodes should be performed.
- Serum TSH. If the serum TSH is subnormal, a thyroid scintigraphy should be obtained to confirm tracer uptake in the nodule. Functioning nodules rarely harbour malignancy.
- Diagnostic US should be performed unless the serum TSH is suppressed and standardized reporting should include:
  - Thyroid volume
  - Echogenicity and vascularity of the gland
  - Nodules (above 5 mm unless highly suspect)
  - Location (side, superior, medial, inferior)
  - Size (three diameters +/– volume)
  - Shape, margins, echogenicity, composition
  - TIRADS score
  - Change of size in case of follow-up US
  - Retrosternal extension and tracheal deviation
  - Study of lymph nodes (levels II, III, IV, V, VI)
  - FNA guided by US is recommended for TIRADS 3–5 (dependent on nodule size)
  - Most impalpable thyroid nodules (incidentalomas) require observation alone, but US-guided FNA is recommended based on TIRADS score [24]

If the nodule is benign on cytology, further immediate diagnostic studies or treatment are not required. Furthermore, an initially benign FNA confers negligible mortality risk during long-term follow-up despite a low but real risk of false negatives [1–2%] in this cytology category. Nodule growth cannot accurately discriminate benign from malignant lesions but cytologically benign nodules in TIRADS 3–5 should be considered for repeat US after 12–24 months [6]. Based on evidence, it is still unclear if patients with thyroid nodules larger than 4 cm and benign cytology carry a higher risk of malignancy and should be managed differently than those with smaller nodules.

Cytology diagnostic for a primary thyroid malignancy or suspicious for malignancy will almost always lead to thyroid surgery. However, an active surveillance management approach can be considered as an alternative to immediate surgery in

× Patients with very low risk tumours (e.g. papillary microcarcinomas without clinically evident metastases or local invasion and no evidence of aggressive disease)
× Patients at high surgical risk because of comorbidity
× Patients with an expected short remaining lifespan

Treatment

Most nodules are asymptomatic and benign and are usually managed by observation only and follow-up. However, some nodules do grow, cause symptoms, and require treatment, but still the optimal therapy for patients with thyroid nodules varies with the lesion and whether it is functioning (see Table 3.5.3.2).

Table 3.5.3.2 Treatment of the single thyroid nodule: comparison of various methods of treatment

Treatment type	Advantages	Disadvantages
Surgery	Nodule ablation, complete relief of symptoms, definite histological diagnosis	Inpatient, high cost, risks associated with surgery, vocal cord paralysis (approximately 3% of patients), hypoparathyroidism (<1%), hypothyroidism (1–10% in case of lobectomy) [25]
L-thyroxine	Outpatient, low cost, may slow nodule growth, may prevent new nodule formation	Low efficacy, need for lifelong treatment, regrowth after cessation of treatment, cardiac tachyarrhythmias, reduced bone density, not feasible when thyrotropin level is suppressed
Radioiodine[a]	Outpatient, low cost, high success rate (normalization of s-TSH in >95% and nodule reduced by 40% within 1 year)	Hypothyroidism (10% in 5 years), risk of radiation thyroiditis and thyrotoxicosis, only gradual reduction of the nodule, use of contraceptives in fertile women
Ethanol injection	Outpatient, relatively low cost, no hypothyroidism, nodule reduced by >40% within 6 months, recurrence rate reduced >80% in cystic nodules	Limited experience with treatment, decreasing efficacy with increasing nodule size, operator dependency, painful (reducing compliance), risk of thyrotoxicosis and vocal cord paralysis (1–2%), seepage of ethanol[b], cytological/histological interpretation impeded in treated nodules, repeat injections often needed. Abandoned by most in solid thyroid nodules
Thermal ablation[c]	Outpatient, relatively low cost, no hypothyroidism, nodule reduced by >40% in 6 months	Limited availability and experience with treatment, operator dependency, cytological/histological interpretation impeded in treated nodules, risk of vocal cord paralysis (1%) following radiofrequency ablation

[a] Treatment of the autonomous thyroid nodule.

[b] Side effects due to ethanol escaping outside the nodule or drainage of ethanol are rare (<1%) and comprise nerve damage, perinodular/periglandular fibrosis jeopardizing subsequent surgery, thrombosis of the jugular vein, and neck haematomas.

[c] Thermal techniques are still experimental and have only been introduced in a limited number of centres. The advantages are similar to those of ethanol injection, but side effects are fewer due to the higher degree of control which limits the risk of extranodular damage.

Surgery

Surgical therapy has so far constituted the mainstay of therapy. The main indications for surgery are malignant or suspicious cytological features and symptoms due to the nodule itself. Certain clinical features raising the suspicion of thyroid malignancy (**Box 3.5.3.1**) lowers the threshold for suggesting surgery despite a benign cytology as recommended by most European thyroidologists [13]. The frequency of complications due to surgery decreases with increasing experience and specialized training. Results from a Danish national thyroid surgery database (6859 patients treated with thyroid surgery) indicate very low complication rates. Thus, recurrent laryngeal nerve injury is seen in 2%, risk factors being malignant histology, neck dissection and extent of the procedure, and favouring the use of intraoperative nerve monitoring [26]. Similarly, the risk of hypocalcaemia, wound haematomas and infections are less than 2–3% [26]. Patients with benign cytology, in whom clinical suspicion results in referral for surgery, may generally be managed with lobectomy (hemithyroidectomy). L-thyroxine postoperatively to prevent regenerative hyperplasia is not recommended routinely in the euthyroid patient [1, 27].

Thyroid Hormone Suppressive Therapy

TSH suppression is intended to shrink or slow the growth of thyroid nodules, and also to prevent the occurrence of new nodules. However, most evidence suggests that changes in nodule size are similar in TSH suppressed and control groups, and treatment seems at best beneficial in a subgroup of patients with smaller solid nodules [12]. Twenty per cent (20%) or less of solitary nodules will regress as a result of L-thyroxine treatment, and regrowth is seen after cessation of therapy [12]. Long-term results confirm that the nodule-reducing effect of L-thyroxine is insignificant [28]. TSH suppression may, however, have adverse effects. Because suppressive treatment (by definition) produces subclinical hyperthyroidism, treated patients are at increased risk of, e.g. atrial fibrillation, other cardiac abnormalities, reduced bone density, and also excess mortality [8]. These side effects, combined with the questionable efficacy, have led to recommendations that vary depending upon the age, sex, and menopausal status of the patient. TSH suppressive thyroxine therapy is least tempting in elderly patients and in postmenopausal women. It should be reserved for small nodules—where treatment is least necessary—in younger patients living in borderline iodine-deficient areas. Based on management guidelines, routine suppression therapy of benign thyroid nodules has been discarded [6, 11].

Percutaneous Tissue Ablation with Ethanol

Ethanol (70–100%) can cause permanent tissue ablation due to coagulative necrosis and local small vessel thrombosis. It has proved useful in the treatment of autonomously functioning thyroid nodules, cystic thyroid nodules, and solid cold thyroid nodules [12]. Using multiple ethanol injections, complete cure (normalization of scintigraphy and serum TSH) can be achieved in two-thirds of patients with toxic nodules and three out of four patients with pretoxic nodules. A single ethanol instillation in recurrent thyroid cysts leads to remission in 80% of patients [29].

Limitations are the need to repeat ethanol injections to achieve complete cure in toxic and pretoxic nodules and to prevent renewed growth in solid cold nodules. Furthermore, the procedure is often painful despite local anaesthesia. Therefore, this procedure is only indicated in benign recurrent cystic nodules [30].

Percutaneous Thermal Procedures

Following an approximately 10-minute session of US-guided laser thermal ablation, a 50% reduction (very similar to that of ethanol injection) in nodule volume can be achieved [31]. This effect seems independent of whether the nodule is hot or cold. One or two additional sessions augment this effect by up to 30% [31]. The main indications for laser ablation are partly cystic nodules resulting in a successful outcome in 70% of patients [15]. Side effects are mainly related to various degrees of local and irradiating pain, which is much milder than with ethanol injection.

Radiofrequency ablation (RFA) is another technique that induces thermal injury to thyroid nodules through the deposition of

electromagnetic energy. Clinical outcome is similar to that obtained by laser ablation, but at a higher cost. Overall complication rate is 3%, with pain being the most common complaint. The major risks include injury to the laryngeal and vagus nerves, although this is rare (1%) [32].

The US-guided thermal procedures also include microwave and high-frequency US therapy with which experience is limited. The techniques are only available in a limited number of centres. And remain experimental to most patients [30].

Radioactive Iodine (Hot Nodule)

In the clinically euthyroid patient, autonomous thyroid nodules may present as a hot lesion on scintigraphy with varying degrees of extranodular suppression. Most of these patients have suppressed serum TSH (see also Chapters 3.3.4 and 3.3.11). Treatment may be dictated either by the nodule size, causing compression of the adjacent structures, or cosmetic disturbances. Additionally, treatment is given to prevent thyrotoxicosis (annual risk about 5%), particularly in older people and those with heart disease [12, 33]. A cure rate (normalization of scintigraphy and serum TSH) of 75% and volume reduction of 40% following a single dose of radioiodine can be anticipated [12, 33]. Side effects are few and consist of hypothyroidism in about 10% after 5 years and seem unrelated to any type of dose planning [33]. Treatment must be individualized based on patient preference and risk factors for adverse effects. Table 3.5.3.2 summarizes the advantages and drawbacks of the treatment options.

The Future

While FNA cytology is currently the most sensitive and specific tool to select thyroid nodules for surgery, after prioritization by assessment of standardized US malignancy criteria, it is characterized by inherent limitations resulting in many 'indeterminate' cytologies. The recent application of molecular analyses has provided a novel opportunity to better 'rule in' or 'rule out' malignancy [22]. Commercially available gene expression classifiers to exclude malignancy as well as gene panels (detection of cancer-specific mutations) to detect malignancy are currently introduced in the daily clinic in the United States but in general the use is limited due to the high cost and limited validation [6, 11].

3.5.4 Pathogenesis of Thyroid Cancer

Massimo Santoro, Barbara Jarzab, Jolanta Krajewska, and Dagmara Rusinek

Introduction

Thyroid cancer (TC), mainly papillary TC (PTC), demonstrates one of the most rapid increases among all malignant neoplasms. Although the widespread use of diagnostic tools (ultrasound, fine needle aspiration biopsy) is considered as a main reason of the growing TC incidence, the role of environmental factors is also emphasized as suggested by the altered relative prevalence of TC-associated genetic lesions, such as *BRAF* and *RAS* point mutations and RET/PTC rearrangements observed during recent years [1, 2].

Numerous studies resulted in a remarkably better understanding of the biology and molecular pathogenesis of TC. Among the most documented factors predisposing to TC are radiation exposure, iodine diet content, or pre-existing thyroid disease. A potential role of hormones, chemicals, lifestyle, and obesity has also been envisaged [3]. The molecular analyses of TCs, in turn, showed a number of genetic alterations, concerning mainly oncogenes, tumour suppressor genes, epigenetic changes, or alterations in miRNA expression, which altogether are responsible for altered cellular pathways, loss of cell-cycle control, and immortalization of cancer cells. Although many of these alterations are common in different TC types, advanced genome and transcriptome studies revealed heterogeneous nature of these tumours. This chapter summarizes the current concepts regarding the role of the environment and other factors in TC development as well as its molecular pathogenesis (Figure 3.5.4.1).

Differentiated TC (DTC), arising from follicular cells, is the most common. DTC includes PTC, follicular (FTC), and Hürthle cell (HCC) carcinoma. PTC is characterized by typical nuclear features, including enlargement, elongation, overlapping, and clearing, the presence of pseudoinclusions and nuclear grooves with rather rare mitotic figures [4]. Numerous PTC variants have been recognized.

FTC is the second most common DTC type. Its diagnosis requires the presence of capsular and/or vascular invasion and the lack of PTC features. However, in some cases, unequivocal differentiation between FTC and benign follicular adenomas (FTA) is not possible even at histopathological evaluation.

Significant changes in the classification of thyroid tumours have been proposed in a new 2017 WHO classification. A new entity, named 'non-invasive follicular thyroid neoplasm with papillary-like nuclear features' (NIFTP), was separated from PTC [5, 6]. Another important change is the introduction of a group of borderline thyroid tumours placed between FTA and FTC or FV-PTC. This new entity includes follicular tumours and well-differentiated tumours of uncertain malignant potential (FT-UMP and WDT-UMP, respectively), that display questionable capsular or vascular invasion, irrespective of the presence or absence of the nuclear features typical for PTC [7].

Hürthle cell (oncocytic) carcinoma (HCC) is characterized by large cells with granular cytoplasm and large nuclei, often with prominent nucleoli [7].

Poorly differentiated (PDTC) and anaplastic (ATC) thyroid carcinomas are rare and aggressive thyroid malignancies that, differently from DTC, are refractory to radioiodine. PDTC is behaviourally intermediate between differentiated (FTC and PTC) carcinomas and ATC [7]. Morphologically, PDTC may display

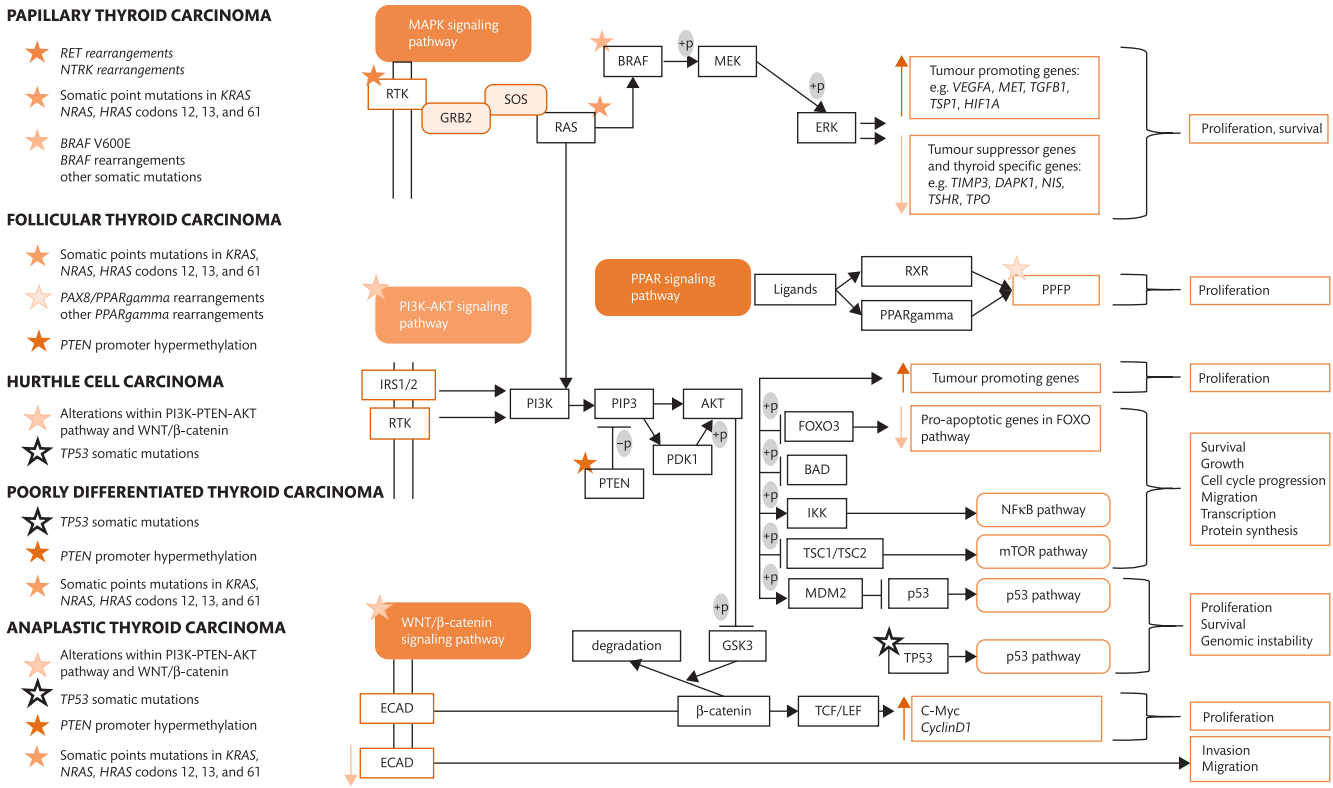

Figure 3.5.4.1 The overview of main signaling pathways altered in thyroid carcinomas. The scheme demonstrates key signal transduction pathways and mechanisms, including major genetic alterations, involved in the regulation of gene expression, the progression of the cell cycle, proliferation, cell migration, and apoptosis that are disrupted in thyroid cancers. Black arrows indicate activation and truncated lines inactivation; light orange arrows = gene downregulation; dark orange arrows = gene upregulation; stars = genetic alterations listed on the left side of the scheme.

insular growth and usually exhibit severe nuclear atypia, mitotic features, necrosis, and vascular invasion, which in ATC are much more intense [7].

Factors Predisposing to Thyroid Cancer

Radiation exposure of the thyroid gland is the most established PTC risk factor. The thyroid is particularly vulnerable to ionizing radiation, with the paediatric population being the most sensitive. Similar to many organs of the body, ionizing radiation may lead to thyroid DNA damage. Depending on the modality and severity of irradiation, it may cause cell death or, if less severe, it may result in specific genetic abnormalities. Accordingly, radiation exposure has been associated with increased formation of oncogenic rearrangements in TC [8].

Iodine intake demonstrates a well-known impact on the incidence and prevalence of thyroid disease and TC. It is believed that iodine prophylaxis changed the epidemiology of DTC. However, there is still a lack of evidence-based data supporting this hypothesis. Iodine deficiency is associated with an increased FTC risk, whereas PTC is more prevalent in regions with sufficient iodine supplementation. Also, the question about the potential role of iodine intake in the increased TC incidence and mechanisms linking the iodine intake and TC remains open. Chronic thyroid-stimulating hormone (TSH) stimulation and *BRAF* mutations are among considered pathways [2, 9].

Some studies demonstrated an increased TC risk in obese individuals [10, 11], probably related to insulin resistance [3].

Information regarding food factors is as yet not conclusive. Some analyses demonstrated decreased TC risk in individuals on fruit, raw, or mixed vegetable diet. Conversely, cruciferous vegetables may increase TC risk [12]. The data concerning the impact of meat or dairy consumption are also inconclusive [12].

One of the highest TC incidences worldwide is noticed in volcanic regions. Active volcanoes produce numerous toxic compounds that might contaminate cultivated fields and affect the animal and food chain that could be involved in thyroid cancerogenesis [3].

Xenobiotics—exogenous compounds and chemicals—may competitively inhibit sodium/iodide symporter, thyroid peroxidase, deiodinase, binding of thyroid hormones to transport proteins, or to thyroid hormone receptors or induce hepatic metabolism of thyroid hormones leading to decreased serum thyroxine concentration and increased TSH level. The question of whether xenobiotics promote or not TC has not been addressed yet [3].

There is a little evidence of a potential association of herpes viruses and DTC, and of a possible role of Epstein–Barr virus in thyroid tumorigenesis [3].

Another important issue is the autoimmune Hashimoto's thyroiditis (HT). Elevated TSH levels, stimulating follicular cells proliferation and promoting TC development, secretion of proinflammatory cytokines, and oxidative stress are considered as plausible mechanisms linking TC risk and HT [9, 13]. Interestingly, while studies using fine-needle aspiration biopsy (FNAB) specimens did not demonstrate an

increased PTC risk in HT, surgical series with histopathological assessment found the coexistence of PTC and HT [9]. However, biased results should be considered.

As TC is more frequent in women, oestrogens are considered a possible risk factor. Oestrogens and cognate receptors are important factors influencing proliferation, migration, and invasion of TC cells *in vitro* [14, 15]. A comparison between 40 TC women and 40 age-matched controls showed that oestrogen metabolism was unbalanced in TC and suggested a possible role of oestrogen-DNA adducts in TC initiation [16]. A significantly higher TC risk was observed in postmenopausal women with hysterectomy comparing to women without hysterectomy, regardless of the ovarian status. Interestingly, when a hysterectomy group was considered alone, hormone therapy was related to a lower TC risk [17]. According to the recently published review, there was a weak association between DTC risk and menstrual or menopausal factors, oral contraceptives, and hormone replacement therapy [18]. Regarding pregnancy, the question of a possible association between the parity and DTC risk remains unanswered. Some reports suggested a possible impact of pregnancy-related factors on DTC progression and short-term outcome in comparison with non-pregnant controls. On the other hand, there is probably no impact of pregnancy on DTC-related death or overall survival [18]. In conclusion, further studies are necessary to provide more direct evidence of the oestrogenic impact on thyroid tumorigenesis.

Medullary thyroid cancer (MTC) in up to 25% of cases is related to a genetic predisposition in the frame of MEN 2A and MEN 2B syndromes caused by germline mutations of the *RET* gene. Non-medullary TC may also develop in some cases in the frame of complex genetic syndromes, including familial adenomatous polyposis, Cowden syndrome, or Carney's complex. Recently, a familial *DICER1* tumour syndrome caused by germline inactivating *DICER1* mutations has been defined. *DICER1* is involved in microRNAs maturation by cleaving ribonucleic acid (RNA) precursors into siRNA and miRNA [19]. Unfortunately, besides these particular conditions, genetic heterogeneity makes it difficult to identify the TC cause in most individual families.

Molecular Pathogenesis of TC

Two models of thyroid carcinogenesis have been proposed, the fetal and the multistep theory [20, 21]. The first one assumes that cancer cells are derived from remnants of the fetal thyroid cells: thyroblasts are PTC precursor cells, prothyrocytes are FTC precursor cells, whereas thyroid stem cells are ATC precursor cells [21]. While the multistep theory is based on genomic alterations, which are indispensable in the carcinogenesis process. This theory hypothesizes that most TCs arise from a single abnormal cell and their progression is a consequence of the accumulation of further genetic alterations. According to this theory, FTC and HCC arise from thyroid adenomas following specific molecular events, while PTCs originate from a thyrocyte carrying a particular mutation. PDTC and ATC, in turn, develop from PTC and FTC through their dedifferentiation [22–24]. Each step of carcinogenesis in this theory is related to the acquisition of subsequent molecular events, which make altered cells more and more aggressive and enable them to escape from defence mechanisms, senescence, and apoptosis. The multistep theory is well supported by experimental data; it is, however, important to highlight that not every adenoma will transform into TC, so these lesions should not be treated as unequivocally precancerous ones. In this frame, the previously mentioned NIFTP may be a precursor lesion of FV-PTC. On the other hand, there is no recognized precursor of CV-PTC, though microcarcinomas are regarded as possible precursors of full-blown CV-PTCs [5].

The majority of genetic changes found in TC concern two types of alterations: gain-of-function mutations in proto-oncogenes, responsible for cell growth, proliferation, and survival stimulation and loss-of-function mutations in tumour suppressor genes that normally negatively regulate cellular growth, cell cycle, and promote DNA repair. Conversion of a proto-oncogene into an active oncogene may result from a point mutation leading to a constitutively acting protein product. This situation is observed in the case of *RAS* genes or the *BRAF* gene, which encode proteins of the MAPK pathway, a critical pathway in cell proliferation, differentiation, and survival. Alternatively, oncogene formation in TC can be mediated by translocations of DNA fragments within or between chromosomes, leading to structural gene rearrangements. These alterations lead to fusions of 5' end of a normally expressed gene with 3' end of a silent gene, usually having kinase activity, which results in constitutive activation of the latter one. In PTC this mechanism leads, e.g. to the *RET* receptor tyrosine kinase gene (another MAPK pathway component) activation. The loss of tumour suppressor function, in turn, usually requires a 'two-hit' ('Knudson') mechanism that leads to impaired function of both alleles coding a particular protein (e.g., loss of genetic material from one chromosome with additional loss or mutation on the other one). There are exceptions from this 'two-hit' mechanism, the most characteristic being represented by the *TP53* gene. Accordingly, specific mutations in the *TP53* gene result in a mutated p53 protein that can prevent the function (dominant negative) of the normal protein encoded by the wild-type allele [25]. Oncogenes and tumour suppressor genes may also be regulated through epigenetic modifications [26]. DNA hypomethylation of CpG-rich regions (CpG islands) in regulatory promoter regions of specific proto-oncogenes leads to their upregulated transcription, whereas DNA hypermethylation may lead to tumour suppressor gene silencing. Epigenetic modifications are also considered as one of the potential mechanisms responsible for thyroid-specific gene silencing and dedifferentiation. Some thyroid-specific genes, like *NIS* or *TSHR*, undergo DNA hypermethylation, which supports the recognition of their aberrant methylation as TC progression marker [26]. Epigenetic changes also include aberrant miRNAs expression. miRNA are small non-coding RNAs that regulate gene expression by binding to the 3' untranslated region of the mRNA targets or, more rarely, to the coding sequence of the target gene [27]. Alterations in miRNAs expression were demonstrated to play a crucial role in cancer cell proliferation, migration, invasion, differentiation, and survival in different cancer types, including TCs.

Molecular Events in PTC

According to the Cancer Genome Atlas (TCGA) study, PTC demonstrates a relatively low mutation rate (11 non-synonymous mutations per tumour; 0.41 mutations per Mb on average), compared to other solid tumours [28]. This may explain the indolent behaviour of most PTCs, although it should be recognized that as aggressive malignancies as leukaemias also carry a reduced mutation burden.

The TCGA study revealed a number of new somatic point mutations and other genetic alterations, which reduced the fraction of PTCs with unknown genetic background approximately to 3.5% [28]. Among commonly mutated genes are those encoding proteins of the MAPK pathway: *BRAF, KRAS, HRAS*, and *NRAS*, whose mutations were present in 74.6% of PTCs, but also *EIF1AX, PPM1D*, and *CHEK2*. The most frequent molecular event in PTC is the $BRAF^{V600E}$ (valine-to-glutamate) point mutation (36–83% PTCs) [29]. The *BRAF* gene encodes a serine-threonine kinase located downstream to RAS in the MAPK pathway, and its activation leads to the phosphorylation of MEK, which, in turn, mediates phosphorylation of MAPKs (ERK) kinases and finally transcription of specific genes. The $BRAF^{V600E}$ mutation is responsible for the constitutive RAS-independent and dimerization-independent activation of BRAF kinase and consequently of the MAPK pathway. This genetic alteration is capable to initiate PTC, as it was demonstrated *in vivo* in mouse models [30, 31], and was described as an early molecular event [32]. However, some studies showed the presence of $BRAF^{V600E}$ mutation in metastatic lymph nodes but not in matched primary thyroid tumour, thus suggesting that the mutation may have arisen *de novo* during progression [33, 34]. Some studies have reported the presence of subclonal *BRAF* mutations in PTC, thus raising the possibility they can be a progression rather than initiating events [35, 36]. However, the TCGA and other studies indicated the clonal nature of $BRAF^{V600E}$ mutation in PTC [28, 37]. Theoretically, there can be a third possibility that $BRAF^{V600E}$ mutation initiates PTC, however, powerful secondary alterations occur during the tumorigenesis and take over cancer progression as drivers, and the *BRAF* mutation is removed by DNA repair mechanisms [38]. $BRAF^{V600E}$ shows a strong association with PTC phenotype being most frequent in its CV-PTC [29] and TCV-PTC (more than 90% of cases) variants [39, 40]. Moreover, many studies demonstrated that the presence of $BRAF^{V600E}$ was associated with poorer PTC outcomes, including aggressive pathological features, loss of sensitivity to radioiodine, or increased recurrence risk [41]. Other *BRAF* point mutations (including K601E) are rather uncommon, less potent MAPK drivers, and usually present in encapsulated FV-PTC [42].

RAS somatic point mutations are mainly restricted to FV-PTC with a frequency of 10% to 21% [43, 44]. *RAS* genes (*NRAS, HRAS, KRAS*) encode members of small GTPase superfamily, which act as molecular transmitters of signals from tyrosine kinase and non-tyrosine kinase receptors to MAPK and PI3K-AKT pathways. *NRAS* is predominantly mutated in TC, mostly in codons 12 and 61.

The *EIF1AX* gene, encoding an essential eukaryotic translation initiation factor, was among the mutated genes in PTC in the TCGA study [28]. Although the frequency of its mutations did not exceed 2%, it was classified as a cancer gene associated with PTC. Further studies indicated the presence of *EIF1AX* mutations, mainly in encapsulated FV-PTC, and also in ATC [45, 46]. The presence of *EIF1AX* mutations in FTA and their absence in FTC may suggest that *EIF1AX*-mutated adenomas may progress to FV-PTC rather than to FTC [45].

Recently *TERT* promoter mutations were detected in a number of cancers, including TCs [47, 48]. The *TERT* gene encodes the reverse transcriptase component of telomerase with the main function, together with its RNA component, of telomere elongation by adding TTAGGG at the end of chromosomes [49]. In addition to unlimited replication, telomerase activation leads to increased proliferation, angiogenesis, resistance to apoptosis, and metastatic potential of cancer cells [50]. Two *TERT* promoter mutations, 1,295,228 C>T and 1,295,250 C>T (–124 and –146 bp from the ATG; termed C228T and C250T, respectively) are common. Both alterations create the 11-nucleotide fragment (5'-CCCCTTCCGGG-3'), which contains a consensus binding site, GGAA, for ETS (E26 transformation specific) transcription factors [48]. It has been demonstrated that both C228T and C250T increase the transcriptional activity of the *TERT* promoter [47]. *TERT* promoter mutations are present in 11.3% of PTCs, with C228T being more frequent than C250T. The frequency is correlated with aggressiveness of the tumour, and it is higher in TCV-PTC, showing an aggressive nature [48, 49]. Recent studies indicated the association of *TERT* promoter mutations with the presence of $BRAF^{V600E}$ mutation and their coexistence with poorer outcomes compared to the impact of each of these alterations alone. Similar consequences were observed in the coexistence of *TERT* promoter and *RAS* mutations [49, 51].

RET rearrangements are characteristic of radiation-induced PTCs. These chromosomal aberrations concern mainly young patients since thyroid cells of children are particularly sensitive to radiation. *RET* encodes a transmembrane receptor with tyrosine kinase activity, and normally, in contrast to C cells, it is not expressed in follicular thyroid cells. Activation of *RET* in these cells results from a fusion of *RET* fragment encoding domain with tyrosine kinase activity with 5' end of other normally expressed genes [52]. More than 16 different *RET* rearrangements have been described so far with *RET/PTC1* (*CCDC6-RET*), *RET/PTC3* (*NCOA4-RET*), and *RET/PTC2* (*PRKAR1A-RET*) being the most frequent and accounting for 60%, 30% and 5% of all *RET/PTC* translocations, respectively [53]. The overall frequency of *RET* rearrangements varies between studies, from 3% to 85% in the adult population, an average of 35% [54]. Although *RET* rearrangements are the hallmark of radiation-induced PTCs, these alterations are also present in benign lesions, like in Hashimoto's disease [55, 56]. Currently, it is obvious that *RET* rearrangements are characteristic of childhood PTC, also sporadic one. In addition to *RET/PTC* rearrangements, other chromosomal aberrations are observed in PTCs, however, in a significantly lower number of cases. *NTRK* rearrangements concern mainly *NTRK1* and *NTRK3* genes with *ETV6/NTRK3* being the most frequent one in radiation-induced TC [57]. There are also *BRAF* gene rearrangements (*AKAP9/BRAF; AGK/BRAF*), detected in about 10% of radiation-induced PTC [58, 59] and *ALK* rearrangements described in 1–5% cases [60–62].

Depending on the underlying driver mutation, two molecular subtypes of PTCs have been proposed: BRAF-like (BRL) and RAS-like (RL) [28]. BRL tumours include not only carcinomas with $BRAF^{V600E}$ mutation but also tumours with *TERT* promoter mutations, *RET/PTC* and *BRAF* gene rearrangements, whereas RL tumours include all cases with *BRAF* point mutations other than V600E, *EIF1AX, RAS* point mutations, and *PAX8/PPARgamma* rearrangements. BRL tumours are most typically CV-PTC, while RL tumours have FV-PTC features. Moreover, the two molecular subtypes differ in terms of genomic, epigenetic, and proteomic profiles, however, the BRL tumours displayed a more heterogeneous nature. BRL PTCs activated mainly the MAPK signaling pathway, whereas

in the RL tumours activation of MAPK, as well as PI3K pathway was observed [28].

As far as the epigenetic modifications, increased expression of miR-146b, miR-221 and miR-222 has been documented in PTC [28, 63]. Moreover, *BRAF*^{V600E} mutation seems to be associated with hypermethylation of several tumour suppressor genes, including *TIMP3, DAPK1*, or *RARB* [64], and with hypomethylation of other genes [65].

Molecular Alterations in FTC

RAS point mutations and *PAX8/PPARgamma* (PAX8/PPARG fusion protein, PPFP) rearrangements are the most frequent molecular events in FTC. Noteworthy, these genetic lesions are also present in FTA. The frequency of *RAS* mutations in FTC is about 40%, mainly in codons 12, 13, and 61. The alterations in *NRAS* 61 codon are related to a more aggressive FTC course [44, 66]. FTCs harbouring *RAS* mutation may demonstrate a higher risk of dedifferentiation [67]. PPFP rearrangements are present in 26–56% of FTCs, in 0–13% of FTAs, 0–3% of HCCs, and 0–1% of PTCs [20]. They result from the translocation between chromosomes 2 and 3 [t(2;3)(q13;p25)] and, although the function of both genes is known, the role of PPFP fusion protein is still unclear. It leads to the downregulation of *PPARG* suppressor gene and the deregulation of *PAX8*, which may contribute to cancer development [68–71]. In addition to PPFP translocation, another *PPARG* rearrangement has been reported in FTC with *CREB3L2* gene as a fusion partner [72]. *TERT* promoter mutations are more frequent in FTC compared to PTC and concern, on average, 17% of FTC [49]. A small number of mutations recently detected in FTC involve *DICER1, IDH1, EZH1*, and genes related to the PI3K-PTEN-AKT pathway [73].

In contrary to PTC, copy number changes are common in FTC. Losses of chromosome 3p are common alterations, however, additional loss of heterozygosity (LOH) sites were detected in FTC, including 1p, 6p/q, 8p/q, 9p, 11q, 13q, 18q, and 22q [74]. Two amplifications, in turn, concerning 11p and 17q, were suggested as potential early molecular events involved in cancer initiation [75].

The knowledge about the miRNA profile in FTC is very limited. Increased expression of miR-181 and miR-200 family and downregulation of miR-199 was reported in FTC [76], and two miRNAs, miRNA-7-5p and miR-206, were proposed as potential markers able to distinguish FTA from FTC [77]. Moreover, miR-146b and miR-221, previously reported as upregulated in PTC, showed increased expression in FTC as well, which suggests these two miRNAs are common players in both DTC types [27].

Molecular Events in HCC

HCC, especially aggressive cases, display molecular signature typical for the activation of PI3K-PTEN-AKT and WNT-β-catenin pathways [78]. The presence of *TP53* mutations in 10–20% of cases speaks for its aggressive nature [79, 80]. A characteristic HCC feature is an increased mitochondrial mass [78]. This phenomenon results from mutations of genes encoding subunits of mitochondrial respiration chain complexes [81]. Mutations in mitochondrial as well as in nuclear DNA were described, however, alterations of the *GRIM-19* gene are the only nuclear gene mutations typical for oxyphilic tumours [53].

Molecular Basis of PDTC and ATC

PDTC and ATC may develop through dedifferentiation of DTC with *BRAF*^{V600E} noticed in 33% and 55% of cases, respectively, and *RAS* mutations present in 29% and 52%, respectively [44, 46, 82, 83]. *BRAF* and *RAS* mutations are frequently accompanied by *TERT* promoter mutations, which are described in 40% and 73% of PDTC and ATC, respectively [46, 48, 82, 84]. Importantly, *TERT* promoter mutations, which are subclonal in PTC, become clonal in PDTC and ATC [82]. *EIF1AX* mutations, in turn, are present in 11% of these malignancies, and in most cases, coexist with *RAS* mutations [46, 82]. *TP53* mutations, with the frequency of 59%, are characteristic for ATC, however, they are also present in PDTC but with a significantly lower frequency (10%) [46, 82, 83]. These alterations may reflect genomic instability and are considered as a late molecular event in TC progression. In contrast to DTC, ATC is associated with more frequently altered PI3K-PTEN-AKT pathway, WNT-β catenin pathway, SWI/SNF complex, and mutations of genes responsible for repair mechanisms [85].

Copy number changes are common alterations in PDTC and ATC. PDTC was described to harbour chromosomal deletions 1p, 13q, and 15q not associated with any known driver mutation and 22q deletion associated to *RAS* mutations [82]. Amplification of 20q and deletions 8p and 17p were found in ATC.

miRNAs profile is strongly deregulated in PDTC and ATC, with many studies reporting a number of miRNAs with altered expression in these tumours. miR-183-3p was reported to be upregulated in PDTC, whereas miR-150 and miR-23b were downregulated, with the latter two being associated with tumour relapse and mortality [27]. The downregulation of miR-200c was observed in ATC. This particular miRNA is related to *TP53* mutations as it is transcriptionally regulated by *TP53*. miR-30 family distinguishes undifferentiated from well-differentiated thyroid carcinomas with downregulation of miR-30 only in ATC. Noteworthy, the miR-17-92 cluster, which expression is stimulated by *BRAF* ^{V600E}, may play an important role in cancer initiation and progression to ATC [27].

3.5.5 Pathology of Thyroid Cancer

Fulvio Basolo and Clara Ugolini

Introduction

Thyroid cancer is a rare neoplasia, accounting for about 1% of all malignancies and less than 0.5% of deaths for disease. However, thyroid cancer represents the most common type of endocrine malignancy, with incidence differently distributed in the various geographical areas, ranging from 0.5 to 10 cases per 100 000 population [1]. Women are more commonly affected, with rates that are two or three times higher than those of men [2].

Thyroid cancers can be classified into two broad types: primary or secondary. Primary cancers can have epithelial or non-epithelial origins. Primary epithelial cancers originate from follicular epithelial cells or from C cells. Only medullary thyroid carcinoma originates from C cells. Most primary epithelial thyroid tumours originate from follicular cells and show a variety of morphological features and clinical behaviours. They include papillary carcinoma with all its variants, follicular carcinomas, Hürthle carcinomas, poorly differentiated carcinomas, and anaplastic carcinomas. Tumours originating from follicular and from C cells (mixed medullary and follicular carcinomas) as well as primary thyroid squamous carcinomas are very rare. Non-epithelial tumours include malignant lymphomas and other mesenchymal tumours. Finally, secondary or metastatic tumours are infrequent. The most common tumours that can metastasize to thyroid are lung, kidney, breast carcinoma and also colon carcinoma [3].

The histological classification of thyroid cancer of the World Health Organization (WHO) has been recently re-elaborated and published [3].

As previously described, thyroid cancer is rare and usually indolent. For this reason, preoperative screening is essential to determine the most suitable clinical or surgical treatment.

Fine needle aspiration (FNA) biopsy is the most commonly used technique. It occurs under the supervision of an expert cytopathologist, and permits a high-accuracy diagnosis of nodules.; the use of this approach in the clinical practice can lead to a more conservative strategy, aimed at reducing surgical interventions [4].

Nowadays in the world there are different cytological classifications, very similar from several points of view, but the best known and more frequently used is the Bethesda System for reporting thyroid cytopathology [5].

According to the American Joint Committee, which develops the American Joint Committee on Cancer (AJCC) staging system describing the extent of cancer progression, last compiled and published thyroid cancer histological staging references in 2017 [6, 7]. The TNM (tumour, node, metastasis) classification considers 'T' the tumour size and its extension on the basis of the following scheme:

T1: tumour < or = 2 cm in greatest dimension limited to the thyroid
- T1a: tumour < or = 1 cm in greatest dimension limited to the thyroid
- T1b: tumour >1 but < or = 2 cm in greatest dimension limited to the thyroid

T2: tumour > 2 but < or = 4 cm in greatest dimension limited to the thyroid

T3: tumour >4 cm in greatest dimension limited to the thyroid or gross extrathyroidal extension, invading only strap muscles (sternohyoid, stenothyroid, or omohyoid muscles)
- T3a: tumour >4 cm in greatest dimension limited to the thyroid
- T3b: tumour of any size with gross extrathyroidal extension invading only strap muscles)

T4: tumour with gross extrathyroid extension
- T4a: gross extrathyroid extension invading subcutaneous soft tissues, larynx, trachea, oesophagus, recurrent laryngeal nerve
- T4b: gross extrathyroid extension invading prevertebral fascia or encasing the carotid artery or mediastinal vessels

With regard to 'N', lymph node staging:
- N0: no evidence of lymph node metatasis
- N1: evidence of loco-regional lymph node metastasis
- pN1a metastasis to VI or VII level lymph nodes
- pN1b metastasis to unilateral, bilateral, or contralateral lateral neck lymph nodes (I, II, III, IV or V levels), or retropharyngeal lymph nodes

With regard to 'M', distant metastasis staging:
- M0: no evidence of distant metastasis
- M0: no evidence of distance metastasis

Papillary Carcinoma

Papillary carcinoma is the most common malignant neoplasia of the thyroid gland, representing about 80% of thyroid cancer. It is more frequent in females in their III-IV decades of life and it is the most frequent thyroid cancer in the paediatric population. A familiar form of papillary carcinoma is frequent, but papillary carcinoma is rarely associated with familial syndromes such as familial adenomatous polyposis or Cowden syndrome [3].

Papillary carcinoma takes the name from its most frequent growth pattern: making papillae. The diagnosis of papillary carcinoma is however based on typical nuclear alterations. Papillary carcinoma generally has a good prognosis with long disease-free survival and high probability of healing. The mortality rate ranges from 5 to 17%. Negative prognostic factors are older age at time of diagnosis, large size, male sex, extension to extrathyroidal tissues (in particular to stripe muscles) and, finally, presence of distant

metastases. Some authors consider variants of papillary carcinoma (e.g. tall cells or hobnail variants) as negative prognostic factors. Papillary carcinoma can indeed show variable clinical behaviour: few variants of papillary carcinoma are very aggressive and may result in distant metastases and sometimes causing fatal outcomes. Papillary carcinoma usually metastasizes lymphatically., Vascular invasion can more rarely be observed, especially in follicular variants or tall cell variants of papillary carcinoma [8]. The most important etiological cause of papillary carcinoma is the exposure to ionizing radiation during childhood and adolescence. Dramatic cases were the nuclear accidents of Chernobyl in 1986 and the more recent one of Fukushima, in which the massive emissions of radioactive elements, in particular of radioiodine^{131} (I131), increased the incidence of papillary carcinoma by more than 100 times. Other evidence is the use of radiotherapy in the head and neck and in the mediastinum regions (in the past used for acne or tinea capitis or thymic hyperplasia in children and adolescents). The risk of cancer has a strong inverse correlation with age at exposure.

The molecular alterations of papillary carcinoma are numerous, of which one of the most important is the V600E mutation of the *BRAF* gene, also considered a diagnostic marker for papillary carcinoma.

Other mutations of the *BRAF* gene have been described, in particular the K601E mutation of *BRAF* has been reported in follicular variants of papillary carcinoma and sometimes in follicular adenomas.

Other important gene alterations are the rearrangements involving the *RET* gene (called *RET/PTC*) alongside a series of other genes, the most frequent being *RET/PTC1* and 3. Their frequency is extremely variable in the different study cases and could be due to a high heterogeneity of papillary carcinoma. Other important gene alterations of papillary carcinoma are the point mutations of *RAS* genes; these mutations are located at several specific sites, which are codons 12, 13, 61 of the N-, H-, K-RAS genes. Rearrangements of the *NTRK1* gene, also called TRK rearrangement, can be present in papillary carcinoma with a frequency of about 10%. It is important to underline that almost all these mutations are mutually exclusive, and are capable of activating the mitogen-activated protein kinase (MAPK) pathway regulating cell growth, differentiation, and survival [9].

Morphology

At gross examination, papillary carcinoma can show different aspects and sizes, and usually arises as a white-grey, irregular area with central scar formation; or as completely solid nodule; or as a solid and partially cystic nodule; or sometimes as a totally cystic lesion. The size of papillary carcinoma can change from only a few millimetres to numerous centimetres, forming voluminous masses with extension in the extrathyroidal tissues and sometimes in closer structures and organs. At microscopic examination papillary carcinoma can show different growth patterns: the most frequent growth pattern, the papillary pattern, shows exclusively papillary structures with a central fibro-vascular core lined by tumour cells (see Figure 3.5.5.1). The papillary carcinoma tumour cells are very peculiar. Accordingly with the WHO, the histological and cytological diagnosis of papillary carcinoma must be made only in presence of typical nuclear alterations.

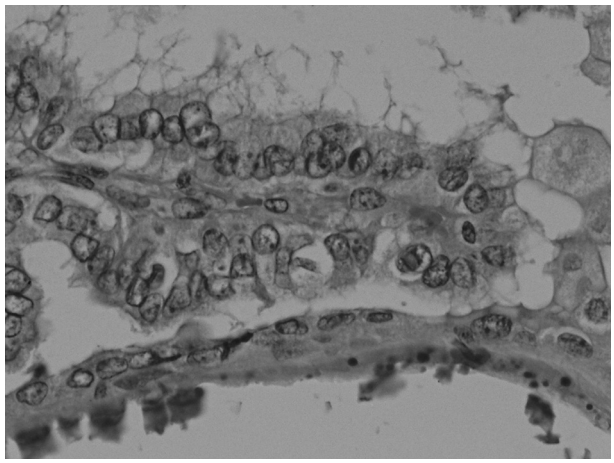

Figure 3.5.5.2 Nuclear features of papillary carcinoma: carcinoma cells are oval or elongated with irregular, large nuclei. The nuclei have a clear appearance with a marked nuclear membrane, show nuclear grooves, usually arranged in parallel to long axis of the nucleus, obtaining a typical coffee bean shape and they can show also nuclear pseudo-inclusions that are cytoplasmatic intranuclear inclusions.

The papillary carcinoma cells are oval or elongated with irregular, large nuclei. These have a clear appearance with a very marked and pronounced nuclear membrane on account of chromatin clearing and lateralization along the nuclear membrane. The nuclei of papillary carcinoma show nuclear grooves, generally arranged in parallel to the long axis of the nucleus, resulting in a typical coffee bean shape. The nuclei of papillary carcinoma can also show nuclear pseudoinclusions that are cytoplasmatic intranuclear inclusions similar to bubbles (see Figure 3.5.5.2). Papillary carcinoma can present psammoma bodies that are calcific, lamelled, and concentric structures. They are the result of cyclical depositions of calcium on tumoural death cells and they are particularly frequent in classical variants of papillary carcinoma [3, 8].

Other Variants of Papillary Carcinoma

Papillary carcinoma can present different histological variants. They are numerous and very different for their aspect and sometimes for their clinical behaviour. The histological variants are described on the basis of cell type, cell size and shape, architecture, and stroma. It is important to repeat that the diagnosis of papillary carcinoma must be made only in the presence of the typical nuclear alterations, independent of variants or growth patterns [3, 8].

Follicular Variant of Papillary Carcinoma

The follicular variant is the most common following the classical variant. As underlined by its name, it is characterized by the exclusive presence of follicular structures lined with cells with nuclear alterations of papillary carcinoma (see Figure 3.5.5.3). The follicular growth pattern can be micro, macrofollicular, or mixed [3, 8].

The follicular variant of papillary carcinoma can show an infiltrative attitude and lacks a fibrous capsule. Instead, its most frequent form presents a complete fibrous capsule, with no kind of infiltration or invasion. This form has an extremely low (quite absent) malignant potential.

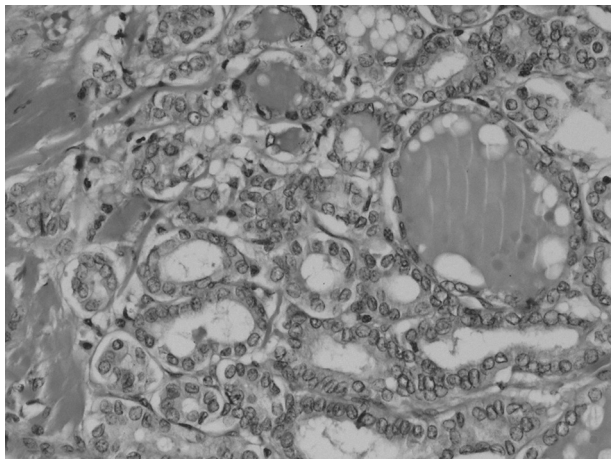

Figure 3.5.5.3 Follicular variant of papillary carcinoma: exclusive presence of follicular structures lined by cell with the typical nuclear alterations of papillary carcinoma.

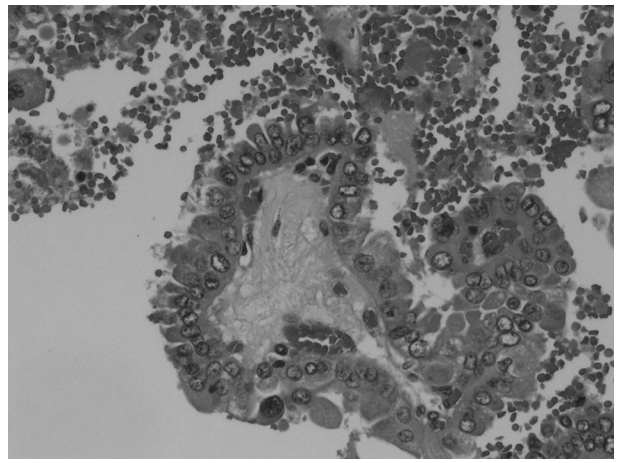

Figure 3.5.5.4 Hobnail variant of papillary carcinoma: papillary or micropapillary structures lined by cell with a wide eosinophilic cytoplasm and with apically located nuclei.

Recently, a task force of thyroid pathologists and molecular pathologists, together with clinicians, has declassified the completely encapsulated follicular variant of papillary carcinoma in Non-invasive follicular thyroid neoplasm with papillary-like nuclear features (named by its acronym NIFT-P) [3–10].

Tall Cell Variant of Papillary Carcinoma

The tall cell variant of papillary carcinoma is a typical variant of older age and male gender. It commonly shows papillary or solid growth patterns. The papillary or solid structures are lined with very particular elongated cells, the so-called tall cells, with a height two or three times the width and with the typical nuclear features of papillary carcinoma. The clinical behaviour of this variant is normally more aggressive than that of the classical variant, showing larger dimensions at the time of tumour diagnosis, with high likelihood of extrathyroidal infiltration and vascular invasion, and a high probability of recurrences and distant metastases. Disease-free survival is usually shorter than that of the classic variant and the mortality rate can reach 25% and more [3, 8].

Oncocytic Variant of Papillary Carcinoma

The oncocytic variant of papillary carcinoma is a rare variant. It is formed by large cells with wide eosinophilic cytoplasm and nuclear features of papillary carcinoma. The growth pattern is generally papillary, with a very low infiltrative behaviour. The clinical outcome is very similar to that of the classical variant [3, 8].

Hobnail Variant of Papillary Carcinoma

The hobnail variant of papillary carcinoma is a rare variant showing a papillary or micropapillary growth pattern, but rarely presents follicular or clustered structures. These structures are lined by cells with a wide eosinophilic cytoplasm and with apically located nuclei (see Figure 3.5.5.4). The nucleus cytoplasm ratio is decreased and the cells lose cellular cohesion. This variant has an aggressive behaviour and presents frequent necroses, mitoses, lymphatic invasion, extrathyroidal extension, distant metastases, and recurrences [3, 8].

Solid Variant of Papillary Carcinoma

The solid variant of papillary carcinoma is a rare variant, representing about 1% of adult papillary carcinoma. It is more common in children and adolescents or in patients exposed to ionizing radiations. The solid variant should be taken into consideration when all the other variants are not represented inside the tumour. It shows a solid, trabecular, or nested growth pattern. This variant has an aggressive behaviour showing distant metastases (in particular in the lung) and higher mortality rates than those of the classical variant [3, 8].

Other rarer variants are: **Warthin's-like variant,** morphologically very similar to **Warthin's-like tumour of salivary gland**; the columnar cell variant, that can be very aggressive and that is characterized by a papillary growth pattern with nuclear overlapping and stratification; the cribriform variant associated with familiar adenomatous polyposis; **papillary carcinoma** with nuclear fasciitis-like stroma in which papillary carcinoma is almost completely substituted by spindle cells arranged in irregular fascicles in a background of fibro-myxoid stroma (see Table 3.5.5.1 for complete list of variants of papillary carcinoma) [3, 8].

Table 3.5.5.1 List of papillary carcinoma variants

Variants of papillary carcinoma	
Papillary microcarcinoma	Papillary thyroid carcinoma with fibromatosis/fasciitis-like stroma
Encapsulated variant	Solid/trabecular variant
Follicular variant	Oncocytic variant
Diffuse sclerosing variant	Spindle cell variant
Tall cell variant	Clear cell variant
Columnar cell variant	Warthin-like variant
Cribriform-morular variant	Hobnail variant

Follicular Carcinoma

Follicular carcinoma represents 5–15% of thyroid cancer. It is more frequent in women and extremely rare in children and more common in areas with iodine deficiency [2, 3].

Most follicular carcinomas are sporadic. The most important factors implicated in the aetiology of follicular cancer are iodine deficiency and exposure to ionizing radiations. A proof is that the increment of iodine with diet substantially decrements the incidence of follicular carcinoma. This is probably due to the increment of TSH (thyroid stimulating hormone), stimulated by iodine deficiency and involved in thyroid cancer development.

Moreover, exposure to ionizing radiations results in the development of follicular cancer, although less than papillary carcinoma.

Another important risk factor is the pre-existence of a benign neoplasia, which may represent a definite risk factor in about 15% of follicular carcinomas. The presence of follicular adenoma could be the precursor of follicular cancer, possibly resulting from *RAS* gene family mutations. On the other hand, the development of follicular cancer in the multinodular goitre could be due to prolonged stimulation of TSH [9].

Follicular carcinoma is a well-differentiated cancer originating from follicular epithelium and characterized by an exclusive follicular growth pattern.

The cells of follicular carcinoma do not show any nuclear features of papillary carcinoma.

Clinically, the follicular carcinoma presents itself as a solitary cold nodule with very slow growth but with high metastatic power. It usually metastasizes by vascular invasion, while lymphatic invasion is extremely rare. Metastases to lung and bone are the most frequent and they sometimes represent the early onset of the disease [3, 8].

We can subdivide follicular carcinoma into a minimally invasive form and in a widely invasive form. The minimally invasive form is an encapsulated tumour, very similar to an adenoma, with histological evidence of tumour capsular and/or vascular infiltration (see Figure 3.5.5.5). The second form of follicular carcinoma is widely invasive, presenting wide infiltrative aspects of vascular, peritumoral, and sometimes perithyroidal tissues. These types differ for their clinical and biological behaviour. In the former type the 10-year survival rate is about 90%, while in the latter form it decreases to 35%.

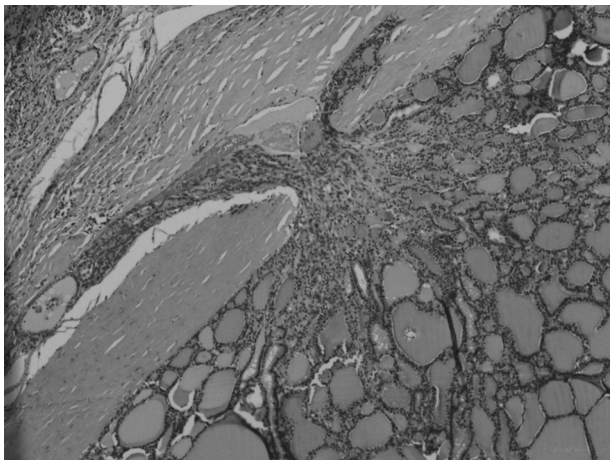

Figure 3.5.5.5 Minimally invasive follicular thyroid carcinoma: histological evidence of tumour capsular infiltration with the typical mushroom-like appearance.

The Hürthle (oncocytic or oxyphilic) tumour was considered the most important 'variant' of follicular carcinoma [3, 8].

As previously described, the most important genetic alterations involved in follicular cancer are the point mutations of the *RAS* gene family. These mutations affect codons 12, 13, and 61 of the H, K, and N-Ras genes. *RAS* gene mutations are present in more than 50% of follicular carcinomas, while the oncocytic or oxyphilic carcinomas present a lower percentage of *RAS* gene mutations. Another important genetic alteration is the PAX8/PPARgamma (peroxisome proliferator-activated receptor gamma) rearrangement, which involves about one-third of follicular carcinomas and about 5% of oncocytic or oxyphilic carcinomas [9].

Morphology

On gross examination follicular carcinoma, usually no larger than just a few centimetres in dimension, appears as an encapsulated, generally oval, solid nodule. A thick fibrous capsule generally surrounds the lesion and foci of invasion can rarely be detected in the tumour capsule; for this reason, extensive sampling of the tumour capsule is essential for a correct diagnosis of follicular carcinoma. In the widely invasive form of follicular carcinoma, thyroid tissue or sometimes extrathyroidal tissue invasion can be macroscopically evident. Vascular emboli are rarely observed, especially in the large vein of the neck.

On light microscopy follicular carcinoma presents a typical follicular architecture (microfollicular, macrofollicular, normofollicular, or mixed), sometimes associated with insular, or solid, or trabecular areas. In these cases, it is fundamental to distinguish the follicular carcinoma from the poorly differentiated thyroid carcinoma, which presents the same growth pattern but worse prognosis. Follicular carcinoma cells are cubic, small, and round, with an even chromatin pattern and small nuclei with small nucleoli. These nucleoli are more frequent and evident in oxyphilic follicular carcinoma, where they acquire a cherry colour. The cells of the follicular carcinoma obviously lack the nuclear features of papillary carcinoma [3–8].

The morphology of the cells and the presence of a thick fibrous capsule make it difficult to differentially diagnose between follicular adenoma and follicular carcinoma. The only fundamental diagnostic features are infiltration of the tumoural capsule and vascular invasion (Figure 3.5.5.5). To date, there is no real consensus about the invasion of the tumour capsule. Most authors require that neoplastic cells penetrate the entire thickness of the fibrous capsule for a diagnosis of follicular carcinoma. Capsule ruptures caused by surgical lacerations or changes due to precedent biopsy or FNAs are considered pseudo-invasions, insufficient for a diagnosis of follicular carcinoma. The typical appearance of infiltration of the tumour capsule is similar to that of a mushroom (Figure 3.5.5.5). Vascular invasion is referred to the invasion of tumour cells into the veins, and such cells must be adherent to the endothelium or take place in the context of a thrombus. Vascular invasion, whose extent has prognostic importance, should be localized in or beyond the capsule. Limited invasion (less than four vessels) has a good prognosis, while extensive invasion (more than four vessels) is associated with a worse outcome. Widely invasive follicular carcinomas show intrathyroidal or extrathyroidal tissue infiltration. They might also

Table 3.5.5.2 Classification of follicular thyroid carcinoma

Traditional	Armed Forces Institute of Pathology (AFIP) 2014		WHO 2017
Minimally invasive	Minimally invasive	With capsular invasion	Minimally invasive
		With limited vascular invasion (<4 vessels)	Encapsulated angioinvasive
		With extensive vascular invasion (> or = 4 vessels)	
Widely invasive	Widely invasive		Widely invasive

show wide vascular infiltration which, alone, is insufficient to be classified as widely invasive. Widely invasive follicular carcinomas are often large tumours with solid or insular or trabecular growth patterns, and they must be distinguished from poorly differentiated thyroid carcinomas or from solid or trabecular variants of papillary carcinomas [3–8] (see Table 3.5.5.2 for classification scheme modified from WHO 2017).

Hürthle (Oncocytic or Oxyphilic) Cell Carcinoma

The Hürthle (oncocytic or oxyphilic) cell carcinoma is a common tumour representing about 20% of follicular carcinomas. It is formed by Hürthle or oncocytic or oxyphilic cells, which are large cells with voluminous granular cytoplasm, and large centrally located nuclei with prominent nucleoli [2, 3, 8]. Most authors require that Hürthle cells should be most of the tumour (more than 75%) for a diagnosis of Hürthle cell carcinoma. Hürthle cell carcinomas present solid, trabecular, and follicular growth patterns with fibrous bands between clusters of cells. The tumours have little stroma and for this reason may show a pseudopapillary pattern. Hürthle cell carcinoma can metastasize through the bloodstream, invading in particular the liver, lungs, and bone. Hürthle cell carcinoma can also metastasize lymphatically and spread to cervical lymph nodes. Tumours with large dimension (more than 4 cm), necrosis, high mitotic rate, presence of atypical mitoses, and foci of small cells have been recently classified as poorly differentiated Hürthle cell carcinoma [3, 8, 9].

Medullary Carcinoma

At the end of the 50s medullary carcinoma was exhaustively described by Hazard and colleagues, who performed a detailed study of its morphology, presence of amyloid, frequency of lymph node metastasis, clinical behaviour and prognosis [7, 8]. The cells of origin, the so-called C cells, were described only some years later. Medullary carcinoma actually derives from C cells, which are usually present in normal thyroid glands localized in the interfollicular zone. Normal C cells do not stain by traditional histochemical methods such as haematoxylin-eosin staining, but they are very reactive to some types of immunohistochemical staining, the most common of which is currently calcitonin [3]. Medullary carcinoma, representing about 10% of malignant thyroid tumours, is particularly studied because of its clinical behaviour, high percentage of familiarity, and probability of being part of a syndrome. However, most medullary carcinomas are sporadic. Mean patient age is 50 years with a minimal prevalence for the female sex [3, 7, 8, 9]; up to 20% are familial cases with an autosomal dominant inheritance. These medullary cancers can appear as tumours that are not associated with the syndrome (familial non-MEN medullary carcinomas), or as a part of multiple endocrine syndromes (MEN), in particular MEN type 2A, MEN type 2B, MEN type 3. In familial cancer (familial non-MEN medullary carcinomas) the onset age is usually less than 50 years, while medullary cancer in MEN can already be present in the first years of life. The most frequent genetic alterations of medullary carcinoma are the RET proto-oncogene mutations present in more than 90% of the MEN2 family. Families with MEN 2A or FMTC present exon-10 and exon-11 mutations of the *RET* gene in 95 and 85% of cases, respectively. Families with MEN 2B present the mutation of codon 918 (in exon 16) in about 95% of cases. Genetic screening is recommended in first-degree relatives of patients with these types of alterations. If positive, they must be subject to prophylactic thyroidectomy. The risk of very early development of carcinomas and metastases makes prophylactic thyroidectomy fundamental in the very first years of life. Finally, also the sporadic form of medullary carcinoma presents RET gene mutations, the most frequent being found in codon 918 [9, 11, 12].

On gross examination, medullary cancer can be single or multifocal with dimensions that can range from few millimetres to some centimetres. The lesion usually presents a white-grey aspect and a clear edge.

On light microscopy, medullary carcinoma can show different growth patterns and may sometimes imitate other thyroid tumours. The cells are in most cases polygonal and present small-size nuclei, sometimes with spindle aspects. Nuclear chromatin is often finely granular and the nucleoli are absent. The cells rarely mimic the small lung cancer cell or can appear spindle as thymic or mesenchymal lesions. The tumour cells of medullary cancer are usually arranged in trabeculae and/or nests, which are separated by dense collagenous or hyalinized material containing amyloid that can be stained with Congo Red. Medullary carcinoma can be definitively diagnosed by immunostaining neoplastic cells show positive staining for chromogranin A and synaptophysin, CEA (carcinoembryonic antigen), NSE (neuro-specific enolase) and, in particular, calcitonin, which represents the most sensitive marker. The number of calcitonin-positive cells can change according to the different cases: of these, about 1.5% show negativity for calcitonin and they are considered medullary cancers only if they present also C-cell hyperplasia or familial genetic alterations. Medullary cancer also shows positive staining for cytokeratin and negative staining for follicular cell markers like thyroglobulin [3, 8, 9].

Sporadic medullary carcinoma appears as a single, painless nodule. More than 50% of cases present cervical or mediastinic

lymph node metastases at diagnosis, and more than 15% show distant metastases to bone, lung, liver, and adrenal gland.

Familial cancers are frequently multifocal and bilateral. Prognosis is associated with the rapidity of diagnosis and prophylaxis, although medullary cancer in FMTC or MEN2A shows a better prognosis than cancer in MEN2B [3, 8].

Poorly Differentiated Thyroid Carcinoma

Poorly differentiated thyroid carcinoma is still a controversial entity. Some authors have proposed to include, in poorly differentiated carcinoma category, tumours with clinical behaviour, morphology, and biological features intermediate between well-differentiated and undifferentiated carcinomas. A large number of carcinomas has been added over the years, making the poorly differentiated carcinoma category extremely heterogeneous. The tumours nowadays considered to be poorly differentiated include some variants of papillary carcinoma such as tall cell variant, hob nail variant, Hürthle cell carcinoma, and insular carcinoma [3, 8, 9].

The poorly differentiated carcinoma represents 5% of thyroid malignancies. The mean age of the patients is about 10 years higher than that of patients with differentiated carcinomas, but younger than that of patients with anaplastic cancer. Poorly differentiated carcinoma shows a prevalence for the female sex (male/female ratio:1/2) [1, 2].

The aetiology can develop in three different directions: poorly differentiated cancer can progress from papillary cancer, or from follicular cancer, or 'de novo'. From a molecular point of view, the most frequent alterations of poorly differentiated cancers are the point mutations. They include very early events that are important for tumourigenesis and that predispose for further mutations (like Ras mutations or BRAF mutations) and also for gene alterations driving de-differentiation (like TP-53 and β-catenin mutations) [9].

On gross examination, poorly differentiated cancer displays a large size (range 1–10 cm) with an aggressive and infiltrative behaviour. This neoplasia very often shows an extrathyroidal extension and very rarely shows a partial tumour capsule. Poorly differentiated carcinoma is usually hard to cut, its aspect is firm and yellowish-white-, and it may present haemorrhagic or necrotic areas.

On light microscopy the diagnosis of poorly differentiated carcinoma displays de-differentiated morphological features. On the basis of Torino's criteria, they result as following [13, 14]:

1. Solid/trabecular/insular growth pattern
2. Lack of nuclear features typical of papillary cancer
3. Presence of one of the following features: necrosis; three or more mitoses per high power fields; convoluted nuclei

Poorly differentiated carcinoma commonly shows a bad prognosis with 5-year survival lower than 50%. It generally presents compression symptoms associated with cough, dyspnoea, dysphagia. Infiltration of the recurrent nerve is frequent and an early event and distant metastases are present at the time of diagnosis in more than 20% of patients. Lymph node metastases are also frequent. Poorly differentiated carcinoma shows a partial response to routine radiometabolic therapy [3, 8].

Anaplastic (or Undifferentiated) Carcinoma

Anaplastic or undifferentiated carcinoma is a malignant neoplasm behaving in a very aggressive fashion, and is constituted by undifferentiated cells. It has an epithelial origin but, in the most cases, it lacks immunoreactivity for follicular markers such as thyroglobulin or TTF-1. It typically presents itself as a large mass (medium 6 cm) with a rapid growth (it may duplicate its volume in less than one week) and with a fatal outcome of a few months [3].

Anaplastic carcinoma is a rare neoplasm, representing about 5% of all malignant thyroid tumours, and it is a typical neoplasm of adult patients, the majority of whom are older than 60 years, whereas patients younger than 40 years are very rarely affected by the tumour. It is a little more common in females than in men (ratio F/M:1.5:1). The etiological factors of anaplastic cancer include the pre-existence of a malignant or of a benign thyroid neoplasia. The aetiology is described by the clinical histories of patients followed-up for goitre or for differentiated thyroid cancer and who have developed anaplastic carcinoma. Another proof of the possibility of transformation from differentiated to undifferentiated or anaplastic carcinoma is sometimes the presence of residual areas of differentiated carcinoma (i.e. papillary carcinoma areas) in the context of anaplastic cancer. Another certain etiological factor is the lack of iodine. The introduction of iodine in a diet (in areas with chronic deficiency) has demonstrated a high decrease of anaplastic cancer. The genetic alterations include somatic point mutations. As already explained for poorly differentiated carcinoma, they include very early event, important for tumorigenesis and predisposition for further mutations (such as Ras mutations or *BRAF* mutations), and also gene alterations that drive the de-differentiation (like TP-53 and β-catenin mutations) [9].

On gross examination, anaplastic carcinoma appears as a large mass infiltrating all the thyroid gland and often the adjacent structures. Size varies from 1 cm to 20 cm (medium about 6 cm). The lesions are friable with multiple necrotic or haemorrhagic foci. In the paucicellular variant of anaplastic carcinoma the lesions may be hard to cut and present a whitish aspect. On light microscopy, anaplastic carcinoma may show heterogeneous aspects, which can coexist in the same tumour. The cells display marked anaplasia and can show spindle, epithelial, giant, rhabdoid features. The nuclei are extremely pleomorphic with irregular edge and granular chromatin. The mitoses, especially atypical mitoses, are very frequent and coagulative necrosis is a recurring feature (see **Figure 3.5.5.6**). Regardless of its morphology, anaplastic carcinoma infiltrates the thyroid gland and its nearby structures as well as the veins and arteries.

The cells of anaplastic carcinoma may show immunohistochemical positivity for epithelial markers (i.e. cytokeratin), but usually lack expression for follicular markers such as thyroglobulin or TTF-1.

Anaplastic cancer is rare but, if present, it rapidly leads to fatal neoplasia. It presents itself as a large infiltrating mass that extends to the neck structures such as the oesophagus, trachea, or big vessels. Distant metastases are present in more than 45% of patients, at diagnosis time, and they are localized in the bone, lung, or brain. Anaplastic carcinoma does not respond to radiometabolic therapy [8].

Non-Epithelial Tumours of the Thyroid Gland

Mesenchymal Tumours

Primary mesenchymal tumours of the thyroid are extremely rare. We can cite smooth muscle tumours such as leiomyomas, leiomyosarcomas, and solitary fibrous tumours. Leiomyoma is a benign neoplasia, typical of women, which shows histological and immunophenotypical features of the smooth muscles and which can be cured, generally by complete surgical removal or by lobectomy. Leiomyosarcoma is a typical neoplasia of older patients, with no gender predilection. On gross examination, it usually appears as a large mass with infiltrative behaviour. On light microscopy pleomorphism, mitosis, atypical mitosis, coagulative necrosis can be found. Primary leiomyosarcoma of the thyroid is a very rare malignant neoplasia and its diagnosis can be made also after the exclusion of secondarism from other sites [3].

Primitive solitary fibrous tumour of the thyroid is a very rare mesenchymal neoplasia, for which only few cases have been reported. Solitary fibrous tumour shows prevalent fibroblastic differentiation. Some tumours can present focal or extended myofibroblastic differentiation that is generally benign [3].

Vascular Tumours

Vascular primitive thyroid tumours are rare and include haemangioma, lymphangioma, and angiosarcoma. In particular, the angiosarcoma is a rare and aggressive lesion representing less than 4% of thyroid lesions, with a geographical predilection of Alpine regions of Italy and of Europe. Its behaviour is similar to anaplastic carcinoma with rapid fatal outcome [3, 8].

Lymphomas

Primitive thyroid lymphomas are rare neoplasms, accounting for less than 5% of all malignant thyroid tumours. They include a heterogeneous group of lesions and originate from B lymphocytes. The most frequent histotypes are large B-cell lymphomas as well as the extranodal marginal zone B-cell lymphomas of mucosa-associated lymphoid tissue (MALT), with its variants. The aetiology of primary thyroid lymphomas is strictly linked to chronic lymphocytic thyroiditis. Clinically, primitive thyroid lymphomas occur in females with mean age 60–65 years, but they can potentially arise at any age (14–90 years). They can present different sizes, from very small to large masses with compression symptoms including pain, dysphagia, dyspnoea, coughing. Differential diagnosis must exclude secondarisms from diffuse lymphomas [8].

3.5.6 Papillary, Follicular, and Anaplastic Thyroid Carcinoma and Thyroid Lymphoma

Ruxandra Dobrescu and Corin Badiu

Introduction

Thyroid cancer is the most frequent endocrine neoplasia. Most of these cancers (>90%) are derived from the follicular epithelium, that is, differentiated thyroid cancers (DTC)—papillary (PTC), and follicular thyroid cancer (FTC). Thyroid cancer incidence has increased significantly in the past 40 years [1, 2], probably mostly due to increased detection of infracentimetric PTC. On the other hand, this rise in incidence has not been paralleled by an increase in mortality [1], which, coupled with the high prevalence rates (up to 35%) of incidentally detected PTCs at autopsy studies, suggests that these newly diagnosed small PTCs might be clinically insignificant. Therefore, care should be taken to avoid overtreatment and treatment-associated morbidity in these patients. At the other end of the spectrum of disease are patients with invasive tumours, aggressive histology, and distant metastases, for whom early diagnosis and correct multimodal treatment is essential. Dynamic risk assessment during follow-up allows a better characterization of tumour behaviour and guides further management decisions.

Diagnosis

Thyroid cancer typically presents as a palpable cervical lump ± lymph nodes, particularly suspicious if consistency is hard, if it occurs in a child or as a single nodule in a man, if personal history reveals head and neck radiation exposure or if family history is positive for familial DTC syndromes (polyposis, Carney complex, Cowden, or Werner syndromes).

It is often discovered incidentally in an asymptomatic patient undergoing ultrasound, CT, or MRI of the neck and can be an isolated finding or part of multinodular goitre. A non-palpable nodule has the same risk of malignancy as a palpable nodule of the same size. Occasionally patients present with locally advanced, invasive disease, involving the adjacent neck structures resulting in hoarseness, dysphagia, dyspnoea, and signs of neurological compression (brachial plexus and recurrent laryngeal nerve compression caused by the primary tumour and spinal cord compression due to bone metastases).

Thyroid function tests are usually normal in these patients, although concurrent autoimmune thyroiditis, particularly frequent in women, can present with hypothyroidism. Hyperthyroidism can rarely occur in patients with FTC with distant metastases and it is often T_3 thyrotoxicosis due to increased activity of type 1 and 2 deiodinases in tumour tissue. Malignant *struma ovarii* is also occasionally associated with T_3 thyrotoxicosis.

Thyroid ultrasound evaluation is essential, as it provides the morphological characterization of the nodule and can identify other significant non-palpable thyroid nodules or pathological lymph nodes. The ultrasound pattern of a thyroid nodule has been widely used to predict the risk of malignancy and to select the nodules for which FNAB might be indicated. The ultrasound features with highest specificity for thyroid cancer are hypoechogenicity, the presence of microcalcifications, 'taller than wide' shape, irregular margins, and presence of suspicious lymph nodes [3].

Fine needle aspiration biopsy is the gold standard for the diagnosis of thyroid cancer. For cytologically indeterminate lesions (follicular neoplasm, follicular lesion of undetermined significance (FLUS) or atypia of undetermined significance (AUS)), with a risk of malignancy between 10% and 40% [4], molecular studies on fine needle aspirates using mutational analysis and mRNA expression profiles have shown promise in better risk-stratifying the patients to avoid un-necessary thyroidectomies [5, 6].

Staging

Thyroid cancer management is based on the concept of risk assessment and stratification. Treatment decisions are taken individually after balancing the risk of recurrence and disease-specific mortality with the risk of treatment-associated morbidity. The aggressiveness of the treatment and follow-up is thus tailored to each patient's tumour characteristics [7].

The preferred initial staging system is the tumour node metastasis (TNM) system [8] (Table 3.5.6.1). It uses age at diagnosis and tumour extension to stratify patients according to their estimated risk of dying of cancer. Age is the most important prognostic factor; mortality increases progressively after around 35 years of age. Large tumours, gross extension beyond the thyroid capsule and clinically apparent lymph nodes are negative prognostic factors.

Most patients with DTC will be stage I and II at diagnosis, with excellent prognosis in terms of survival, but although mortality is generally very low, recurrences can be very frequent. The American Thyroid Association (ATA) risk stratification system [7], updated in 2015, uses clinical and pathology data to stratify patients into low, intermediate and high-risk groups, in order to guide the best initial treatment decision based on estimated risk of recurrence (Figure 3.5.6.1). Precise histological characterization is important

Table 3.5.6.1 Differentiated thyroid carcinoma TNM staging, AJCC UICC 2017

Age	Stage group	TNM	10 yrs estimated survival
<55	I	Any T, Any N, M0	98–100%
<55	II	Any T, Any N, M1	85–95%
≥55	I	T1, N0/x, M0 T2, N0/x, M0	98–100%
≥55	II	T1, N1, M0 T2, N1, M0 T3, Any N, M0	85–95%
≥55	III	T4a, Any N, M0	60–70%
≥55	IV A	T4b, Any N, M0	<50%
≥55	IV B	Any T, Any N, M1	

TNM, tumour, node, metastasis; AJCC, American Joint Committee on Cancer; UICC, Union of International Cancer Control.

Primary tumour: T1: tumour ≤2 cm in greatest dimension limited to the thyroid; T2: tumour >2 but ≤4 cm limited to the thyroid; T3: tumour >4 cm limited to the thyroid or any size tumour with gross extrathyroidal extension invading only the strap muscles; T4: Gross extrathyroidal extension: T4a: if invading subcutaneous soft tissues, larynx, trachea, oesophagus, or recurrent laryngeal nerve; T4b: if invading prevertebral fascia or encasing the carotid artery or mediastinal vessels.

Regional lymph nodes: N0: no evidence of locoregional lymph node metastasis; N1: Metastasis to regional nodes.

Distant metastases: M0: no metastases, M1: distant metastases.

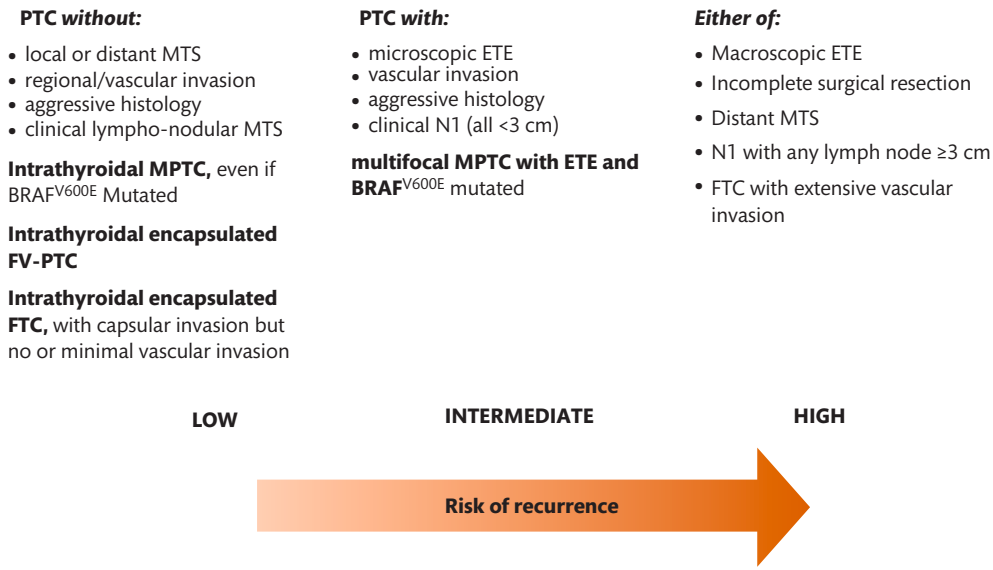

Figure 3.5.6.1 Risk of recurrence stratification system according to ATA 2015. ATA, American Thyroid Association; PTC, papillary thyroid carcinoma; FV-PTC, follicular variant papillary thyroid carcinoma; MPTC, micropapillary thyroid carcinoma; FTC, follicular thyroid carcinoma; MTS, metastases; ETE, extrathyroidal extension.

as certain histological subtypes (tall cell, hobnail variant, columnar cell carcinoma) tend to be more aggressive and can respond poorly to standard treatment. Nodal micrometastases can be present in up to 90% of patients with PTC but evidence suggests that adverse prognosis is limited to those patients with macroscopic, clinically evident node involvement [9]. The extent of extrathyroid extension (ETE) and the presence of vascular invasion are also important. The presence of $BRAF^{V600E}$ mutation is generally associated with aggressive histology, ETE, and lymph nodes metastases, and appears to convey a higher risk of recurrence [10], particularly if associated with another oncogenic mutation, such as the TERT promoter mutation [11].

During follow-up, new clinical, biological, and imaging data that reflect each patient's individual response to treatment are used to restratify that patient according to his/her current risk of recurrence, in a dynamic risk stratification system [7].

Treatment

Surgical resection is the essential first step in the management of thyroid cancer. Due to the ability of DTC to concentrate iodine and respond to thyroid-stimulating hormone (TSH) stimulation, adjuvant treatment is based on a combination of **radioiodine therapy** and **TSH suppression**, tailored on each patient's risk of recurrence. Treatment decisions should ideally be taken in a multidisciplinary tumour board (MDT) [12].

The optimal management is constantly re-evaluated in light of accumulating new evidence related to prognostic factors, risk of recurrence, and optimal treatment modalities, with guidelines published by several societies [7, 12–14]. Despite numerous biological differences, papillary and follicular thyroid carcinomas are generally treated in the same way, and have similar prognosis.

Surgery

Complete surgical tumour resection is essential, irrespective of stage and the possible presence of distant metastases, as this increases disease-related survival, decreases the risk of recurrence, and allows staging and decision-making for further management.

Presurgical imaging is important for proper planning of the procedure. Neck ultrasound will provide morphological details related to the tumour, extension, possible multifocality, and can identify suspicious lymph nodes. High resolution imaging with CT or MRI is needed in extensive local disease to assess the degree of infiltration of the trachea, oesophagus, and vascular structures and identify an intrathoracic extension for which thoracotomy might be necessary.

Extent of Surgery

Lobectomy is recommended for infracentimetric thyroid nodules with a positive FNA diagnosis in the absence of extrathyroidal extension and lymph node involvement, as the risk of recurrence is extremely low. Lobectomy can also be performed in selected patients with tumour size between 1 and 4 cm without any suspicious features, as the outcomes appear similar compared to total thyroidectomy, with fewer side effects. These patients do not require radioiodine ablation and can be followed-up with ultrasound and thyroglobulin measurements [7, 14].

Total thyroidectomy should be performed for multifocal tumours and in patients with positive family history of thyroid cancer or personal history of neck irradiation, as their risk of recurrence is higher. It is also preferred if ultrasound reveals contralateral lobe changes (e.g. thyroiditis) or non-specific adenopathy that can complicate follow-up. Total thyroidectomy is required in patients with large tumours bigger than 4 cm, with ETE, or in the presence of metastases [7, 12, 14].

Clinically evident lymph node metastases (on palpation, ultrasound or intraoperative examination) are present in 20–50% of patients with DTC and they convey a higher risk of recurrence [9] so **therapeutic node dissection** of clinically apparent node disease is recommended [7, 12, 14]. Up to 90% of patients have micrometastases evident at histology but their risk of recurrence is negligible [9] so prophylactic neck dissection is not recommended.

The most frequent complications after surgery are hypoparathyroidism and recurrent laryngeal nerve injury. The risk is higher with total thyroidectomy, node dissection, and with repeat interventions. Transient hypoparathyroidism is seen in up to 20% of thyroid cancer patients after surgery and becomes permanent in around 1%. Laryngeal nerve monitoring might help in redo surgery/recurrences, to decrease the recurrent damage.

Adjuvant Therapy Based on Risk Stratification

Radioiodine Treatment

Differentiated thyroid cancer arises from the follicular epithelium and similar to normal thyroid cells has the ability to take up iodine from the blood through the membrane sodium-iodide symporter. ^{131}I is taken up by normal thyroid and cancer cells and causes acute cell damage by emission of beta particles. Gamma radiation is also emitted by ^{131}I and can provide a map of thyroid cancer spread through the body after scanning with a gamma camera.

After total thyroidectomy, radioiodine therapy can be used in DTC patients for:

1. Remnant ablation—to destroy normal thyroid remnants, in order to minimize the risk of cancer recurrence in high-risk patients. After ablation, thyroglobulin can be used as a specific marker of disease persistence/recurrence and whole-body ^{131}I scanning can identify foci of disease activity.
2. Adjuvant therapy in case of subclinical, microscopic residual disease, or clinically significant residual disease that is not surgically accessible.

The necessity of radioiodine treatment is assessed individually based on the estimated risk of recurrence with the goal of administering the minimal amount of radioactivity needed in the best tolerated method [7, 14].

Low-risk patients: ^{131}I is not recommended for small tumours less than 1 cm without other risk factors, even with coexisting microscopic lymph node metastases, because no benefit was proven in terms of survival or risk of recurrence [15, 16]. ^{131}I is not required for tumours of 1–4 cm in diameter in the absence of other risk factors.

Intermediate risk patients: ^{131}I should be considered in selected patients with microscopic ETE, clinically documented lymph node metastases, vascular invasion, or in the presence of aggressive histologies, but the evidence so far concerning its benefit is conflicting [15].

High-risk patients: ^{131}I therapy should be administered to all high-risk patients as this improves survival and decreases the risk of recurrence [7, 12, 14].

Optimal uptake of ^{131}I by thyroid cancer cells is dependent on adequately increased TSH levels and a low-iodine diet in the weeks preceding radioiodine administration. Medications containing iodine and exposure to iodine-based contrast agents should be avoided, as a high load of iodine can take weeks to be eliminated (more than 4 weeks for CT with contrast/angiography; months/years after stopping amiodarone treatment). Twenty-four hour urinary iodine concentrations (UIC) can be helpful in monitoring iodine excretion.

The radioiodine uptake is increased by high TSH, achievable either by thyroid hormone withdrawal or by administrating recombinant human TSH.

Thyroid hormone withdrawal (THW) is essential in high-risk patients to treat gross residual disease for optimal ^{131}I uptake (7). Serum TSH should be above 30 mUI/L, which is usually achieved after 3–4 weeks of THW. To minimize symptoms of hypothyroidism, shorter-acting T_3 can be given (25 ug bds or tds) for 2 weeks after LT4 is withdrawn, but should be used with caution in older patients and in patients with ischaemic cardiac disease. T3 is stopped 2 weeks before radioiodine treatment.

Recombinant human TSH (rhTSH) has the advantage of avoiding prolonged hypothyroidism, thus improving quality of life, and reducing radiation exposure, as radioiodine is cleared more rapidly than in a severely hypothyroid patient. It can be used for remnant ablation and as adjuvant therapy of potential residual microscopic disease in low and intermediate risk patients [7]. It can also be used in high-risk patients in whom THW and subsequent hypothyroidism can seriously aggravate concurrent illnesses (i.e. congestive heart failure, depression, etc). rhTSH is essential in patients with central hypothyroidism of any cause in whom TSH stimulation is not possible with THW. rhTSH is administered as 0.9 mg intramuscular daily injections on two consecutive days and ^{131}I is administered on the third day, then after 2–7 days a whole-body scan (WBS) is performed.

^{131}I Dose

For remnant ablation in low-risk patients a low 30 mCi dose after rhTSH is as successful as a higher 100 mCi dose administered after THW, although long-term outcome data are lacking [17]. In intermediate risk patients with suspected microscopic residual disease, lower doses (30 mCi) appear to have similar ablation rates and long-term clinical outcomes to higher doses (100–150 mCi) [18, 19]; higher doses (75–100 mCi) might be appropriate for patients with higher risk features, such as vascular invasion. In high-risk patients with distant metastases higher doses (100–200 mCi) should be used after THW, as there is insufficient data concerning long-term outcomes with rhTSH administration [7]. Certain histological variants (Hürthle cell FTC, tall cell PTC or poorly DTC) have poor radioiodine sensitivity and they also require higher doses. Dosimetric studies might allow a more precise estimation of administered ^{131}I activity than empiric fixed doses.

Pretreatment radioiodine diagnostic scanning is rarely indicated. It can be useful when the extent of residual disease cannot be established with certainty after surgery using ultrasound and thyroglobulin measurement or if the results could potentially alter the need to administer ^{131}I or the required dose [7, 12, 14]. Diagnostic use of ^{131}I is hypothesized to cause 'stunning', i.e. lower uptake of the treatment dose of ^{131}I administered afterwards, due to sublethal radiation cell injury caused by the diagnostic dose. To minimize this

risk, diagnostic scanning should use low dose ^{131}I (1–3 mCi) or the lower energy isotope ^{123}I (1.5–3 mCi). The WBS should be obtained after 48–72 h for ^{131}I and 6–24 h for ^{123}I.

Side Effects and Complications

Acute and chronic side effects occur in up to 30% of patients after radioiodine treatment, especially if higher radiation doses are administered [20].

Most patients present with salivary and lacrimal gland dysfunction. Xerostomia, ageusia, and sialadenitis are frequent and lemon juice and candies can be helpful. Radiation thyroiditis is occasionally seen in the presence of large thyroid remnants. Similar to acute sialadenitis, it usually responds to non-steroidal anti-inflammatory drugs but steroids can sometimes be required.

In the acute setting, particularly after thyroxine withdrawal, high TSH values acts as a potent stimulus for cancer cell growth and together with the accompanying oedema can cause important tumour swelling, leading to airway obstruction, nerve compression, or severe bone pain, depending on the location. Steroids can be helpful (dexamethasone 8 mg bds or prednisone 60 mg/day), started 1 or 2 days before radioiodine administration then tapered during the following days.

Gonadal dysfunction is sometimes seen, ranging from transient oligospermia or ovarian dysfunction to infertility after high cumulative doses.

Patients are at increased risk of secondary malignancies, particularly leukaemia and solid tumours in sites that concentrate ^{131}I: breast tissue, urinary, and digestive tract [20]. This risk is higher in younger patients and with high cumulative doses (>500–600 mCi). Patients are encouraged to drink large volumes of fluids to avoid accumulation of the isotope in the bladder, and laxatives are prescribed to ensure regular bowel movements.

^{131}I administration is contra-indicated in pregnancy because it crosses the placenta and destroys the fetal thyroid leading to cretinism. Women are advised to avoid pregnancies for at least 6 months after radioiodine treatment. ^{131}I administration is forbidden during lactation as it crosses to the child through the milk; in addition, accumulation in the breast tissue leads to increased radiation exposure of the mother.

For radiation protection, most patients receive radioiodine therapy as inpatients in dedicated nuclear medicine units, with limited access. After treatment, patients must respect strict personal hygiene, avoid public gatherings and close contact, particularly with young children and pregnant women for a few days following ^{131}I administration, in order to reduce radiation exposure to the community.

Thyroid Hormone Suppression

After surgery, thyroxine treatment is tailored to counteract TSH stimulation of potential tumour remnants. The degree of TSH suppression in individual patients is decided based on the estimated risk of recurrence [7, 14]. A robust TSH suppression improves progression-free survival in high-risk patients but a moderate suppression of TSH is probably enough for intermediate risk patients and no benefit was proven for low-risk patients [21].

Low-risk patients with partial thyroidectomy or total thyroidectomy and non-detectable non-stimulated thyroglobulin should have a low-normal TSH (0.5–2 mUI/L). Certain patients have enough thyroid tissue left after a lobectomy to maintain normal thyroid function without thyroxine replacement.

Intermediate risk patients should have a TSH between 0.1 and 0.5 mUI/L. The same moderate TSH suppression is indicated for low-risk patients with low level detectable non-stimulated thyroglobulin.

High-risk patients require a TSH maintained below 0.1 mUI/L [7, 14].

Thyroxine dose can be reduced if required due to advanced age, the presence of atrial fibrillation, ischaemic heart disease, or severe osteoporosis.

Follow-up and Long-Term Management

The principal objectives of follow-up are to ensure adequate thyroid hormone replacement with the recommended level of TSH suppression and to monitor for possible disease recurrence. This active surveillance is mostly based on serial measurements of **thyroglobulin** and **neck ultrasound** [7, 14]. In patients with evidence of persistent disease further imaging will be required to define disease extension and to plan management. This will imply a combination of radioiodine WBS, CT/MRI, bone scan, ^{18}FDG-PET/CT.

Thyroglobulin

Synthesized exclusively in thyroid follicular cells, thyroglobulin (Tg) is a good marker for DTC providing information about persistent and recurrent disease.

Serum Tg is generally measured by immunometric assays based on antigen-antibody interactions. Up to 25% of patients with thyroid cancer have high antithyroglobulin antibody (TgAb) titres which can disrupt the thyroglobulin assay, making follow-up difficult. Additionally, there is significant interassay Tg variability, so in any given patient the same Tg assay should be used for serial measurements and TgAb should always be measured at the same time [7, 14]. High Tg values above the upper range of the assay should be re-measured after dilution until an accurate result is obtained, so precise data are documented allowing correct serial evaluation during follow-up.

Thyroglobulin reaches its nadir at 3–4 weeks after surgery; positive serum levels reflect presence of small thyroid remnants and/or disease remnants. There is no clear cut-off to discriminate between these scenarios, but levels above 30 ng/ml after lobectomy and above 5 ng/ml after total thyroidectomy should raise suspicion of residual/metastatic disease [7].

Radioiodine ablation destroys normal thyroid remnants thus increasing the specificity of thyroglobulin in detecting recurrences. TSH stimulation increases the sensitivity of thyroglobulin measurement. An undetectable TSH-stimulated thyroglobulin can safely identify disease-free patients. Newer super-sensitive thyroglobulin assays, with functional sensitivity of less than 0.05 ng/ml, might obviate the need for TSH stimulation, as non-stimulated thyroglobulin values correlate well with TSH-stimulated thyroglobulin measured by these assays [22].

For low-risk patients who have not received ^{131}I, the variation trend in serial Tg measurements can have an excellent negative (declining values) or positive (increasing values) predictive value for disease recurrence during long-term follow-up [15].

In a patient with positive TgAb, Tg measurement is unreliable due to assay interference, but rising TgAb levels suggest disease recurrence.

Ultrasound

The vast majority of DTC recurrences are localized in the neck and ultrasound is highly sensitive in detecting lymph node involvement, irrespective of ^{131}I ablation status and Tg levels [15]. Suspicious lymph nodes are defined by the presence of microcalcifications, cystic changes, peripheral vascularity, round shape and loss of hilar image and hyperechogenicity [23]. If repeat surgery is considered, FNAB should be previously performed with cytology and measurement of thyroglobulin in the aspirate fluid to confirm recurrent lymph node disease [24].

Radioiodine Scanning

The combination of neck ultrasound and serum thyroglobulin measurement is equal to or superior in detecting residual disease compared to radioiodine WBS, which should not be used routinely [15]. During follow-up, repeat WBS is indicated in patients with post-treatment scans showing areas of increased ^{131}I uptake suggestive for pathological lymph nodes/distant metastases. It is also indicated in patients with normal ultrasound but high TgAb in whom Tg measurement is unreliable to evaluate disease status [7]. SPECT/CT has the advantage of superimposing functional and anatomical images thus providing a more accurate localization of disease recurrence.

^{18}FDG-PET/CT

In patients with negative WBS despite high thyroglobulin levels (stimulated thyroglobulin >10 ng/ml), ^{18}FDG-PET can localize the residual disease [7]. The sensitivity ranges between 45% and 100% and is dependent on tumour burden, histological subtype, and degree of differentiation [25]. It is more sensitive in patients with more aggressive histological variants, such as poorly differentiated, tall cell, insular, Hürthle cell carcinomas, and identifies patients with poorer prognosis. The sensitivity is generally low in patients with stimulated thyroglobulin <10 ng/ml as this indicates low burden disease (with the exception of a poorly DTC where the low serum thyroglobulin is a sign of dedifferentiation). Integrating ^{18}FDG-PET and CT imaging allows colocalization of hypermetabolic and morphological data; CT has higher spatial resolution and can increase the specificity of PET scan by providing structural information about areas of physiological uptake or inflammatory lesions. PET is particularly useful in identifying mediastinal lymph nodes and in differentiating cervical residual disease from post-surgical fibrosis [25]. PET scan performed after rhTSH administration has slightly higher sensitivity than basal PET but this changes the planned management only in a minority of patients [26].

CT and MRI

High resolution axial CT of the neck and chest with iv contrast allows better definition of large nodal recurrences in the neck and mediastinum. It is also needed to describe extensive, invasive disease involving the trachea, oesophagus and adjacent blood vessels [7]. If dyspnoea or dysphagia are present, fibre optic laryngoscopy and endoscopy might be necessary to evaluate for possible intraluminal tumour invasion. CT of the chest is the most sensitive method to diagnose small lung metastases. CT and MRI of the brain or abdomen should be performed to evaluate for distant disease in patients with high thyroglobulin levels (Tg >10 ng/ml) or high and rising antithyroglobulin antibodies, if symptoms of organ-specific involvement are present or if radioiodine treatment is planned and tumour swelling after ^{131}I is a concern [7].

Follow-up Plan

During follow-up, data reflecting the patient's response to treatment is collected and the risk of recurrence is reassessed according to a dynamic risk stratification system [7] (Table 3.5.6.2).

Excellent response: no clinical, biochemical, structural signs of disease.

Table 3.5.6.2 Response to therapy definitions based on initial therapy (total thyroidectomy with/without radioiodine ablation), predicted outcomes, and recommended management plan

Category	Excellent response	Biochemical incomplete response	Structural incomplete response	Indeterminate response
Definition	• Negative imaging *and* • nsTg <0.2 ng/ml *or* • sTg <1 ng/ml after RAI sTg< 2 ng/ml without RAI • Negative TgAb	• Negative imaging *and* • nsTg ≥1 ng/ml after RAI nsTg ≥5 ng/ml without RAI *or* • sTg ≥10 ng/ml *or* • Rising TgAb	Structural or functional evidence of disease, regardless of Tg, TgAb levels	• Non-specific imaging findings • Faint uptake in thyroid bed on RAI scans • Detectable Tg (below cut-offs for biochemical incomplete response) *or* • TgAb stable/declining without structural/functional disease
Management plan	• nsTg every 1–2 yrs • sTg not necessary • Regular neck ultrasound • CT/MRI follow-up may be indicated in high-risk patients for 3–5 years after attaining excellent response	• nsTg every 6 months • If stable/declining Tg → observation; ultrasound yearly; sTg at 2 years to evaluate for excellent response • If rising Tg/TgAb → consider WBS, CT/MRI, ^{18}FDG-PET, and treatment of persistent disease	• nsTg every 6 months • Yearly ultrasound • Diagnostic WBS to evaluate iodine avidity of lesions • MRI, CT at 6–12 months depending on progression • 18FDG-PET—additional disease sites → Additional therapy of persistent disease	• nsTg 6–12 months • sTg after 2 yrs to evaluate for excellent response • Neck ultrasound every 6–12 months • If suspicious findings appear → consider WBS, CT/MRI, ^{18}FDG-PET, and treatment of persistent disease
TSH goal	0.5–2 mUI/L (0.1–0.5 mUI/L for 3–5 yrs in high-risk patients)	0.1–0.5 mUI/L	<0.1 mUI/L	0.1–0.5 mUI/L

nsTg, non-stimulated thyroglobulin; RAI, radioiodine ablation; sTg, stimulated thyroglobulin; TgAb, antithyroglobulin antibodies. Based on [7], [27], [28].

Box 3.5.6.1 Predicted outcomes in patients treated with total thyroidectomy and radioiodine ablation based on response to therapy

Excellent response:
<4% recurrence at 5–10 years (5–15% in high-risk patients)

Biochemical incomplete response:
30% spontaneously evolve to no evidence of disease (NED)
20% achieve NED after additional therapy
20% structural disease at end of follow-up

Structurally incomplete response:
50–85% persistent disease despite therapy
Deaths: 11% in regional disease
50% in distant disease

Indeterminate response:
15–20% with structural disease identified at follow-up
The rest—the changes are stable or resolve

Biochemical incomplete response: high thyroglobulin, increasing antithyroglobulin antibodies, but negative imaging.

Structurally incomplete response: persistent/recurrent structural disease, regardless of thyroglobulin or antibody levels.

Indeterminate response: unspecific biochemical/structural changes.

This system allows, for example, for a patient initially included in a high-risk group after surgery but with a good response after ^{131}I therapy, with stimulated thyroglobulin <1 ng/ml, negative antibodies, and imaging, to move to a lower risk group due to the excellent response to treatment, which would imply a decrease in the intensity of follow-up and a lesser degree of TSH suppression.

The definitions were originally developed and validated based on the outcome of patients with DTC treated with total thyroidectomy and radioiodine ablation (Box 3.5.6.1) [7], but the system was subsequently validated also for low and intermediate risk patients treated with lobectomy and total thyroidectomy without RIA [27, 28]. After lobectomy, a stable non-stimulated Tg of less than 30 ng/ml in the context of undetectable TgAb and negative imaging is considered an excellent response [28]. An increasing trend in non-stimulated thyroglobulin or TgAb in these patients represent an increased risk of structural disease and should prompt additional investigation [27].

Persistent/Recurrent Disease

In most patients with persistent disease the lesions are identified in the neck: lymph node recurrences or residual disease in the thyroid bed. Distant metastases can be present at diagnosis in up to 10% of patients or can develop over time. Persistent disease is suggested by high thyroglobulin or increasing TgAb titres and is certified by ultrasound, radioiodine scanning, CT/MRI, bone scan, or ^{18}FDG-PET which identify the site of disease.

Surgery is preferred if the location of the identified lesion allows it, followed by radioiodine if the lesion is ^{131}I avid [7, 14].

Clinically significant, biopsy proven, **cervical lymph node recurrences** should be resected. In high-risk surgical patients, percutaneous ethanol injection, laser, high intensity focused ultrasound or radiofrequency ablation can be considered as alternatives [7, 23, 29].

In **extensive, invasive disease**, surgical resection can be followed by external beam radiotherapy to lower the risk of recurrence [7].

Pulmonary metastases respond well to radioiodine therapy, particularly in younger patients. Complete remission is possible, particularly in case of micrometastases. In persistent disease therapy should be repeated every 6–12 months as long as it continues to concentrate ^{131}I, but high cumulative radioiodine doses can lead to pulmonary fibrosis.

Bone metastases usually require higher doses and ^{131}I therapy is usually not curative. Surgical resection and stabilization are sometimes needed to prevent fracture and neurological complications; bisphosphonate treatment with pamidronate or zoledronic acid can provide pain relief and even a small 2–10% decrease of bone tumour volume; external beam radiation therapy can help control bone pain.

Brain metastases usually occur in older patients and have a poorer prognosis. Surgical resection, if feasible, should be attempted before ^{131}I; otherwise external beam radiation therapy is an option. If the lesions are radioiodine-avid, ^{131}I therapy should be performed accompanied by glucocorticoid treatment to prevent tumour and neighbouring brain structures swelling [7].

Radioiodine Resistant Differentiated Thyroid Carcinoma

DTC usually caries a good prognosis due, in great measure, to its good response to radioiodine therapy. There are, however, patients with radioiodine refractory structurally evident disease in whom the lesions lose the ability to concentrate ^{131}I or progress despite continuing to exhibit ^{131}I uptake, probably due to dedifferentiation [26]. ^{18}FDG-PET/CT can identify distant metastases in these patients and should be used in conjunction with radioiodine scans as patients can present with both radioiodine-avid and resistant lesions. ^{18}FDG-PET uptake generally signals lesions with aggressive histologies and poor prognosis. For these patients, new therapeutic options are required. Tyrosine kinase inhibitors (sorafenib, lenvatinib, vandetanib) partially inhibit multiple kinases and affect multiple signalling pathways, including angiogenesis [30]. They are recommended in patients with radioiodine refractory, progressive, metastatic disease and have been shown to increase progression-free survival and induce sustained tumour regression [31–33]. The risk-benefit must be carefully weighted in each patient, as treatment is frequently accompanied by numerous side effects: hypertension, nausea, fatigue, weight loss, skin changes, risk of gastrointestinal perforation, hepatotoxicity, bleeding, etc. [7]. New research is focused on finding ways to increase radioiodine sensitivity. Two small studies suggested that treatment with selumetinib (an inhibitor of MAPK pathway) and dabrafenib (a selective *BRAF* inhibitor) can restore radioiodine sensitivity in patients with ^{131}I resistant DTC [34, 35]. Cytotoxic chemotherapy with doxorubicin or taxanes has limited efficacy in DTC patients but can be attempted in patients who cannot tolerate or progress despite tyrosine kinase therapy.

Anaplastic Thyroid Carcinoma

Anaplastic thyroid cancer (ATC) is an undifferentiated tumour of the follicular epithelium. It is rare but extremely aggressive, with a median survival of 5–7 months after diagnosis and a 20% 1-year survival rate [36]. It tends to develop in older individuals (mean age 65 years) and can be associated with DTC. Genetically, anaplastic cancer presents with activating *BRAF* and *RAS* mutations (similar to DTC), but also new mutations involving p53 tumour suppressor protein, TERT, or PIK3CA. It is thus believed that anaplastic cancer develops from more differentiated tumours after a dedifferentiation event, which is probably the acquisition of a new mutation.

ATC generally presents as a rapidly growing, fixed cervical tumour mass. It can extend into the perithyroidal fat to the strap muscles, trachea, oesophagus, blood vessels, and laryngeal recurrent nerves which leads to pain, dysphonia, dysphagia, dyspnoea, and cough. Distant metastases are present in up to 50% of patients at diagnosis (often in the lungs, bone, brain, skin, adrenal glands) and can manifest as systemic symptoms: fatigue, anorexia, weight loss or focal signs of compression: bone pain, neurological symptoms.

The initial evaluation should include a full blood count, biochemistry, thyroid function tests and neck ultrasound [37]. Marked leukocytosis is sometimes present due to tumour secretion of lymphokines. Some patients present with hypocalcaemia due to invasion of the parathyroid glands or humoral hypercalcaemia of malignancy. Thyroid function is usually normal, but hypothyroidism can occur in extensive disease destroying the normal parenchyma. Ultrasound reveals a hypoechoic, infiltrative mass, often with areas of extensive necrosis and lymph node metastasis. Diagnosis requires FNAB or core needle biopsy and immunohistochemistry is needed to distinguish ATC from poorly differentiated and medullary thyroid carcinomas, thyroid lymphoma, melanoma, and sarcoma [37].

Cross-sectional CT or MRI studies should be performed for staging purposes and to define local extension and the potential for surgical resection. ^{18}FDG-PET/CT is helpful to identify distant metastases. According to the TNM staging system, all ATCs are considered stage IV: intrathyroidal tumours are stage IVA, gross extrathyroidal extension means stage IVB and distant metastases—IVC [8].

Due to their aggressive nature, prompt management of ATC is essential. Surgery should be performed for all intrathyroidal tumours as complete resection increases survival. In invasive tumours surgical resection should be followed by radiotherapy and chemotherapy. Combination therapy decreases the risk or recurrence but doesn't influence survival [36]. In patients with distant metastases no therapy was proven effective and median survival is 4 months. External beam radiation therapy (EBRT) can provide pain relief in patients with bone metastases. Cytotoxic chemotherapy with doxorubicin, doxorubicin + cisplatin, or paclitaxel usually provides only short-term responses. If available, patients should be enrolled in clinical trials with new therapies based on the molecular profile of the tumour [37]. Radioiodine therapy and TSH suppression have no role in ATC, because the undifferentiated cells are not capable of ^{131}I uptake, but can be useful in patients with associated DTC. Palliative treatment should focus on securing the airway and maintaining access for nutritional support (tracheostomy and gastrostomy), as death usually occurs due to aerodigestive obstruction. Adequate management of pain should be provided as well as emotional and spiritual support.

Thyroid Lymphoma

Primary thyroid lymphoma (PTL) is a rare malignancy, representing less than 2% of all thyroid cancers. It typically presents in the seventh life decade, affecting predominantly women (female:male ratio—4:1). The major known risk factor for PTL is Hashimoto's thyroiditis, which was identified in up to 90% of patients [38].

Thyroid lymphomas are almost always of the non-Hodgkin type and of B-cell lineage; the most frequent are diffuse large B-cell lymphomas (DLBCL) and mucosa-associated lymphoid tissue (MALT) lymphomas [38, 39].

PTL typically presents as a rapidly expanding neck mass which is often hard, sometimes tender, fixed to the trachea, and often extending substernally. Because of invasion into the adjoining neck structures, patients can present with hoarseness, dyspnoea, and dysphagia. Lymph node enlargement can be identified in approximately 50% of cases. Systemic B-type symptoms can also be present: fever, night sweats, and significant weight loss. Occasionally, MALT lymphomas present as a single, asymptomatic, slow-growing thyroid nodule.

Patients are usually euthyroid; hypothyroidism sometimes occurs because of coexisting Hashimoto's thyroiditis/severe thyroid infiltration by the lymphoma. Rarely, transient thyrotoxicosis occurs due to rapid destruction of thyroid follicles.

Ultrasound reveals an intensely hypoechoic, pseudo-cystic structure, sometimes nodular, with 'broccoli-like borders', other times diffuse, infiltrative. Enhancement of posterior echoes is always present and can help to distinguish it from severe thyroiditis [40]. FNAB can suggest the diagnosis, but management is decided after large-bore or surgical biopsy with immunohistochemistry which is needed to evaluate the histological subtype.

^{18}FDG-PET, CT, or MRI are performed for staging purposes, to define local extension, to plan treatment, and monitor response to treatment.

Management depends on histological subtype and tumour stage. MALT lymphomas usually have an indolent clinical course and can be treated by surgery alone, radiotherapy alone or a combination of them [39]. The benefit of surgical resection in these patients is debatable, so it is not typically recommended, but MALT lymphomas are sometimes detected incidentally after thyroidectomy performed for other indications, and in this case no further treatment may be needed. DLBCL are generally aggressive and require combined modality treatment using the monoclonal antibody rituximab, combined chemotherapy (cyclophosphamide, doxorubicin, vincristine, prednisone) and radiotherapy [39]. Radiotherapy provides local control and combined chemotherapy is used to decrease the incidence of distant recurrences. If critical airway obstruction occurs, surgical resection may be an option; however, tumours typically respond in a few hours to chemotherapy and glucocorticoids and airway permeability is restored.

The prognosis of PTL depends largely on the histological subtype, patient age, disease stage, and treatment. The reported 5-year disease-free survival is 95% for MALT lymphomas and 75% for DLBCL [39].

3.5.7 Medullary Thyroid Carcinoma

Friedhelm Raue and Karin Frank-Raue

Classification and Epidemiology

Medullary thyroid carcinoma (MTC) is a rare tumour of the parafollicular or C cells of the thyroid, that produce calcitonin (Ctn) and not iodine-rich thyroid hormone, making it not susceptible to treatment with radioactive iodine. New genetic studies in mice indicating that the genuine progenitors to C cells arise in the endoderm germ layer and are not of a neural crest origin [1]; but MTC often have the clinical and histological features of neuroendocrine tumours. They account for 3–5% of all thyroid carcinomas and occur in both sporadic and hereditary forms [2]. The majority of patients have sporadic MTC (70%), while 30% have hereditary MTC. The sex ratio in sporadic MTC is 1:1.3 (male to female), while both sexes are nearly equally affected in the familial variety [3]. The highest incidence of sporadic disease occurs in the fifth decade of life, while hereditary disease can be diagnosed earlier, depending on the possibility of genetic and biochemical screening.

Table 3.5.7.1 Classification of medullary thyroid carcinoma

Variety of MTC	Incidence (%)	Age at onset	Associated endocrinopathies
Sporadic MTC	70	Fifth decade	None
Hereditary MTC	30		
- MEN 2A	~27	Third decade	Phaeochromocytoma, parathyroid adenoma/ hyperplasia, Hirschsprung disease, cutaneous lichen amyloidosis, only MTC (familial MTC)
- MEN 2B	~3	First decade	Phaeochromocytoma, mucosal neuromas, marfanoid habitus

MEN 2A, multiple endocrine neoplasia type 2A; MTC, medullary thyroid carcinoma.

The familial variety of MTC is inherited as an autosomal dominant trait with a high degree of penetrance and MTC is the dominant component of the multiple endocrine neoplasia type 2 syndrome (MEN2) [4]. It is caused by germline-activating mutations of the RET proto-oncogene. Two distinct hereditary varieties of MTC are known, MEN2A and MEN2B, they differ with respect to incidence, genetics, age of onset, association with other diseases, aggressiveness of MTC, and prognosis (Table 3.5.7.1.):

1. The MEN 2A syndrome (OMIM 171400), characterized by the association of MTC, pheochromocytoma, and tumours of the parathyroids, sometimes Hirschsprung's disease, and cutaneous lichen amyloids. In some cases MTC is isolated without other endocrinopathies (familial MTC, FMTC). The subtype FMTC has been diagnosed more frequently in recent years and is reported to account for 35–40% of all MEN 2 cases [5].
2. The MEN 2B syndrome (OMIM 162300), consisting of MTC, phaeochromocytoma, ganglioneuromatosis of the gastrointestinal tract, and marfanoid habitus; in this phenotype hyperparathyroidism is absent. It is the most aggressive form (5–10% of all cases) [6].

Many patients with MEN 2B have an earlier onset in the first year of life and more aggressive MTC with a higher morbidity and mortality than in patients with MEN 2A. They often do not have a family history of the disease. Their tumours and characteristic appearance are therefore due to de novo germline RET mutations that present as sporadic cases of potentially hereditary disease. In contrast, the clinical course of MTC in FMTC is more benign than MEN 2B with a late onset or no clinically manifest disease, and the prognosis is relatively good. Therefore, a family history is often inadequate in establishing familial disease and more thorough evaluation by genetic and biochemical screening often reveals a family history of MTC in a patient originally thought to have the sporadic form of the disease [7].

Detection of MTC in patients has changed in recent years with the introduction of specific strategies: Ctn screening in patients with thyroid nodules and screening with molecular methods for

RET proto-oncogene mutations in patients with apparently sporadic MTC and in family members at risk for MTC. By earlier identification of patients with MTC, the presentation has changed from clinical tumours to preclinical disease, resulting in a high cure rate of affected patients with much better prognosis [8].

Pathology and Biochemical Markers

The histological appearance of MTC is enormously variable with regard to cytoarchitecture (solid, trabecular, or insular) and cell shape (spindle, polyhedral, angular, or round). The presence of stromal amyloid is characteristic in about 50–80% of MTC patients. This feature had been an auxiliary diagnostic criterion for MTC before the use of calcitonin immunocytochemistry. MTC without stromal desmoplasia is associated with a very low potential for metastasis [9].

Hereditary MTC characteristically presents as a multifocal process with neoplastic C-cell hyperplasia in areas distinct from the primary tumour. Bilateral neoplastic C-cell hyperplasia is a precursor lesion to hereditary MTC, in contrast non-MEN2-associated C-cell hyperplasia which is found with a great variety of pathological conditions, including non-medullary thyroid tumours, nodular goitre, autoimmune thyroiditis, renal failure, and disorders of calcium metabolism, and is not related to the development of sporadic MTC [10]. Metastasis may be found first in central and lateral cervical and mediastinal lymph nodes of the neck in 10% of patients with a micro-MTC operated on after discovery by familial screening, and in up to 90% of patients operated on for clinical MTC. Metastases outside the neck and mediastinum may occur during the course of the disease in the liver, lung, and bone.

The primary secretory product of MTC is Ctn, which serves as a highly sensitive tumour marker. Measurement of monomeric Ctn with two-site assays remains the definitive test for prospective diagnosis of MTC [11]. The test is widely available, accurate, reproducible, and cost-effective. Reference intervals are gender-dependent with higher levels in men than in women. Basal Ctn concentrations usually correlate with tumour mass and are almost always high in patients with palpable tumours. Similarly, elevated plasma Ctn levels following surgery to remove the tumour are indicative of persistent or recurrent disease. Measurement of plasma Ctn has been part of the routine evaluation of patients with thyroid nodules; up to 3% of patients with thyroid nodules have pathological Ctn concentrations and about 0.6% have an MTC [12]. The prevalence of MTC was nearly 100% when basal Ctn levels were more than 100 pg/ml. For basal Ctn, the best cut-off points able to separate non-MTC (including normal and C-cell hyperplasia cases) from MTC patients were 26 pg/ml in females and 68 pg/ml in males [13]. The predictive value for detection of micro-MTC in the grey zone between upper reference value and cut-off value is low; small MTC could be diagnosed sufficiently early enough allowing curative thyroidectomy by increasing Ctn values during follow-up. All patients with basal Ctn below 100 pg/ml could be cured by surgery [14]. Ctn assays with improved functional sensitivity and gender specific reference values may avoid stimulation testing with pentagastrin or calcium. In rare cases MTC does not secrete Ctn, the prevalence of non-secretory MTC with no measurable Ctn is 0.83% [15].

After careful evaluation, Ctn measurement in nodular thyroid disease allows early diagnosis and early surgery of MTC, reducing the significant mortality associated with this malignant tumour. There are a number of other substances, including carcinoembryonic antigen (CEA), PDN-21 (katacalcin), procalcitonin, chromogranin A, neuron-specific enolase, somatostatin, and adrenocorticotrophic hormone (ACTH), that are produced by MTC and which may help to differentiate it from other tumours.

Genetic Abnormalities

The responsible gene for MEN 2 (OMIM 171400, 162300, 155240) was localized to centromeric chromosome 10 (10q11.2) by genetic linkage analysis in 1987. Activating germline point mutations of the RET proto-oncogene were identified in 1993 [16]. Analysis of RET in families with MEN 2 revealed that only affected family members had germline missense mutations in eight closely located exons (5, 8, 10, 11, and 13–16) [16, 17]. Genetic testing detects nearly 100% of mutation carriers and is considered the standard of care for all first-degree relatives of patients with newly diagnosed MTC [18].

The *RET* gene has 21 exons and encodes a receptor tyrosine kinase that appears to transduce growth and differentiation signals in several developing tissues including those derived from the neural crest. It is expressed in cells such as C cells, the precursors of MTC, and in adrenal medullary cells, the precursors of pheochromocytomas, and parasympathetic and sympathetic and colonic ganglia cells, precursors of the ganglioneuromas. Unregulated *RET* activation leads to various cancers, including hereditary MTC, while humans lacking *RET* expression due to inactivating germline mutations develop Hirschsprung's disease.

The *RET* protein consists of an extracellular segment with a ligand-binding domain, a cadherin (Ca^{2+}-dependent cell adhesion)-like domain, and a cysteine-rich domain that is positioned near the cell membrane. RET protein has a single transmembrane domain and an intracellular segment with two tyrosine kinase subdomains, TK1 and TK2. It is activated by ligand-induced dimerization [19].

Hereditary MTC is caused by autosomal dominant gain-of-function mutations in the RET proto-oncogene. Mutation of the extracellular cysteine at exon 11 codon 634 causes ligand-independent dimerization of receptor molecules, enhanced phosphorylation of intracellular substrates, and cell transformation. Mutation of the intracellular tyrosine kinase (codon 918) has no effect on receptor dimerization but causes constitutive activation of intracellular signalling pathways and also results in cellular transformation. There is a significant age-related progression from C-cell hyperplasia to MTC, which correlates with the transforming capacity of the respective RET mutations.

At present, mutation analysis has identified over 100 different missense mutations associated with the development of MEN 2 (**Figure 3.5.7.1.**). Although some overlap exists between RET mutations and the resulting clinical subtype of MEN 2, most of patients with MEN 2A have a mutation of codon 634 (exon 11), followed by mutations of codons 609, 611, 618, and 620 (exon 10). In FMTC, germline mutations are distributed throughout the RET gene with an accumulation in exon 13 (codons 768, 790, and 791), exon 14 (codons 804 and 844), and rarely exon 10 (codons 618 and 620); MEN 2B patients have mutations in codon 918 (exon 16), but mutations are rarely identified at codon 883 exon 15 [20]. Phaeochromocytomas are associated with codon 634 and 918 mutations in approximately

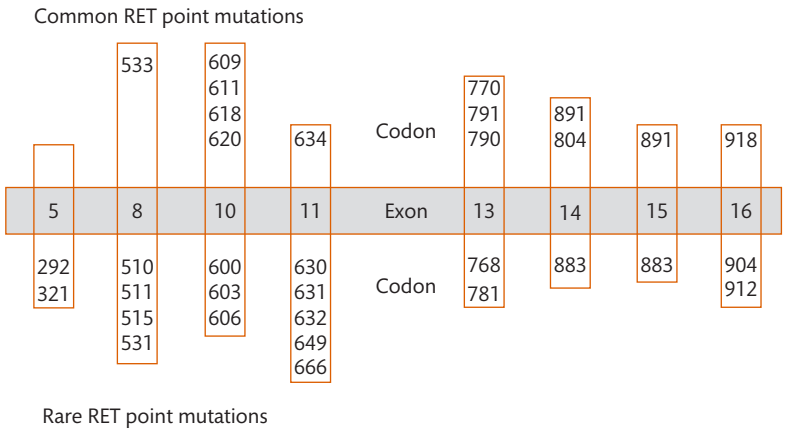

Figure 3.5.7.1 Germline mutations of the RET proto-oncogene associated with MEN 2 and FMTC. Numbers indicated mutated codons of the RET gene.

40–50% of patients, and are associated with mutations in exon 10 (codon 609, 611, 618, 620) in about 30% of patients and rarely in exon 15 (codon 791, 804) [21]. Hyperparathyroidism in MEN 2A is most commonly associated with codon 634 mutations, and in particular with the C634R mutation. The association between disease phenotype and RET mutation genotype has important implications for the clinical management of MEN 2 patients and their families. There is a correlation between the specific germline RET mutation and the age of onset and aggressiveness of MTC development and the presence of nodal metastases [22].

This information is used to stratify RET mutations into three risk levels namely moderate, high, and highest risk concerning the age of onset and aggressiveness of MTC: MEN2-patients with ATA (American Thyroid Association)-moderate risk have mutations at exon 10 (codons 609, 611, 618, 620), exon 13–15 (codon 768, 790, 791, 804, and 891), with ATA higher risk at exon 11 (codon 634) and at exon 15 (codons 883) and with ATA highest risk at exon 16 (codon 918). This risk classification is important in presymptomatic *RET* mutation carriers because prophylactic thyroidectomy must be performed before MTC development or while the tumour is confined to the thyroid gland. This strategy for preventing familial MTC should be tailored according to the specific risk of the mutation carried by each patient [2] (see next).

Approximately 23–60% of sporadic MTC have a somatic (present in tumour only) mutation at codon 918 identical to the germline mutation found in MEN 2B. Some reports suggest that patients with sporadic MTC with codon 918 somatic mutations have more aggressive tumour growth and a poorer prognosis [23].

Clinical Syndrome and Diagnostic Procedure

Sporadic Medullary Thyroid Carcinoma

The most common clinical presentation of sporadic MTC is a single nodule or thyroid mass found incidentally during routine examination [24]. The presentation does not differ from that observed in papillary or follicular thyroid carcinoma. A thyroid nodule identified by physical examination is generally evaluated by ultrasonography and radioisotopic scanning (Figure 3.5.7.2). MTC shows hypoechogenic regions, sometimes with calcifications, and a thyroid scan almost always shows no trapping of radioactive iodine or technetium. Cytological examination of the cold hypoechogenic nodule will lead to a strong suspicion, or a correct diagnosis in most cases, of sporadic MTC.

A plasma Ctn measurement can clarify the diagnosis, since preoperative Ctn levels correlate significantly with tumour size and, in the presence of a palpable MTC, the plasma Ctn concentration will usually be greater than 100 pg/ml. The CEA level will be elevated in most cases with clinically evident tumours. Therefore, measurement of plasma Ctn in patients with thyroid nodules has been advocated as a routine procedure by some European consensus groups [25].

Genetic testing for RET mutations in patients with elevated Ctn levels may also be helpful in apparently sporadic cases of MTC, since, if a mutation is found, it will imply that the disease is hereditary and that the family should be screened. The frequency of germline mutations, either inherited or de novo, in a larger series of apparently sporadic MTC patients varied between 1% and 7% [7].

Metastases to cervical and mediastinal lymph nodes are found in two-thirds of patients at the time of initial presentation. Distant metastases to lung, liver, and bone occur late in the course of the disease. Diarrhoea is the most prominent of the hormone-mediated clinical features of MTC and is often seen in patients with advanced disease. In addition, occasional tumours secrete ACTH causing Cushing's syndrome. Given the possibility that any patient with MTC may have MEN 2, preoperative testing must also include a 24-hour urinary excretion of catecholamines (to rule out phaeochromocytoma) and measurement of calcium (to rule out hyperparathyroidism).

Hereditary Medullary Thyroid Carcinoma

The clinical presentation and manifestation of familial MTC in index cases does not appear to differ from that in patients with sporadic MTC. MTC is often the initial manifestation of MEN 2 syndrome, as the other manifestations, phaeochromocytoma and hyperparathyroidism, develop later in the course of the disease. Less common presentations of MTC include recognition during search initiated after an associated disease such as bilateral pheochromocytoma or multiglandular hyperparathyroidism becomes apparent. The diagnosis of familial MTC in index cases is often made postoperatively

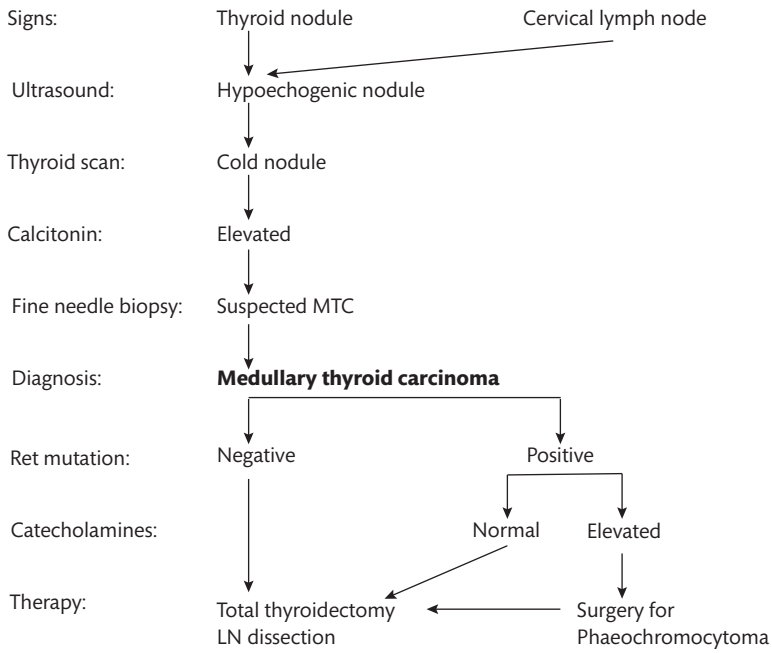

Figure 3.5.7.2 Clinical evaluation of patients at risk for medullary thyroid carcinoma.

when pathohistological examination may show multifocal bilateral MTC accompanied by diffuse C-cell hyperplasia. Rare variants of MEN 2A exist, including MEN 2A with cutaneous lichen amyloidosis and FMTC (or MEN 2A) with Hirschsprung's disease. The diagnosis of FMTC can only be considered when four or more family members across a wide range of ages have isolated MTC. In general, the clinical course of MTC in familial MTC is more benign and typically has a late onset or is not a clinically manifest disease [26].

MEN 2B has a typical phenotype with visible physical stigmata such as raised bumps on the lips and tongue (due to cutaneous neuromas), ganglioneuromas throughout the gastrointestinal tract, and a marfanoid habitus (long thin extremities, an altered upper–lower body ratio, slipped femoral epiphysis, pectus excavatum) with skeletal deformations and joint laxity. These patients have disease onset in the first year of life with the most aggressive form of MTC.

DNA testing becomes the optimal test for early detection of MEN 2 especially in 'at risk' families. At present, genetic testing is performed before the age of 5 years in all first-degree relatives of an index case (in MEN 2B patients directly after birth). Mutations in the RET proto-oncogene can be used to confirm the clinical diagnosis and identify asymptomatic family members with the syndrome (Figure 3.5.7.3). Those who have a negative test can be reassured and require no further biochemical screening.

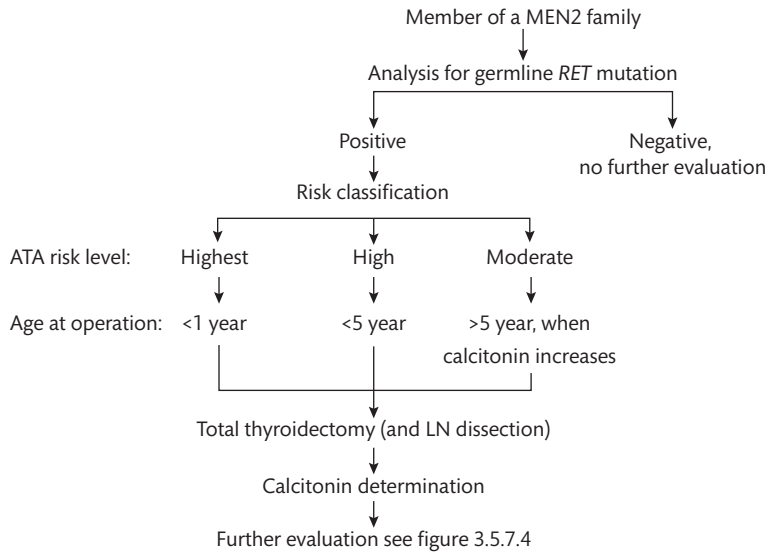

Figure 3.5.7.3 Work-up of family members at risk for medullary thyroid carcinoma/multiple endocrine neoplasia type 2.

The age of onset of MTC and tumour aggressiveness in MEN 2 depends on the codon mutated. This genotype–phenotype correlation is the basis for stratifying mutations into three risk levels concerning the risk for MTC development and growth. Decision making in the clinical management of MEN 2 patients depends on the risk level classification and calcitonin level, especially the timing of prophylactic thyroidectomy and the extent of surgical resection in presymptomatic RET mutation carriers.

Phaeochromocytoma

Phaeochromocytomas occur in approximately 20–50% of MEN 2A patients depending on the mutation. Phaeochromocytomas are associated with codon 634 and 918 mutations in approximately 50% of patients, and are associated with mutations in exon 10 (codons 609, 611, 618, and 620) in about 30% of patients and rarely in exon 15 (codons 791 and 804) [21]. As with MTC, the phaeochromocytomas of MEN 2 are also multicentric with diffuse adrenomedullary hyperplasia developing bilateral phaeochromocytomas in one-half of the cases, but often after an interval of several years. Almost all phaeochromocytomas are located in an adrenal gland, and malignant phaeochromocytomas are rare. In index cases, the clinical manifestation of phaeochromocytoma associated with MEN 2 is similar to that in sporadic cases with signs and symptoms such as headache, palpitations, nervousness, tachycardia, and hypertension. However, phaeochromocytomas are usually identified early as a result of regular biochemical screening in gene carriers, and clinical manifestations are thus subtle or absent. It is unusual for phaeochromocytoma to precede the development of MTC and be the initial manifestation of MEN 2. Annual biochemical screening by measuring plasma and/or 24-h urinary excretion of catecholamines and metanephrines should be performed. Once the biochemical diagnosis is made, imaging studies such as MRI or metaiodobenzylguanidine (MIBG) scanning are appropriate. The presence of phaeochromocytoma must be ruled out before any surgical procedure. Patients with MTC should be evaluated for possible phaeochromocytoma. A coexisting phaeochromocytoma should be removed before thyroidectomy.

Primary Hyperparathyroidism

Primary hyperparathyroidism, with hypercalcaemia and an elevated serum parathyroid hormone level occurs in 10–25% of MEN 2 gene carriers (especially codon 634). Hyperparathyroidism develops slowly, is usually mild, and clinical features do not differ from those seen in mild sporadic hyperparathyroidism. The diagnosis is established by finding high parathyroid hormone concentrations in the presence of hypercalcaemia. Pathological findings show chief cell hyperplasia involving multiple glands. Annual measurement of serum calcium concentration in gene carriers is probably adequate for screening purposes [27].

Treatment and Prognosis

Surgery

The definitive treatment for MTC is surgery no matter whether MTC is sporadic or familial. Several studies have shown that survival in patients with MTC is dependent upon the adequacy of the initial surgical procedure. The appropriate surgery for MTC is total thyroidectomy and careful lymph node dissection of the central and if necessary lateral compartment of the neck [28]. The presence of 10 and more cervical lymph node metastases is inconsistent with surgical cure [8]. Central lymph node dissection is also necessary for tumour staging and prevention of later midline complications related to local metastatic disease. If there is no evidence of local lymph node metastases during the primary surgical procedure, a surgical cure is likely and further neck dissection is probably unnecessary. The preoperative Ctn level can predict nodal metastasis and guide extent of neck dissection: Ctn levels of 20, 50, 200, and 500pg/ml predict nodal metastases in the ipsilateral central and lateral neck, contralateral central neck, contralateral lateral neck, and upper mediastinum, respectively [14]. Total thyroidectomy is absolutely necessary in hereditary cases because of the bilateral and multifocal nature of MTC. In contrast, unilateral lobectomy is sufficient in a patient with incidentally discovered sporadic MTC showing a single unilateral tumour focus and normal/ not measurable plasma Ctn levels after operation. All patients should receive adequate thyroxine replacement therapy after total thyroidectomy.

Patients with persistent elevation of plasma Ctn after total thyroidectomy should be thoroughly evaluated to define the extent of local and distant disease. Persistent elevation of plasma Ctn implies the presence of tumour. If there is no evidence of distant metastases, Ctn level below 1000pg/ml and if local disease is suspected/ found in the neck, and/or the initial surgical procedure was inadequate, then reoperation is advocated using meticulous dissection and microsurgical techniques. Unfortunately, many patients with MTC who have regional lymph node metastases also have systemic disease and are not cured biochemically despite aggressive surgery, including bilateral lateral neck dissection [14, 29]. If distant metastases are found, there is no indication for surgical reintervention unless the patient develops symptoms like local complications, for which tumour debulking may be beneficial.

Recommendations for the timing of prophylactic thyroidectomy in MEN 2 patients are based upon a model that utilizes genotype–phenotype correlations to stratify mutations into three risk levels. In the cases of highest risk mutations, patients with mutation of codons 918, a thyroidectomy is recommended as early as possible in the first year after birth, with higher risk mutation, patients with codon 634 and 883 mutation at the age of 5 years and with moderate risk mutations (codons 609, 611, 618, 620, 768, 790, 791, 804, and 891) thyroidectomy is recommended at age of 5, or surgery may be postponed until the Ctn value increases in the pathological range. By operating these patients before MTC has spread to neck lymph nodes or beyond they could be cured. Currently, the generally accepted practice is to use a combination of genetic testing and the basal serum Ctn level to decide the timing of thyroidectomy. The surgeon can avoid dissecting the central zone of the neck if calcitonin is in the normal range, since lymph node metastases rarely occur by this age.

Surgery for phaeochromocytoma in MEN 2 should precede surgery for MTC. Before adrenalectomy all patients should receive appropriate pharmacotherapy (α - with/or without β -adrenergic antagonist). Approximately one-third of patients who undergo a unilateral adrenalectomy will eventually require a second operation for contralateral phaeochromocytoma, but this may not occur for many years, during which time the patient will not be steroid dependent. Adrenal cortical-sparing adrenalectomy is an appropriate technique for preventing adrenal insufficiency [21, 30].

The parathyroid glands in MEN 2 patients are frequently found to be enlarged at thyroidectomy for MTC and should therefore be carefully evaluated. The goal in MEN 2 patients with primary hyperparathyroidism is to excise the enlarged glands and to leave at least one normal parathyroid gland intact. If they are all enlarged, a subtotal parathyroidectomy or total parathyroidectomy with autotransplantation should be performed [31].

Postsurgical Follow-up and Management

After surgery, patients with MTC should be assessed regarding the presence of residual disease, the localization of metastases, and the identification of progressive disease. Postoperative staging is used to separate low-risk from high-risk patients with MTC. A risk stratification system using TNM/AJCC staging system, nadir of CTN and CEA measured within the first year after initial treatment, and imaging studies identifying metastases allows to stratify MTC patients in three risk groups: excellent (biochemical cured), biochemical incomplete (detectable Ctn, and no evidence of disease initially), and structural incomplete (metastases at diagnosis) [32].

Normal/not measurable Ctn levels suggest an excellent tumour-free state and thus patients require no further treatment (biochemically cured) [33]. They can be followed-up at yearly intervals with physical examination and Ctn determination (Figure 3.5.7.4). Only in a small number of patients Ctn may rise after years.

In patients remaining Ctn-positive with evidence of occult disease (no local recurrence is found and adequate operation has been done: biochemical incomplete), or non-curable and non-operable disease (diffuse distant metastases: structural incomplete), close observation of changes in tumour markers and tumour growth is required. If the postoperative serum Ctn level exceeds 150 pg/ml patients should be evaluated by imaging procedures including ultrasonography of the neck and abdomen, CT (computed tomography) of neck, mediastinum, lung, and liver, or an MRI technique, and, bone scintigraphy. [18F]2-fluoro-2-deoxy-glucose (FDG), or the more sensitive 6-.^{8}F-fluoro-L-dihydroxyphenylalanine (.^{8}F-DOPA) positron emission tomography (PET) scanning in combination with CT (PET/CT) may also be helpful, especially in identifying yet unknown metastases [34]. In the absence of treatment, imaging should be repeated every 6–12 months or at more frequent intervals if progressive disease is present.

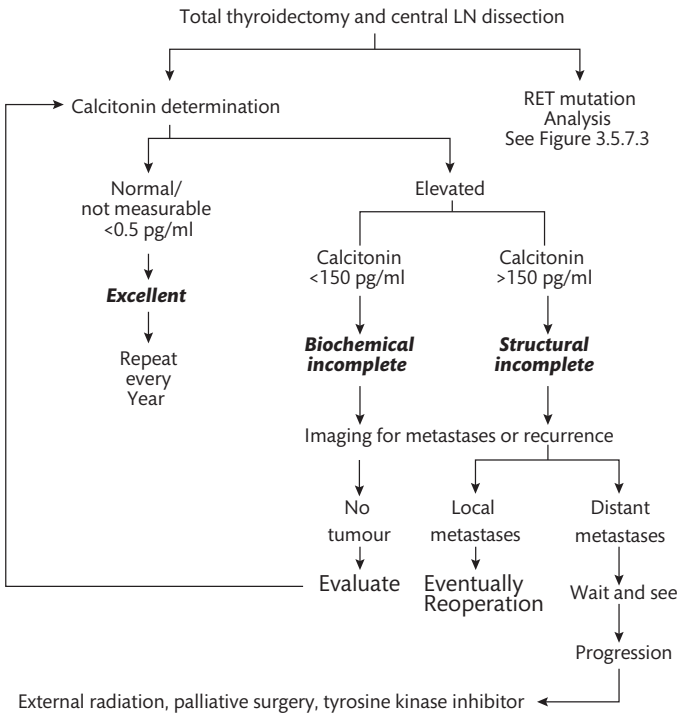

Figure 3.5.7.4 Recommended postoperative management of patients with medullary thyroid carcinoma. LN, lymph node.

One can estimate the growth rate of MTC metastases from sequential imaging studies using response evaluation criteria in solid tumours (RECIST) [35] that document increases in tumour size over time and by measuring serum levels of Ctn or CEA over multiple time points to determine the tumour marker doubling time [36–38]. Because serum Ctn concentration is closely associated with tumour volume, the doubling time is a strong predictor of tumour progression and survival.

Many patients may exhibit a remarkably stable indolent course over years and no further treatment is recommended; a 'watchful waiting' approach is advocated, as experience with non-surgical therapy in the management of slowly growing metastatic MTC has been disappointing [39].

Local treatment approaches are used in patients with local symptoms or those at high risk of local complications, preferably before initiation of systemic treatment. Palliative surgery and external radiation therapy to the neck or mediastinum might also be indicated in patients with tumours entering the aerodigestive structures. In patients with inoperable symptomatic tumour, radiotherapy can offer prolonged palliation and achieve local tumour control. External radiation therapy can procure rapid relief of bone pain and increase recalcification of bone lesions. Surgery could be indicated for bone metastases in patients with orthopaedic or neurological complications. Bisphosphonates (especially zoledronic acid) and the drug denosumab (directed at receptor activator of nuclear factor-κ B ligand) have been shown to improve local pain and to delay time to occurrence of skeletal-related events in other solid tumours with bone metastases. Symptomatic treatments of diarrhoea are done with loperamide, diphenoxylate, or atropine methonitrate, and codeine.

In a small subset of patients whose disease shows rapid and steady progress, e.g. more than 20% RECIST criterion and doubling of tumour marker in less than 1 year, intervention with tyrosine kinase inhibitors (TKI) like vandetanib (200–300 mg/d) [40] or cabozantinib (80–120 mg/d) [41] can be considered as a palliative therapeutic modality. With these substances, significant improvement of progression-free survival but not overall survival in patients with progressive MTC can be achieved. Life quality, toxic side effects, and survival have to be taken into account when TKI is recommended.

Once metastases appear the clinician must decide which patients require therapy, balancing the often slow rate of tumour progression associated with a good quality of life, against the limited efficacy and potential toxicities of local and systemic therapies. Considering that metastatic MTC is incurable the management goals are to provide loco-regional disease control, palliate symptoms of hormonal excess such as diarrhoea, palliate symptomatic metastases like pain or bone fracture, and control metastases that threaten life such as bronchial obstruction or spinal cord compression.

Prognostic Factors

The natural history of sporadic MTC is variable. The spectrum ranges from years of dormant residual disease after surgery to rapidly progressive disseminated disease and death related to either metastatic thyroid tumour or complications of phaeochromocytoma in MEN 2. The 10-year survival rates for all MTC patients ranges from approximately 61% to 76%. The overall prognosis is inferior to differentiated papillary and follicular carcinoma of the thyroid and much better than in the more aggressive anaplastic thyroid cancer. There is general agreement that tumour stage at diagnosis and surgical management have a favourable influence on the clinical course of the disease [8]. Early detection and surgical treatment of MTC is likely to be curative; more than 95% of patients detected at an early stage of disease remain disease-free (normal or undetectable Ctn values). The main factors that influence survival are the stage of disease at the time of diagnosis, size of the tumour, and lymph node involvement. The excellent prognosis associated with identification of MTC at its earliest stage underscores the importance of prospective screening (calcitonin screening) and early diagnosis (RET mutation analysis) which must be followed by adequate therapy.

Future

Early detection of MTC can enhance clinical outcome with a high surgical cure rate before it has spread to neck nodes or beyond. This goal is reached in most MEN2 patients by stratifying them depending on RET mutation into three risk groups concerning the age of onset and aggressiveness of MTC, enabling personalized approaches to appropriate treatment. This goal is not reached in patients with sporadic MTC and index cases of MEN2; increased clinical awareness especially in MEN2B patients, systematic Ctn screening in patients with thyroid nodules, primary operation of MTC by high volume surgeons, identifying high-risk patients in the follow-up, monitoring them appropriately, and treating advanced MTC with molecular targeted therapeutics is necessary. Advances in our understanding of the molecular pathways in MTC tumour cells may aid in the development of individualized risk stratification and therapeutic modalities based on target specific inhibition of tumour growth.

Parathyroid, Calcium and Bone Metabolism Disorders

4.1

Parathyroid Anatomy, Hormone Synthesis, Secretion, Action, and Receptors

David Goltzman and Geoffrey N. Hendy†

Parathyroid Embryology, Anatomy, and Morphology

Humans have two pairs of parathyroid glands lying in the anterior cervical region. The fetal parathyroid glands begin developing at 5 weeks from the third and fourth pharyngeal pouches. The third pharyngeal pouch that contains tissue that will become the thymus and parathyroid migrates downward and gives rise to the two inferior parathyroid glands normally located at the lower poles of the thyroid. The fourth pharyngeal pouch does not migrate and gives rise to the two upper parathyroid glands that normally are attached to the upper poles of the thyroid [1].

Eighty-five percent of normal adults have four parathyroid glands, but the number can vary markedly in some individuals. The location of the glands is also variable with the upper glands sometimes located behind the pharynx or the oesophagus. The lower glands may be found close to or within the thymus in the superior mediastinum. Because of the variability in location surgical exploration of the neck can be problematic especially in hyperparathyroidism of chronic kidney disease [2]. Use of preoperative localization techniques, such as technetium-99-sestamibi scanning, ultrasound, MRI, or CT scanning may be helpful in localizing enlarged parathyroid glands, however referral to an experienced parathyroid surgeon is essential to maximize localization of affected glands and minimize complications. Conversely, hypoparathyroidism most commonly occurs as a result of surgical excision of, or damage to, the parathyroid glands during non-parathyroid surgery, for example, total thyroidectomy for thyroid cancer and radical neck dissection for laryngeal or oesophageal carcinoma, as well as repeated surgery for hyperparathyroidism.

Most patients with primary hyperparathyroidism, about 80%, have a single benign adenoma [3]. Multiple (so-called) adenomas are rarely found and probably represent asynchronous parathyroid hyperplasia. Hyperplasia accounts for 15–20% of cases, and malignant parathyroid carcinoma is extremely rare, less than 1% of cases. In secondary hyperparathyroidism, all four glands are enlarged.

The chief cell is the predominant parathyroid cell type in humans, with some oxyphil cells, which have an acidophilic cytoplasm and mitochondria also present. Parathyroid cells have limited numbers of secretory granules containing parathyroid hormone (PTH), indicating that relatively little hormone is stored in the gland. Parathyroid cells normally divide at an extremely slow rate—mitoses are rarely observed.

Knowledge of the embryological formation of the parathyroids has been gained by study, on the one hand, of mouse models in which deletion of specific genes has led to lack of parathyroid gland development [4], and, on the other, of human inherited (autosomal dominant, autosomal recessive, or X-linked) familial hypoparathyroidism in which the formation of the parathyroid glands is defective [1].

The mouse has a single pair of parathyroid glands, and at day e10 both the precursor thymus and parathyroid cells in the third pharyngeal pouch endoderm, express the four transcription factors, Hoxa3, Pax1, Eya1, and Pax9. The conjoined thymus and parathyroid rudiment develop at day e11 and the primordium also expresses transcription factors Six1 and Pbx1. At day e12, separate pathways distinct for the different parts of the rudiment that will develop into

† It is with regret that we report the death of Geoffrey N. Hendy.

the thymus and parathyroid become apparent. Signalling molecules including sonic hedgehog, bone morphogenetic protein-4, noggin, and fibroblast growth factor-8 act in a complex fashion to affect the outgrowth of the parathyroid precursor. By day e13.5, the parathyroid cell mass and thymus cell mass are separate. The thymic cells express *Foxn1* that is not present in the parathyroid cells and that in turn specifically express glial cells missing-2 (Gcm2). *Gcm2* expression continues into adulthood and it transactivates the calcium-sensing receptor (*Casr*) gene and thereby influences the expression of the parathyroid calciostat [5].

In humans, hypoparathyroidism is part of several syndromes, for example, the DiGeorge type 1 syndrome that occurs because of a 22q11.2 microdeletion. Congenital defects arise as a result of the failure to develop the derivatives of the third and fourth pharyngeal pouches leading to agenesis or hypoplasia of the parathyroid glands and thymus [6]. Haploinsufficiency of the *TBX1* transcription factor gene appears to play an important role in the disorder. In DiGeorge syndrome type 2 patients harbour 10p13-14 deletions encoding the actin-binding protein nebulette (NEBL) although its mechanistic link to hypoparathyroidism is not clear. Some DiGeorge patients have features of the CHARGE syndrome which is caused by heterozygous mutations in the chromodomain helicase DNA-binding 7 gene (CHD7) on 8q12.2 that is expressed within pharyngeal ectoderm. Hypoparathyroidism is a part of the Barakat or HDR (Hypoparathyroidism nerve Deafness, and Renal dysplasia) syndrome that maps to 10p15. HDR is due to haploinsufficiency and loss-of-function mutations in the *GATA3* gene that encodes a zinc finger transcription factor [7]. *GATA3* is essential for normal embryonic development of the parathyroids, auditory system, and kidney in humans. Hypoparathyroidism together with growth and mental Retardation, and characteristic Dysmorphism (HRD) occur in autosomal recessive Kenny-Caffey type 1 and Sanjad-Sakati syndromes. The HRD syndrome is due to mutations in the tubulin chaperone E (*TBCE*) gene that maps to 1q42.3 [8]. Autosomal dominant forms of Kenny-Caffey type 2 and Gracile bone dysplasia with hypoparathyroidism are due to mutations in the family with sequence similarity 111 member A (*FAM111A*) gene on 11q12.1 involved in DNA replication and chromatin maturation.

Rare cases of primary hypoparathyroidism inherited in either an autosomal recessive or dominant manner due to mutations in the *GCM2* gene on chromosome 6p24 have been identified. In the latter case, the mutated GCM2 acts in a dominant-negative fashion [5]. Heterozygous and homozygous mutations in the *PTH* gene cause rare cases of hypoparathyroidism and more commonly heterozygous activating mutations in the *CASR* gene are implicated in hypoparathyroidism (see next). In an X-linked recessive form of hypoparathyroidism there is an interstitial deletion-insertion involving chromosomes 2p25.3 and Xq27.1 near the *SOX3* gene that encodes a high mobility group box transcription factor. It is proposed that the hypoparathyroidism is caused by disruption of regulatory elements of the *SOX3* gene [1].

Parathyroid Hormone Synthesis

In mammals PTH is the 84-amino-acid product [9, 10] of a single-copy gene (**Figure 4.1.1**). The gene, which encodes a larger precursor molecule of 115 amino acids, preproparathyroid hormone (preproPTH), is organized into three exons. Exon I encodes the 5'-untranslated region of the messenger RNA, exon II encodes the NH_2-terminal pre- or signal peptide and a part of the short propeptide, and exon III encodes the Lys^{-2}–Arg^{-1} of the prohormone cleavage site, the 84 amino acids of the mature hormone, and the 3'-untranslated region of the mRNA (**Figure 4.1.2**). The importance of correct splicing of the primary *PTH* gene transcript, or premessenger RNA, was emphasized by the identification of a donor splice mutation in the *PTH* gene in affected members of a family with autosomal recessive isolated hypoparathyroidism, resulting in the loss of exon II which encodes the initiation codon and signal peptide [1].

A second member of the *PTH* gene family encodes the parathyroid hormone-related protein (PTHrP) which is the responsible causal factor in the majority of cases of hypercalcaemia associated with malignancies. PTHrP plays a critical role in fetal development, especially skeletogenesis [11, 12], but is not involved in normal calcium homeostatic control in the adult. In postnatal life, PTHrP regulates the epithelial mesenchymal interactions that are critical for development of the mammary gland, skin, and hair follicle. The *PTH* gene and *PTHLH* gene that encodes PTHrP map to chromosomes 11p15 and 12p12.1-11.2, respectively. These two human chromosomes are thought to have arisen by an ancient duplication of a single chromosome, and their respective gene clusters have been maintained as syntenic groups across the genomes of several species. Because of the similarity in NH_2-terminal sequence of their mature peptides, their gene organization, and chromosomal locations, it is likely that the *PTH* and *PTHLH* genes evolved from a common ancestral gene, with that for PTHrP being the more ancient gene.

The gene for tuberoinfundibular peptide of 39 residues (*TIP39*), a more distantly related member of the *PTH* gene family, resides on chromosome 19q13.33. TIP39 is a neuropeptide [13]. The *TIP39* gene shares organizational features with the *PTH* and *PTHrP* genes having one exon encoding the 5'UTR, one encoding the precursor leader sequence, and one encoding the prohormone cleavage site and the mature peptide (**Figure 4.1.2**).

Transcription of the *PTH* gene occurs almost exclusively in the endocrine cells of the parathyroid gland, and is subject to strong repressor activity in all other cells. Ectopic PTH synthesis (i.e. synthesis outside parathyroid tissue) has been documented in only a very few cases of malignancies associated with hypercalcaemia. Activation of genes in a particular tissue is often related to demethylation of cytosine residues, and the *PTH* gene in parathyroid cells is hypomethylated at CpG residues relative to other tissues. In one of the few cases of true ectopic PTH production, involving a pancreatic tumour, the upstream regions of the *PTH* gene were abnormally hypomethylated [14]. The human *PTH* gene has two functional TATA box-controlled transcription start sites, a cyclic AMP response element (CRE), and a negative vitamin D response element (VDRE) in its proximal promoter. While *PTH* gene transcription is negatively regulated by the hormonally active metabolite of vitamin D, $1,25(OH)_2D$, any regulation by extracellular calcium remains to be established. Also located distally are sequences that function to silence transcription in non-parathyroid cells. In a further case of ectopic PTH production, an ovarian carcinoma, this repressor regulatory region was replaced by a foreign

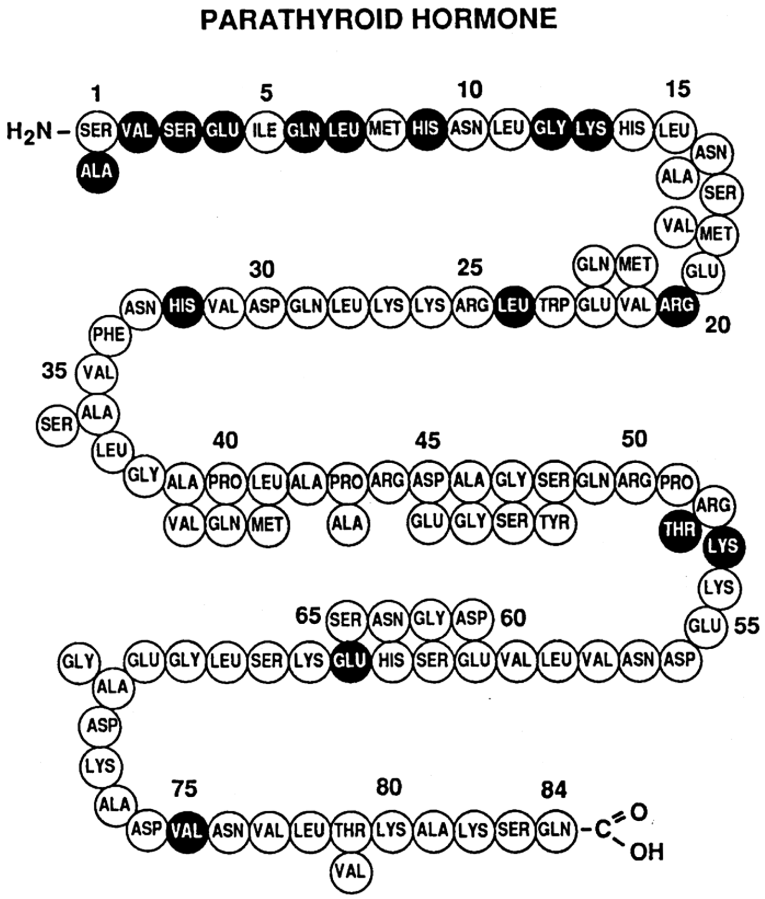

Figure 4.1.1 Amino acid sequence of mammalian PTH. The backbone sequence is that of the human with substitutions in the rat hormone shown at specific sites. Biological activity is a property of the amino-terminal one-third of the molecule [PTH(1-34)]. The solid circles show those amino acids that are identical in the human and rat PTH and PTH-related peptide (PTHrP) molecules.

sequence that allowed inappropriate transcription of the *PTH* gene to take place [3].

The human PTH produced by patients with hyperparathyroidism is structurally normal [9, 10]. In a small number of parathyroid tumours examined, the *PTH* gene sequence is rearranged, and the 5' flanking region of the *PTH* gene is placed upstream of the cyclin D1 (*CCND1*) gene located on the long arm of chromosome 11. This is thought to lead to deregulated expression of the *CCND1* gene that contributes to tumour development [3]. However, this type of gene arrangement occurs very infrequently in parathyroid tumours.

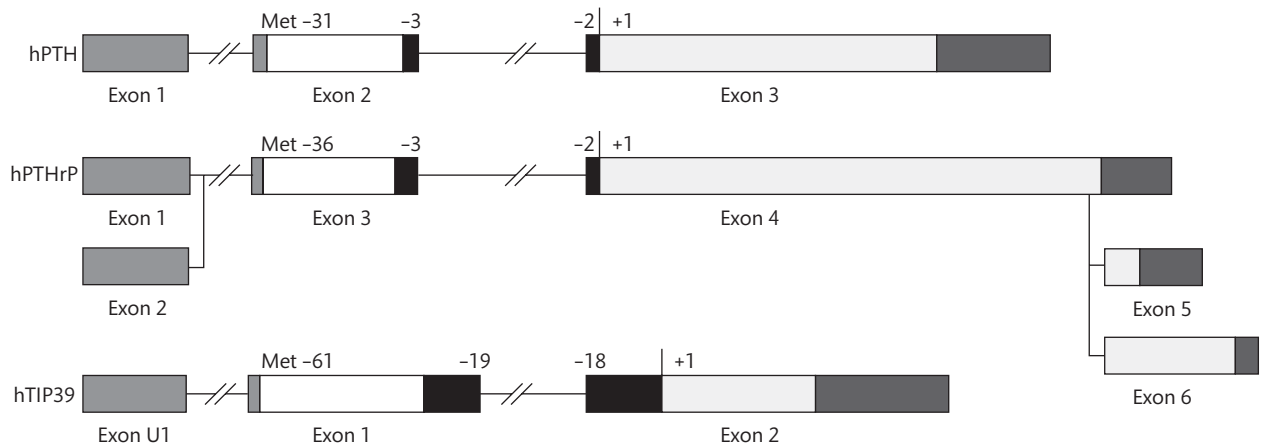

Figure 4.1.2 Comparison of structural organization of the human *PTH*, *PTHrP*, and *TIP39* genes. Exons are boxed: from left to right, dark grey boxes denote 5'UTRs, white boxes denote presequences, black boxes denote prosequences, light grey boxes denote mature polypeptide sequences, and dark grey boxes denote 3'UTRs.

A more common event involves the loss or inactivation of the multiple endocrine neoplasia type 1 (*MEN1*) gene, also on the long arm of chromosome 11. The protein encoded by the *MEN1* gene [15, 16] called menin, is a 610-amino acid nuclear protein [17]. Germline mutations in the *MEN1* gene cause familial and sporadic MEN1 and are found in 20% of non-MEN1 parathyroid adenomas. Loss of heterozygosity at 11q13 is found in MEN1 tumours and sporadic parathyroid adenomas consistent with *MEN1* being a tumour suppressor gene.

A target of the Wnt pathway, β-catenin, encoded by the *CTNNB1* gene, is a candidate for involvement in parathyroid neoplasia. Very few of the parathyroid adenomas examined so far have stabilizing missense *CTNNB1* mutations suggesting that mutation of the β-catenin gene itself is unlikely to be involved in the initiation or early progression of parathyroid adenomatosis. However, other components of the Wnt signalling pathway (e.g. a constitutively active LRP5 receptor derived from an alternatively spliced mRNA may be implicated in parathyroid tumorigenesis) [18].

Early onset recurrent parathyroid tumours occur as part of the uncommon autosomal dominant hyperparathyroidism and jaw tumour (HPT-JT) syndrome in which parathyroid carcinoma is frequent. The responsible gene, *HRPT2* (also known as *CDC73*), at 1q31.2, encodes a novel transcription factor, parafibromin, of 531 amino acids [19]. Sporadic parathyroid carcinomas very commonly contain somatic mutations of the *HRPT2* gene and some of these patients harbour germline mutations. In these cases, genetic testing in family members provides for early diagnosis [3]. Loss of heterozygosity at chromosome 1q occurs in carcinomas of the familial and sporadic disorder usually by intragenic mutations.

PTH follows a pattern of biosynthesis and of vectorial transport through organelles of the cell similar to that of many other peptide hormones. It is biosynthesized on the polyribosomes of the rough endoplasmic reticulum (ER) of the parathyroid endocrine cell. The *PTH* gene encodes a precursor, preproPTH, extended at the aminoterminus of PTH 1-84 by 31 residues. The NH_2-terminal 25-residue portion, characterized by its hydrophobicity, is called the signal, leader, or presequence, and it facilitates entry of the nascent hormone into the cisternae of the ER. One patient with autosomal dominant hypoparathyroidism was reported to have a mutation within the protein coding region of the *PTH* gene in which there was a single base substitution (T->C) in exon II, resulting in the replacement of arginine (CGT) for cysteine (TGT) in the signal peptide. This places a charged amino acid in the hydrophobic core of the signal peptide, leading to inefficient processing of the mutant preproPTH to PTH [3]. In cases like this it is suggested that the mutant polypeptide acts in a dominant-negative fashion by promoting ER stress leading to apoptosis and pharmacological chaperones may be beneficial in restoring proper processing of the PTH [20].

Normally, as the signal sequence of the synthesized hormone emerges from the ribosome, it binds to a signal recognition particle that stops further synthesis of the nascent protein. The signal recognition particle carrying the ribosome then binds to an integral membrane protein of the ER, called the docking protein or signal recognition particle receptor. This protein releases the block in protein synthesis, and the nascent peptide is transported across the membrane into the cisternae of the ER. The signal sequence is simultaneously removed at the inner surface of the ER, at a glycyl-lysyl bond, by a signalase enzyme. (Therefore, note that under normal circumstances the preproPTH molecule never exists as a complete entity.) The resultant precursor molecule, proparathyroid hormone (proPTH), is extended at the NH_2-terminus of PTH 1-84 by only six amino acids. The pro sequence is necessary for efficient translocation and cleavage of the signal peptide. Once formed, proPTH is transported to the Golgi apparatus.

The prohormone hexapeptide has several basic residues that serve as a recognition sequence to yield the mature hormone. Unlike many other prohormones, proPTH does not contain another sequence at the COOH-terminus and has not been detected within the circulation even in states of parathyroid gland hyperfunction. ProPTH has little biological activity until cleaved to create the hormonal form [21]. The conversion of proPTH to PTH takes place within the *trans*-Golgi network rather than the secretory granules as occurs with other prohormones like proinsulin. The enzymes involved include furin and PC7, mammalian proprotein convertases that are related to bacterial subtilisins [22]. Little proPTH is stored within the gland.

The resultant mature 84-amino acid form of the hormone is packaged in secretory granules and transported to the region of the plasma membrane. The hormone is released by exocytosis in response to the principal stimulus to secretion, hypocalcaemia. The calcium ion does not influence the enzymatic cleavages involved in the processing of preproPTH or proPTH.

Parathyroid Hormone Secretion

Relatively little PTH is stored in secretory granules within the parathyroid glands. In the absence of a stimulus for release, intraglandular metabolism occurs, causing complete degradation to its constituent amino acids or partial degradation to fragments (**Figure 4.1.3**). This has been postulated to occur through a specific calcium-regulated enzymatic mechanism. In the case of hypercalcaemia, the predominant hormonal entities released from the gland are fragments comprising midregion or COOH-terminal sequences. In response to hypocalcaemia, degradation of PTH within the parathyroid cell is minimized, and the major hormonal entity released is the bioactive PTH 1-84 molecule. Thus, in the presence of hypocalcaemia, increased amounts of bioactive PTH are secreted, even in the absence of additional synthesis of hormone. Hormone stores are insufficient, however, to maintain secretion for more than a few hours in the presence of a sustained severe hypocalcaemic stimulus, and other mechanisms—transcriptional and posttranscriptional—come into play to increase hormone production. For example, hypocalcaemia promotes stabilization of the preproPTH mRNA leading to increased PTH synthesis. In the presence of a sustained severe hypocalcaemic stimulus, additional PTH secretion depends on an increase in the number of parathyroid cells. Such an increase may also be stimulated by the reduction in circulating 1,25-dihydroxyvitamin D [1,25$(OH)_2$D] that often accompanies hypocalcaemia. Normally, the sterol inhibits parathyroid cell proliferation by suppressing expression of immediate early response genes, such as the *MYC* proto-oncogene [23].

A circadian rhythm has been reported for PTH secretion, with increased blood levels occurring at night and small amplitude pulses of PTH secretion occurring at much shorter intervals. This suggests neural or central nervous system influences on PTH secretion, or reflects circadian alterations in the levels of extracellular calcium.

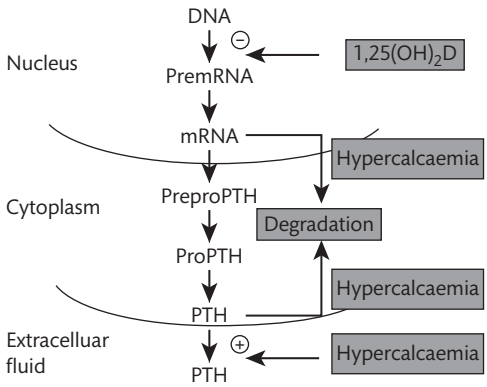

Figure 4.1.3 Schema of the sites of regulation of parathyroid hormone (PTH) biosynthesis, intraglandular degradation, and secretion. Both extracellular fluid calcium and 1,25-dihydroxyvitamin D levels negatively regulate transcription of the PreproPTH gene. Hypercalcaemia increases PreproPTH mRNA turnover and PTH degradation while hypocalcaemia stabilizes PreproPTH mRNA and promotes the production and synthesis of mature PTH.

Calcium

There is an inverse relationship between ambient calcium levels and PTH release that is curvilinear rather than proportional [24]. This relationship between PTH and extracellular calcium contrasts with the influence of the calcium ion as a secretagogue in most other secretory systems in which elevations in this ion enhance release of the secretory product. This distinction between the parathyroid cell and other secretory cells is maintained intracellularly, where elevations rather than decreases in cytosolic calcium correlate with decreased PTH release. Alterations in extracellular fluid calcium levels are transmitted through a parathyroid plasma membrane calcium-sensing receptor (CaSR) that couples through a Gq/11-protein complex to phospholipase C. Increases in extracellular calcium lead to increases in inositol 1,4,5-trisphosphate (IP_3) and mobilization of intracellular calcium stores. The CaSR also couples to a Gi-protein complex thereby inhibiting cyclic AMP production.

The human CaSR comprises 1078 amino acids with a large extracellular domain (ECD) (~600 amino acids), a seven-transmembrane-spanning domain and a cytoplasmic tail [25]. The CaSR is a member of group C of the G-protein-coupled receptor (GPCR) superfamily that includes the metabotropic glutamate, γ-aminobutyric acid-B, and taste and odorant receptors. These receptors function as dimers with the ECDs of each monomer having a so-called Venus flytrap domain consisting of two lobes that close upon the ligand leading to conformational changes in the transmembrane domain of the receptor allowing coupling of G proteins to the intracellular loops and the cytoplasmic tail. The CaSR has a low affinity for Ca^{2+} appropriate for it monitoring the relatively high levels of the mineral ion in the blood. Besides the parathyroid, the CaSR is also expressed in other cells having Ca^{2+}-sensing functions, such as those of the kidney tubule, the calcitonin secreting thyroid C-cells and in diverse other organs and tissues such as brain, bone, and cartilage, haematopoietic stem cells, keratinocytes, gastrointestinal tract, mammary gland, placenta, and vascular smooth muscle. Neomycin binds the receptor, which may account for the toxic renal effects of aminoglycoside antibiotics.

Inherited abnormalities of the *CASR* gene located on chromosome 3q13.3-21 can lead to either hypercalcaemia or hypocalcaemia depending upon whether they are inactivating or activating, respectively [25]. Heterozygous loss-of-function mutations give rise to familial (benign) hypocalciuric hypercalcaemia type 1 (FHH1) in which the lifelong hypercalcaemia is asymptomatic. The homozygous condition manifests itself as neonatal severe hyperparathyroidism (NSHPT), a rare disorder characterized by extreme hypercalcaemia and the bony changes of hyperparathyroidism. Cases of neonatal hyperparathyroidism (NHPT) may be caused by a paternal or de novo mutation in the *CASR* gene. FHH is heterogeneous and FHH2 and FHH3 are due to heterozygous inactivating mutations in the GNA11 gene (encoding the Gα11 protein) and *AP2S1* gene (encoding a subunit of the adaptor protein complex important for cell internalization of the CaSR), respectively. The disorder autosomal dominant hypocalcaemia type 1 (ADH1) is due to gain-of-function mutations in the *CASR* gene. ADH1 may be asymptomatic or present with neonatal or childhood seizures. Because of the overactive CaSR in the nephron, these patients are at a greater risk of developing renal complications during vitamin D therapy than patients with idiopathic hypoparathyroidism. ADH2 is due to heterozygous activating mutations in the GNA11 gene. A common polymorphism in the intracellular tail of the CaSR, Ala to Ser at position 986, has a modest effect on the serum calcium concentrations in healthy individuals [26]. *CASR* polymorphisms might also affect urinary calcium excretion and therefore the *CASR* is a candidate gene for involvement in disorders such as idiopathic hypercalciuria, and primary hyperparathyroidism.

The CaSR is a target for phenylalkylamine compounds—so-called calcimimetics—which are allosteric stimulators of the CaSR's affinity for cations. These orally active compounds have been approved for use in patients with chronic kidney disease and tertiary hyperparathyroidism, in parathyroid cancer, and in primary hyperparathyroidism when patients are not surgical candidates for parathyroidectomy. By their direct action on the parathyroid gland CaSR they provide an effective medical means of lowering PTH secretion and reducing hypercalcaemia [27]. Ongoing clinical trials in patients with mild primary hyperparathyroidism (PHPT) have shown that calcimimetics reduce serum calcium and PTH levels and increase serum phosphate levels but do not significantly affect bone turnover or bone mineral density (BMD).

The CaSR expressed in the developing parathyroid glands—and in the placenta—plays an important role in regulating fetal calcium concentrations. Normally, the fetal blood calcium level is elevated above the maternal level. This depends upon the action of PTHrP released from the placenta on placental calcium transport. Disruption of the CaSR, as shown by studies in CaSR-deficient mice, causes fetal hyperparathyroidism and hypercalcaemia due to fetal bone resorption. The transfer of calcium across the placenta is reduced and renal calcium excretion is increased.

Some patients with inactivating anti-CaSR autoantibodies, often associated with autoimmune disorders such as sprue or autoimmune thyroid disease, present as an FHH phenocopy termed acquired hypocalciuric hypercalcaemia (AHH). The anti-CaSR antibodies are directed against the ECD and interfere with elevated extracellular Ca^{2+}-mediated suppression of PTH release and perturb Ca^{2+}-sensing in the kidney, thereby closely mimicking FHH [24]. Activating autoantibodies that inhibit PTH secretion have

been identified in some patients with autoimmune hypoparathyroidism and the CaSR has also been identified as a self-antigen in patients with autoimmune polyendocrine syndrome type 1 (APS1) or acquired hypoparathyroidism associated with autoimmune hypothyroidism or idiopathic hypoparathyroidism. The activating autoantibodies are directed against epitopes in the ECD of the receptor.

In vivo, PTH mRNA levels are markedly stimulated by decreased circulating calcium concentrations. This occurs, in part, by a posttranscriptional mechanism whereby hypocalcaemia stabilizes and hypercalcaemia destabilizes the PTH mRNA. Prolonged hypocalcaemia *in vivo* may stimulate DNA replication, cell division, and the production of increased numbers of parathyroid cells or parathyroid hyperplasia. This would increase the synthesis of proteins, including PTH, within the hypercellular parathyroid gland and ultimately would increase PTH release. In primary parathyroid gland hyperfunction resulting in hyperparathyroidism, alterations in the calcium-sensing mechanism may manifest as a set-point error, producing a shift to the right of the curve relating PTH secretion to extracellular calcium levels. Consequently, elevated concentrations of extracellular fluid calcium may be required to reduce PTH secretion, resulting in an adenomatous or hyperplastic parathyroid gland that is incompletely suppressed by calcium. Such a mechanism may underlie the observation that an increase in the mass of parathyroid tissue like that produced by transplantation can be associated with hypercalcaemia. The parathyroid glands of patients with primary and severe uremic secondary hyperparathyroidism have reduced CaSR expression as assessed by immunostaining. Loss of a functional CaSR as in humans with NSHPT or in mice in which the *Casr* gene has been ablated leads to severe parathyroid hyperplasia. If basal secretion per cell produces a significant amount of bioactive PTH, the cumulative increase in this basal or non-calcium-suppressible secretion arising from an increase in parathyroid cells could also be responsible for the hypercalcaemia. The precise mechanistic relationship of extracellular calcium to parathyroid cell growth remains to be determined.

1,25-Dihydroxyvitamin D

Vitamin D metabolites modulate PTH release. There is a feedback loop between PTH-induced increase in $1,25(OH)_2D$ and vitamin D metabolite-induced decrease of PTH levels [28]. This latter effect is achieved by a direct action, via the vitamin D Receptor (VDR) on *PTH* gene transcription, thus altering the quantities of hormone available for immediate release by secretagogues.

Other Factors

In addition to calcium and vitamin D metabolites, several other factors influence the release of PTH from parathyroid glands. The cation magnesium affects PTH release like calcium, although with reduced efficacy. (The CaSR is also a magnesium sensor.) High concentrations of aluminium also suppress PTH release. Hyperphosphatemia is associated with increased levels of PTH, an effect that is most often indirect and a result of the hypocalcaemia and/or the decreased $1,25(OH)_2D$ production that accompanies the rise in serum phosphate. However, the anion can exert a more direct effect on PTH synthesis with hyperphosphatemia stabilizing and hypophosphatemia destabilizing PTH mRNA levels. Glucocorticoids (in some studies) increase PTH secretion. Agents such as biogenic amines, which increase parathyroid gland cAMP levels, induce PTH secretion, and those that lower cAMP levels within the parathyroid gland decrease PTH secretion. Lithium, often used to treat bipolar disease, has been associated with hypercalcaemia presumably due to hyperparathyroidism, however, the precise mechanism of lithium action, in this respect, remains to be determined.

PTH Measurement

Circulating PTH is heterogeneous. The major circulating bioactive moiety is similar or identical to intact PTH(1-84). This is metabolized by the liver, which releases midregion and COOH-terminal fragments into the circulation for subsequent clearance by the kidney. These biologically inert moieties generated by metabolism and secretion from the parathyroid gland are cleared more slowly than intact PTH. Circulating bioactive PTH is best measured by sensitive double antibody immunoassays that simultaneously recognize NH_2 and COOH epitopes on the PTH molecule, and detect intact PTH(1-84). This is the method of choice for the accurate diagnosis of patients with hypercalcaemia, especially in distinguishing patients with primary hyperparathyroidism from those with hypercalcaemia of malignancy and in assessing hyperparathyroidism in chronic kidney disease.

Actions of Parathyroid Hormone

€of extracellular fluid calcium [24] (Figure 4.1.4). The hormone exerts important effects on bone and kidney and indirectly influences the gastrointestinal tract. In response to a fall in the extracellular fluid ionized calcium concentration, PTH is released from the parathyroid cell and acts directly on the kidney to enhance renal calcium reabsorption and promote the conversion of 25-hydroxyvitamin D to $1,25(OH)_2D$. In the cortical thick ascending limb of the loop of Henle (CTAL) PTH binds to the PTH receptor (PTHR1) [29, 30], and enhances Ca reabsorption., by increasing the activity of the Na/K/2Cl cotransporter that drives NaCl reabsorption and stimulates paracellular Ca and Mg reabsorption [31]. In the distal convoluted tubule (DCT) PTH, after binding to its receptor, increases luminal Ca transfer into the renal tubule cell by augmenting the epithelial apical Ca channel of the transient receptor potential vanilloid family, TRPV5, followed by translocation of Ca across the cell from apical to basolateral surface via proteins such as calbindin-D28K, and then active extrusion of Ca from the cell into the blood via a Na+/Ca exchanger, NCX1, whose activity is stimulated by a cyclic AMP-mediated mechanism [32]. PTH can also stimulate the 1α(OH)ase, in the proximal tubule leading to increased synthesis of $1,25(OH)_2D$ from 25OHD [33]. The $1,25(OH)_2D$ increases gastrointestinal absorption of calcium and, with PTH, induces skeletal resorption, causing the restoration of extracellular fluid calcium and the neutralization of the signal initiating PTH release. In bone, PTHR1 is localized on cells of the osteoblast phenotype which are of mesenchymal origin [34] but not on osteoclasts which are of hematogenous origin. PTH then enhances release of the cytokine,

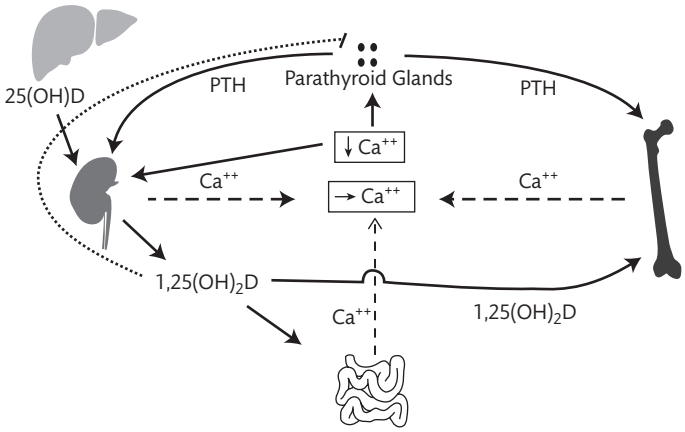

Figure 4.1.4 Parathyroid hormone (PTH) and vitamin D control calcium (as shown) and phosphate homeostasis. A fall in extracellular calcium concentration triggers PTH secretion. PTH directly acts on the kidney to promote renal calcium reabsorption and conversion of 25-hydroxyvitamin D [25(OH)D] to 1,25-dihydroxyvitamin D [1,25$(OH)_2$D]. 1,25$(OH)_2$D increases intestinal absorption of calcium (and phosphate) and, with PTH, mobilizes calcium (and phosphate) from bone. Thus, extracellular fluid (ECF) calcium is restored to normal neutralizing the signal initiating PTH release. PTH inhibits renal phosphate reabsorption promoting phosphaturia. Fibroblast growth factor 23 (FGF23),not shown, may be stimulated by 1,25$(OH)_2$D and also enhance phosphaturia, however FGF23 may then inhibit further 1,25$(OH)_2$D production.

receptor activator of NFκB ligand (RANKL) which binds to its receptor, RANK, on osteoclast precursors and osteoclasts, increasing the formation of mature osteoclasts from precursors and increasing the resorptive activity of existing osteoclasts especially in cortical bone. PTH may also reduce the osteoblastic protein, osteoprotegerin, which normally binds to RANKL, forms an inactive complex, and prevents it from binding to RANK, thus reducing osteoclastic activity [35, 36]. It has also been suggested that PTH can acutely release mineral at the bone surface in an osteoclast-independent manner by modifying its solubility [37]. The opposite series of homeostatic events occur in response to a rise in extracellular fluid calcium levels and a fall in PTH.

Although this scheme outlines the overall events that occur after a fall in calcium, aspects of the response may vary. Certain actions of PTH, such as renal calcium retention may predominate at relatively low circulating concentrations of PTH. Furthermore, PTH appears to be essential as a bone anabolic factor in the fetus [38] and neonate [39], particularly in trabecular bone but may be predominantly resorptive, especially in the cortical compartment of bone, in older animals [40] when the source of external calcium changes. PTH and PTHrP regulate osseous cellular differentiation, proliferation, and development, and via their actions on osteoblastic cells can function as anabolic skeletal agents when administered intermittently rather than continuously *in vivo*. Thus, intermittent doses of PTH(1-34)—and PTHrP(1-34) and related analogues—promote bone formation [41] directly by stimulating osteoblastic activity and indirectly, both by stimulating IGF-I production and suppressing sclerostin, thereby increasing Wnt signalling. Daily injections of human PTH(1-34), teriparatide, or a human PTHrP analogue, abaloparatide, increase hip and spine BMD, and prevent vertebral and non-vertebral fractures in osteoporosis, and each has been approved clinically for use as a bone anabolic agent to treat osteoporosis.

Besides regulating calcium homeostasis, PTH elicits various other responses. Among these responses are perturbations of other ions, the most marked of which are those involving phosphate. As a consequence of PTH-enhanced 1,25$(OH)_2$D production, the gastrointestinal absorption of phosphate is facilitated to some extent, and with PTH-induced skeletal lysis, phosphate and calcium are released. These effects increase the extracellular fluid phosphate levels. However the predominant effect of PTH on phosphate homeostasis is to inhibit renal phosphate reabsorption in the proximal renal tubule by enhancing rapid internalization and lysosomal degradation of the type II sodium phosphate cotransporters, NPT2a (SLC34A1) and Npt2c (SLC34A3) thus decreasing luminal transport of phosphate and causing phosphaturia [42, 43]. Consequently, a net decrease in extracellular fluid phosphate concentration occurs which is adjunctive to the role of PTH in raising calcium levels.

Parathyroid Hormone Receptors

Like other peptide hormones, PTH interacts through a receptor on the plasma membrane of target cells. This same receptor binds PTHrP [44, 45]. The type 1 PTH/PTHrP receptor (PTHR1) is a seven-transmembrane G-protein-linked receptor that has the 'signature' GPCR topology, a seven-membrane-spanning, 'serpentine' domain, as well as an extracellular ligand-binding domain and an intracellular COOH-terminal domain [46]. It is a member of group B of the GPCR superfamily. The receptor can couple to the stimulatory G protein, G_s, leading to increased adenylate cyclase activity, the generation of cAMP, and activation of the protein kinase A (PKA) pathway, and can couple to G_q, leading to an increase in the protein kinase C (PKC) pathway and to an increase in IP_3, diacylglycerol, and intracellular Ca^{2+} [46, 47]. As with other GPCRs, PTHR1 undergoes cyclical receptor activation, desensitization, and internalization [48]. After ligand binding and endocytosis, the PTHR1 is either recycled to the cell membrane or targeted for degradation. High circulating levels of PTH in hyperparathyroid states have been associated with hormonal desensitization in target tissues. Arrestins contribute to the desensitization of both G_s and G_q mediated PTHR1 signalling. PTHR1 activation and internalization can be selectively dissociated [49]. PTHR1 signalling can be modified by scaffolding proteins such as the Na^+/H^+ exchanger regulatory factor (NHERF) 1 and 2 through PDZ1 and PDZ2 domains [50, 51]. PTHR1 signalling via the cAMP pathway, leading to PKA activation, results in phosphorylation of the cyclic AMP response element binding protein (CREB). CREB binds to the CRE in the promoter region of many genes and transcriptionally modulates their expression. The difference in the extent of anabolic versus catabolic activity of PTH and PTHrP analogues may be explained, at least in part, by the way in which these two peptides interact at two PTHR1 conformations, R0 and RG. Higher affinity for R0 is associated with increased internalization, more cyclic AMP generation and longer-lived catabolic effects, whereas greater binding to RG is associated with shorter-duration anabolic responses.

The PTHR1 is highly expressed in kidney and bone, the primary target tissues of PTH, but is also expressed in a wide variety of embryonic and adult tissues, including cartilage, liver, brain, smooth

muscle, spleen, testis, and skin. In most of these tissues, the receptor appears to mediate the autocrine/paracrine actions of locally produced and secreted PTHrP. Nevertheless, PTHrP may also exert some of its bioactivity through domains of the molecule that do not interact with PTHR1 [52].

The human PTH/PTHrP receptor gene *(PTHR1)* localizes to chromosome 3p21.1-22 [53]. A second related receptor which is the product of a distinct gene (*PTHR2* on chromosome 2q33), and which binds PTH, TIP39, but not PTHrP, has been identified [54]. It is expressed in brain, pancreas, testis, and placenta, and its endogenous ligand is TIP39.

Direct evidence that the PTHR1 mediates the calcium homeostatic actions of PTH and the skeletal growth plate actions of PTHrP in humans has come from the study of rare genetic disorders. Jansen's metaphyseal chondrodysplasia (JMC) is inherited in an autosomal dominant fashion although most reported cases are sporadic [55]. The disorder comprises short-limbed dwarfism secondary to severe growth plate abnormalities, asymptomatic hypercalcaemia, and hypophosphatemia. There is increased bone resorption similar to that in primary hyperparathyroidism and urinary cAMP levels are elevated, but circulating PTH and PTHrP levels are low or undetectable. Although PTHR1 is found widely in fetal and adult tissues, it is most abundant in three major organs, the kidney, bone, and metaphyseal growth plate. The changes in mineral ion homeostasis and the growth plate in JMC are caused by heterozygous gain-of-function mutations (Figure 4.1.5) in the *PTHR1* giving rise to constitutively active receptors.

Inactivating or loss-of-function mutations in the *PTHR1* have been implicated in the molecular pathogenesis of Blomstrand

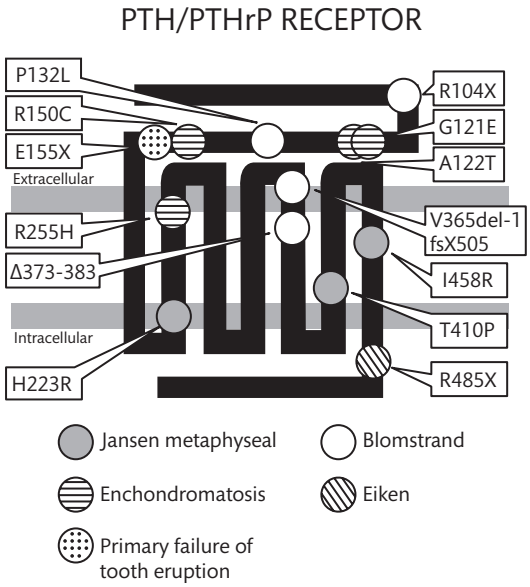

Figure 4.1.5 Schematic representation of the type 1 human PTH/PTHrP receptor. The locations of the H223R, T410P, and I458R activating mutations identified in patients with Jansen's metaphyseal chondrodysplasia, the R104X, P132L, V365del-1fsX505, and D373-383 inactivating mutations found in patients with Blomstrand chondrodysplasia, the R485X Eiken syndrome mutation, the G121E, A122T, R150C and R255H endochondromatosis mutations, and the E155X primary failure of tooth eruption (PFE) mutation, are indicated. Splice-site mutations that would result in predicted mutant C351fsX485 and E182fsX203 proteins have been identified in additional PFE cases.

lethal chondrodysplasia (BLC) [55]. This rare disease is characterized by advanced endochondral bone maturation, short-limbed dwarfism, abnormal breast and tooth morphogenesis, and fetal death, thus mimicking the phenotype of *Pthr1*-less mice [56]. The majority of BLC cases were born to phenotypically normal, consanguineous parents, suggesting an autosomal recessive mode of inheritance. Mutant PTHR1s (Figure 4.1.5) identified in BLC fetuses fail to bind ligand or stimulate cAMP or inositol phosphate production. A milder form of recessively inherited skeletal dysplasia, known as Eiken syndrome, has been linked to mutations of *PTHR1*, suggesting a wider range of skeletal phenotypes to this gene. Dominantly acting heterozygous *PTHR1* mutations have been identified in familial, non-syndromic primary failure of tooth eruption [57]. Heterozygous *PTHR1* mutations have been identified in endochondromas of patients with endochondromatosis (Ollier's disease), a familial disorder with evidence of autosomal dominance characterized by multiple benign cartilage tumours, and a predisposition to malignant chondrosarcomas [58]. As many patients with Ollier's disease do not apparently have *PTHR1* mutations the condition may be genetically heterogeneous.

Heterozygous inactivating mutations in the *GNAS1* gene encoding Gαs cause an ~50% reduction in amount/activity of the protein leading to resistance to PTH and other hormones in the disorder, pseudohypoparathyroidism (PHP) type 1a [59–61]. In contrast, patients with PHP type 1b have end-organ resistance to PTH without the typical physical stigmata—termed Albright's hereditary osteodystrophy—of PHP type 1a. Linkage to chromosome 20q13.3, which includes the *GNAS1* locus was established in kindreds with PHP type 1b [62]. In addition, the genetic defect is imprinted paternally and is inherited in the same fashion as the PTH resistance in kindreds with PHP type 1a, and in a mouse model heterozygous for ablation of the *GNAS* gene [63]. In PHP type 1b patients, mutations some distance upstream of the *GNAS1* coding regions affect the normal differential methylation of maternal and paternal alleles leading to silencing of the *GNAS* gene specifically in the renal proximal tubules [64].

PTH controls renal phosphate reabsorption. Mutations in the genes encoding the two renal sodium phosphate cotransporters, NPT2a and NPT2c, have been identified in a few patients with hyperphosphaturia. The sodium-hydrogen exchanger regulatory factor 1 (NHERF1) interacts with the PTHR1 and NPT2a. Study of hyperphosphaturic patients referred initially for nephrolithiasis or osteopaenia identified a few cases having NHERF1 mutations that could contribute to the renal phosphate loss [65].

Summary

PTH is responsible for the minute-to-minute maintenance of calcium homeostasis. PTH secretion is controlled via the parathyroid CaSR, and inactivating or activating mutations in this receptor lead to inherited hypercalcaemic and hypocalcaemic disorders, respectively. Both PTH (and the related gene family member, PTHrP) act through the PTHR1 that is widely expressed and signals through multiple second messenger pathways. Inactivating mutations in the PTHR1 cause Blomstrand's lethal chondrodysplasia, whereas activating mutations are found in JMC.

4.2

Hypercalcaemia

Claudio Marcocci, Federica Saponaro, and Filomena Cetani

Introduction

Hypercalcaemia is a common finding in general medical practice and in emergency departments. Hypercalcaemia is incidentally discovered in most patients evaluated for unrelated disorders, particularly after the widespread availability of multichannel biochemistry autoanalyser which also include the measurement of serum calcium. The principal challenge in the evaluation of hypercalcaemia is distinguishing parathyroid hormone (PTH)-related hypercalcaemia from other causes, that may need different diagnostic approach and treatment.

The total calcium content of the human body is about 1–2 kg and the large majority (98–99%) is stored in the skeleton, with two main functions: structural support for the human body and calcium deposit which can be exchanged with other compartments. The remaining 1–2% is present in the extracellular and intracellular space: the maintenance of calcium in a very narrow range in both compartments is very important for the adequate functioning of cellular calcium-dependent effects. Approximately 50% of the total amount of calcium present in blood is bound to proteins (mainly albumin) or complexed to some anions, namely phosphate and citrate [1]. The remaining part is in the ionized state (ionized calcium, Ca^{2+}), that represents the only biologically active form and is involved in the regulation of several functions, namely neuromuscular activity, cells membrane structure, bone homeostasis, coagulation, and endocrine functions.

Intestine, kidney, and bone are involved in the maintenance of calcium homeostasis. When dietary calcium intake is normal (1000 mg per day), approximately 200 mg of calcium is absorbed by the gastrointestinal apparatus and constitutes the only source to maintain calcium deposits. Duodenum, jejunum, and ileum display a high calcium absorptive capacity, depending from the length of each segment and the characteristics of the food bolus. Two mechanisms of calcium absorption are involved, depending from the calcium concentration in the intestinal lumen. A passive transport through a paracellular space between intestinal cells is operating when calcium level in the intestinal lumen is high. This pathway is only indirectly controlled by $1,25(OH)_2$vitamin D ($1,25(OH)_2D$), that activates a transduction signalling mediated by protein kinase C, leading to more permeable tight junctions between cells [2]. On the other hand, when calcium levels in the intestinal lumen are low, an active, $1,25(OH)_2D$ dependent, transport process mediates the entry of calcium into the enterocytes through a calcium channel [3].

When renal function is normal, 10 grams of calcium are filtrated daily, the large majority (98–99%) is reabsorbed by renal tubules, and about 100–200 mg are excreted. Reabsorption of filtered calcium mostly (90–95%) occurs in the proximal tubule and loop of Henle by a Na-Ca exchanger, the remaining being absorbed in the distal nephron by a finely-regulated PTH-dependent transcellular mechanism [2].

Calciotropic hormones, and particularly PTH and $1,25(OH)_2$vitamin D ($1,25(OH)_2D$), regulate serum calcium levels, acting on bone, kidney, and intestine

Increased bone resorption and gastrointestinal absorption and/or decreased renal excretion of calcium may lead to hypercalcaemia.

Hypercalcaemia is defined by a value of serum calcium levels two standard deviation above the normal mean. The total serum calcium concentration is commonly used in general practice, even though the measure of Ca^{2+} is more accurate, since the protein content may affect the total serum calcium levels. However, in many laboratories the measurement of $Ca^{2+}$is not available, and the following formula can be used to calculate the albumin-adjusted serum calcium (Alb-Ca):

$$\text{Alb-Ca (mg/dl)} = \text{measured serum calcium (mg/dl)} + [(4 - \text{plasma albumin g/dl}) \times 0.8].$$

The Alb-Ca can be used as an acceptable measure in most clinical circumstances.

Epidemiology

Epidemiological data regarding calcium disorders are challenging, because they are dependent from the specific settings where patients are evaluated, geographical differences, and clinical features of the underlying diseases.

The prevalence of persistent hypercalcaemia in the general population is about 1%, but it rises up to 3% in hospitalized subjects [4]. In a recent retrospective study on 12 334 hospitalized subjects, hypercalcaemia was found in 585 patients (4.74%) and its rate slightly, but not significantly, increased from 3.5% in the year 2011 to 6.9% in the year 2014 [5], with no gender differences.

Primary hyperparathyroidism (PHPT) is one of the most common causes of hypercalcaemia in free-living individuals. High variability in the incidence of PHPT has been reported in United Kingdom and United States studies, ranging from ~0.4 to 82 cases per 100 000, according to the different population analysed [6, 7]. Hypercalcaemia of malignancy (HCM) is the second cause of hypercalcaemia and the most common in hospitalized patients. The estimated prevalence based on retrospective studies ranges between 3% and 30%, depending upon the kind of primary tumour and age. In the paediatric population HCM occurs in 0.4–1.3% of patients with cancer mainly in those with cancer of the haematopoietic system. In 2016 Gastanaga *et al.* evaluated a large series (about 12 000) of cancer patients in the United States collected between 2009 and 2013 and found a prevalence of HCM of 2.8%, with a higher rate in patients with multiple myeloma (7.5%) and lower in those with prostate cancer (1.4%) and its prevalence was found to decrease over the study period [8]. Conversely, a lower (1%) prevalence of HCM was reported in another large series (37 442 over the 2003–2012 period) of cancer patients in the United Kingdom, but its rate increased during the follow-up, because serum calcium measurement was most commonly measured in the more recent years of the study [8].

Clinical Signs and Symptoms

Hypercalcaemia is commonly encountered in emergency department. A typical case could be 60-year-old women presenting with lethargy, confusion, profound weakness, progressive anorexia, and constipation since a few weeks. These clinical manifestations are usually present when serum calcium concentration is above 14 mg/dl (severe hypercalcaemia). These classical symptoms include neuropsychiatric symptoms (anxiety and depression), musculoskeletal involvement and bone pain, renal (polyuria, dehydration, and nephrolithiasis) and gastrointestinal manifestations (anorexia, nausea, constipation, and peptic ulcer). When serum calcium is above 13 mg/dl and hyperphosphatemia is also present, calcifications in the cardiovascular system, kidney, cornea, and joints usually occur.

Symptoms generally, but not always, correlate with the degree of hypercalcaemia and its duration. When hypercalcaemia is rapidly progressing reaching severe levels, nausea, vomiting, ventricular fibrillation, and coma may occur. Severe hypercalcaemia represents an emergency and treatment is urgently required.

The clinical manifestations of hypercalcaemia are reported in Table 4.2.1.

Pathophysiology

As mentioned before, calcium homeostasis is maintained by the equilibrium among renal excretion, bone resorption, and intestinal absorption of calcium. Parfitt *et al.* in 1979 proposed three different pathophysiologic mechanisms of hypercalcaemia: (i) the 'equilibrium' hypercalcaemia, which typically occurs in patients with mild-to-moderate PHPT, where the average serum calcium is elevated but constantly maintained at the same level, with few fluctuations. This is related to a perturbance of the so-called calcium homeostatic system on bone surface, where the increased calcium resorption is balanced by an increased renal tubular excretion; (ii) the 'disequilibrium' hypercalcaemia, which is characterized by a rapid increase in serum calcium, increased bone resorption, and negative calcium balance at the bone surface. The general mechanism involves osteoclast progenitor's differentiation, mature osteoclasts recruitment, and stimulation of bone resorption activity. 'Disequilibrium' hypercalcaemia can develop when 'equilibrium' hypercalcaemia is broken by precipitating conditions, or it can arise from the beginning in all situations in which a disturbance of the bone remodelling system occurs [9]; (iii) hyperabsorption hypercalcaemia, which is associated with increased intestinal calcium absorption and positive calcium

Table 4.2.1 Clinical manifestations of hypercalcaemia

Manifestations	Mild hypercalcaemia <12 mg/dl (3.0 mmol/L)	Moderate hypercalcaemia 12–14 mg/dl (3.0–3.5 mmol/L)	Severe hypercalcaemia >14 mg/dl (3.5 mmol/L)
Neuropsychiatric	Lack of concentration and memory, anxiety, depression, irritability	Confusion, cognitive and personality changes	Confusion, lethargy, hallucinations, psychosis, coma
Muscle-skeletal	Asymptomatic	Muscle weakness, osteoporosis	Muscle weakness, bone pain, arthritis, osteitis fibrosa-cystica
Renal	Polyuria and polydipsia	Dehydration, polyuria, polydipsia, nocturia	Nephrolithiasis and colic, renal failure
Gastrointestinal	Nausea, constipation, weight loss	Anorexia, nausea, vomiting	Abdominal pain, pancreatitis, peptic ulcer
Cardiovascular	Hypertension	ECG: shortened QT interval, prolonged PR interval and widened QRS complex, vascular calcification	Arrhythmias, ventricular tachycardia, and cardiovascular arrest, syncope
Others	Asymptomatic	Itching, keratitis, conjunctivitis	Cornea calcification, haematological disorders (anaemia)

balance, as in vitamin D intoxication [1]. All types of hypercalcaemia are associated with increased calcium absorption and hypercalciuria is the first biochemical abnormalities in patients developing severe hypercalcaemia, unless renal function is markedly deteriorate, followed by an increase of serum calcium concentration [10].

Severe hypercalcaemia develops when there is some limitation in the capacity of the kidney to excrete the increased calcium overload, most commonly due to a combination of decreased renal function and increased renal calcium reabsorption

Specific pathophysiology issues will be discussed in the dedicated sections.

Diagnosis

The diagnosis of hypercalcaemia is primarily made on the basis of serum calcium and preferably serum Alb-Ca or, whenever possible, Ca^{2+} levels (Figure 4.2.1). When serum calcium is above the normal range of the laboratory, the first step should be to confirm hypercalcaemia by a second measurement.

It is important to know that serum calcium results are affected by important preanalytical, analytical, and postanalytical factors. Fasting blood samples should be collected, avoiding venous stasis. Haemoconcentration and haemodilution are the most common preanalytical causes of misleading results. Haemoconcentration is usually due to dehydration and venous stasis and may increase serum calcium concentration. Other factors can be posture, abnormal proteins levels, temperature, anions, and pH [11]. Moreover, some analytical variables should be considered: the most common method for total serum calcium measurement is the spectrometry analysis, using metallochromic indicators or an ion-specific electrode (ISE). The within- and between subjects' variation of total serum calcium ranges between 1.9 and 2.8%, and the desirable value for inaccuracy, imprecision, and total assay error are 0.8%, 1%, and 2.4%, respectively. It is very important to validate the assay using appropriate quality control (QC) methods and have adequate laboratory coefficients of variation [11]. Finally, post-analytical interpretation is also very important. The large majority of laboratories that use high accuracy methods for total calcium measurement have a reference interval of approximately 8.8–10.2 mg/dl*. The reference interval is generally established at the central 95% of the Gaussian distribution, so at the extreme

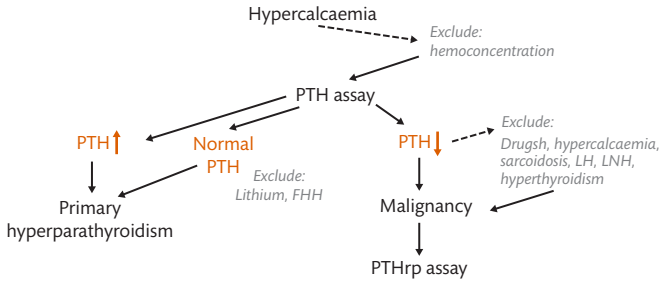

Figure 4.2.1 Differential diagnosis of hypercalcaemia. PTH, parathormone; FHH, familial hypocalciuric hypercalcaemia; LH, Hodgkin's lymphoma; NHL, non-Hodgkin's lymphoma.

* Use the formula serum calcium mg/dl: 2.5 = serum calcium mmol/L.

2.5% two sites of the curve values obtained in normal individuals will be interpreted as hyper- or hypocalcemia. In bordeline cases we recommend using the serum Alb-Ca obtained by the previously reported formula. However, values derived from this formula does not take into account the binding of calcium to proteins other than albumin and therefore do not accurately reflect the free serum calcium concentration [11].

Wherever available, serum Ca^{2+} should be measured, because it provides a more accurate assessment of the calcium status. It has been demonstrated that serum Ca^{2+} has a higher sensitivity for malignant hypercalcaemia and for the diagnosis of PHPT [12].

Moreover, in particular conditions, the measurement of serum Ca^{2+} is critical. In patients with kidney failure, comparison of results of total and Alb-Ca with Ca^{2+} demonstrated that the former measurements improperly classified as hypercalcaemic 20% of patients. The correct interpretation of calcium levels in those patients is important for the appropriate treatment [13]. In patients with critical diseases there is a redistribution of free, protein-bound, and complexed calcium and, therefore, the measurement of serum Ca^{2+} should be preferred [14]. The measurement of serum Ca^{2+} is also preferable in neonates and infants [15]. Exercise and hyperventilation may influence the concentration of serum Ca^{2+}: exercise may increase serum Ca^{2+} largely because exercise-induced acidosis decreases the binding of calcium to serum proteins, but reduction of plasma volume and influx form extracellular sources may also contribute; conversely hyperventilation may decrease Ca^{2+} because of hyperventilation-induced alkalosis increases the binding of calcium to serum proteins [11].

Once the diagnosis of hypercalcaemia is confirmed plasma PTH levels should be measured to distinguish PTH-dependent and PTH-independent hypercalcaemia. Second and third generation immunoradiometric PTH assays demonstrated a higher sensitivity (88–97%) in the diagnosis of PHPT compared to first generation assays and are the most commonly used [11, 16]. When PTH measurement is not easily available serum phosphate may be used to guide the differential diagnosis, being usually normal in PTH-independent hypercalcaemia and low or in the lower normal range in PTH-dependent hypercalcaemia. Serum creatinine and kidney function should also be evaluated.

A 24-hour urine collection for calcium and creatinine measurements should be obtained to calculate the calcium to creatinine clearance ratio and rule out familial hypocalciuric hypercalcaemia (FHH) (see next). Indeed, a calcium to creatinine ratio of less than 0.01 is suggestive of FHH. The measurement of serum 25(OH) vitamin D (25(OH)D) and, especially, $1,25(OH)_2D$ may help in the diagnosis of vitamin D-dependent forms of hypercalcaemia.

Aetiology

Hypercalcaemic disorders are highly variable and can be classified according to the underling diseases or conditions, as summarized in the Box 4.2.1.

Hypercalcaemia Mediated by Parathormone (PTH)

Primary hyperparathyroidism (PHPT) is the most common cause of PTH-dependent hypercalcaemia. PHPT is a common endocrine disease, characterized by increased serum calcium and high or

Box 4.2.1 Aetiological classification of hypercalcaemia

PTH-mediated hypercalcaemia
- Primary hyperparathyroidism
- Tertiary hyperparathyroidism
- Familial hypocalciuric hypercalcaemia (FHH)
- Authentic ectopic secretion of PTH

Hypercalcaemia of malignancy (HCM)
- Humoral hypercalcaemia of malignancy (HHM)
- Local osteolytic hypercalcaemia (LOH)

Vitamin D-mediated hypercalcaemia
- Hypercalcaemia associated with granulomatous diseases
- Malignant hypercalcaemia
- Hypercalcaemia associated with vitamin D intoxication
- Hypercalcaemia associated with 24α hydroxylase mutations

Drug-related hypercalcaemia
- Vitamin A
- Oestrogen and oestrogen modulators
- Lithium
- Thiazides

Endocrine conditions
- Hyperthyroidism
- Addison's disease/hypoadrenalism
- Others endocrinopathies

Others
- Pregnancy/lactation
- Milk-alkali syndrome
- Immobilization
- Post-acute kidney failure
- Miscellaneous

inappropriately normal serum levels of PTH [17]. PHPT is prevalent in the sixth decade of life, with a female to male ratio of 3–4:1 [18], whereas there is no gender difference below the age of 40 years [19]. PHPT generally occurs sporadically, but occasionally it may be part of familial syndromes: multiple endocrine neoplasia type 1, 2 A, and 4 (MEN1, MEN2A, and MEN4), hyperparathyroidism-jaw tumour syndrome (PHPT-JT), familial isolated PHPT (FIHP). In the majority of patients PHPT is due to a single parathyroid adenoma, rarely to a multiglandular disease and very rarely (less than 1%) to parathyroid carcinoma. In the latter case, hypercalcaemia is usually severe. During the last decades the clinical presentation of PHPT changed and in industrialized countries the disease commonly occurs as an asymptomatic disorder: patients rarely present hypercalcaemic symptoms, overt bone disease, and neuromuscular weakness; conversely silent nephrolithiasis is still rather common (up to 35%) [18, 20, 21]. Parathyroidectomy is the only definitive cure for PHPT and should be recommended in symptomatic patients. Moreover, parathyroidectomy should also be recommended in those with asymptomatic PHPT with target organs involvement, as suggested by international guidelines. Some important novelties in patient's evaluation and management were introduced in the lastly updated version in 2013, particularly regarding the evaluation of bone and kidney involvement and the impact of related abnormalities on patient's management [22].

Tertiary hyperparathyroidism In patients with severe vitamin D deficiency, resistance to 1,25 $(OH)_2$ vitamin D and endstage renal failure, parathyroid hyperplasia may be followed by autonomous overgrowth of a clone of parathyroid cells and development of adenomas and hypercalcaemia, a condition known as tertiary hyperparathyroidism [23].

Familial hypocalciuric hypercalcaemia FHH is a rare autosomal dominant disorder characterized by moderate hypercalcaemia and relative hypocalciuria, namely the urinary calcium excretion is low in relationship to the increased levels of serum calcium and renal calcium load. The reported prevalence of the disease is about 1 in 78 000 individuals, but it is probably underestimated, because of the subclinical picture and misdiagnosis [24]. FHH is due to a genetic disorder associated in the most cases with a loss-of-function mutation in the calcium-sensing receptor (CaSR) gene. This accounts for lower sensitivity to the inhibitory effect of serum Ca^{2+} on the parathyroid synthesis, secretion of PTH and increased renal tubular reabsorption of calcium. Patients are generally asymptomatic. The diagnosis should be considered in asymptomatic patients with mild-to-moderate hypercalcaemia and inappropriately normal or slightly increased PTH levels. The clue for the diagnosis of FHH is the finding of a calcium to creatinine clearance ratio, less than 0.01 (in patients with PHPT this ratio is usually above 0.02–0.03). Vitamin D deficiency, if present, should be corrected before urine collection. Laboratory testing (serum and urinary calcium) in relatives may be of value for supporting the diagnosis, which should be confirmed by genetic testing. It is important to remember that FHH is extremely rare as compared with PHPT and therefore in equivocal cases the latter diagnosis is the most likely one.

Authentic ectopic secretion of PTH. Since 1990 rare cases of patients with malignancies were reported, in whom hypercalcaemia was associated with authentic PTH secretion by the tumours. Streweler *et al.* for the first time described a patient with a neuroectodermal neck tumour shown to produce intact PTH [25]. Circulating PTH levels are usually particularly high in patients with a true intact PTH ectopic secretion. In the last 20 years 32 articles describing authentic ectopic secretion of PTH have been published. PTH secreting tumours can be found in the neck (medullary and papillary thyroid carcinoma, cervical paraganglioma, nasopharyngeal rhabdomyosarcoma, squamous tonsil carcinoma), in the thorax (lung carcinoma, thymoma), and in the gastrointestinal tract and pelvis (hepatocarcinoma, pancreatic adenocarcinoma, oesophageal carcinoma, pancreatic islet carcinoma, ovarian carcinoma, adenosquamous endometrium carcinoma) [26]. Ectopic PTH secretion should be considered when moderate-to-severe hypercalcaemia is found in a cancer patient, particularly if associated with high levels of PTH. When hypercalcaemia is mild, the diagnosis of PHPT, which is much more common than ectopic PTH secretion, should be considered, and therefore we cannot exclude that these two conditions may coexist in the same patient. Neck imaging studies and selective venous blood sampling for PTH measurement may be of help in selected cases.

Hypercalcaemia of Malignancy

Hypercalcaemia associated with malignancy (HCM) is the most common cause of PTH-independent hypercalcaemia and is responsible of the majority of cases of hypercalcaemia in hospitalized patients. HCM can be distinguished in humoral hypercalcaemia of malignancy (HHM), the most common form due to endocrine or paracrine effects on bone of tumour-produced molecules, and local osteolytic hypercalcaemia (LOH) that is mainly, but not only, due to the direct invasion of bone by tumour cells.

HCM can be associated at any type of cancer. It generally occurs at endstage of the disease, is associated with severe gastrointestinal, renal, neuropsychic, and cardiovascular symptoms and is predictive of a poor prognosis. In some patients serum calcium may increase over a short period of time and hypercalcaemia may be of difficult control leading to fatal hypercalcaemic crisis [27].

Lung and breast cancers and multiple myeloma account for more than half of all cases of HCM. Other cancers frequently associated with HCM are squamous cells carcinoma of the head and neck, and renal and kidney cancers [28].

Humoral hypercalcaemia of malignancy. HHM is due to the paracrine or endocrine actions of molecules secreted by the tumour cells, mainly the PTH-related peptide (PTHrP) (Figure 4.2.2). The hypothesis that a factor similar to PTH could be responsible for hypercalcaemia in cancer patients was firstly proposed by Albright in 1940, but it was only in 1980s that PTHrP was identified and shown to be similar to native PTH in its N-terminal end [29]. PTH and PTHrP are encoded by the same gene, but the two molecules have different structure and mechanism of control, even if they share the same PTH1 receptor [30]. PTHrP mimics most of the actions of PTH: it increases bone resorption and distal tubular calcium reabsorption, and inhibits proximal tubular phosphate transport. Conversely, PTHrP does not stimulate the production of $1,25(OH)_2$ vitamin D and has no effect on intestinal calcium absorption. Despite the use of the same cellular receptor, PTHrP and PTH act in a different way on bone, likely because of the activation of different intracellular signal pathways [31]. PTH induces a high, but still coupled bone turnover, whereas PTHrP produces an uncoupling of bone remodelling (non-equilibrium hypercalcaemia) and a negative bone balance. Moreover, However, PTHrP-induced hypercalcaemia is also and largely caused by its action of on the renal tubule with increased calcium reabsorption and phosphate excretion. PTHrP production is common in patients with adenocarcinomas of breast, prostate, and ovary. An epidemiological follow-up study demonstrated a strong association between ovarian cancer and hypercalcaemia, with a 63% increased risk of mortality when hypercalcaemia occurs [32]. HHM can also occur in patients with squamous cell carcinoma (lung, cervix, oesophagus), renal carcinomas, and lymphomas, although in the latter cases overproduction of $1,25(OH)_2$ vitamin D may also play an important role.

Local osteolytic hypercalcaemia. Since the 1940s, it has been recognized that some solid tumours (e.g. breast cancer) and haematological malignancies (e.g. myeloma, lymphoma, and leukaemia) may led to hypercalcaemia due to a widespread skeletal involvement (LOH). In these patients an extensive bone marrow invasion by the tumour was found at pathology and the initial understanding was that hypercalcaemia was due to the extensive bone marrow destruction by osteolytic tumours. Subsequently, it was clear that some tumours produced factors that could act in a paracrine way, inducing calcium mobilization from bone [33]. The current understanding is that tumour cells, after their interaction with the bone marrow microenvironment, produce different factors with activating (osteoclast activating factors, OAFs) or inhibitory (osteoblast inhibitory factors, OIFs) effects. OAFs, namely interleukin (IL)1, IL6, IL11, macrophage inflammatory protein 1 a (MIP1a) and, particularly PTHrP, directly increase maturation and activity of osteoclasts. This effect is mediated by an increased production by osteoblasts and stromal cells of RANK ligand (RANKL), associated with and inhibition of osteoprotegerin (OPG) production by the same cells. RANKL transduction signal induces osteoclast maturation by the mitogen activated protein kinase (MAPK) pathway, thus leading to bone resorption. The bone matrix destruction releases some growth factors such as TGFβ, FGF, PDGF, and IGF1 that stimulates tumour cells growth in a vicious cycle [34]. At the same time, the Wnt/dikkopf-1 pathway is inhibited, leading to a decreased osteoblast activation. The final effect is an uncoupling of bone remodelling, with prevalent bone destruction and calcium release [35]. Clinical features of LOH are hypercalcaemia, bone pain, bone loss, and fragility fractures.

Vitamin D-mediated Hypercalcaemia

$1,25(OH)_2D$, the active form of vitamin D produced in the kidney, acts as a classical hormone on tissues which express the vitamin D

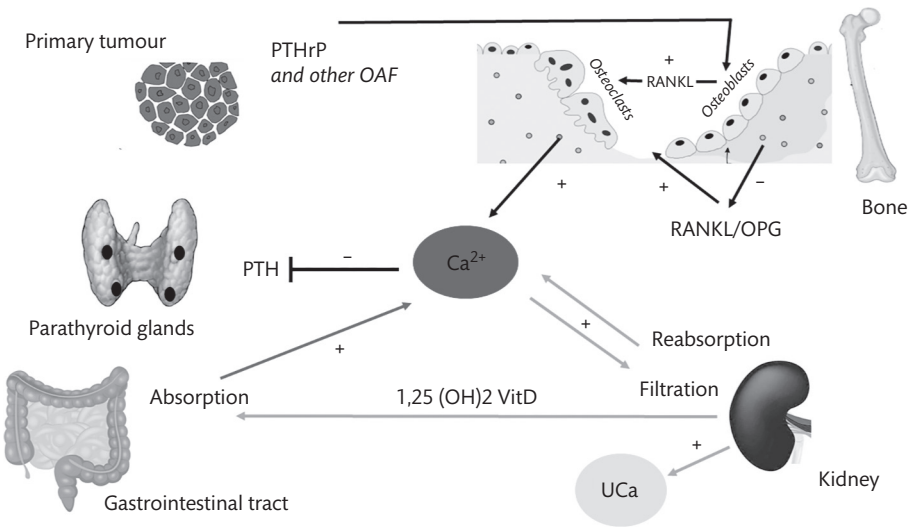

Figure 4.2.2 Mechanism involved in the humoral hypercalcaemia of malignancy (HHM). PTH: parathormone; PTHrP, PTH-related peptide; OAF, osteoclast activating factors; Ca2+, ionized serum calcium; UCa, urinary calcium; 1,25 (OH)2 VitD, 1,25 didroxy vitamin D.

receptor (VDR), like bone and intestine. It may also be locally produced by several non-renal cells expressing the 1-α-hydroxylase enzyme. This extrarenal production of 1,25 $(OH)_2D$ acts in a paracrine/autocrine fashion and mediates the so-called extraskeletal effects of vitamin D, which have received great attention in the recent years [36]. Vitamin D-mediated hypercalcaemia is caused by different mechanisms that are discussed next: (i) ectopic 1-α-hydroxylase overactivation, which may occur in granulomatous diseases and malignant tumours; (ii) intoxication of vitamin D and (iii) inactivating mutations of genes encoding key enzymes of $1,25(OH)_2$ catabolism and degradation (namely mutations of 24-hydroxylase gene) (see Box 4.2.1).

Hypercalcaemia associated with granulomatous diseases. Activation of 1-α-hydroxylase enzyme in macrophage is a well-known cause of hypercalcaemia associated with granulomatous diseases. It was originally described in sarcoidosis, tuberculosis, Crohn's, and Wegener's diseases.

Sarcoidosis. The first case of hypercalcaemia associated with sarcoidosis was reported in 1930 and since then several case reports were published, claiming that 10% of patients with sarcoidosis may experience hypercalcaemia [37]. It was subsequently demonstrated that serum levels of 1,25 $(OH)_2D$ are increased in patients with sarcoidosis and that the source of vitamin D is extrarenal. Indeed, elevated serum 1,25 $(OH)_2D$ levels were shown in anephric patients and in patients with endstage kidney failure [38]. It was shown that sarcoid-associated pulmonary alveolar macrophages produce their own 1-α-hydroxylase, which is stimulated by interferon γ, but not under the control of PTH [39, 40]. Hypercalcaemia is usually mild to moderate, and symptoms and laboratory findings are similar to those of other forms of PTH-independent hypercalcaemia. In addition, the serum level of angiotensin-converting enzyme is increased, and its concentration generally correlates with the severity of the disease. Serum levels of $1,25(OH)_2D$ are increased whereas those of 25(OH)D are either normal or decreased. The activity of sarcoid-associated pulmonary alveolar macrophages is efficiently suppressed by glucocorticoids, which are effective in lowering serum calcium. Ketoconazole has also been successfully used in the management of sarcoidosis-associated hypercalcaemia [40].

Tuberculosis. Patients with tuberculosis may experience hypercalcaemia with a highly variable (2.3–48%) prevalence in different studies. Hypercalcaemia is mainly due to the production of $1,25(OH)_2D$ by macrophage of the pleural cavity. $1,25(OH)_2D$ has been shown to have an antimicrobial action on mycobacterium tuberculosis, stimulating the secretion of cathelicidins and other antimicrobial peptides. Rifampicin and isoniazid, the most commonly used drugs in the management of patients with tuberculosis, are also helpful in controlling hypercalcaemia: rifampicin induces enzymes that degrade 25(OH)D, and isoniazid inhibits the synthesis of $1,25(OH)_2D$.

Other granulomatous diseases. Several other granulomatous diseases have been reported to be associated with hypercalcaemia, including infection (mycobacterium avium-complex disease, leprosy, fungal infections, pneumocystis pneumonia, and cat-scratch disease) [40] as well as non-infectious diseases. A recent meta-analysis reviewed all cases of hypercalcaemia associated to cosmetics injections [41]. The authors identified 23 patients, who mostly used silicon, polymethylmethacrylate, and paraffin oil injected in buttock and breast. Hypercalcaemia was severe with a mean serum Alb-Ca of 3.43 mmol/L and detected years after the initial injection. In these patient's serum $1,25(OH)_2D$ was elevated and PTH low or suppressed in the majority of cases [41]. Finally, hypercalcaemia has been reported in some cases of Wegener's granulomatosis, Chron's diseases, giant cell polymyositis, and berylliosis.

Malignant hypercalcaemia. Hypercalcaemia complicates up to 13% of non-Hodgkin and 5% of Hodgkin lymphoma, and when occurs is associated with a worse prognosis. The pathogenesis of lymphoma-related hypercalcaemia involves the increased production of ectopic $1,25(OH)_2D$, probably in lymph nodes, as suggested by *in vivo* studies [42]. Increased serum levels of $1,25(OH)_2D$ have been demonstrated in 20–40% of patients with non-Hodgkin and 100% of those with Hodgkin lymphoma [43, 44].

Hypercalcaemia associated with vitamin D intoxication. Vitamin D insufficiency is very common worldwide in the general population, particularly in older people and in subjects living in the Eastern countries, as well as in patients with several disease states affecting vitamin D absorption and metabolism (celiac diseases, malabsorption, etc.). Guidelines developed by the Institute of Medicine (IOM) in 2011 recommend different dietary vitamin D allowances in children, adults, elderly, and pregnant women and indicate that the daily intake of vitamin D should not be greater of 4000 UI in adults, 3000 UI in children 4–8 years, 2500 UI in children 1–3 years, and 100–1500 UI in infants [45]. Diseases unrelated to bone and calcium homeostasis may be associated with a low vitamin D status and decreased locally produced $1,25(OH)_2D$ by circulating 25OHD may have a pathogenic role in these conditions. This knowledge led to wide use vitamin D supplements not only to correct insufficiency in the general population but also to increase serum 25OHD in patients with several diseases, despite lack of evidence of benefit from vitamin D supplementation. Vitamin D intoxication is a rare event, but when occurring may lead to life-threatening hypercalcaemia [46, 47]. A recent meta-analysis reported 13 patients presenting with severe hypercalcaemia and related symptoms such as vomiting, dehydration, pain, and anorexia. In all cases, vitamin D intoxication was due to either excessive dosing by the patients or the prescribing physicians, and, rarely, by manufacturing errors. The daily dose of vitamin D ranged between 50 000 IU and 2 604 000 IU. Serum calcium ranged between 11.1 and 23.1 mg/dl and serum 25(OH)D concentration was greater than 150 ng/ml [48]. Vitamin D intoxication is different from vitamin D hypersensitivity, a condition in which a pre-existing hypercalcaemia is exacerbated by high doses of vitamin D.

Hypercalcaemia associated with CYP24A1 hydroxylase mutations. Idiopathic infantile hypercalcaemia (IIH, OMIM 143880) is a rare disease characterized by hypercalcaemia, hypercalciuria, nephrocalcinosis, usually diagnosed in infant between 3 and 7 months of age. The disease is rare and is related to an impairment of vitamin D catabolism. IIH is a genetic disorder due to loss-of-function mutations in the human cytochrome P450 24 subfamily A member 1 (CYP24A1) gene, encoding the 24-hydroxilase enzyme, which is involved in the catabolism of vitamin D [49]. The diseases can present with different phenotypes ranging from severe forms diagnosed early in the infancy and sometimes lethal [50] to milder forms, often diagnosed in the adulthood during workout for recurrent nephrolithiasis [51]. The first case described in 2011 lead to the identification of the genetic cause and thereafter around 200 cases have been reported leading to an increased insight into the diagnostic and therapeutic management of this disease [49].

Drug-Related Hypercalcaemia

Vitamin A. Vitamin A and its analogues are often used in the treatment of neoplastic and dermatologic diseases. Hypervitaminosis A can rarely be complicated by hypercalcaemia. The mechanisms proposed include either an increased bone resorption due to the fact that osteoclasts and osteoblasts express retinoic acid receptors or an action of vitamin A on calcium release following lysosomal degradation [52]. The susceptibility to develop hypervitaminosis A is highly variable, and the daily intake up to 50 000 UI is safe. Effective treatments, when needed later after discontinuation of vitamin A, include hydration, bisphosphonates, and glucocorticoids.

Oestrogen receptor modulators. Hypercalcaemia is rarely seen in women with breast cancer, in the early phase of treatment with tamoxifen, a selective oestrogen receptor modulator. The exact mechanism is not completely understood, and it is thought to be related to the presence of oestrogen receptor on cancer cells [53]. Hypercalcaemia is generally transient and, in some cases, may be moderate to severe.

Lithium. Lithium, effectively used worldwide in the management of patients with bipolar disorders, has been shown to interfere with thyroid and parathyroid functions. There are many studies that demonstrate that lithium can associated with a biochemical profile similar to that of PHPT. Lithium competes with calcium for the binding to the CaSR in the parathyroid glands, leading to a shift to the right of the calcium set-point and hypersecretion of PTH [54]. This effect is transient and resolves after lithium discontinuation, when used for limited time, but persists when lithium is chronically used [54]. In a few cases treatment with lithium has been associated with the development of parathyroid adenomas and, therefore, a 'true' PHPT. The optimal treatment is surgical as suggested in other forms of PHPT. Recently calcimimetics have been shown to be effective in lowering hypercalcaemia due to lithium treatment [55].

Thiazides. Treatment with thiazides has been associated with hypercalcaemia in 2% of cases and this side effect has been known for decades, even if the exact pathogenetic mechanism is poorly understood. Two possible triggers are the volume depletion induced by thiazides and the possible inhibition of the transient receptor potential cation channel subfamily V member 5 (TRVP5), a specific calcium selective channel [56]. Hypercalcaemia due to thiazides is generally mild and resolves after thiazides withdrawal. However, some cases of occult PHPT and persistent hypercalcaemia after drug discontinuation have been described. This can be due to the fact that thiazides may worsen hypercalcaemia and reveals the presence of a previously undiagnosed mild PHPT characterized by normal or intermittently mildly elevated serum calcium [57].

Hypercalcaemia Related to Endocrine Diseases

Hyperthyroidism. Thyroid hormones are known to have a role in the regulation of calcium metabolism and about 20% of patients with hyperthyroidism, especially in those with severe disease, may experience mild hypercalcaemia. Hypercalcaemia related to hyperthyroidism is generally mild to moderate, rarely above 3 mmol/L. Only few cases of serious hypercalcaemia have been described [58]. The pathophysiology of hyperthyroidism-related hypercalcaemia is still not completely clear. One hypothesis is that thyroid hormones induce an increase of the osteoclastic activity, as shown in fetal rat bones cultures exposed to an excess of thyroid hormones [59]. Other studies suggested that thyroid hormones excess could act on bone metabolism increasing the sensitivity of bone to PTH and also catecholamines [60]. Finally, serum IL6 is increased in thyrotoxicosis and correlated with serum thyroid hormone levels [61]. IL6 is known to activate osteoclastogenesis through the RANK-RANKL signalling pathway, leading to an increased bone resorption and calcium release [58]. As matter of fact, bone resorption markers are often increased in patients with hypercalcaemia associated with hyperthyroidism [62]. The primary treatment of patients with hyperthyroidism-induced hypercalcaemia is the adequate control of hyperthyroidism, followed by the other general measurement described next.

Addison's disease/hypoadrenalism. Hypercalcaemia has been reported in 6% of primary adrenal insufficiency, associated with PTH and $1,25(OH)_2$ D suppression and increased bone turnover [63]. Its pathophysiology is still unclear,

Others endocrinopathies. Some cases of hypercalcaemia have been reported in patients with VIPoma and pheochromocytoma, with uncertain pathophysiology [64].

Hypercalcaemia Related to Other Conditions

Hypercalcaemia during pregnancy. Hypercalcaemia rarely occurs in pregnant women (0.03%), but its recognition is challenging since the pregnancy itself induces significant changes in calcium homeostasis. During the whole pregnancy total serum calcium is decreased because of haemodilution-dependent hypoalbuminemia, Ca^{2+} is normal, and urinary calcium is increased. The renal 1α-hydroxylase activity is stimulated by oestradiol, prolactin, placental lactogen, calcitonin, and PTHrP of placenta and mammary gland origin [65, 66]. The increased 1α-hydroxylase activity may lead to hypercalcaemia. Symptoms of hypercalcaemia during pregnancy are the same as in the general population but can overlap with the symptoms related to the pregnancy: nausea, vomiting, constipation. Some cases of severe hypercalcaemia have been reported in pregnancy presenting with pancreatitis or kidney failure [67]. Fetal complication may occur, depending on the severity of hypercalcaemia: neonatal death (2%), neonatal hypocalcaemia and tetany (15%), and intrauterine growth decline (2%) [40]. PHPT is the most common cause of hypercalcaemia during pregnancy. Other rare causes of pregnancy-associated hypercalcaemia have been reported: FHH [68], milk-alkali syndrome, malignancy and benign tumours (dermoid cysts, pheochromocytomas, fibromas) [69]. The same pharmacological and surgical approach used for general population could be theoretically used in women with hypercalcaemia during pregnancy, even though there are few studies on safety and maternal-fetal outcomes. Hydration may help to control hypercalcaemia in mild cases. When this approach in insufficient parathyroidectomy could be considered in pregnant women with PHPT when serum calcium is above 2.85 mmol/L, preferably in the second trimester [70]. In a recent series of 28 pregnant women with PHPT followed between 2000 and 2015, 22 were treated with intravenous fluids, antihypertensive drugs, and cinacalcet (one case), and six patients underwent PTx. In the former group, 30% had pre-eclampsia and 50% a preterm delivery. On the other hand, in the latter group no complications were observed. Moreover, in a retrospective study of 109 pregnant women with PHPT, PTx was shown to reduce the rate of fetal complications [71]. Cinacalcet use has been described in few cases. Even though there is some concern about a potential negative effect of this drug in the placenta, where CaSR is expressed, animal

studies have shown no toxic effects in pregnant rats and rabbits [72]. Moreover, no adverse maternal and fetal effects were reported in pregnant women [73]. Bisphosphonates are not extensively studied during pregnancy, but in few series of newborns exposed at intrauterine bisphosphonates no serious adverse events were reported after delivery [74]. Finally, calcitonin does not seem to cross the placenta and is considered safe during pregnancy and lactation [75].

Milk-alkali syndrome. This is a rare syndrome in which hypercalcaemia and alkalosis occur in patients treated with calcium carbonate for peptic ulcer. Hypercalcaemia arises when the intestinal absorption of calcium is higher than its renal excretion, as it may occur in patients with reduced kidney function. Factors that contribute to the maintenance of hypercalcaemia are volume depletion, reduced glomerular filtration rate, and metabolic alkalosis that stimulates renal resorption. Hypercalcaemia may arise acutely or can be a chronic complication [76].

Immobilization. Hypercalcaemia is often seen after long period of immobilization in young patients with spinal injury and in elderly hospitalized people. In 1998 Zerwekh *et al.* studied a group of young healthy volunteers, in whom 12 weeks of skeletal unloading induced hypercalcaemia associated with reduced levels of PTH and 1,25(OH)2D, hypercalciuria and hypophosphaturia [77]. An increased bone resorption is thought to be the cause. Indeed, osteocytes seem to act as mechanoreceptors and are sensitive to unloading. Unloading results in an increased expression and synthesis of sclerostin, which leads to an inhibition of the Wnt signalling pathway. This results in a reduction of the production of osteoprotegerin, the decoy receptor for RANKL and regulator of bone resorption [78].

Post-acute kidney failure. Hypercalcaemia may occur during the recovery phase after an acute kidney failure because of secondary hyperparathyroidism caused by hyperphosphatemia and hypocalcaemia of the oliguric initial phase [79].

Miscellaneous. Several other conditions may be rarely associated with hypercalcaemia such as manganese intoxication, hypophosphatasia, Paget's disease, chondrodysplasia, William's syndrome.

Therapy

The management of hypercalcaemia should be addressed at the underlying cause/mechanisms and the prevention/management of target organ damages. The timing and the type of therapy are related to the cause and severity of hypercalcaemia, clinical symptoms, and renal function impairment. When hypercalcaemia is mild and the underlying cause has been identified, the treatment could be limited at the underlying cause. When hypercalcaemia in moderate to severe, the aim is also and most importantly directed to decrease serum calcium, by increasing renal calcium excretion and decreasing bone resorption and intestinal calcium absorption.

Increase Renal Calcium Excretion

Dehydration occurs in hypercalcaemic states because of a decreased fluid intake due to anorexia, nausea and vomiting, and polyuria due to a decreased renal water reabsorption. Therefore, signs and symptoms of vascular volume depletion are present in patients with hypercalcaemia. Hydration should be the first therapeutic approach to promote extracellular volume expansion, using oral fluids in patients with mild hypercalcaemia and intravenous saline in those with severe hypercalcaemia.

Patients with severe hypercalcaemia require an immediate treatment which includes intravenous 0.9% saline administration 3–4 litres per day or a bolus of 1–2 litres followed by 200–250 ml saline/hour [80]. Patients with heart or kidney failure should be carefully monitored for the risk of fluid overload. After volume expansion, loop diuretics, such as furosemide, may be considered to further increase renal calcium excretion, but caution is mandatory for the risk of dehydration and electrolytes imbalance. This view is not generally accepted nowadays. As a matter of fact, a metanalysis published in 2008 did not show benefit of adding loop diuretics to hydration in RCT [81]. When the aforementioned treatments fail, haemodialysis with low-calcium dialysate could be an option, which does not treat the cause of hypercalcaemia, but leads to a rapid solution in emergency situations. Some studies have shown that continuous veno-venus haemofiltration using citrate as calcium chelator could be more effective that haemodialysis. Haemodialysis may be complicated by infections, thromboembolism, and hypotension [82].

Decrease Bone Resorption

Increased osteoclastic activity and bone resorption is the most common mechanism responsible of hypercalcaemia. Bisphosphonates decrease bone resorption by several mechanisms: inhibition of monocyte/macrophages differentiation into mature osteoclasts, increased osteoclasts apoptosis, and binding to hydroxyapatite crystals thus decreasing their degradation. The use of bisphosphonates is limited to patients with moderate-to-severe hypercalcaemia. The intravenous route is preferable since bisphosphonates are poorly adsorbed when given orally and large doses are needed. Etidronate and clodronate were initially used but have been subsequently replaced by the novel and more potent aminobisphosphonates. Pamidronate and zoledronate have been approved by the Food and Drug Administration (FDA) in the United States and by the European Medicines Agency (EMEA) in Europe for the management of hypercalcaemia of malignancy. Both agents have proved their efficacy and safety in several randomized clinical trials [42, 83]. Either pamidronic acid or zoledronic acid should be started as soon as possible, because both require 48–72 hours for the initial response and the serum calcium nadir is obtained 4–7 days after the intravenous administration. Zoledronic acid compared with pamidronic acid has a more rapid onset of action and greater hypocalcaemic effect [84]. Zoledronic acid is usually administered at the dose of 4 mg in 100 ml of saline over 15 minutes and normocalcaemic state is restored in a few days in the large majority of patients. In patients with kidney failure and serum creatinine exceeding 3 mg/dl, the American Society of Oncology recommends a reduction in the dose of zoledronic acid, because of potential nephrotoxic effect. A worsening of renal failure has been reported after multiple infusions of zoledronic acid [85]. When there are concerns for renal toxicity, ibandronate, a less potent but less toxic bisphosphonate, could be used. Subcutaneous administration of clodronate is an option in those endstage cancer patients who need domiciliary therapy.

Calcitonin also is effective in rapidly reducing serum calcium and its effect begins within 2 hours. Salmon calcitonin is generally more

effective than human calcitonin and is preferably used at the dose of 4–8 units/kg of body weight, either intramuscularly or subcutaneously [86, 87]. However, tolerance to the drug (or tachyphylaxis) generally occurs and the hypocalcaemic effect wanes. In clinical practice calcitonin could be used when a rapid hypocalcaemic effect is aimed, while waiting for the more potent hypocalcaemic effect of bisphosphonates.

Denosumab, a fully human monoclonal antibody directed to the RANK ligand, decreases osteoclasts differentiation and survival. Denosumab is approved for the management of postmenopausal osteoporosis and in the prevention and management of osteoporosis due to adjuvant therapy in patients with breast and prostate cancers. Preclinical studies in a mice model of malignant hypercalcaemia due to PTHrP showed that denosumab rapidly decreases serum calcium [88]. Recently some case reports have shown a potent hypocalcaemic effect of denosumab in cancer patients [89, 90]. The value of denosumab in the management of hypercalcaemia of malignancy has been further proved in a single-arm, multicentre, international phase II study who enrolled 33 patients with malignant hypercalcaemia and no-response to bisphosphonates treatment. Patients were treated with 120 mg sc of denosumab every 4 weeks. The large majority (70%) of patients shoved a decrease of serum calcium from 13.7 mg/dl to value ≤11.5 mg/dl and 64% reached serum calcium levels ≤10.8 mg/dl; the median duration of response was 104 days. Serious adverse events were reported in two cases [91]. In 2014 the FDA approved denosumab for the treatment of malignant hypercalcaemia refractory to bisphosphonate therapy. More recently a meta-analysis of two randomized double-blind trials in cancer patients with bone metastases has shown that denosumab treatment significantly delayed, compared to zoledronic acid, the occurrence of malignant hypercalcaemia [92].

Preclinical studies, in a mice model of PTHrP-dependent malignant hypercalcaemia administration of monoclonal PTHrP antibodies was shown to have a hypocalcaemic effect, opening the potential development of this therapeutic approach also in selected cases in humans [93].

Decrease Intestinal Calcium Absorption

Increased intestinal calcium absorption contributes to the development of hypercalcaemia, particularly when due to vitamin D intoxication. A general measure in these patients consists of avoiding calcium and vitamin D intake. Glucocorticoids represent the first-choice option, because of their inhibitory effect on 1α hydroxylase enzyme, thus reducing intestinal calcium absorption. No guidelines are available to guide this treatment: a generally accepted schedule is the intravenous administration of hydrocortisone at a daily dose of 200–400 mg for 3–5 days, followed by oral daily prednisone at the dose of 10–20 mg for 7 days [86].

Calcimimetics

Cinacalcet, a calcimimetic agent, is approved for the management of hypercalcaemia in patients with PHPT, in whom parathyroidectomy would be indicated on the basis of serum calcium concentration but not performed because contraindicated or refused by the patient. The efficacy of cinacalcet in lowering and often normalizing serum calcium has been shown in several PHPT settings [94], including patients with intractable hypercalcaemia related to parathyroid cancer [95]. Interestingly, cinacalcet was effective in reducing hypercalcaemia in two cases of humoral malignant hypercalcaemia due to metastatic renal cell and breast carcinomas [96].

Primary Hyperparathyroidism

John P. Bilezikian

Introduction

Primary hyperparathyroidism (PHPT), the most common cause of hypercalcaemia, is characterized by excessive parathyroid hormone (PTH) secreted from one or more of the four parathyroid glands [1–3]. It is virtually always a benign disorder with 80% of patients harbouring a single parathyroid adenoma. Within the past 50 years, the disease has undergone a transformation in its clinical presentation from a disorder that was virtually always symptomatic to one that is discovered incidentally in the course or routine biochemical screening. Target organs such as the skeleton and the kidneys, while still a focus of the prudent evaluation, requires application of imaging and other technologies in order to discern what used to be clear-cut manifestations. When these technologies are applied even to patients who are discovered incidentally, it is evident the PHPT still has the potential to be a pervasive disease. This potential, however, is part of a variable natural history that ranges from an asymptomatic disorder to one with overt symptomatology. Even more recently, we recognize that PHPT, as defined by elevated PTH levels in the absence of any other aetiologies, can present with normal total and ionized serum calcium concentrations, giving rise to the phenotype known as normocalcaemic PHPT [4]. With these different clinical presentations, the challenge has been to apply guidelines with which decisions for surgical or medical management can be reasonably offered and based upon the best evidence. These guidelines have been regularly updated over the past 25 years [5–9].

From a historical perspective, it is interesting to note that in the 1930s, PHPT was so rare that when encountered, it often led to a case report [10]. Almost a century later, a casual literature search turns up over 6000 published papers in the 2000s alone. Another key ramification of ongoing interest in PHPT has been interest in the PTH molecule itself, with ongoing insights into its pleotropic cellular and molecular mechanisms of action [11, 12].

Epidemiology

PHPT is seen most often in postmenopausal women with a gender difference of 3–4:1. The prevalence of the disease varies depending upon country and representation by race. In the United States, prevalence figures centre around 0.86% [13]. African Americans are more prone that Caucasian women [14]. Prevalence figures have been reported to be lower (0.4%) and much higher (11%), the latter representing cohorts of patients with normocalcaemic PHPT [15–17]. Epidemiology is also influenced by medical practices, such as biochemical screening. When screening is a routine aspect of medical care, the prevalence of PHPT is higher, because the serum calcium is typically included in the multichannel screening test and patients are discovered in that context. When biochemical screening is commonly used in countries, as demonstrated in North America and Western Europe, the disease is common [3]. When biochemical screening is not a routine feature of medical care, such as in many locations in India, PHPT is uncommon. Screening, however, is not a complete explanation for the increasing prevalence of PHPT. In the United States, for example, after screening had become well established, the incidence of PHPT has continued to increase [14]. Perhaps, more proactive approaches to skeletal diseases, particularly in the context of mild elevations in the serum calcium, could account, at least in part, for this observation [14, 18, 19]. It is also noteworthy, but not surprising, that the incidence of PHPT increases in countries that adopt biochemical screening, as in China and in Latin America [20–23].

In most patients, there is no clear-cut aetiology to the disease although a history of childhood face and neck radiation can be obtained in a small percentage of individuals [24]. The genetics of PHPT are described next.

Diagnosis

PHPT is almost always a benign expression of excessive production and secretion of PTH. In 80% of adult patients, the cause is a single parathyroid adenoma while in the remaining 20%, all four parathyroid glands are involved with a hyperplastic histology [2]. Double parathyroid adenomas are seen infrequently [25]. Classically, PHPT is a hypercalcaemic disorder. In patients whose serum albumin is low, the total serum calcium measurement will read lower than it would if the level were 4.0 g/dl. The serum calcium is adjusted upwards by 0.8 mg/dl for every gram by which the albumin is below 4.0 g/dl. In centres where the ionized calcium is routinely measured, it will be elevated and, of course, no adjustment for albumin is needed. In PHPT, the PTH level is elevated but not infrequently, the PTH level will be within the normal reference range for the assay. The hypercalcaemic state defines that 'normal' PTH level as abnormal because normal parathyroid tissue would instantly reduce PTH secretion to undetectable levels if the cause of the hypercalcaemia were not parathyroid hormone dependent. Theoretically, any detectable level of PTH in the context of frank hypercalcaemia is compatible with a diagnosis of PHPT. Since second generation PTH assays, that are most commonly used, can detect inactive circulating fragments, it is helpful to set a lower limit of detectability below which one would look for other causes of hypercalcaemia. Well-documented PHPT has been described with levels of PTH as low as 20–25 pg/ml, assuming a normal reference range of 10–65 pg/ml. A PTH concentration of 20 pg/ml would seem to be a reasonable lower limit below which non PTH-dependent hypercalcaemia becomes more plausible. Bear in mind that PTH levels increase with age. While reference ranges have not been completely established by age, in those under the age of 45, an upper limit of 45 pg/ml, not 65 pg/ml would seem to be reasonable.

The recent controversy over normal reference ranges for 25-hydroxyvitamin D [26, 27] has stimulated discussion about normal reference ranges for PTH. The generally accepted reference ranges for PTH, as noted earlier, do not take into account the levels of 25-hydroxyvitamin D. Since there is a linear, inverse relationship between 25-hydroxyvitamin D levels and PTH [28], the reference range for PTH may well be lower in a vitamin D replete population [29].

In addition, the PTH assay can read low, in certain assays, by virtue of moieties that interfere with the assay, such as biotin [30]. If a patient who reports the use of biotin is rechecked after discontinuing it, the level PTH may become more compatible with the diagnosis of PHPT.

Thiazides and lithium can be associated with PTH-dependent hypercalcaemia, that is with elevated calcium and PTH levels [31, 32]. Most of these patients have PHPT and, if one were able to discontinue the thiazide or lithium, the serum calcium would remain elevated in the clear majority of patients. If there is doubt, thiazides can be substituted for other agents, but stopping or substituting lithium should only be done under careful supervision.

In the differential diagnosis of PTH-dependent hypercalcaemia, familial hypocalciuric hypercalcaemia (FHH) is often considered. This is clearly appropriate because one does not want to mistake PHPT for FHH, particularly if parathyroid surgery is being considered for the patient. The consideration of FHH is highly relevant in young patients under the age of 30 because the disease has high penetrance by then. If there is family history of hypercalcaemia, particularly if it includes members who have had unsuccessful parathyroid surgery one should consider FHH [33]. These patients represent a very small proportion of the hyperparathyroid universe. Since most patients with PHPT are postmenopausal women whose serum calcium was known to be normal years before, the development of hypercalcaemia in their adult years virtually rules out FHH. It should be emphasized that FHH is a rare disorder and, from a statistical point of view, a postmenopausal woman who develops hypercalcaemia and elevated levels of PTH does not have FHH. A key point of distinction between PHPT and FHH, as the name implies, is that urinary excretion of calcium is very low. When compared to the creatinine clearance, the ratio of the calcium clearance:creatinine clearance (CCCR) is less than 0.01. Patients with PHPT can also have a low urinary excretion of calcium because PTH is a calcium-conserving hormone. For any amount of calcium filtered at the glomerulus, under the influence of PTH, there will be greater tubular reabsorption and less calcium excretion. A CCCR less than 0.01 can, therefore, be compatible with PHPT particularly if the patient is on a low calcium diet. If there is doubt, genetic testing for an inactivating mutation in the calcium-sensing receptor can be done readily.

Patients with PHPT can demonstrate a normal albumin-corrected serum calcium level from time to time. As noted just now, if the albumin is low, the total serum calcium can read normal. If the patient has severe vitamin D deficiency, the serum calcium can read normal. If the patient has PHPT, correction of the vitamin D deficiency can unmask the hypercalcaemia of PHPT.

Variants of Classical Primary Hyperparathyroidism

Normocalcaemic primary hyperparathyroidism. The entity now known as normocalcaemic PHPT was discovered over 15 years ago [34]. During evaluation, but not necessarily long-term, these patients demonstrate normal corrected serum calcium levels [35]. Discover of this phenotype of PHPT is due, in large part, to the proactive approach to low bone mass with regard to testing in which the PTH is measured even when the serum calcium is normal. When these patients are confirmed to have normal serum calcium levels and elevated PTH, a consideration of secondary causes for an elevated PTH level becomes mandatory. One of the most important secondary causes to rule out is vitamin D deficiency. The Institute of Medicine has stated that vitamin D insufficiency can be defined when the 25-hydroxyvitamin D level is less than 20 ng/ml and that levels between 20 and 30 are acceptable. It stated, furthermore, that levels from 30 to 20 ng/ml are not reliably associated with elevated levels of PTH [27]. It is also true, though, that some patients will show an inflection upwards in their PTH levels when the 25-hydroxyvitamin D level is between 30 and 20 ng/ml [36]. In order to be sure that vitamin D insufficiency is not contributing to

the elevated PHT, a level of more than 30 ng/ml seems reasonable. In some situations, a goal might be to set the 25-hydroxyvitamin D level at 40 ng/ml, on the chance that this form of PHPT may be associated with an element of vitamin D resistance [37].

When considering the diagnosis of normocalcaemic PHPT, other secondary causes for an elevated PTH, besides vitamin D insufficiency, should be considered. Renal insufficiency with an eGFR of less than 60 cc/min can be associated with an elevated PTH level, but PTH levels do not tend to show levels in the abnormal range until renal function has declined to chronic kidney disease has reached stage 3B (i.e. <45 cc/min).

Medications, as noted earlier with regard to thiazide diuretics and lithium, can be associated with a high PTH. While not generally appreciated, bisphosphonates and denosumab can be associated with elevated levels of PTH [38, 39]. Patients with other metabolic bone disease such as Paget's disease can occasionally show elevated levels of PTH.

The diagnosis of normocalcaemic PHPT depends upon ruling out secondary causes of elevated PTH levels. Even with due diligence, one may miss a secondary cause such as a subclinical malabsorption syndrome.

The discussion of normocalcaemic PHPT should take into account also the possibility that the patient doesn't have a disease at all but that the PTH level is merely representing the fringe of the normal distribution curve. The normal distribution curve captures about 95% of the normal population with about 2.5% falling either above or below those defined limits. Such patients are not necessarily abnormal. Another consideration in the discussion of normocalcaemic PHPT is the 'normal' serum calcium level. Is the serum calcium normal for that patient? For an analyte like calcium, the control in a given individual is much tighter than it is for the entire population. If patients have spent most of their years with serum calcium levels averaging 9.0 mg/dl and develops PHPT, the serum calcium might increase to10.0 mg/dl. Without a history of those patients' earlier serum calcium levels, the measured calcium appears to be normal. If one had a history of those patients' earlier calcium levels, the levels measured as 'normal' would not be normal for that patient. The 1 mg/dl increase in serum calcium would still be within the normal population range but for that given patient, it is decidedly high. We describe the patient as one with normocalcaemic PHPT but in fact the patient is hypercalcaemic with regard to her own calcium homeostasis.

Finally, a form of abnormal parathyroid tissue has been described with a normal serum calcium and PTH concentration made only by pathological examination of abnormal parathyroid tissue has been proposed [40, 41].

Acute Primary Hyperparathyroidism

The onset of marked hypercalcaemia and elevated levels of PTH can occur in patients with a history of mild hypercalcaemia. Typically, mild hypercalcaemia due to PHPT is not likely to lead to acute, symptomatic hypercalcaemia, the incidence of which is less than 1% [42–45]. If there is an antecedent history of mild hypercalcaemia, the possibility of acute PHPT becomes likely. The inciting factors are not understood but an intercurrent illness in which the patient does not maintain good hydration and is bed ridden is a typical scenario [45]. Haemorrhage or infarction of the offending parathyroid gland is almost never seen at the time of parathyroidectomy. A previous history of mild hypercalcaemia is not always obtained, leading to the possibility that the patient has parathyroid cancer. While this is certainly a possibility, the rarity of parathyroid cancer makes acute primary hyperparathyroidism statistically more likely.

Parathyroid Carcinoma

The differential diagnosis of marked hypercalcaemia and very high levels of PTH usually comes down to either acute PHPT or parathyroid cancer. Because parathyroid cancer is so unlikely, the patient presenting with acute symptomatic hypercalcaemia is more likely to have a benign parathyroid adenoma. Among patients with PHPT, malignant disease constitutes less than 0.5%. In parathyroid cancer, the serum calcium tends to high (>14 mg/dl) and associated with hypercalcaemic symptoms, along with markedly elevated levels of PTH. It is not unusual for levels of PTH to be 20 times normal. It is exceedingly rare for a parathyroid cancer to be non-secretory. There are other differentiating features when parathyroid cancer becomes a consideration. For example, the carcinoma can present with a neck mass that is easily palpable. They are 40–50 years old, on average, about a decade younger than patients with benign disease [46, 47]. Different from its benign counterpart, there is no difference in incidence by gender. The natural history of parathyroid cancer can be cure, if surgery if successful at the outset. But many patients are not cured but follow, rather, a slow, indolent clinical course. Patients will typically live for several decades after the diagnosis is made. Recurrent parathyroid cancer can resurface 20 years later [48]. While parathyroid cancer is typically a sporadic disease, it has seen in association with the hyperparathyroid-jaw tumour syndrome [49]. That presentation and other aspects of parathyroid cancer genetics are covered elsewhere in this chapter.

Hyperparathyroidism due to true ectopic PTH production. While malignancies have been associated with hypercalcaemia, it is very rare for the tumour to be producing authentic PTH [50]. Much more common is the situation in which the patient has both a malignancy and PHPT. The production of parathyroid hormone related peptide (PTHrP) by the tumour is very well described but this peptide does not cross-react in the commercially available immunoassays for PTH. Thus, in this setting, the PTH level will be undetectable.

Hereditary Primary Hyperparathyroidism: Forms and Genetics

The Multiple Endocrine Neoplasia (MEN) syndromes, known classically as type 1 and type 2, are autosomal disorders. Of the glands that can be involved in MEN 1 or 2, PHPT is the most common and often the first to be involved. By the age of 50, penetrance is virtually complete with rare de novo cases seen thereafter [51]. In MEN 1, the other common glands that are involved include the pancreas and the anterior pituitary. In MEN 2, PHPT is seen with medullary thyroid cancer and pheochromocytoma. In the syndrome known as MEN 2b or MEN 3, PHPT is not seen. Along with medullary thyroid cancer and pheochromocytoma, MEN 2b (MEN 3), can feature mucosal neuromas, autonomic ganglia dysfunction of the gastrointestinal (GI) tract and a marfanoid habitus. In MEN 4, PHPT is seen in association with anterior pituitary, gonadal, adrenal, or renal tumours. PHPT, which can be a frank parathyroid malignancy or as part of the hyperparathyroidism-jaw tumour (HPT-JT) syndrome [52].

These genetic disorders are of great interest, in part, because they have helped to elucidate genetic controls of normal endocrine glands. But, they constitute a small percentage of patients with PHPT. One is advised to pursue a genetic aetiology only when setting is suggestive such as PHPT in those less than 30 years old or in those with a family history of PHPT or other hypersecretory endocrine syndromes. Familial isolated PHPT has also been well-described in the absence of any other endocrine disorder [53].

The tumour suppressor gene known as *MENIN* is inactivated in MEN 1 [51, 54]. Mutations in the RET proto-oncogene are responsible for MEN2 and MEN 2b (MEN3) [55]. The gene that controls the cyclin-dependent kinase inhibitor (p27kip1), CKNK1B, is affected in MEN 4. The *HRPT2* gene (CDC73) is abnormal in the HPT-JT syndrome. This gene directs the production of parafibromin which can be immunochemically detected in parathyroid tissue [56].

Other familial syndromes cannot be neatly classified. Familial isolated hyperparathyroidism (FIH) [55], for example, can be associated with multiglandular syndromes [57, 58]. It will be of great interest when these genes are identified and compared to regulatory aspects of the genes that have already been characterized in the familial syndromes of PHPT [59]. Thakker *et al.* presents a well-reasoned approach to questions related to the genetic basis for the hyperparathyroid states [54].

Familial hypocalciuric hypercalcaemia (FHH). The clinical aspects of FHH have already been discussed. The genetic basis of this disease is inactivation of the calcium-sensing receptor (CaSR).

Neonatal severe primary hyperparathyroidism (NSHPT). This rare but life-threatening presentation in newborns is identified by marked hypercalcaemia, very high levels of PTH, hypotonia, and respiratory distress. A homozygous mutation of the CaSR gene is responsible for this disease [60].

Molecular Pathogenesis

The search for genetic abnormalities has focused upon the familial syndromes described earlier.

The two genes that have been most clearly implicated in the sporadic (non-familial) forms of PHPT are cyclin D1 [61] and the gene associated with MEN1 [62]. Thus, both familial and sporadic forms of PHPT can be associated with the MEN 1 gene. With regard to sporadic PHPT, some studies have reported that as many as 25–40% of parathyroid adenomas are due to allelic loss of chromosome 11 markers [63, 64]. In the particular cases of parathyroid cancer and the hyperparathyroidism = jaw–tumour syndrome, the *HRPT2* gene (also known as CDC73), has been implicated [61].

Pathology

The single, benign parathyroid adenoma is the most common abnormality in PHPT. Multiple parathyroid adenomas are much less common, with an incidence less than 5% [25]. While double adenomas can be found, it is important to ascertain that the other glands are normal because some of these patients actually have four-gland disease [65]. Even if normal parathyroid tissue has been documented at the time of the parathyroid surgery for double adenomas, there is always the possibility that the patient will in time develop hyperfunction of the remaining parathyroid glands. In these situations, time is the key determinant and, thus, monitoring is highly recommended. Parathyroid adenomas are notoriously variable in location. While they are usually found at the inferior–anterior and superior–posterior poles of the thyroid gland, they can be found almost anywhere in the neck. Some typical 'hiding places' for adenomas in ectopic locations include the thyroid gland parenchyma, itself, and the superior mediastinum. In the mediastinum, the gland can be found within the thymus. More unusual locations for ectopic parathyroid glands include the lateral neck, the carotid sheath, behind the oesophagus and even in the oropharynx.

Four-gland parathyroid hyperplasia is present in approximately 15% of patients with primary hyperparathyroidism. While one immediately considers a familial syndrome, in this context, only about 30% of patients will be shown to have the familial form of PHPT [66]. Before localization procedures and surgery, itself, no clinical features raise suspicion for multiglandular disease. Invariably, the pathology of PHPT is benign, overactive tissue with the malignant parathyroid gland found in fewer than 0.5% of patients. In the case of parathyroid cancer, clinical clues are often apparent, such as marked hypercalcaemia and very high levels of PTH, along with a palpable neck mass. The pathological features raise suspicion for malignancy because the tissue may have invaded local tissues and show histological features of cancer. On the other hand, parathyroid cancers can present pathologically as rather benign tissue. Careful examination of the pathological specimen in parathyroid cancer will often show the cardinal features of malignancy, namely tissue invasion and local or distant metastases. Parathyroid cancers present as functional tumours, secreting PTH.

Biochemical Features

The biochemical features of PHPT in most publications depict the mild hypercalcaemic form of the disease as shown in Table 4.3.1. The serum calcium concentration is usually within 1 mg/dl of the upper limits of normal. The serum phosphorus is rarely frankly below normal but values usually are in the low normal range [67]. Circulating markers of bone turnover are often in the upper quartile of the normal range, but can be frankly elevated. The specific markers of bone turnover that are readily available and can be helpful in assessing the activity of the disease are the bone formation markers: bone-specific alkaline phosphatase activity and osteocalcin—and the bone resorption markers—serum CTx and urinary NTx [68].

One has to go back to almost 50 years ago to appreciate the prescient work of Lumb and Stanbury who proposed that the clinical manifestations of PHPT are worsened by vitamin D deficiency [69]. This association has since been substantiated by several studies [70, 71]. Even in mild, asymptomatic PHPT, indices of disease activity are more apparent when the 25-hydroxyvitamin D concentration is low [72]. This association may be more difficult to detect in view of the fact that vitamin D deficiency in PHPT [73, 74], is not as widespread as it used to be. This is because vitamin D supplements are now commonly used [75]. The hypothesis that parathyroid disease is worse when vitamin D deficiency is present describes a stimulus for further stimulation of PTH synthesis by the abnormal parathyroid gland(s). Stein *et al.* has correlated low 25-hydroxyvitamin D levels with higher PTH level [76]. The

Table 4.3.1 Changes in biochemical indices in primary hyperparathyroidism over the past several decades. The data represent cohorts from earlier and more recent series

Index	1984–1991 (n = 103)	2000–2014 (n = 100)
Calcium (mg/dl)	10.6 ± 0.06	10.7 ± 0.6
PTH (pg/ml)	127 ± 69	85 ± 48[1]
25-hydroxyvitamin D (ng/ml)	23 ± 10	29 ± 10[1]
1,25-dihydroxyvitamin D (pg/ml)	57 ± 20	69 ± 24[1]
Urinary calcium (mg/24 hrs)	229 ± 119	250 ± 144
P <0.005

microstructural and densitometric profile is not as consistent as the biochemical correlates [77–79].

Levels of 25-hydroxyvitamin D will vary according to the country's nutritional status. In the United States, a prototypical country in which the modern profile of PHPT the most common, 25-hydroxyvitamin D levels no longer tend to be below 30 ng/ml. Over the past 15 years, with the population routinely taking vitamin D supplements, the average 25-hydroxyvitamin D from the centre in New York has increased from 21 ng/ml to 36 ng/ml [75]. 1,25-dihydroxyvitamin D levels are no longer routinely measured in PHPT but as per previous experience, the level of this active form of vitamin D would be expected to be in the upper range of normal or frankly elevated. As previously shown, elevations in 1,25-dihydroxyvitamin D concentration can be seen in as many as 25% of the hyperparathyroid population [80]. This observation is due to the catalytic effect of PTH on renal 1-alpha hydroxylase that converts 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D. PTH conserves renal tubular handling of calcium and, thus, for any level of the serum calcium, patients with PHPT will show reduced concentrations. The reason why hypercalciuria can be seen in as many as 40% of individuals with PHPT is because the filtered calcium load overwhelms the conserving capacity of the kidneys.

Target Organ Features

The Skeleton

With the change in clinical profile of PHPT to a milder hypercalcaemic disorder, it is not surprising that the frequency of disease-specific radiological manifestations would decline. The historic Cope series reported a prevalence of 23% [81] while the series of Silverberg *et al.*, coming several decades later, reported a prevalence of less than 2% [82]. With the advent of technologies that permit evaluation of the skeleton in ways that are more sensitive than the routine skeletal X-ray, we now appreciate that skeletal involvement, even in mild 'asymptomatic' PHPT, is pervasive.

Bone densitometry. Bone mineral densitometry (BMD) by dual energy X-ray absorptiometry (DXA) came of age as a major clinical tool when PHPT was being recognized in the western world as primarily a biochemical disorder without classic radiographic findings. DXA made it possible to appreciate skeletal involvement even when radiographic signs were absent.

By DXA, one can measure three sites that each represents different proportions of trabecular and cortical bone. The lumbar spine is predominantly trabecular bone while the distal third radius is predominantly cortical bone. The hip is comprised of an even proportion of cortical and trabecular bone. In a disorder characterized by excessive PTH, the cortical compartment would be expected to be compromised preferentially. By DXA, this was shown by the distal third radius being preferentially reduced [83]. The lumbar spine, on the other hand, was the site least involved with the hip regions showing reductions mid-way between the lumbar spine and the distal third radius (Figure 4.3.1). This pattern of involvement necessitates three-site DXA in all patients with PHPT. If only the lumbar spine and hip are measured, an incomplete picture emerges that, in fact, could be misleading. It should be recognized, though, that other patterns of skeletal involvement have been described in PHPT, from preferential reduction of the lumbar spine to equivalent involvement of all three sites to completely normal bone density [84].

One of the tenets of DXA is that it predicts fracture risk. There is certainly true for osteoporosis and was logically assumed to be the case for PHPT. DXA would predict that fractures in PHPT would be more common at non-vertebral sites which are predominantly cortical bone. This expectation was brought into doubt first by Khosla *et al.* [85] and a decade later by Vignali *et al.* [86]. Both reports demonstrated that vertebral fractures were also seen in PHPT with a frequency that argued against trabecular bone being protected in

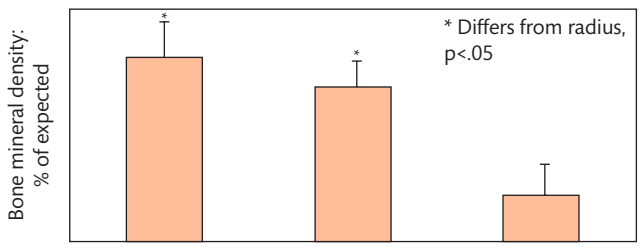

Figure 4.3.1 The pattern of bone loss in primary hyperparathyroidism. A typical pattern of bone loss is seen in asymptomatic patients with primary hyperparathyroidism. The lumbar spine is relatively well preserved while the distal radius (1/3 site) is preferentially affected.

PHPT. Imaging technology advanced [87, 88] with high resolution peripheral computed tomography (HRpQCT), showing that both cortical and trabecular bone are in fact affected in PHPT [89–91]. When the HRpQCT image was assessed further by individual trabecular segmentation analysis, Stein, Silva *et al.* [89] showed that microstructural orientation of trabeculae was suboptimally configured for bone strength.

While HRpQCT gave insight into skeletal microstructure that not even histomorphometry was able to discern [92], it is a research tool. The practising physician does not have access to HRpQCT. To meet a practical need for assessment of microstructure in medical practice, yet another advance in imaging technology was developed, namely the trabecular bone score (TBS). TBS is a semiquantitative textural analysis of the lumbar spine image by DXA [93, 94]. Anyone with TBS software can apply it to the DXA image. The textual analysis distinguishes between homogeneity and heterogeneity of the image. The homogenous image is akin to normal bone while the markedly heterogeneous image is akin to osteoporotic bone. As is the case for DXA, TBS of the lumbar spine DXA image is measuring predominantly trabecular bone. Silva *et al.* and others have documented lower mean TBS scores in PHPT [95, 96].

With these advances in imaging technology applied to the form of PHPT known as 'asymptomatic', It is now apparent that both cortical and trabecular compartments of bone can be affected in the absence of radiographic manifestations or even reductions in lumbar spine BMD by DXA. The observations are consistent with the clinical documentation that fracture risk is increased, overall, in PHPT.

Renal Involvement

The kidneys, along with the skeleton, constitute the major target organ for complications of PHPT. Similar to the decline in overt skeletal disease, the incidence of kidney stones has declined from approximately 60%, when biochemical screening was not routine, to more recent series that document an incidence of kidney stones in fewer than 20% of patients [20]. When applying sensitive renal imaging technologies, such as computed tomography (CT) and ultrasound, some studies have confirmed the incidence of stones and/or nephrolithiasis at about 20% but work of Cristiani *et al.* observed a much higher incidence of 55% [97–99].

Clearly, the composition of urine is a likely predisposing factor in the development of kidney stones. This extends beyond elevated urinary calcium excretion. Peacock has summarized these other aspects of stone risk factors in PHPT [100]. Schillitani *et al.* has raised the possibility that the calcium receptor gene, in terms of specific polymorphisms, might be an important contributing factor [101].

The persistence of renal involvement in PHPT has led to a consensus that renal imaging should be an integral aspect of its evaluation. The imaging modalities can be ultrasonography, CT, or routine abdominal X-ray. A 24-hour urinary calcium, on a normal calcium intake, should also be part of every evaluation. Since, the urinary calcium excretion, alone, is not always indicative of stone risk in PHPT [102], a complete urinary stone risk profile should be undertaken when hypercalciuria is apparent (100).

In addition to concerns about nephrolithiasis and nephrocalcinosis, creatinine clearance may be reduced in PHPT. While the mechanisms by which the creatinine clearance may be reduced in PHPT are not clear, reductions below 60 ml/min/1.73 m^2 are seen, in the absence of any other explanation for a reduction in creatinine clearance. Thus, a reduction in renal function can be and often is ascribed to this disorder. A concern about reduced renal function in PHPT, even if it isn't related specifically to this disorder, raises concern because it is a potential stimulus for secondary increases in PTH, thus aiding and abetting the primary hyperparathyroid process. It would seem from the work of Walker *et al.*, that clearance values above 30 cc/min are unlikely to contribute independently to higher PTH levels [103]. This point does not obviate another one, namely that by dynamic histomorphometric assessment of bone biopsies, clearance values below, <60 cc/min are associated with evidence for more active parathyroid disease [104]. Thus, renal involvement in PHPT can take the forms of hypercalciuria, nephrolithiasis, nephrocalcinosis, and/or reduced renal function [105].

Neuromuscular Dysfunction

The apparent change in the clinical profile of PHPT has had an impact on the incidence of recognizable neuromuscular dysfunction. Once, it was a regular feature of the disease [106] but now it is seen only when the disorder presents in its overtly symptomatic fashion. With the emergence of the mild form of the disease, Turken *et al.* [107] found no evidence either clinically or electromyographically for neuromuscular dysfunction. Sural nerve conduction velocity was reduced in the study of Diniz *et al.* but as in the study of Turken *et al.* these patients had no clinical neurological manifestations [108].

Gastrointestinal Manifestations

The three major gastrointestinal aspects of PHPT are all uncertain from an etiological view. Glucose intolerance has been seen [109] but the association is far from established [110, 111]. Similarly, peptic ulcer disease occurs with a frequency that approximates the disease in the general population, about 10%. The only exception to this lack of association is in those whose PHPT occurs with MEN1. The frequency of peptic ulcer disease in MEN1 can approach 40% [112]. Some mechanistic credence can be attributed to the relationship between PHPT and pancreatitis because it is well known that hypercalcaemia can be causative. However, when hypercalcaemia is mild, as it often is, most series no longer report this relationship to be a significant one [113, 114].

Non-Classical Manifestations of Primary Hyperparathyroidism

Neurobehavioral and Neurocognitive Features

While viewed as non-classical manifestations of PHPT, these features such as easy fatigability, anxiety, poor concentration, cognitive decline, and reduced quality of life are among the most vexing [115, 116]. The clinician is often faced with these complaints in the context of many other chronic diseases. Thus, they lack specificity. Another problem is that they are very hard to quantitate with reproducible metrics that can tract changes after parathyroid surgery. The confounding variables among the reports that have attempted to link neurocognitive and neuropsychiatric features to PHPT include

study design (observational vs. prospective), selection bias, small numbers of study subjects, heterogeneity of bassline manifestations, short testing intervals after parathyroid surgery, and problems with control groups selected for comparison.

Even with newer testing instruments to test quality of life and cognitive function, some studies have shown improvements while others have not [43]. As a result of these inconclusive studies, it is difficult to make any recommendations regarding surgical intervention in these patients who otherwise do not meet the generally agreed upon guidelines for parathyroid surgery in this disease.

Cardiovascular Manifestations

The cardiovascular manifestations of primary hyperparathyroidism used to be heralded by hypertension, but now, with many patients demonstrating only modest hypercalcaemia, hypertension is no longer regarded as a feature of the disease [117]. The problem with a common disease such as hypertension is that to demonstrate a clear association, one would have to show unequivocally that after parathyroid surgery, the condition is ameliorated. The older published literature provided some support for this link [118–120], but it is much more likely now not to see a difference in blood pressure after parathyroid surgery [120, 121].

Coronary artery disease was linked to PHPT when the disease was associated with higher calcium levels than are seen today [122]. Most current studies do not show that patients with PHPT have a greater incidence of coronary calcification beyond those acknowledged risk factors for coronary calcification [123, 124]. In a similar manner, calcifications of the myocardium and cardiac valves are seen only when patients have marked hypercalcaemia [125, 126].

Left ventricular mass index (LVMI) is another focus for studies that have attempted to link PHPT to the cardiovascular system [127, 128]. While some studies have associated the PTH level itself, and not the blood pressure, with LVMI [126–130], other studies have not been confirmatory when other cardiovascular risk factors are taken into account [131, 132]. Again, conflicting data emerge with regard to regression of LVMI after parathyroidectomy [127–130, 133–135].

Calcium concentration and carotid plaque thickness may be related [136] but as shown by Walker *et al.* [137] after adjustment for cardiovascular risk factors, parathyroidectomy was not associated with improvement [138].

Vascular dysfunction has been observed both in severe PHPT and in patients whose serum calcium is only mildly elevated [139–143].

Thus, despite a plethora of data regarding PHPT and cardiovascular manifestations, the results are inconclusive with regard to all the indices that have been measured. This is not to say, however, that the symptomatic form of PHPT is not be associated with cardiovascular manifestations. In fact, it is probably only in the symptomatic cohorts of patients with PHPT that one is likely to observe these manifestations.

Malignancy

Reports associating cancers with PHPT [144, 145] are subject to qualification due to the likelihood of selection bias. Hypercalcaemia usually triggers a search for malignancy since in its differential diagnosis, cancer is high on the list. Another aspect of selection bias relates to the common discovery of thyroid malignancy in patients who undergo parathyroidectomy. Thyroid cancer probably would not have been discovered were it not for the parathyroid surgery. In contrast, Wermers *et al.* have reported death due to cancer is reduced in PHPT with a hazard ratio of 0.58 [146].

Mortality

Mortality rates in PHPT appear to follow the dictum that the more severe the disease is the more likely mortality will be increased. In cohorts of mild hypercalcaemia, mortality does not seem to be increased [147] while more symptomatic cohorts show an increase in mortality [148–149]. Supporting this expectation, mortality rates do correlate with the level of the serum calcium as well as parathyroid gland weight [150]. The experience from the Mayo Clinic also attributed higher mortality only in the quartile that had the highest serum calcium level [146]. However, an epidemiological study has reported increased mortality and morbidity in 'mild hyperparathyroidism' [144]. Nevertheless, with the common phenotype of mild hypercalcaemia seen in many parts of the world, it would appear that mortality rates are not increased in PHPT.

The Variable Clinical Expressions of Primary Hyperparathyroidism

The symptomatic disorder. Primary hyperparathyroidism was ushered into clinical recognition as a symptomatic disorder in the period from 1930 and 1970, It was truly a disease of bones and stones with serum calcium levels that were invariably over 12 mg/dl, and often much higher [151].

The asymptomatic disorder. In the 1970s, when biochemical screening became widespread in many countries, the form of PHPT that we call 'asymptomatic' began to dominate the clinical landscape. Identifying these patients with mild hypercalcaemia and no overt bone or stone disease as asymptomatic seemed reasonable. As described in this chapter, it is now evident that among patients who are discovered incidentally, more diligent studies using modern technologies that can detect skeletal and renal involvement, upon further inspection, will reveal that the disease often does involved those classic organ systems. With signs of skeletal and/or renal involvement, it might be time to reclassify these patients. Perhaps they are asymptomatic but they do demonstrate target organ involvement. Taking this concept one step further, if we reach a point where we can be confident of tools to measure neurocognitive and neuropsychiatric features, some of these patients might be classified as symptomatic.

The normocalcaemic disorder. After mild hypercalcaemia become the most common biochemical feature of PHPT, another four decades passed before the third variant of this disease, namely normocalcaemic PHPT became widely recognized [34]. These patients are not being discovered incidentally, as patients with mild hypercalcaemia are identified, but rather in the context of being evaluated for low bone density or frank osteoporosis [34–37, 152–155]. Paradoxically, these patients demonstrate at the time of presentation more signs of the disease than those with mild hypercalcaemia. Routine measurement of PTH in these settings explains how normocalcaemic PHPT became recognized. We now know that normocalcaemic PHPT can be discovered without low BMD if population screening is undertaken [156]. Thus, as is the case for the hypercalcaemic variant, normocalcaemic PHPT can be asymptomatic or symptomatic.

An International View of Clinical Variability in Primary Hyperparathyroidism

The historical perspective of PHPT implies a chronology of evolution. Symptomatic PHPT evolved to an asymptomatic disease which in turn evolved into a normocalcaemic disorder. This 90-year historical perspective can be misleading because it implies that the disease has actually changed. Given that all three forms of PHPT exist concurrently in the world today, another perspective argues that these three forms of PHPT have always coexisted. What sets the clinical stage for one or another variant may well be dependent upon country-specific factors. For example, in countries where biochemical screening is not part of the healthcare system, such as India [157], patients are unlikely to be discovered incidentally. In these countries, symptomatic PHPT is more likely and, as was the case throughout the world prior to the 1970s, the disease in those countries is considered to be uncommon. In our more modern approach to country-wide health and biochemical screening, asymptomatic PHPT has become the more common variant. It is not considered to be a rare disorder. Parenthetically, as noted already, the use of the term asymptomatic probably needs some adjustment, even if only semantically, because with greater imaging tools applied to this population, it is apparent that such patients can often be shown to have involvement of the skeleton and/or kidneys. Finally, in countries where PTH is routinely measured in the context of low BMD, normocalcaemic PHPT becomes a recognized clinical entity. The point to be made here is that PHPT has probably always existed in all three forms. The proportion of the hyperparathyroid population that will show them will depend upon these factors. Another consideration is the extent to which the population is vitamin D deficient. As noted already, vitamin D deficiency is associated with more signs of active disease. In a country that is markedly vitamin D deficient, on average, and does not employ widespread population screening, PHPT is likely to be viewed as an uncommon, symptomatic disorder. In a country that is not markedly vitamin D deficient, on average, and employs widespread population screening, PHPT is likely to be viewed as a common, asymptomatic disorder.

Management of Primary Hyperparathyroidism

Surgery for Signs and/or Symptoms

Patients who have clear signs of hyperparathyroidism whether they are skeletal (fractures) or renal (stones) or symptomatic hypercalcaemia should have parathyroid surgery, unless there are medical or other contraindications [8]. Areas of uncertainly relate to patients who have the asymptomatic and normocalcaemic forms of the disease.

Surgery in Asymptomatic Primary Hyperparathyroidism

Since surgery is curative when successful, patients and physicians can opt for surgery even if the patients do not meet guidelines that have been proposed for surgical management. Some patients find this to be an attractive option while others are inherently reluctant to consider surgery under almost any circumstances.

Over the past three decades, four international workshops on the management of asymptomatic primary hyperparathyroidism [5–8, 158] have periodically reviewed and updated the evidence that would argue either for a surgical or non-surgical management approach. The 4th International workshop [8] offered the following recommendations. They are listed here and shown in Table 4.3.2:

1. Serum calcium concentration greater than 1 mg/dl above the upper limit of normal;
2. a. BMD by DXA T score <–2.5 at lumbar spine, total hip, femoral neck, or distal third radius;
   b. vertebral fracture by X-ray, CT, MRI, or vertebral fracture assessment (VFA)
   c. evidence of a clinical fracture
3. a. estimated GFR (eGFR) <60 cc/min;
   b. 24-hour urine for calcium >400 mg/day (>10 mmol/day) and increased stone risk by biochemical stone risk analysis;
   c. nephrolithiasis or nephrocalcinosis by X-ray, ultrasound, or CT;
4. Age <50.

Any one of these criteria is sufficient to recommend surgery. These recommendations have not been updated recently, but we look forward to refinements and modifications based upon new data that have become available at the time of the next international conference.

It should be emphasized that these guidelines are not rules and, in fact, like many other guidelines, they are not based on strong evidence. Physicians and patients modify them according to the individual clinical situation. Some physicians feel that all patients with PHPT should undergo parathyroid surgery, as long as there are no contraindications. Some patients will resist surgery even though there are clear candidates and are strongly advised to have parathyroid surgery. Others will base their recommendations on other criteria.

Surgical Approach in Primary Hyperparathyroidism

A key dictum in this field is that parathyroid surgery should be undertaken by those who are experienced and highly skilled in the procedure [159–161]. While this dictum has not changed, over the past several decades, the approach to parathyroid surgery has. Rather than full exploration of the neck with visualization of all four parathyroid glands, many centres perform a limited procedure

Table 4.3.2 Guidelines for parathyroid surgery in asymptomatic primary hyperparathyroidism. Surgery is also indicated in patients for whom medical surveillance is neither desired nor possible. If any one of these criteria are met, the patient is considered to be a candidate for parathyroid surgery

Measurement	Surgery recommended
Serum calcium	>1.0 mg/dl (0.25 mmol/L) above normal
Renal system	Marked hypercalciuria (>400) with other stone risk factors; nephrolithiasis, nephrocalcinosis or creatinine clearance <60 cc/min/1.73 m²
Bone mineral density	T score <–2.5 at spine, hip (total or femoral neck), or radius (distal 1/3 site); or fragility fracture
Age	<50 years

Data derived from Bilezikian JP, Brandi ML, Eastell R, Silverberg SJ, Udelsman R, Marcocci C, Potts JT Jr: Consensus Statement: Guidelines for the Management of Asymptomatic Primary Hyperparathyroidism: Summary Statement from the Fourth International Workshop. *J Clin Endocrinol Metab* 2014;99:3561–3569.

when there is pre-intraoperative evidence for single gland disease and that at the time of surgery, there is intraoperative evidence for cure [162]. This is ascertained by intraoperative measurement of the PTH level at baseline and 2, 5, and 10 minutes following the removal of the parathyroid adenoma. If the PTH level falls by greater than 50% into the normal range, the resected parathyroid adenoma is considered to be the only gland involved and the operation is ended. With successful preoperative localization (see next), this operation can be performed by those skilled in the procedure under local anaesthesia and conscious sedation [163]. The minimally invasive parathyroidectomy (MIP), performed in an ambulatory care hospital setting, is a shorter operation without general anaesthesia, and with fewer complications [164–167]. If the intraoperative PTH level does not meet the criteria for success, namely it doesn't fall by greater than 50% and/or remains above normal, the operation is converted to a full neck exploration to seek other glands that are presumably overactive [168]. Success rates for this procedure that generally does not require an overnight hospital stay are greater than 90%, similar to the outcome of the full neck exploration [163, 169].

When the patient has multigland disease, a full exploration is necessary. Options are subtotal parathyroidectomy, consisting of removal of 3.5 glands, or total parathyroidectomy with transplantation of parathyroid tissue slices into the forearm. If the autotransplantation is successful, the patient will re-establish normal homeostatic control of the serum calcium by this ectopically placed parathyroid tissue. It is important to recognize that the tissue transplanted is abnormal and, thus, could become overactive in time. In that eventuality, the forearm site is convenient because the tissue could be accessed and debulked. Some centres have cryopreservation facilities which can be very helpful should the initial graft not take [170]. Lebastchi *et al.* have reported using the minimally invasive approach in multigland disease [171].

Surgery for Parathyroid Cancer

The surgical approach to parathyroid cancer is total removal of all malignant tissue and local neck dissection, when indicated. Sometimes, it is not known whether all malignant tissue has been removed because local and distant metastases can appear years after resection. Parathyroid cancer is one of the unusual malignancies in which metastases, if surgically approachable, can be removed with satisfactory results than can be measured sometimes in years [46]. Multiple therapeutic approaches along with resection of the metastases have also been associated with long-term survival [172].

Parathyroid Gland Imaging

While parathyroid imaging was for years considered to be a useful adjunct, prior to parathyroid surgery, advances in imaging technology have made this a mandatory aspect of the surgical protocol [9, 173, 174]. Preoperative parathyroid imaging is not done to make the diagnosis of PHPT. The decision to proceed with parathyroid surgery should have been made prior to the preoperative imaging test. Many approaches are available with endocrinologists, surgeons and radiologists all showing preferences for one or another procedure [175, 176].

Ultrasound is very convenient and with many endocrinologists and parathyroid surgeons having an ultrasound instrument in their offices, this approach is often utilized. It is unusual for the ultrasound image to be sufficient for confident localization without a confirmation by another approach. The sensitivity of neck ultrasound ranges from 42 to 82% but specificity is close to 90% [177].

Sestamibi imaging in many centres is a mainstay of the preoperative imaging repertoire. In some hands, sestamibi imaging can show sensitivity of about 90% and specificity of about 95% [178, 179]. When sestamibi is performed with single photon emission computed tomography (SPECT) alone [180] or in combination with CT, successful localization is even better [181]. A negative aspect of sestamibi is that its sensitivity for small adenomas or double adenomas or hyperplasia is poor. In a situation characterized by multigland disease, but one predominant parathyroid gland, the sestamibi scan typically will show only the dominant gland. To identify ectopic tissue, particularly in the mediastinum, sestamibi can be useful.

CT scanning of the neck and mediastinum is being used more frequently for parathyroid localization, particularly with contrast. The use of contrast identifies the procedure as 4D-CT with time being the fourth dimension. The contrast also gives functional identification along with anatomical localization of the parathyroid glands [182, 183]. It is also useful when the parathyroid tissue is ectopically present in the mediastinum [184]. The recent experience of Yeh *et al.*, compared 4DCT with sestamibi and found that 4DCT alone was more successful than sestamibi and that sestamibi did not provide additional value to the high success rate of 4DCT alone [185].

MRI has utility when the parathyroid gland is in the mediastinum and in the case of persistent disease after parathyroid surgery [186]. MRI has been used with positron emission tomography (PET) scanning with promising results [187].

Arteriography and Selective Venous Sampling. Rarely used these days, arteriography and selective venous sampling can be helpful in very special situations of persistent PHPT without successful localization by the aforementioned imaging modalities [188].

Clinical Course of Primary Hyperparathyroidism

Natural History Without Surgery

Prospective follow-up of asymptomatic PHPT for up to 15 years without surgery or specific medical therapy [189, 190] has shown that for the first 10 years, biochemistries are all stable. In years 10–15, however, the serum calcium shows a tendency to increase slightly, but renal function, as measured by the creatinine clearance does not decline. The serum calcium increased above 12 mg/dl in 4% while 15% became markedly hypercalciuric with urinary calcium excretion >400 mg/day. By BMD, the first decade of observation shows stability at all three sites. In years 11–15, however, the femoral neck and more evidently the distal 1/3 radius show progressive declines. Overall, 12% showed declines in BMD at any site, meeting guidelines for parathyroid surgery. Overall, 37% of subjects followed for this 15-year period met one or more indications for parathyroid surgery. No specific index could be shown to be predictive of disease progression with the one exception be age under 50. In those younger patients, the risk of progression was over 60%. In those over 50, risk of progression was 25%, over the same period of time.

Among patients who met one or more indications for surgery but who opted against surgery, progression was the rule. Recurrent nephrolithiasis for example was often experienced by these patients.

Monitoring Patients with PHPT Who Do Not Undergo Parathyroid Surgery

The natural history of PHPT followed without surgery has led to the following recommendations for monitoring. They are shown in Table 4.3.3 and summarized here.

1. Yearly or twice-yearly serum calcium measurement.
2. Yearly or every other year—three-site DXA (lumbar spine, hip regions, and distal 13 radius). While yearly DXA is unlikely to show significant changes, from year to year, having these data points allows one to spot downward trends more expeditiously. If clinically indicated, X-ray or VFA of the spine should be performed (i.e. height loss, back pain).
3. eGFR annually. If renal stones are suspected in the interim, a 24-hour urine for biochemical stone profile along with renal imaging by X-ray, ultrasound, or CT are advised.

Natural History of Normocalcaemic PHPT

In one study of normocalcaemic PHPT [35], 37 patients were followed for 3 years on average (range 1–9). Hypercalcaemia emerged in 7 (19%) individuals. A greater percentage, 40%, developed evidence of kidney stones, fractures, marked hypercalciuria or greater than a 10% decline in BMD. Seven patients had successful parathyroidectomy of whom three were hypercalcaemic and the rest met other criteria for surgery.

The Fourth International Workshop on the Management of Asymptomatic PHPT, suggested, for the first time, a management protocol for normocalcaemic disease [8]. In patients who develop hypercalcaemia, the recommendations for the hypercalcaemic form of PHPT should be followed as noted as described. If complications of PHPT develop, even if the serum continues to be normal, they should be regarded as candidates for parathyroidectomy [191].

Natural History After Parathyroidectomy

Successful parathyroid surgery is followed by correction of hypercalcaemia along with a return of the PTH level to normal. Urinary calcium levels, if elevated, will also fall. Bone turnover makers also decline [192, 193]. Bone resorption markers fall more rapidly after successful parathyroid surgery than bone formation markers [192]. The persistence of bone formation markers coupled with rapid declines in bone resorption markers is compatible with a pattern that should indicate accrual of bone mineral postoperatively.

In fact, one of the reliable aspects of successful parathyroid surgery is an increase in BMD. The lumbar spine shows increases within a 1 year (Figure 4.3.2), following by slower but eventual increases in the hip and distal one-third radius BMD [189, 190, 193–199]. In a meta-analysis of these postoperative findings, Sankaran *et al.* confirmed these findings [199]. Surgery also appears to be associated with a reduction in fracture risk [198, 199]. The marked increase in BMD following successful parathyroid surgery has led experts to suggest that pharmacological intervention for low bone mass can be safely withheld because bone mass accrues so quickly without intervention.

A dramatic example of this point was demonstrated by Kulak *et al.* [200] who reported two young patients with severe parathyroid bone disease (*osteitis fibrosa cystica*) who improved their BMD by 260 to 430%, within 4 years of after successful surgery.

Table 4.3.3 Management guidelines for patients with asymptomatic primary hyperparathyroidism who do not undergo parathyroid surgery

Measurement	Frequency
Serum calcium	Annually
Renal	Clcr annually; stone risk profile and/or abdominal imaging if clinically indicated
Bone mineral density	DXA every 1 or 2 years; vertebral imaging with CT or VFA if clinically indicated

Data derived from Bilezikian JP, Brandi ML, Eastell R, Silverberg SJ, Udelsman R, Marcocci C, Potts JT Jr: Consensus Statement: Guidelines for the Management of Asymptomatic Primary Hyperparathyroidism: Summary Statement from the Fourth International Workshop. *J Clin Endocrinol Metab* 2014;99:3561–3569.

Non-Surgical Approaches to Primary Hyperparathyroidism

Patients who are not going to have parathyroid surgery should maintain hydration at all times. Their intake of calcium should follow established nutritional guidelines. While it seems intuitive to want to restrict calcium intake in PHPT, there are reasons not to restrict dietary calcium. Calcium excretion is not substantially affected by calcium intake [201]. There is reason to be concerned about low calcium intakes as this could be a signal for the abnormal parathyroid gland(s) to become even more active. On the other hand, one does not want to encourage high calcium intake which can be a particular problem if the 1,25-dihydroxyvitamin D_3 is elevated [202]. As is the case for subjects without PHPT, dietary sources of calcium are to be recommended instead of supplemental forms.

Phosphate

Oral phosphate is virtually never used in PHPT anymore. Concerns about GI tolerance, further increases in PTH levels, and ectopic calcifications have essentially relegated oral phosphate to a historical footnote [201].

Oestrogen

Studies of oestrogen in PHPT have typically been high, but lower doses have also seemed to be beneficial [203]. Given the limited data, it is nevertheless, reasonable to consider oestrogen among postmenopausal women for whom surgery is not an option, are willing to take oestrogen, and there are no contraindications. When oestrogen is effective, the serum calcium will fall by 0.5 to 1.0 mg/d. PTH levels will remain stable. BMD will increase in the lumbar spine and femoral neck [203].

Selective Oestrogen Receptor Modulator (SERM)

There are very limited data on the use of SERMs in PHPT. In a small study of 18 postmenopausal women, Rubin *et al.* [204] reported a significant decline in the serum calcium by about 0.5 mg/dl after 8 weeks of raloxifene. The results were transient with return of the serum calcium and reduced bone turnover markers to baseline

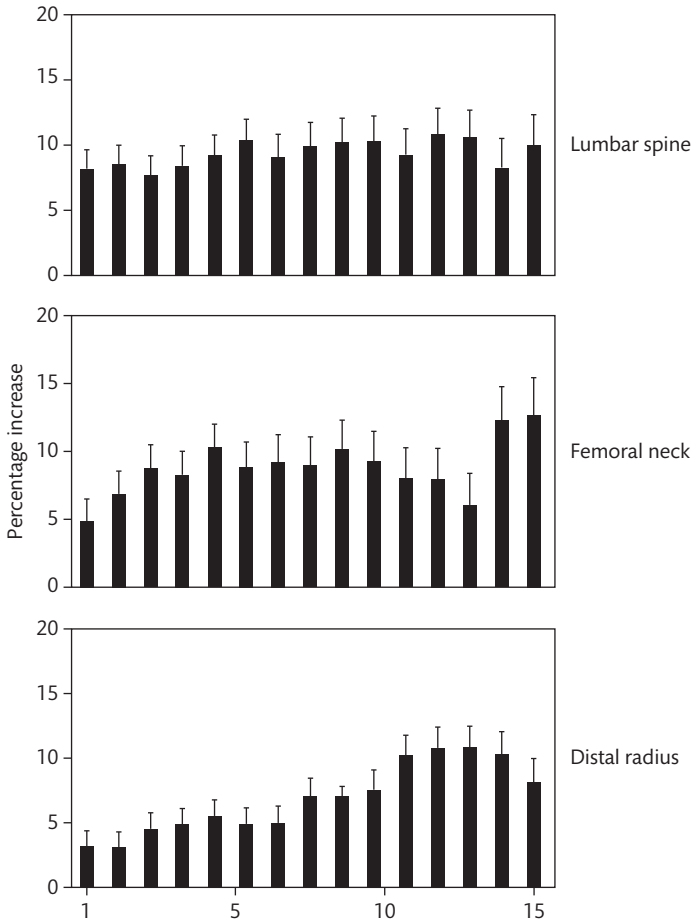

Figure 4.3.2 Increases in bone mineral density after successful parathyroid surgery in primary hyperparathyroidism. Data shown are the cumulative percentage changes from baseline over 15 years of follow-up.

Reproduced with permission from Rubin MR, Bilezikian JP, McMahon DJ, et al. The Natural History of Primary Hyperparathyroidism With or Without Parathyroid Surgery after 15 Years. *J Clin Endocrinol Metab* 2008;93:3462–3470. Copyright © 2008, Oxford University Press. (ref 190).

during the 4-week wash out period. There were no changes in PTH or urinary calcium excretion. Zanchetta and Bogado [205], with an even smaller number of subjects and without a blinded experimental design, showed a similar reduction in serum calcium with raloxifene.

Vitamin D

Referencing the discussion earlier in this chapter on vitamin D deficiency being related to activity of disease, the logic follows that vitamin D replacement should be associated with better control of the hyperparathyroid state. Grey *et al.* [206] administered vitamin D_3 to 21 patients with mild PHPT. The repletion regimen in these subjects whose 25-hydroxyvitamin levels averaged 20 ng/ml, was 50 000 international unit (IU)s weekly for 4 weeks followed by 50 000 IU monthly for the next 11 months. After 12 months, the average 25-hydroxyvitamin D levels increased to 31 ng/ml. The serum PTH levels fell by about 25% without any change in the serum calcium. Three subjects developed marked hypercalciuria (>400 mg/day). Although this report supports the idea that vitamin D insufficiency can worsen the hyperparathyroid state, it does not provide guidance as to how vitamin D should be replaced. A more reasonable approach employed 2800 IU/day for 6 months and showed, in a randomized trial, that mean PTH levels fell by 17% without any change in the serum calcium concentration [207]. In addition to the biochemical effects of vitamin D, muscle strength might be improved as shown by Amstrup *et al.* [208]. This suggestion could not be confirmed by Rolighed *et al.* in a short 6-month study [209].

In short, the 25-hydroxyvitamin D level should be normal in PHPT. While the definition of 'normal' is controversial, that controversy relates to the 'right number' in subjects without evidence for metabolic bone diseases. Given the upside safety of vitamin D and the work of Walker *et al.*, in which the inflection point below which the PTH level appears to rise further in PHPT, namely at around 25 ng/ml, it seems reasonable to aim for a level greater than 30 ng/ml (75 nmol/L).

Bisphosphonates

The bisphosphonates are attractive in PHPT, not because they affect PTH secretion directly but because they reduce bone turnover in a disease characterized by high bone turnover. Theoretically, they could reduce serum and urinary calcium levels and increase BMD. The amino substituted bisphosphonates, in common use for osteoporosis, have been of interest. A limited but positive experience with risedronate [210], has been followed by more detailed studies with alendronate. Several promising studies of alendronate

in PHPT [211–212] have been followed by three well-controlled studies [213–215]. The work of Khan *et al.* [215] utilizing a randomized, double-blinded, placebo-controlled design, in 44 patients with mild, asymptomatic PHPT, showed a significant 5.3% increase in BMD of the lumbar spine, which rose further to almost 7% % by year 2 (Figure 4.3.3). Total hip BMD increased by 4.01% in year 2. As expected, bone turnover markers fell by more than 50%. Calcium, phosphorus, and PTH levels did not change. Men with PHPT have also been studied with similar results [216, 217]. Chow *et al.* [214] have reported an experience similar to Khan *et al.*, except that the serum calcium fell by 0.34 mg/dl.

These promising results suggest that in patients with low BMD who are not candidates for parathyroid surgery, for whatever reason, might show improvements in BMD when alendronate is use. An unusual finding of increased fracture risk in those receiving alendronate compared to those who underwent successful parathyroidectomy deserves comment [218]. The selection bias of the two groups would appear to be the best explanation for these unexpected results. Those who received alendronate were at greater risk for fracture than those who underwent parathyroid surgery. Obviously, if a patient is a candidate for parathyroid surgery, that is preferred but the body of reports with alendronate do substantiate its utility in situations where parathyroid surgery is not a consideration.

Denosumab

The use of denosumab is theoretically attractive in PHPT because it interferes with RANK L, a cytokine intimately related to a catabolic pathway utilized by PTH. In the study of Eller-Vainicher *et al.* (Figure 4.3.4), denosumab was shown to improve BMD to a significantly greater extent than a comparable group of postmenopausal women with osteoporosis but without PHPT [219]. One looks forward to further controlled studies of denosumab in PHPT.

Calcimimetics

Different from the aforementioned pharmacological approaches to PHPT, an approach that targets the parathyroid gland secretory apparatus is most attractive. Interference with the CaSR would provide this more specific approach. Calcimimetics increase the calcium signal to the parathyroid cell and should reduce the secretion of PTH. Following promising early studies with an early calcimimetic, the phenylalkylamine (R)-N-(3-methoxy-alpha-phenylethyl)-3-(2-chlorophenyl)-1- propylamine [R-568], a more potent calcimimetic, cinacalcet hydrochloride was studied and approved by the US Food and Drug Administration (FDA). The indication is for control of the serum calcium in patients with PHPT who present a challenge to control [220–221]. The work of Shoback, Peacock, and their associates have documented the efficacy of cinacalcet in reducing the serum calcium in PHPT [222–224]. The studies have been carried out for up to 5 years, demonstrating continuous control of the serum calcium [224]. The drug has been shown to effective among a spectrum of clinical manifestations and in those with severe disease [225–227]. One negative aspect of this drug is that BMD does not improve.

Cinacalcet has also been shown to be effective in parathyroid cancer but high doses may be required [228].

ACKNOWLEDGEMENTS

The work in this chapter that refers specifically to the author's research was supported by NIH grant, DK32333 from NIDDK.

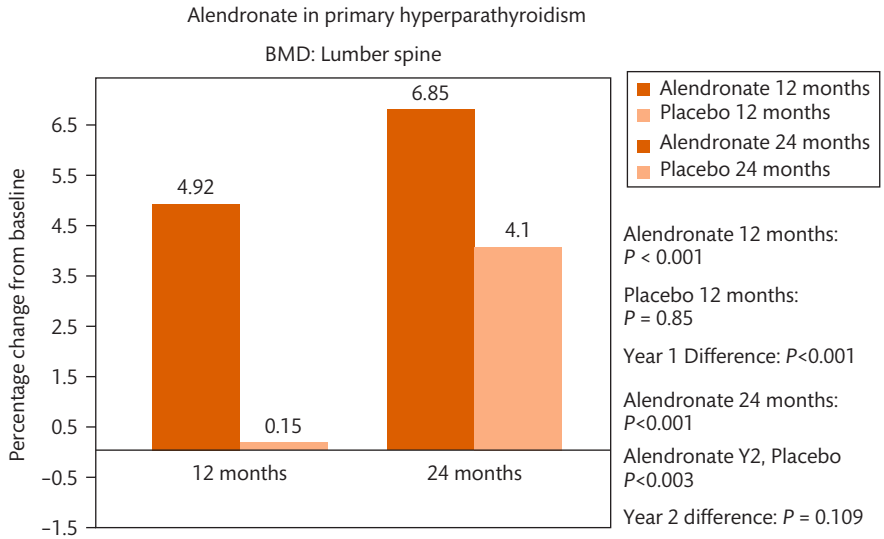

Figure 4.3.3 The effect of alendronate on bone mineral density in primary hyperparathyroidism. With alendronate, bone mineral density increases significantly after 1 year, while the placebo group shows no change until it is crossed over to alendronate in year 2.

4.4

Familial Hypocalciuric Hypercalcaemia Types 1–3 and Neonatal Severe Primary Hyperparathyroidism

Muriel Babey and Dolores M. Shoback

Introduction

Familial hypocalciuric hypercalcaemia (FHH) is a benign autosomal dominant disorder of calcium homeostasis most often caused by a loss-of-function mutation in the *CASR* gene encoding the extracellular calcium-sensing receptor (CaSR) [1]. This form of FHH is now called FHH1. In FHH1, the mutant CaSR in the parathyroid glands responds less potently to changes in extracellular calcium concentration, leading to higher levels of parathyroid hormone (PTH), associated with an altered calcium set-point for the regulation of PTH secretion (**Figure 4.4.1**). CaSRs in the kidney directly inhibit renal calcium reabsorption, thereby counteracting the effect of PTH)[2]. An inactivating mutation in G alpha 11, one of the guanine nucleotide binding (G) proteins which links the CaSR to activation of phospholipase C, is responsible for FHH2 [3]. The phenotype of FHH type 1 and 2 is characterized biochemically by mild-to-moderate, PTH-dependent hypercalcaemia and relative to absolute hypocalciuria)[4]. FHH3 is due to a loss-of-function mutation of adaptor-related protein complex 2, sigma 1 subunit (AP2S1) which is involved in clathrin-mediated endocytosis of G-protein-coupled receptors)[5]. The FHH3 phenotype may be the more severe variant with symptomatic hypercalcaemia, low bone mineral density, and cognitive deficits in some affected individuals in childhood [6, 7].

Mutations in the *CASR, G11* or *AP2S1* are typically heterozygous and lead to loss of protein function with their predominant phenotypic features affecting parathyroid and kidney function. Individuals with FHH1 and FHH2 are usually asymptomatic. Neonates with homozygous mutations in the *CASR* tend to lack functioning CaSRs and present at the other end of the clinical spectrum with life-threatening hypercalcaemia—a disorder called neonatal severe hyperparathyroidism (NSHPT). In addition to the common presentation of FHH, occasionally patients with heterozygous inactivating mutations of *CASR* can present as NSHPT)[8], neonatal hyperparathyroidism (NHPT) [9], which is intermediate in severity between FHH and NSHPT, but is a more severe degree of hypercalcaemia in infancy and childhood than usually encountered in FHH [10], or mild hypercalcaemia characteristic of primary hyperparathyroidism (PHPT) [11].

This chapter will review key concepts in calcium homeostasis and the role of the CaSR and associated proteins Gα11 and AP2σ in CaSR function. The clinical and laboratory features of FHH types 1–3, NSHPT, NHPT, and severe hypercalcaemia in infancy will be discussed. We highlight the differential diagnosis of PTH-dependent forms of hypercalcaemia (especially PHPT), the molecular pathogenesis of CaSR signalling defects that produce hypercalcaemia, and the treatment and monitoring for these conditions.

Calcium Homeostasis and the Role of the CaSR

The extracellular calcium concentration is tightly regulated, given its involvement in many key biological processes such as muscle and heart contraction, neuronal excitability, bone mineralization, and hormone secretion. The CaSR plays a key role in calcium homeostasis by regulating the secretion of PTH from the parathyroid glands and the reabsorption of urinary calcium by the kidney. The transfer of calcium between the environment and extracellular fluid takes place in the intestine. Bone constitutes the main

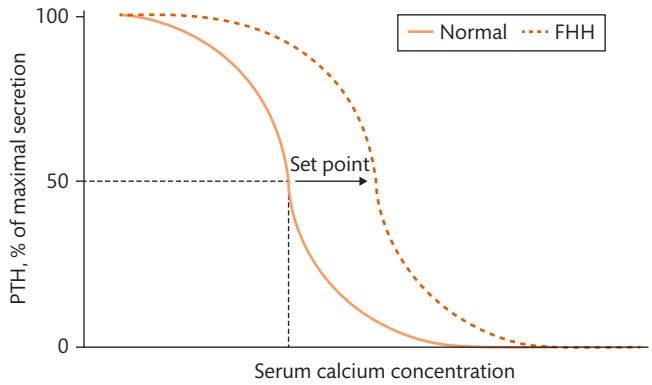

Figure 4.4.1 Relationship between levels of serum calcium and plasma PTH. Depicted is the inverse sigmoid relationship between levels of serum calcium and plasma PTH in patients with familial hypocalciuric hypercalcaemia (FHH; dotted line) and normal individuals (solid line). The calcium set-point is defined as the extracellular calcium level which produces half-maximal inhibition of PTH secretion. FHH results in a shift of the curve to the right. Increased levels of serum calcium are needed to suppress plasma PTH levels in FHH. The therapeutic effect of calcimimetic leads to a shifting of the set-point to the left.

calcium reservoir. Calciotropic hormones such as PTH and 1,25-hydroxyvitamin D_3 mediate changes in calcium homeostasis via actions in bone, kidney, intestine and parathyroid gland [12]. The relationship between extracellular calcium and PTH levels is represented by an inverse sigmoidal curve (Figure 4.4.1). The activity and/or the expression level of parathyroid CaSRs predicts the calcium set-point, defined at which the extracellular calcium level at which PTH secretion is half-maximal.

CaSRs serve as the calcium-sensing mechanism *in vivo*. CaSRs are predominantly expressed in the chief cells of the parathyroid gland and along the whole nephron and are also found in other tissues such as pancreatic islet, intestine, bone, breast and skin and in some areas of the brain [13–16]. The CaSR is a G-protein coupled receptor (GPCR) and belongs to the Family C of this receptor superfamily. The CaSR belongs to the group II subfamily, which contains the CaSR, the vomeronasal receptors (VRs) and odorant receptors, and has more than 20% amino acid identity over their transmembrane domains (TMD) comprising the 7-TM-spanning region.

The human *CASR* gene maps to 3q13.3-21 and has eight exons. Six exons, exon 2–6, encode the CaSR protein which is made up of 1078 amino acids. The large extracellular domain (ECD) of the CaSR has approximately 600 amino acids including the bi-lobed Venus flytrap-like domain (VFT). The VFT is responsible for ligand binding and connects via cysteine-rich region and peptide linker to the seven TMD. The intracellular COOH-terminal tail is 216 amino acids long [17]. The CaSR functions as a dimer on the cell surface, which is in part due to intermolecular disulphide bonds in the ECD [18]. Three to five calcium ions bind to the cleft of each VFT and cause closure of the VFT lobes with ensuing rotation of the VFT and a transfer of a conformational change to the cysteine-rich region of a CaSR dimer. Upon activation, the CaSR forms a novel dimer interface between subunits [19]. The conformational change reconfigures some TM-helices such that intracellular loops contact G proteins and initiate cell signalling. In addition to calcium, other polycations such as magnesium and barium, charged polyvalent molecules such as spermine, and β-amyloid peptides can activate the CaSR [20]. The sensitivity to calcium can also be positively modulated by pH, ionic strength, and aromatic L-α-amino acids such as phenylalanine, tryptophan, and histidine [19, 20]. According to the crystal structures of the CaSR, there are not only multiple binding sites for calcium, but unexpectedly also for phosphate ions. While calcium ions promote the active state, phosphate ions stabilize the inactive confirmation [19].

After ligand binding and likely dimerization of individual receptor molecules and conformational changes, the CaSR couples to multiple intracellular signalling pathways, depending on the target cell. CaSRs can couple with several G proteins (Gi, Gq/11, G 12/13). The CaSR stimulates activation of phospholipase A2, C, and D as well as various mitogen-activated protein kinases (MAPKs) and inhibits adenylate cyclase [9]. In particular, G-protein subunit α11 stimulates phospholipase C-β (PLC-β) activity (Figure 4.4.2) [21, 22]. PLC-β increases inositol 1,4,5-triphosphate, a mediator of rapid mobilization of calcium from intracellular stores [23], whereas the diacylglycerol (DAG) produced activates protein kinase C (PKC). PKC in turn initiates the MAPK pathway (Figure 4.4.2) [24].

Current thinking, based on work in model *in vitro* systems with high levels of receptor expression, is that cell surface CaSR expression is regulated by two main mechanisms. The first mechanism has been called agonist-driven insertional signalling or ADIS [25]. ADIS leads to increased anterograde trafficking of newly synthesized receptors to the plasma membrane after prolonged exposure to calcium. The second mechanism depends on an endocytic complex comprising clathrin, β-arrestin and the AP2 complex [5]. The endocytic complex transports CaSRs to the endosomal-lysosomal degradation pathway or recycles them to the cell surface through retrograde trafficking [26] (Figure 4.4.2).

Elevated serum calcium levels are sensed by CaSRs, and activation of downstream signalling leads to downregulation of PTH secretion [1, 2]. The expression of the CaSR on the cell surface seems to be upregulated by extracellular calcium and 1,25-dihyroxyvitamin D_3 [27, 28]. Decreased PTH secretion will reduce bone resorption, urinary calcium reabsorption [15–19], and renal synthesis of 1,25-hydroxyvitamin D_3, thereby decreasing intestinal calcium absorption. CaSRs respond to elevated calcium levels in the kidney, and urinary calcium reabsorption by PTH in the cortical thick ascending limb decreases by interfering directly with sodium/chloride reabsorption [29, 30]. The interference with sodium/chloride reabsorption impairs the generation of the medullary osmotic gradient which is critical for urinary concentration. In the proximal tubule, CaSRs reduce the inhibitory effect of PTH on renal phosphate reabsorption [31]. CaSRs also reduce the urinary concentrating ability in the inner medullary collecting duct by counteracting the action of vasopressin [32]. A decrease in serum or extracellular calcium reduces CaSR activation.

Familial Hypocalciuric Hypercalcaemia

Clinical and Laboratory Features of FHH

Familial hypocalciuric hypercalcaemia was first described in 1966 [33]. The disorder was initially named 'familial benign hypercalcaemia' in the case description of a 7-year-old boy and his extended 11-member family by Foley *et al.* in 1972 [34]. The distinctive clinical features were lack of clinical symptoms, mild hypercalcaemia, normal levels of PTH, normal or low serum phosphate for age, and

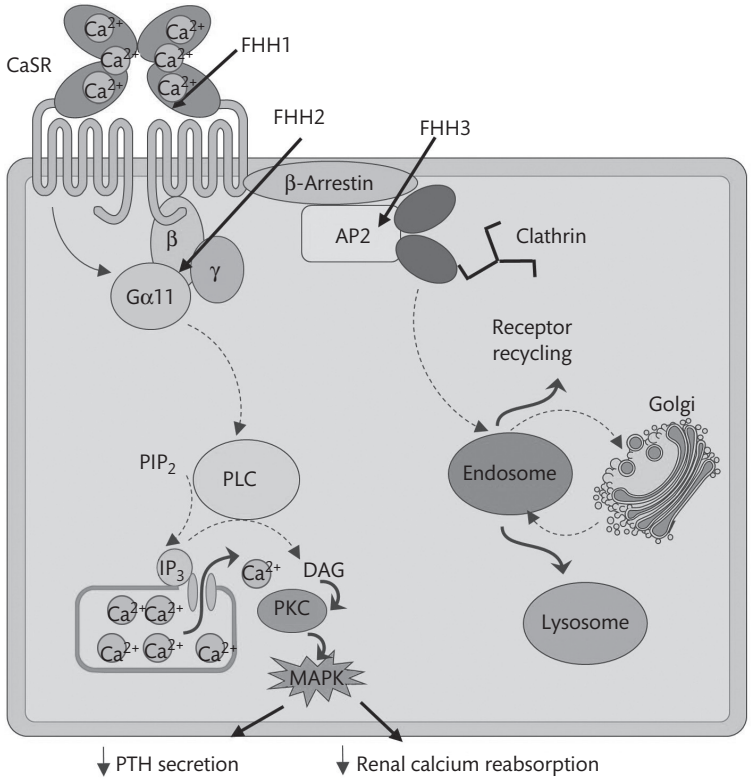

Figure 4.4.2 Role of the CaSR, Gα11 and AP2 complex in regulation of PTH secretion and renal calcium reabsorption. Multiple calcium ions bind to the extracellular bi-lobed Venus fly trap (VFT) domain of the CaSR. Upon activation, CaSR binds to the G11 and Gq (not shown) proteins which dissociate into the respective Gα-subunits and Gβγ heterodimers. Gα11 stimulates phospholipase C (PLC). PLC catalyses the formation of inositol 1,4,5-triphosphate (IP3) and diacylglycerol (DAG) from phosphatidylinositol 4,5-biphosphate (PIP2). IP3 accumulates and leads to a rapid release of calcium intro the cytosol from intracellular stores. DAG activates protein kinase C (PKC) which in turn initiates the mitogen-activated protein kinase (MAPK) pathway. Ultimately, these intracellular signalling pathways decrease PTH secretion from parathyroid chief cells and reduce renal tubular calcium absorption. CaSR cell surface expression is dependent on the endocytic complex, which consists of clathrin, β-arrestin and the AP2 complex, and on agonist-driven insertional signalling (ADIS) (not shown). The endocytic complex transports the CaSR to the endosomal-lysosomal degradation pathway or recycles it back to the cell surface. Loss-of-function mutations in CASR lead to FHH type 1, whereas loss-of-function mutations of GNA11 are associated with FHH type 2. FHH type 3 is caused by loss-of-function mutations of AP2S1.

low urinary calcium excretion. The pattern of inheritance in that family was compatible with an autosomal dominant mode of transmission. The authors postulated that there might be an abnormality in the calcium-sensing mechanism in the parathyroid glands [34]. Marx *et al.* examined kindreds with the same syndrome and named it FHH to highlight the absolute to relative hypocalciuria for the degree of hypercalcaemia being demonstrated [4].

The prevalence of FHH is estimated to be 1% or less to that of primary hyperparathyroidism (PHPT). Given its benign clinical features which may lead to cases escaping medical detection, FHH may be more common than the estimated prevalence of ~1/78 000 from data from developed countries [35]. FHH is inherited in an autosomal dominant manner and approaches a 100% penetrance of the trait.

Patients are usually asymptomatic despite chronic hypercalcaemia. Typical manifestations of hypercalcaemia (nausea, anorexia, constipation, nephrolithiasis, nephrocalcinosis) are usually not present [36]. Even patients with FHH with the higher serum calcium levels, are often asymptomatic. Chondrocalcinosis with advanced age and cases of pancreatitis associated with FHH1 have been described [37, 38]. Patients with three most frequent FHH2 mutations (p.I200del, p.L135Q, p.T54M) display a mild FHH phenotype with serum adjusted calcium concentrations of less than 2.8 mmol/L [3, 39]. FHH3 patients may experience symptomatic hypercalcaemia, reduced fractional excretion of calcium, low bone mineral density and cognitive dysfunction, and/or behavioural disturbances in children with the p.R15C or p.R15L AP2σ mutations [40, 41]. Adults with FHH3 with the heterozygous germline p.R15C mutation display elevated PTH levels and mild hypophosphatemia, and even osteomalacia after the age of 30 has been reported in at least one family [6, 7].

Biochemically, FHH1 is characterized by lifelong mild-to-moderate hypercalcaemia, inappropriately low urinary calcium excretion, a normal or mildly elevated circulating PTH level, and high-normal to elevated serum magnesium levels. Serum calcium levels for most affected families range from 2.6 to 2.9 mmol/L and average at about 10% above the upper limit of normal. In some kindreds, the serum calcium levels can range from the upper half of the normal range [42] to as high as 3.24–3.49 mmol/L [10]. Serum calcium levels within a kindred are usually clustered within a relatively narrow range [4]. Serum magnesium levels in FHH are measured at the upper half of normal or mildly elevated [4]. Serum magnesium levels correlate positively with the serum calcium concentration [4]. Serum phosphate levels in FHH are usually in the lower half of the normal range and rarely low [43]. Renal function remains intact in FHH despite hypercalcaemia, and renal complications such as nephrocalcinosis are not present [4, 43].

Table 4.4.1 Characteristics of patients with familial hypocalciuric hypercalcaemia type 1–3 (FHH) and primary hyperparathyroidism (PHPT)

Variable	FHH type 1–3	PHPT
Age of onset and gender distribution	At birth, equal gender distribution	Usually >50 years, women affected twice as often as men
Genetic pathogenesis	Loss-of-function germline mutation in *CASR* for FHH type 1, in *GNA11* for FHH type 2 and *AP2S1* for FHH type 3	Most often implicated in the development of sporadic PHPT: somatic mutations in *CCND1* and *MEN1* in parathyroid adenoma/hyperplasia
Symptoms and clinical findings	Usually asymptomatic for FHH type 1 and 2, although occasionally pancreatitis is seen There is possibly a more severe phenotype for FHH type 3, including symptomatic hypercalcaemia, low bone mineral density, and cognitive dysfunction	Asymptomatic in >80% Cortical bone loss, urolithiasis in <20%
Serum levels		
Calcium	Elevated	Elevated
Magnesium	Normal to elevated	Variable, usually normal
Phosphorus	Normal to slightly low	Normal to very low
Intact PTH	Normal, 80–85%; elevated, 15–20%	Elevated, >80%
$1,25(OH)_2D$	Normal	Normal to elevated
Urinary excretion		
Calcium	Normal to low	Normal to elevated
Ca/Cr clearance	Usually <0.01	Usually >0.02
Magnesium	Normal to low	Normal to elevated

Inappropriately low urinary calcium excretion is found in 95% of patients [44]. In a Danish study, 24-hour urinary calcium excretion was measured within the lower range of normal at approximately 2.7446 mmol/24 hours in FHH patients vs. a normal cohort in which it ranged from 1.996 to 7.984 mmol/24 hours [43]. Inappropriately low urinary calcium excretion demonstrates the enhanced renal tubular absorption of calcium. The calcium-to-creatinine clearance ratio (CCCR) which is also known as fractional excretion of calcium is defined by:

$$CCCR = \frac{urinary\ calcium}{plasma\ calcium} \times \frac{plasma\ creatinine}{urinary\ creatinine}.$$

Approximately 80% of individuals with FHH demonstrate a CCCR of <0.01 equivalent to less than 1%, whereas approximately 80% of patients with PHPT have a CCCR higher than 0.01 (Table 4.4.1). Patients with FHH are able to concentrate urine normally, while patients with PHPT show reduced urinary concentrating capacity if they are dehydrated [45].

Approximately 80% of patients with FHH have normal plasma PTH levels, with the other 20% having mildly elevated levels [46]. Elevated PTH levels may be mirroring the functional effect of a specific mutation [47]. 25-hydroxyvitamin levels and 1,25-dihydroxyvitamin levels are generally within normal range [43]. The elevated 1,25-dihyrdoxyvitamin levels of PHPT are usually not encountered and might be due to the generally normal PTH levels in FHH (Table 4.4.1). Bone mineral density is comparable to age-matched controls, even though markers of bone turnover can be mildly elevated [48]. In patients with FHH, bone mineral density does not need to be measured, unless there are other reasons to consider excessive bone loss. The parathyroid glands are usually of normal size and histology in patients with FHH. In a few cases of FHH, a single or multiple parathyroid adenomas or mild chief cell proliferation were shown [49, 50]. Parathyroid localization studies need not be done, unless the case is one of NSHPT or NHPT or the rare patient with FHH with a coexistent superimposed parathyroid adenoma. Most cases of FHH that have gone to surgery demonstrate four-gland parathyroid hyperplasia. After an erroneous subtotal parathyroidectomy for FHH, hypercalcaemia will recur, despite normal appearing parathyroid glands in most affected individuals with FHH.

Differential Diagnosis

The differential diagnosis in FHH is limited to the various aetiologies of PTH-dependent hypercalcaemia, since PTH is not appropriately suppressed for the degree of hypercalcaemia. The distinction between FHH and PHPT is important, given the different management approaches (Table 4.4.1). Parathyroid surgery should be avoided in FHH.

Ten to twenty per cent (10–20%) of patients with PHPT display a CCCR of <0.01 [51]. A similar percentage of FHH patients show a value higher than this level [4]. The value of CCCR providing the optimal diagnostic identification between FHH and PHPT was calculated as 0.0115 (Figure 4.4.3) [52] similar to the clinically used value of 0.01 which delivers 80% sensitivity and 88% specificity. There is an inverse correlation between the serum calcium and magnesium levels in patients with PHPT. Patients with PHPT and concomitant very low calcium intake, vitamin D deficiency, or mild-to-moderate renal insufficiency, or patients taking thiazide diuretic or lithium therapy can have low CCCR. In the evaluation of PTH-dependent (hypocalciuric) hypercalcaemia, these associated factors should be investigated by thorough history-taking and laboratory tests. Only a few patients have been described in the literature with acquired autoimmune hypocalciuric hypercalcaemia due to antibodies that inactivate or dampen CaSR signalling. Other autoimmune disorders in such patients (Hashimoto's thyroiditis or celiac sprue) might hint at that diagnosis.

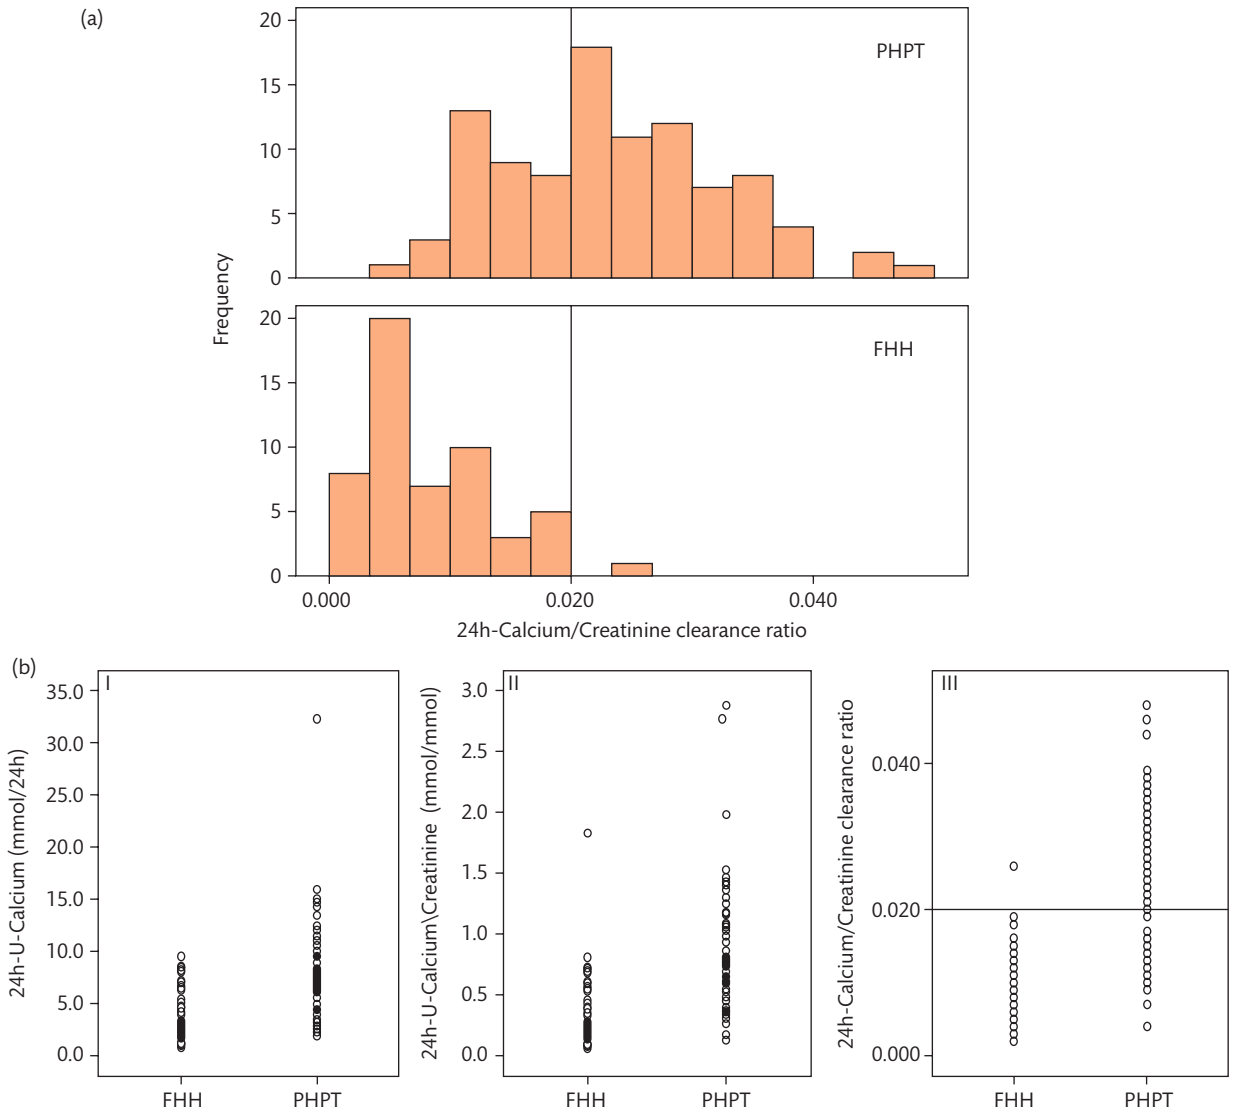

Figure 4.4.3 Ability of three indices of renal calcium excretion to differentiate between familial hypocalciuric hypercalcaemia and primary hyperparathyroidism. (a) The calcium/creatinine clearance ratio (CCCR) in patients with familial hypocalciuric hypercalcaemia (FHH, N = 54) and primary hyperparathyroidism (PHPT, N = 97) overlaps considerably, as shown in the two histograms. A CCCR cut-off value of < 0.02 included 98% of the FHH patients in this study, but a group so defined also included 35% of PHPT patients. (b) Scatterplots of 24-h calcium excretion (CE), 24-h calcium/creatinine excretion (CR) and 24-h CCCR in patients with FHH (N = 54) and PHPT (N = 97) are depicted. Based on overlap analyses, the CCCR misclassified fewer PHPT patients compared to the CE or CR index.

Reproduced with permission from Christensen SE, Nissen PH, Vestergaard P, Heickendorff L, Brixen K, Mosekilde L. Discriminative power of t+I294hree indices of renal calcium excretion for the distinction between familial hypocalciuric hypercalcaemia and primary hyperparathyroidism: a follow-up study on methods. *Clin Endocrinol (Oxf)*. 2008;69(5):713–20 (48).

In patients with PTH-dependent hypercalcaemia and CCCR <0.01 or in the CCCR overlap range of 0.01–0.02 between FHH and PHPT, the diagnosis usually can be made using the family history and biochemical screening of family members, if appropriate, to demonstrate an autosomal dominant pattern of hypercalcaemia in the patient and in two or more additional family members. Recently, a risk equation named Pro-FHH was developed and tested in two prospective cohorts to predict whether a patient has PHPT [53]. Pro-FHH incorporates the serum calcium, plasma PTH, and serum osteocalcin concentrations, and the calcium-to-creatinine clearance ratio calculated from 24-hour urine collection (24h-CCCR). This approach had a 100% specificity and 100% positive predictive value for the diagnosis of PHPT. This approach correctly categorized 60% of patients in one cohort, and the remainder of patients (40%) was recommended to undergo genetic testing. A prospective trial is necessary to assess its usefulness in a larger population and in patients with elevated PTH concentrations.

In patients with PTH-dependent hypercalcaemia in whom the diagnosis of FHH is suspected, screening for *CASR* mutations and mutations in *AP2S1* codon 15 is appropriate. If the screening is negative, then *GNA11* sequencing should be considered [54]. Patients with FHH may not have a family history, either because they may have a *de novo* mutation and/or because family members have not been previously studied. Genetic testing should be performed in children less than 10 years old with PTH-dependent hypocalciuric hypercalcaemia, including in children with NHPT and NSHPT and in patients and associated family members with hypocalciuric hypercalcaemia and recurrent pancreatitis [55]. Inactivating *CASR* mutations have been found in kindreds with familial isolated hyperparathyroidism (FIH)

as well [11, 56]. Their clinical presentation could not be differentiated from that of PHPT including at times the presence of hypercalciuria. Parathyroid surgery in such cases of FIH have led to persistent or recurrent hypercalcaemia in most patients [11].

Molecular Pathogenesis of FHH

FHH encompasses three genetically distinct disorders known as FHH types 1–3.

Familial Hypocalciuric Hypercalcaemia Type 1 (FHH1)

FHH1 (OMIM #145980) is caused by heterozygous loss-of-function mutations in the *CASR* gene on chromosome 3q21 as described here [1]. FHH1 is transmitted as an autosomal dominant disorder and is highly penetrant. FHH1 is the most common cause of the FHH phenotype accounting for approximately 65% of FHH cases in the database from McGill University summarizing many known *CASR* mutations (CaSRdb: calcium-sensing receptor database: https://www.casrdb.mcgill.ca) [57].

More than 130 different mutations of the *CASR* have been reported in patients with FHH1. Most commonly (≥85% of cases), a missense mutation reduces the function of the CaSR. Twenty-eight codons, equivalent to more than 20% of all mutated codons, are found to be mutational hot spots for missense mutations. They are clustered in three regions: the second loop of the ECD, the VFT cleft region with calcium binding sites, and the region encompassing TMD 6 and 7 [57].

The CaSR and its mutant forms have been functionally characterized *in vitro* in overexpression systems in which a mammalian expression vector with a cDNA insert is transfected into HEK293 (human embryonic kidney 293) or COS (CV-1 in Origin with SV40 gene) cells either transiently or stably. The cDNA encodes either a wild-type or mutant CaSR. More physiological renal or parathyroid cell model systems do not exist in which to study the function of the CaSR and its mutant forms. Altered CaSR signalling in renal tubular or parathyroid chief cells *in vivo* leads to altered CaSR signalling and excessive PTH secretion in the presence of hypercalcaemia and to increased renal calcium reabsorption and hypocalciuria, respectively. Mutated residues within the VFT cleft region likely affect binding of calcium or alter the conformational changes of the CaSR upon calcium binding [57, 58]. Specific VFT residues may act as an intramolecular switch to allow access to and binding of calcium within the VFT cleft region. When mutated, this can lead to opposing effects on CaSR signalling [57, 59]. Approximately 50% of mutations in *CASR* in FHH1 result in reduced cell surface CaSR levels due to impaired synthesis and/or increased degradation of the CaSR. Mutant CaSRs can be trapped intracellularly being unable to exit the endoplasmic reticulum (ER) or Golgi apparatus [60, 61], or there may be defective trafficking of the receptor from the ER to the plasma membrane [62]. Some mutant CaSRs are unable to couple to G proteins to activate intracellular cell signalling pathways. In addition, there may be dominant-negative effects of the mutant CaSR to reduce the function of the wild-type CaSR through the dimerization. As noted just here, mature cell surface CaSRs are thought to assemble as dimers [63]. However, coexpressed wild-type CaSRs might also increase transport of mutant CaSR receptors to the plasma membrane via ADIS [64]. Rarely, a nonsense, deletion, insertion, or splice-site mutation will lead to a truncated, inactive CaSR, but this occurs it seems in less than 15% of cases [36].

Familial Hypocalciuric Hypercalcaemia Type 2 (FHH2)

FHH2 (OMIM #145981) is caused by heterozygous loss-of-function mutations in the *GNA11* gene on chromosome 19p13.3, which encodes the $G\alpha_{11}$ protein [3, 39]. $G\alpha_{11}$ protein functions as a signalling partner for the CaSR (21) and is highly expressed in the parathyroid gland [65]. There are three most frequent FHH2 mutations (p.I200del, p.L135Q, p.T54M). $G\alpha_{11}$ mutations that cause FHH2 have given key information that has helped to elucidate the critical functions of the $G\alpha_{11}$ protein. All of the studies on the coupling between CaSR and $G\alpha_{11}$ were conducted in overexpression systems, described here, and not in a parathyroid or renal cellular context. The p.I200del mutation is localized by molecular modelling to the GTPase domain of $G\alpha_{11}$, which undergoes considerable conformational changes upon guanosine triphosphate (GTP) binding [3]. The p.L135Q mutation likely reduces CaSR signal transduction with downstream effectors. The p.T54M mutation likely diminishes coupling and/or dissociation of $G\alpha_{11}$ [39].

Familial Hypocalciuric Hypercalcaemia Type 3 (FHH3)

FHH3 (OMIM #600749) is caused by heterozygous loss-of-function mutations in the *AP2S1* gene on chromosome 19q13.3, which encodes the σ-subunit of the AP2 complex. The AP2 molecular complex is part of clathrin-coated vesicles and promotes endocytosis of GPCRs and other plasma membrane proteins [66]. Over 60 FHH3 patients and families have been reported with *AP2S1* mutations. At present, only three mutations (p.R15C, p.R15H, and p.R15L) have been identified [5, 40, 41, 67, 68]. According to *in vitro* overexpression cell models, these FHH3-causing mutations at the Arg 15 residue likely diminish the interaction between the AP2 complex and the intracellular carboxyl terminus of the CaSR and, therefore, impact the endocytosis of the CaSR [5]. In expression studies *in vitro*, AP2σ mutations change CaSR cell surface expression levels and affect signal transduction in a dominant-negative way [5, 40]. Other AP2σ mutants that are not observed in patients (p.R15G, p.R15P, and p.R15S) have been shown to disrupt cell growth *in vitro* and are likely embryonically lethal [40].

Treatment and Monitoring

The majority of patients with FHH do not need specific treatment due to its typically benign clinical course. Patients with FHH and their affected family members need to be screened and counselled against surgical intervention. Vitamin D and calcium can be supplemented in the same way as for persons of the same age and sex. There is no evidence that supplementation of vitamin D and calcium exacerbates hypercalcaemia or induces hypercalciuria in FHH.

There have been no systematic studies on how often patients with classically mild FHH should be monitored. Serum calcium, serum creatinine, and estimated glomerular filtration rate can be examined annually or biannually. Bone mineral density (BMD) at 3 skeletal sites (lumbar spine, hip, and distal third radius) can be determined according to country-specific guidelines initially, based on age, gender, and menopausal status. One can follow the suggested monitoring recommendations for patients with asymptomatic PHPT who do not meet current guidelines for parathyroid surgery [69]. Less frequent monitoring can also be employed given the typically benign clinical course of FHH. Dual-energy X-ray absorptiometry (DXA) may show reduced cortical bone mass if the

distal third radius site is measured [70]. However, ongoing cortical bone loss is not expected in patients with FHH [71]. A more extensive renal evaluation in FHH patients, as might be done in patients with PHPT, is not needed in patients with FHH, since the risk of renal stone disease and nephrocalcinosis is not significant. Tests of cardiovascular function need not be part of the evaluation or monitoring of patients with FHH for this indication. Monitoring aims to detect changes in the serum calcium level, significant reduction in BMD, or change in renal parameters. There is no increased risk of fracture at non-vertebral (cortical) or vertebral (trabecular) sites due to FHH as a sole aetiology.

Pregnancy in an FHH patient or in the spouse of an FHH carrier requires special consideration.

An unaffected newborn of a mother with hypercalcaemia due to FHH might experience transient hypocalcaemia due to suppression of the infant's PTH secretion *in utero* by the mother's hypercalcaemia. This transient hypoparathyroid state in the infant might last up to two months [72]. An affected newborn of a mother with FHH will be hypercalcaemic and could display features of NSHPT, depending on the specific CaSR mutation that the baby has. The affected newborn of a mother without FHH, but whose father has FHH and conferred the mutation to the offspring, that infant could show severe neonatal hypercalcaemia as well. Under those circumstances, the affected infant who has defective CaSR function is being exposed to a normocalcaemic milieu from its mother. This could produce a form of secondary hyperparathyroidism in the fetus *in utero* as well. The severe nature of the hypercalcaemia in such an infant may be transient. Paediatric endocrinologists and geneticists will need to distinguish this presentation from NSHPT due to homozygous CaSR mutations.

Efficacy of Calcimimetics in Patients with FHH

Calcimimetics mimic or enhance the effects of calcium on CaSRs and are categorized as two types. Polyvalent cations including the naturally occurring ligands of the CaSR (e.g. calcium, magnesium, barium, strontium, and others) are type I calcimimetics. Type II calcimimetics are positive allosteric modulators that increase the sensitivity of the CaSR to its main physiologic ligand—calcium [73]. Type II calcimimetics may have some intrinsic agonistic activity [74], but they generally require extracellular calcium to be present to be active. Calcimimetics likely stabilize the transmembrane domain of the CaSR in a conformation that enhances CaSR coupling to downstream signalling molecules. To enhance CaSR function, calcimimetics may only need to bind to one monomer of a putative dimeric form of the CaSR [75]. In addition, calcimimetics have been proposed to act via ADIS to increase CaSR synthesis and trafficking to the cell surface [64]. Cinacalcet is the first CaSR allosteric modulator approved by the US Food and Drug Administration (FDA) for the treatment of patients with secondary hyperparathyroidism due to end-stage renal failure, inoperable PHPT, and parathyroid carcinoma [76].

Recent case reports have described treating FHH with calcimimetics [77–81]. Successful treatment included subjective improvement of the patient and a decreased serum calcium level, although not necessarily into the normal range. The conclusions from these case reports are limited. A controlled clinical trial would be the ideal means to test such therapy, but this has not been done. The calcimimetic cinacalcet can be used in adults with FHH in whom the serum calcium level is elevated to a level sufficient, in the assessment of the treating clinician, to cause symptoms of hypercalcaemia [77–82]. Adverse effects were mild in the cases reported to date [77–81]. Information on the safety and efficacy of calcimimetics in FHH is limited to a few reports in children [83] and adolescents [84].

In Vitro and *in Vivo* Studies with Calcimimetic: FHH Type 1

In the systems *in vitro* that have been studied, prolonged exposure of CaSR-expressing cells to a calcimimetic enhances the signalling responses and/or expression of most loss-of-function mutant CaSRs [60, 61, 77, 85–87]. These agents likely function as pharmacochaperones to promote mutant receptor synthesis and trafficking by binding to the transmembrane domain of newly synthesized CaSR within the ER [60, 61, 87]. In adults with FHH1 who are symptomatic from hypercalcaemia (usually with serum calcium levels >0.25 mM above the upper limit of normal), cinacalcet can be initiated (as deemed necessary) and increased according to the product prescribing information for PHPT [88]. Recurrent pancreatitis, which is rare in FHH1, may suggest the need for considering drug treatment [81], but this has not been studied in any prospective or controlled manner. At the beginning of treatment, serum calcium should be monitored at short intervals and then after any dose adjustments until the serum calcium level has stabilized. If there is an amelioration of symptoms or improvement in serum calcium levels during a trial of 8 to 12 weeks, the decision to continue treatment should be discussed with the patient. Serum calcium levels do not need to be normalized. Serum PTH levels often decrease, but not in all cases [79, 89]. In patients with FHH1, cinacalcet lowered serum calcium and PTH levels without major adverse effects such as hypocalcaemia and improved hypercalcaemia-related symptoms in the majority of reported case reports [77–79, 90]. A periodic trial off the drug every 1 to 2 years should be considered for one to three weeks to gauge the need for long-term treatment.

In Vivo and *in Vitro* Studies with Calcimimetic: FHH Type 2

Cinacalcet improves the signalling responses of CaSRs *in vitro* when $G\alpha_{11}$ proteins bear the loss-of-function mutations associated with FHH2 [91, 92]. The response to cinacalcet is likely determined by the location of the $G\alpha_{11}$ mutation [91]. The p.I200del mutation within the GTPase domain has required higher cinacalcet dosing to correct the intracellular calcium responses that mutant G-protein subunit generates, compared to cells expressing the p.L135Q mutation that is located within the $G\alpha_{11}$ helical domain [91]. In a patient with FHH2, treatment with cinacalcet (60 mg daily) normalized the serum calcium concentration. The treatment, however, failed to improve the patient's symptoms of headaches, constipation and pruritus and was discontinued after 4 months [92].

In Vitro and *in Vivo* Studies with Calcimimetic: FHH Type 3

Cinacalcet tends to correct the intracellular calcium signalling responses to high extracellular calcium in HEK293 cells in which mutant CaSR proteins are overexpressed. All three FHH3-causing AP2σ mutations (p.R15C, p.R15H, and p.R15L), when expressed in

HEK293 cells, demonstrated increased intracellular calcium signalling and MAPK responses to extracellular calcium after cells were treated with cinacalcet. This treatment, therefore, caused the cells to have signalling responses to high extracellular calcium comparable to cells expressing wild-type CaSRs and AP2σ proteins [80].

Three patients with FHH3, each with a different heterozygous mutation (p.R15C, p.R15H, or p.R15L), were treated with 30–60 mg cinacalcet daily. These patients included a 34-year-old female with a 12-year history of hypercalcaemia and fatigue, headaches, and persistent generalized aches which did not resolve after parathyroidectomy; a 22-year-old male suffering from hypercalcaemia, fatigue, and generalized rib pain; and a 52-year-old woman with hypercalcaemia, headaches, abdominal pain, vomiting, fatigue, and musculoskeletal pain that did not resolve after pamidronate infusion or parathyroidectomy. Cinacalcet reduced the serum calcium by ≥20% and lowered serum PTH levels to within the normal range [80]. Cinacalcet improved hypercalcaemia-related symptoms (fatigue, musculoskeletal pain, and headaches) without causing adverse effects such as hypocalcaemia. Treatment was well tolerated over a period of over 30 months [80].

One child with a chromosome 22q11.2 deletion syndrome and a FHH3-causing AP2σ mutation was treated with cinacalcet (30–60 mg daily). He developed symptoms of hypocalcaemia with a serum calcium in the lower half of the normal range, and therapy was discontinued [84]. Long-term surveillance of patients with different forms of FHH taking cinacalcet is recommended to assess the safety of this approach especially with regard to hypocalcaemia [80].

Prognosis

The prognosis of typical FHH is usually excellent. Patients with FHH in multiple kindreds have not demonstrated increased mortality, compared to unaffected family members. Atypical forms of FHH including type 3, particularly those with higher serum calcium and/or PTH levels or recurrent pancreatitis, have not been systematically examined for overall prognosis and long-term complications.

Neonatal Severe Primary Hyperparathyroidism (NSHPT)

NSHPT (OMIM #239200) is caused most commonly by homozygous or compound heterozygous loss-of-function mutations in the *CASR* [93]. NSHPT is typically a life-threatening disorder in early infancy, if left untreated. Newborns with NSHPT usually suffer from severe hypercalcaemia with levels as high as 7.7 mmol/L reported (normal range for a full-term newborn with birth weight over 1500 g, 2.10–2.65 mmol/L) [42], marked (5-to-10-fold) elevations of serum PTH concentrations, enlarged parathyroid glands, hypotonia, respiratory distress, and hyperparathyroid bone disease leading to bone deformities and multiple fractures [94]. Without functioning CaSRs in the parathyroid glands, PTH is not suppressed even at these very high serum calcium levels. If the mutant CaSR retains some capacity to signal, PTH might be suppressed but to a very limited degree. Emergent parathyroidectomy is usually required and lifesaving. More than 25 different mutations are associated with NSHPT, of which more than 40% are either nonsense or frameshift mutations, that lead to a truncated CaSR [36]. Often neonates with NSHPT are born to parents who are first-degree relatives and who both have FHH and the same mutation in the *CASR*. This leads to the homozygous form of the disease (NSHPT) in an offspring with both alleles affected identically [95]. NSHPT has also been described in a neonate with compound heterozygous mutations—one in each *CASR* allele [96]. Since such neonates (with either homozygous or compound heterozygous mutations) have no or very low levels of normal CaSRs, these infants present with severe hypercalcaemia and typically (but not always) will require urgent parathyroidectomy. Not every patient with homozygous inactivating mutation of the *CASR* suffers from NSHPT. One patient was described who was homozygous for a p.P39A mutation in the CaSR and was only identified in adulthood, despite serum calcium levels of 3.74–4.24 mmol/L [97]. When the mutation was studied *in vitro*, it displayed only mild functional impairment. Another patient presented at age 2 with moderate hypercalcaemia and fractional excretion of calcium below 0.01. Genetic analysis of the *CASR* in that case demonstrated a homozygous p.Q459R mutation within the ECD of the receptor. The patient displayed an autosomal recessive inheritance pattern. All affected individuals in the family who were heterozygous for the mutation were normocalcaemic, although in the upper range of normal. Unaffected individuals had serum calcium levels which were significantly lower [42].

Some infants with only a mild impairment of CaSR function, due to the presence of compound heterozygous *CASR* mutations, develop instead neonatal hyperparathyroidism (NHPT). These infants present with symptomatic hypercalcaemia and often fail to thrive. This presentation seems to occur instead of classical FHH (mild asymptomatic hypercalcaemia often discovered incidentally) due to additional environmental and/or genetic factors that result in fetal calcium deficiency [98]. Infants with NHPT may show less elevated but more symptomatically transient hypercalcaemia than the dramatic presentations of NSHPT. They may further show moderate to severe elevations in PTH and hyperparathyroid bone disease. Following conservative treatment, some infants even transition to the more asymptomatic form of FHH and have not even required parathyroid surgery. Factors contributing to a more severe phenotype *in utero* include gestation in an unaffected mother or coexistence of maternal vitamin D deficiency, which can worsen the degree of hyperparathyroidism [99]. The neonate might also experience a dominant-negative effect of an abnormal *CASR* gene on the remaining normal allele, due to CaSR surface dimerization. When a mutant receptor is coexpressed with the wild-type CaSR *in vitro*, the affinity for calcium may be reduced, possibly due to the abnormally functioning heterodimers that can form under such conditions [10]. Sequence analysis of the *CASR* will help to distinguish NSHPT and NHPT.

Before parathyroid surgery, bisphosphonates and the calcimimetic cinacalcet have been used in newborns to treat severe hypercalcaemia and slow bone demineralization. The response to cinacalcet is dependent on the underlying *CASR* mutation. If cinacalcet can bind to the mutated CaSR as a positive allosteric modulator, it can often improve CaSR signalling associated with many loss-of-function mutations and improve hypercalcaemia and bone mineralization [100–102]. However, in infants with NSHPT due to biallelic truncating

CASR mutations, for example, cinacalcet has been shown to be ineffective, due to the inability of the drug to bind to the CaSR and/or couple to downstream signalling pathways [103, 104].

Hypercalcaemia After Infancy and Primary Hyperparathyroidism (PHPT) in Patients With FHH

Cases have been reported in which loss-of-function *CASR* mutations become apparent in childhood or early adulthood, often because of pronounced hypercalcaemia. Homozygous loss-of-function mutations at the N-terminal region of the CaSR have led to symptomatic hypercalcaemia after infancy and required parathyroidectomy [105, 106]. Patients with PHPT due to parathyroid adenomas or hyperplasia have even been diagnosed with heterozygous or homozygous loss-of-function *CASR* mutations [107]. Homozygous *CASR* mutations in these adult-onset PHPT patients seem to affect extracellular calcium-sensing and intracellular calcium signalling less compared to homozygous mutations in infants with NSHPT [107]. *CASR* mutations located in the ECD of the receptor in patients with PHPT or severe FHH are associated with more pronounced hypercalcaemia and multigland disease. Surgical treatment might therefore require a four-gland rather than a focused minimally invasive parathyroid exploration [36, 107].

Conclusions

Several decades ago, the clinical entities of FHH and NSHPT emerged from clinical reports, which described the disorders as separate ones initially and then as related familial syndromes. As individual patients were studied in more depth with biochemical and physiologic testing, abnormalities in the calcium-sensing mechanism in the parathyroid glands and the kidneys emerged as the means to understand the clinical presentation. Finally, the pathogenesis of FHH types 1–3 and NSHPT were delineated, once *CASR* sequencing became available, and a deeper understanding of the signalling, biosynthetic, and trafficking pathways for the CaSR in target cells began to emerge.

The CaSR is the key molecule responsible for sensing tiny changes in calcium levels that are physiologically relevant and ultimately sets the serum calcium level. $G\alpha_{11}$ protein mediates downstream CaSR signal transduction by coupling to phospholipase C and eventually the mobilization of intracellular calcium. The AP2σ protein likely participates in CaSR signalling and trafficking.

In patients with PTH-dependent hypercalcaemia and CCCR <0.01 or in the CCCR overlap range of 0.01–0.02 between FHH and PHPT, the diagnosis of FHH usually can be established using the family history and biochemical screening of family members, if appropriate, to demonstrate an autosomal dominant pattern of hypercalcaemia in the patient and two or more additional family members. Mutational screening for *CASR* and *AP2S1* codon 15 is appropriate in patients in whom the diagnosis of FHH is suspected. If the screening is negative, then *GNA11* sequencing should be considered. Cinacalcet has been effective in lowering serum calcium and PTH concentrations in selected patients with FHH 1–3 and in some infants with NSHPT. Other types of CaSR modulators with different modes of action and potency may be developed in the future that will benefit those patients with hypercalcaemia-related symptoms.

4.5

Hypocalcaemic Disorders, Hypoparathyroidism, and Pseudohypoparathyroidism

Fadil M. Hannan, Bart L. Clarke, and Rajesh V. Thakker

Introduction

The concentration of ionized extracellular calcium is tightly regulated through the actions of the parathyroid glands (**Figure 4.5.1**). The parathyroids synthesize and secrete parathyroid hormone (PTH) in response to a reduction in the prevailing extracellular calcium concentration, which is sensed by the calcium-sensing receptor (CaSR) (**Figure 4.5.1**) [1]. The secreted PTH acts on the PTH1 receptor (**Figure 4.5.1**) to increase osteoclast-mediated bone resorption, promote urinary calcium reabsorption and the synthesis of 1,25-dihydroxyvitamin D, which in turn increases intestinal calcium absorption [1]. The causes of hypocalcaemia (**Box 4.5.1**) can be classified according to whether serum PTH concentrations are low (that is, hypoparathyroid disorders) or high (that is, disorders associated with secondary hyperparathyroidism or PTH resistance, as occurring in pseudohypoparathyroidism). Hypocalcaemia is most commonly caused by chronic renal failure, vitamin D deficiency, hypomagnesaemia, and hypoparathyroidism [2].

Hypocalcaemia

Epidemiology

Relatively few studies have described the epidemiology of hypocalcaemia, hypoparathyroidism, or pseudohypoparathyroidism. A recent large internal medicine hospital series including 30 813 patients showed that 3% had recognized hypocalcaemia at hospital admission [3]. Post-thyroid surgical clinical series describe transient hypocalcaemia in 25.4–83% of patients [4], with chronic hypocalcaemia more than 6 months after surgery occurring in 0.12–4.6% [5].

The prevalence of chronic hypoparathyroidism has been reported from various European countries and the United States to range between 10.1/100 000 in Norway [6], and 40/100 000 in Tayside, Scotland [7]. Most studies have shown the prevalence to be in the 20–30/100 000 range [8–12]. Only two studies have evaluated the incidence of hypoparathyroidism. One study in Denmark estimated the incidence to be 0.8/100 000/year [8], and the other study in India estimated the incidence to be 2.6/100 000/year [13].

The best prevalence estimate of chronic hypoparathyroidism in the United States is based on analysis of a large health plan claims database, which identified a total of 77 000 cases [9]. The longitudinal population-based Rochester Epidemiology Project was used to derive a prevalence estimate of 37/100 000 [10]. In the nationwide Danish historic cohort study, the prevalence of postsurgical hypoparathyroidism [8, 11, 12] was estimated to be 22/100 000, with the prevalence of non-surgical hypoparathyroidism 2.3/100 000. The study of hospitalized patients with hypoparathyroidism in Norway [6] showed the prevalence of postsurgical hypoparathyroidism to be 6.4/100 000, and non-surgical hypoparathyroidism 3.0/100 000.

The same Norwegian study estimated the prevalence of pseudohypoparathyroidism to be 0.8/100 000 [6]. The same study in India estimated the incidence of pseudohypoparathyroidism to be 0.16/100 000/year [13].

Clinical Features and Investigations

The clinical presentation of hypocalcaemia (serum ionized calcium <1.10 mmol/L or albumin-adjusted calcium <2.20 mmol/L) relates to its severity and rapidity of onset, and may range from an asymptomatic biochemical abnormality to a life-threatening disorder [2]. Severe hypocalcaemia (serum ionized calcium <0.95 mmol/L or serum albumin-adjusted calcium <1.90 mmol/L), particularly in the setting of acute-onset hypoparathyroidism (e.g. following surgical resection of the parathyroid glands), may lead to symptoms of neuromuscular irritability such as paraesthesiae of the circumoral region, fingers

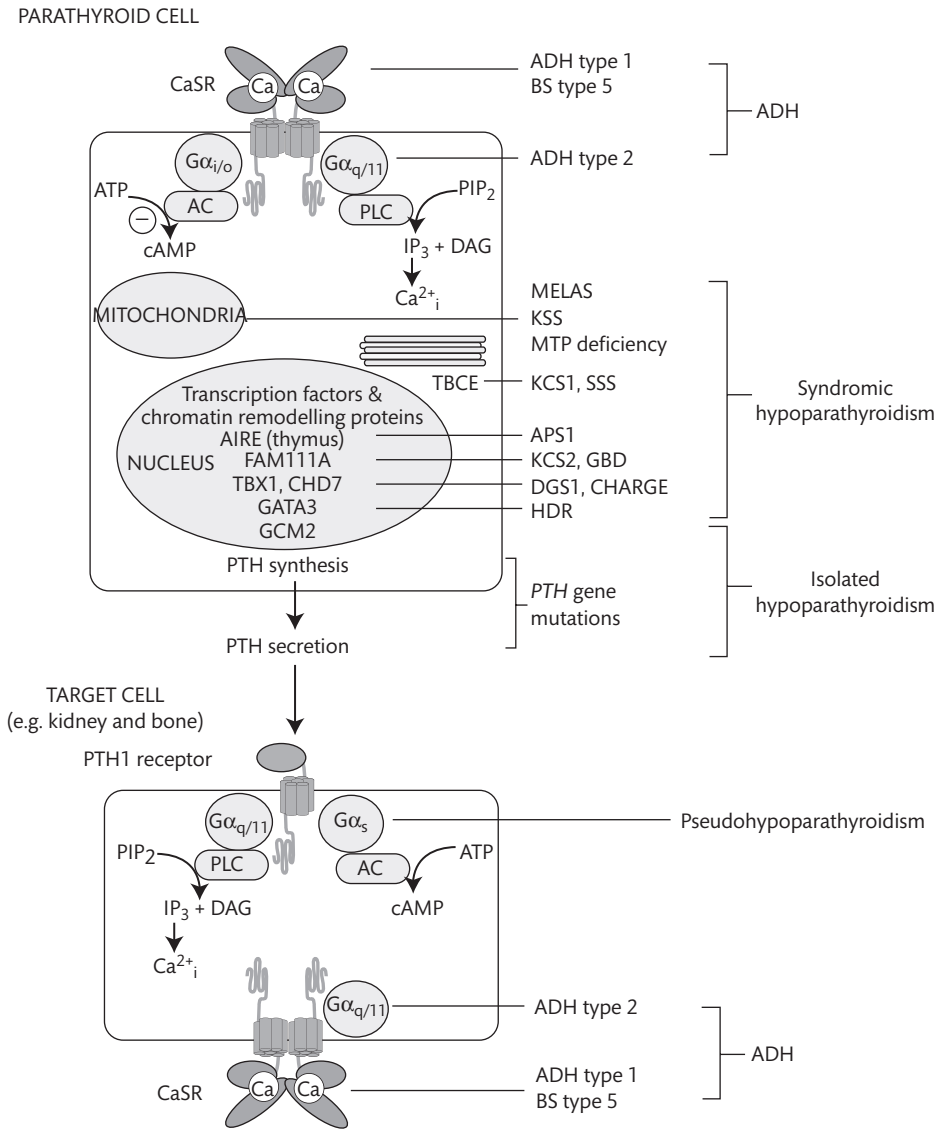

Figure 4.5.1 Components involved in the parathyroid regulation of calcium homeostasis. Alterations in extracellular calcium are detected by the calcium-sensing receptor (CaSR), which is expressed in parathyroid, kidney, and bone cells. The CaSR signals via the Gαq/11 proteins to stimulate phospholipase C (PLC), which catalyses the hydrolysis of phosphoinositide (PIP2) to inositol triphosphate (IP3), thereby increasing intracellular calcium (Ca2+i), and diacylglycerol (DAG). The CaSR also signals via the Gαi/o proteins, which inhibit adenylate cyclase (AC), thereby leading to a reduction in the formation of cAMP from adenosine triphosphate (ATP). In parathyroid cells, these proximal signals modulate downstream pathways, which lead to alterations in the synthesis and secretion of PTH. Secreted PTH acts on the PTH1 receptor in kidney and bone cells, which mediates signalling via the Gαs and Gαq/11 proteins to regulate calcium reabsorption, 1,25-dihydroxyvitamin D synthesis and bone resorption. Abnormalities in several genes and encoded proteins in these pathways—which regulate calcium-sensing and G-protein function; mitochondrial activity; tubulin formation; and gene transcription and chromatin remodelling—have been identified in patients with hypoparathyroid disorders (Table 4.5.2). ADH type 1, autosomal dominant hypocalcaemia type 1; ADH type 2, autosomal dominant hypocalcaemia type 2; BS type 5, Bartter syndrome type 5; MELAS, mitochondrial encephalopathy, stroke-like episodes, and lactic acidosis; KSS, Kearns-Sayre syndrome; MTP; mitochondrial trifunctional protein; KCS1, Kenny-Caffey syndrome type 1; KCS2, Kenny-Caffey syndrome type 2; SSS, Sanjad-Sakati syndrome; GBD, Gracile bone dysplasia; DGS1, DiGeorge syndrome type 1; HDR, hypoparathyroidism, deafness, and renal anomalies.

and toes; and also muscle cramps, carpopedal spasms, laryngospasm and bronchospasm, seizures of all types, and cardiac arrhythmias associated with prolongation of the QT interval on electrocardiogram (ECG) [1, 2]. Chronic hypocalcaemia (which has occurred over a period of months to years) may be associated with subcapsular cataracts, papilloedema and abnormal dentition [1, 2]. Moreover, patients with chronic hypocalcaemia caused by hypoparathyroidism frequently develop ectopic mineralization. Indeed, more than 70% of patients with idiopathic hypoparathyroidism have been reported to have calcifications within intracerebral regions such as in the basal ganglia [14].

Biochemical investigations are helpful in identifying the cause of hypocalcaemia and establishing the cause (Figure 4.5.2). For example, in hypoparathyroidism, serum calcium is low, phosphate is high, and PTH is low; renal function and concentrations of

Box 4.5.1 Causes of hypocalcaemia

Low parathyroid hormone levels (hypoparathyroidism)

- Parathyroid agenesis
  Isolated or part of complex developmental anomaly (e.g. DiGeorge syndrome)
- Parathyroid destruction
  Surgery*, irradiation
  Infiltration by metastases or systemic disease (e.g. amyloidosis or sarcoidosis) or by copper or iron overload (e.g. Wilson's disease, haemochromatosis, recurrent iron transfusions for thalassaemia)
  Autoimmune
  – Isolated
  – Pluriglandular Autoimmune Hypoparathyroidism
- Reduced parathyroid function
  Parathyroid hormone gene defects
  Hypomagnesaemia*
  Neonatal hypocalcaemia (may be caused by maternal hypercalcaemia)
  Autosomal dominant hypocalcaemia†

High parathyroid hormone levels (secondary hyperparathyroidism or parathyroid hormone resistance)

- Vitamin D deficiency*
  Reduced sunlight exposure*, nutritional lack*, malabsorption*, liver disease, chronic renal failure*
- Vitamin D resistance (rickets)
  Renal tubular dysfunction (Fanconi's syndrome), vitamin D receptor defects
- Drugs
  Calcium chelators (e.g. citrated blood transfusions, phosphate)
  Antiresorptives (e.g. bisphosphonates, denosumab)
  Calcimimetics (e.g. cinacalcet)
  Altered vitamin D metabolism (e.g. phenytoin, ketoconazole)
- Miscellaneous
  Acute pancreatitis
  Rhabdomyolysis
  Massive tumour lysis
  Osteoblastic metastases (e.g. from prostate)
  Toxic shock syndrome
  Hyperventilation
- Parathyroid hormone resistance
  Hypomagnesaemia, pseudohypoparathyroidism

* Most common causes
† Plasma parathyroid hormone concentrations may be normal

the 25-hydroxy and 1,25-dihydroxy metabolites of vitamin D are normal [2]. The features of pseudohypoparathyroidism (PHP) are similar to those of hypoparathyroidism except for PTH, which is markedly increased [1, 15]. In chronic renal failure, serum phosphate is high and alkaline phosphatase, creatinine and PTH are elevated; 25-hydroxyvitamin D is normal and 1,25-dihydroxyvitamin D is low. In vitamin D deficiency and osteomalacia, serum calcium, and phosphate are low, alkaline phosphatase and PTH are elevated, renal function is normal, and 25-hydroxyvitamin D is low [2].

Management of Acute Hypocalcaemia

Treatment should be given to symptomatic patients or asymptomatic patients with a serum calcium of less than 1.90 mmol/L who may be at high risk of developing complications. The preferred treatment for acute symptomatic hypocalcaemia is 10 ml 10% calcium gluconate (~2.25 mmol of calcium per 10 ml) i.v., diluted in 50 ml of 5% dextrose or 0.9% sodium chloride and given by slow injection (>5 min); this can be repeated to control symptoms. ECG monitoring and regular serum calcium assessment is required [16]. Continuing hypocalcaemia may be managed acutely by administration of a calcium gluconate infusion, e.g. 100 ml 10% gluconate (~22.5 mmol of calcium), in 1 litre of 5% dextrose or 0.9% sodium chloride. Generally, 0.30–0.40 mmol/kg of elemental calcium infused over 4–6 hours increases serum calcium by 0.5–0.75 mmol/L. If hypocalcaemia is likely to persist, oral vitamin D therapy should also be commenced. In hypocalcaemic patients who are also hypomagnesaemic, the hypomagnesaemia must be corrected before the hypocalcaemia will resolve. This may occur in the post-parathyroidectomy period or in those with severe intestinal malabsorption (e.g. as in coeliac disease) [17].

Management of Persistent Hypocalcaemia

The two major groups of drugs available for the treatment of hypocalcaemia are: supplemental calcium, about 10–20 mmol calcium 6–12 hourly and vitamin D preparations [18–20]. Patients with hypoparathyroidism seldom require calcium supplements after the early stages of stabilization on vitamin D. A variety of vitamin D preparations have been used (Table 4.5.1). These include: alfacalcidol (1α-hydroxycholecalciferol), 0.25–1.0 μg/day; and calcitriol (1,25-dihydroxycholecalciferol), 0.25–2.0 μg/day. In children, these preparations are prescribed in doses based on body weight. Calcitriol is probably the drug of choice because it is the active metabolite and, unlike alfacalcidol, does not require hepatic 25-hydroxylation. Close monitoring (at 1–2 week intervals) of the patient's serum and urine calcium are required initially, and at 3–6 monthly intervals once stabilization is achieved. The aim is to avoid hypercalcaemia, hypercalciuria, nephrolithiasis, and renal failure. In patients with hypoparathyroidism, which is inadequately controlled on vitamin D preparations, recombinant human PTH (rPTH) has been used to normalize serum calcium while reducing the risk of hypercalciuria [1]. A phase 3 randomized controlled clinical trial has demonstrated that once daily administration of rPTH(1-84) is effective at reducing the requirements for calcium and active vitamin D preparations in hypoparathyroid patients while maintaining stable serum calcium values [21]. In addition to its effects on mineral metabolism, rPTH(1-84) therapy has been shown to improve quality of life outcomes for hypoparathyroid patients [22]. This recombinant form of PTH is now licenced in the United States and Europe as an adjunct to calcium and vitamin D for the long-term management of hypoparathyroidism.

Hypocalcaemic Disorders

The application of molecular biology to the study of hypocalcaemic disorders has provided insights into the regulation of parathyroid gland development, PTH secretion, and action. Thus, studies of patients and mouse models with syndromic and non-syndromic forms of hypoparathyroidism have revealed that transcription factors (e.g. TBX1, GCM2, and GATA3) mediate patterning of the third pharyngeal pouch and parathyroid organogenesis, and are also involved in the elimination of auto-reactive T cells within the thymus (e.g. AIRE). Whereas characterization of the mutations causing autosomal dominant hypocalcaemia has demonstrated that the CaSR and G-protein

subunit α-11 (Gα11) proteins regulate PTH secretion. Furthermore, the identification of *PTH* mutations as a cause of hypoparathyroidism has provided insights into the cellular biosynthesis of PTH and the mechanisms governing its binding to the PTH1 receptor. Moreover, the demonstration of G-protein subunit α-s ($G\alpha_s$) mutations as the cause of PHP type Ia, PHP type Ib, and pseudopseudohypoparathyroidism, has highlighted the importance of $G\alpha_s$ in mediating the target organ actions of PTH. These advances together with the clinical features of these disorders will be reviewed in this chapter.

Hypoparathyroidism

Hypoparathyroidism is characterized by hypocalcaemia and hyperphosphataemia, which arise from a deficiency in PTH secretion or action (Box 4.5.1) [1]. Hypoparathyroidism may result from agenesis (e.g. DiGeorge syndrome) or parathyroid gland destruction (e.g. following neck surgery, or in autoimmune diseases), from reduced secretion of PTH (e.g. hypomagnesaemia or autosomal dominant hypocalcaemia), or resistance to PTH (which may occur as a primary disorder, e.g. pseudohypoparathyroidism or secondary to

hypomagnesaemia). In addition, hypoparathyroidism may occur as an inherited disorder (Table 4.5.2) that may either be part of a complex congenital defect (e.g. DiGeorge syndrome), or as part of a pluriglandular autoimmune disorder, or as a solitary endocrinopathy, which has been referred to as isolated hypoparathyroidism [1].

Isolated Hypoparathyroidism

Isolated hypoparathyroidism may either be inherited as an autosomal disorder caused by *PTH* or *GCM2* mutations, or as an X-linked disorder (Table 4.5.2), or it may be acquired as a consequence of surgical or autoimmune destruction of the parathyroid glands.

Autosomal Hypoparathyroidism Due to PTH Mutations

Autosomal dominant and recessive forms of isolated hypoparathyroidism are caused by mutations of the *PTH* gene, which consists of three exons and is located on chromosome 11p15 (Figure 4.5.3) [23]. Exon 1 of the *PTH* gene is untranslated, whereas exons 2 and

3 encode the 115-amino acid pre-pro-*PTH* peptide. Exon 2 encodes the initiation (ATG) codon, the prehormone sequence and part of the prohormone sequence, while exon 3 encodes the remainder of the prohormone sequence, the mature 84-amino acid PTH peptide, and the 3' untranslated region (Figure 4.5.3) [24].

Autosomal dominant hypoparathyroidism due to heterozygous *PTH* mutations has been reported in two unrelated families [25, 26]. In one family, a heterozygous single base substitution (T→C) in exon 2 of the *PTH* gene, which resulted in a p.Cys18Arg missense substitution within the hydrophobic core of the signal peptide was shown to impair processing of the mutant pre-pro-PTH to pro-PTH *in vitro* [25]. However, secretion of the preproPTH peptide harbouring the p.Cys18Arg mutation could be enhanced by the addition of 4-phenylbutyric acid, which is a pharmacological chaperone [27]. In another family, a heterozygous single base substitution (T→A) in exon 2 of the *PTH* gene, which resulted in a p.Met14Lys missense substitution in the signal peptide has been reported [26]. This mutation was predicted to impair cleavage of pre-pro-PTH, and *in vitro* studies showed intracellular retention of the mutant pre-pro-PTH peptide, which could be partially rescued by the addition of 4-phenylbutyric acid [26].

Autosomal recessive hypoparathyroidism due to homozygous *PTH* mutations that impaired processing of the PTH peptide have been identified in three unrelated families [24, 28, 29]. In one such family a donor splice-site mutation at the exon 2-intron 2 boundary has been identified [24]. This mutation involved a single base transition (g→c) at position 1 of intron 2 and an assessment of the effects of this alteration in the invariant gt dinucleotide of the 5' donor splice-site consensus on mRNA processing revealed that the mutation resulted in exon skipping, in which exon 2 of the *PTH* gene was lost and exon 1 was spliced to exon 3. The lack of exon 2 would lead to a loss of the initiation codon (ATG) and the signal peptide sequence, which are required respectively for the commencement of PTH mRNA translation and for the translocation of the PTH peptide [24]. In another family with autosomal recessive hypoparathyroidism a homozygous single base substitution (T→C) in exon 2, which resulted in a p.Ser23Pro missense substitution in the signal peptide was detected [29]. This mutation leads to the introduction of a mutant proline residue at the –3 position of the pre-pro-PTH protein cleavage site and is predicted to disrupt cleavage of the mutant pre-pro-PTH protein [29]. In the third unrelated family with autosomal recessive hypoparathyroidism, a homozygous single base substitution (C→A) in exon 2, which resulted in a stop codon (p.Ser23Stop) was detected [28]. This stop codon was predicted to be introduced at the pre-pro-PTH protein cleavage site, and would lead to a truncated and inactive PTH peptide [28]. A homozygous arginine-to-cysteine mutation has also been identified at codon 25, (p.Arg25Cys), of the mature PTH(1-84) peptide in a family with hypocalcaemia [30]. The plasma PTH levels of affected family members varied from low-normal to markedly elevated, depending on the type of PTH assay used [30]. In contrast to previously reported *PTH* gene mutations, which affect secretion of PTH, the p.Arg25Cys missense substitution was shown to diminish the binding of the mutant PTH peptide with the PTH/PTHrP receptor [30]. Moreover, the *PTH* p.Arg25Cys mutation interfered with PTH immunoassays that utilized antibodies affinity-purified using PTH 1-34 and 13-34 fragments, thereby explaining why some assays were unable to detect the mutant PTH peptide [30].

Autosomal Hypoparathyroidism Due to GCM2 Mutations

GCM2 (glial cells missing homolog 2) encodes the GCM2 transcription factor, which is expressed exclusively in the parathyroid glands, and promotes the differentiation and survival of parathyroid cells in the developing embryo [31], as well as upregulating CaSR and PTH expression (Figure 4.5.4) [32–34]. In support of this, mice homozygous for the deletion of *Gcm2* (*Gcm2*$^{-/-}$) lacked parathyroid glands and developed hypocalcaemia and hyperphosphatemia [35]. However, *Gcm2*$^{-/-}$ mice had PTH levels indistinguishable from

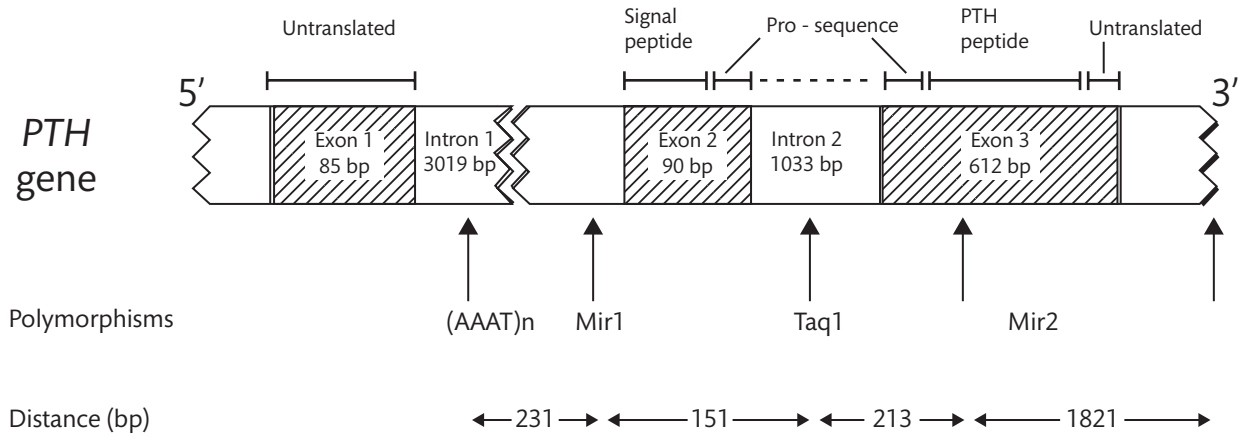

Figure 4.5.3 Schematic representation of the *PTH* gene. The *PTH* gene consists of three exons and two introns; the peptide is encoded by exons 2 and 3. The PTH peptide is synthesized as a precursor which contains a pre- and a pro-sequence. The mature PTH peptide, which contains 84 amino acids, and larger carboxy-terminal PTH fragments are secreted from the parathyroid cell. The polymorphic sites associated with the *PTH* gene are indicated. Two restriction fragment length polymorphisms (RFLPs) are associated with the PTH gene, and the TaqI polymorphic site is within intron 2 and the PstI polymorphic site is 1.7 kbp downstream in the 3′ direction of the gene. Two other polymorphisms of the PTH gene designated Mir1 and Mir2 are located in intron 1 and exon 3, respectively, and the tetranucleotide (AAAT)n polymorphism is in intron 1. Linkage disequilibrium between the (AAAT)n, TaqI, and PstI polymorphic sites has been established.

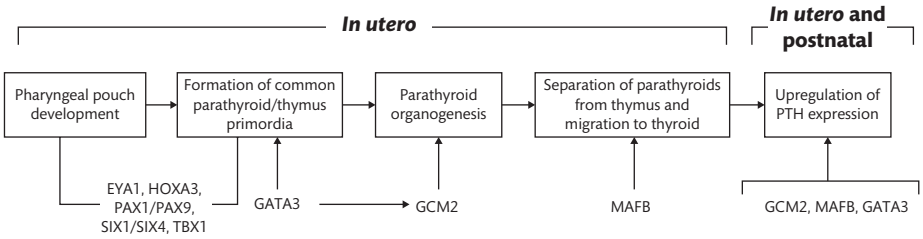

Figure 4.5.4 Transcription factors involved in parathyroid gland development and function. In humans, the parathyroid glands are derived from the endoderm of the third and fourth pharyngeal pouches. Whereas, in mice, the parathyroid glands develop with the thymus from the third pharyngeal pouch endoderm. A network of transcription factors such as the *EYA1*, *HOXA3*, *TBX1*, PAX1/PAX9, SIX1/SIX4, and GATA3 proteins mediate patterning of the third pharyngeal pouch and formation of the common parathyroid-thymus primordia. These transcription factors act in a spatiotemporal manner, for example, TBX1 is expressed in the pharyngeal endoderm and required for the development of the third pharyngeal pouch; whereas GATA3 is expressed in the common parathyroid-thymus primordia and mediates the differentiation of parathyroid and thymus progenitor cells. Moreover, GATA3 regulates the expression of GCM2, which is expressed in the parathyroid domain of the common primordia and mediates the initial stages of parathyroid organogenesis. MAFB is also expressed in the parathyroid domain and facilitates separation of the parathyroid glands from the thymus, and also the migration of the parathyroids towards the thyroid gland. GATA3, GCM2, and MAFB also act synergistically to upregulate PTH expression.

those of wild-type ($Gcm2^{+/+}$) mice, and the source of this auxiliary PTH in $Gcm2^{-/-}$ mice was identified to be a cluster of thymic PTH-expressing cells [35].

GCM2 mutations are associated with autosomal recessive and dominant forms of isolated hypoparathyroidism (Table 4.5.2). Homozygous *GCM2* mutations have been identified in patients with autosomal recessive hypoparathyroidism [36], while in another family a homozygous missense mutation (p.Arg47Leu) of the DNA binding domain was identified [37]. Functional analysis, using electrophoretic mobility shift assays (EMSAs), of this p.Arg47Leu *GCM2* mutation revealed that it resulted in a loss of DNA binding ability of the mutant *GCM2* protein [37]. Heterozygous *GCM2* mutations, which consist of single nucleotide deletions (c.1389delT and c.1399delC) that introduce frame-shifts and premature truncations, and a missense mutation, p.Asn502His, have also been identified in three unrelated families with autosomal dominant hypoparathyroidism [38, 39]. These mutations were shown, by using a *GCM2*-associated luciferase reporter, to inhibit the action of the wild-type transcription factor, thereby indicating that these *GCM2* mutants have dominant-negative properties [38, 39].

X-Linked Recessive Hypoparathyroidism

Hypoparathyroidism with an X-linked recessive transmission pattern was initially reported in two multigenerational kindreds [40, 41]. Only males were noted to be hypocalcaemic, which occurred in association with an absence of parathyroid tissue [42]. The relatedness of the two kindreds has been established by mitochondrial DNA sequence analysis [43]. Studies utilizing X-linked polymorphic markers in these families localized the mutant gene to chromosome Xq26-q27 [44], and a molecular deletion-insertion that involves chromosome 2p25 and Xq27 has been identified [45]. This deletion-insertion is located ~67 kb downstream of the SRY-box 3 (*SOX3)* gene (Table 4.5.2), which is related to *SRY*, the sex determining gene on the Y chromosome. The deletion-insertion is likely to result in altered *SOX3* expression, as *SOX3* expression has been reported to be sensitive to position-effects caused by X-chromosome abnormalities [46]. Indeed, reporter-construct studies of the mouse *Sox3* gene have demonstrated the presence of both 5' and 3' regulatory elements [47] and thus it is possible that the deletion-insertion in the X-linked recessive hypoparathyroid patients may have a position-effect on *SOX3* expression. More recently, another unrelated family with X-linked hypoparathyroidism was identified and whole genome sequence (WGS) analysis revealed an interstitial deletion-insertion that cosegregated with the hypoparathyroidism [48]. This deletion-insertion involves an ~50 kb region of chromosome 2p25.3 that has been duplicated and inserted into the X-chromosome, and which has resulted in a 1.4 kb deletion located 81.5 kb downstream of *SOX3* [48]. Thus, these findings support a role for *SOX3* in parathyroid gland development, and consistent with this, *SOX*3 has been shown to be expressed in the developing parathyroids of mouse embryos [45].

A recent report has also highlighted that the four and a half LIM domains 1 (*FHL1*) gene, which is located on chromosome Xq26.3, may also represent an additional gene for X-linked hypoparathyroidism [49], as a *FHL1* missense variant (p.Arg95Trp) was detected in a 4 year old male with isolated severe hypoparathyroidism [49]. Functional studies showed that knockdown of the FHL1 paralog in zebrafish increased plasma calcium concentrations, and that introduction of wild-type FHL1 into cells transfected with a luciferase reporter gene that is under the control of the human PTH promoter, resulted in increased PTH promoter activity [49]. However, FHL1 is predicted to have a low level of expression in human parathyroids [49], and thus the role of this protein in calcium homeostasis remains to be established. The possible deleterious effects on mammalian parathyroid gland activity of this p.Arg95Trp missense variant of FHL1 also remain to be established.

Acquired Forms of Isolated Hypoparathyroidism

Anterior neck surgery represents the major cause of acquired hypoparathyroidism (Box 4.5.1) and accounts for ~75% of cases [1]. Hypoparathyroidism may arise in patients undergoing total parathyroidectomy, or because of intraoperative trauma to the parathyroid glands, inadvertent gland removal, or gland devascularization; and occurs most commonly following total thyroidectomy or after radical neck dissection for head and neck malignancies [50]. Hypoparathyroidism may also occur following neck

irradiation, or because of parathyroid gland infiltration by metastases or systemic disease (e.g. amyloidosis and sarcoidosis), or from copper or iron overload (e.g. Wilson's disease, haemochromatosis, or recurrent blood transfusions for thalassaemia) [1]. Transient or reversible forms of acquired hypoparathyroidism include neonatal hypoparathyroidism caused by maternal hypercalcaemia, and hypoparathyroidism caused by hypomagnesaemia (serum magnesium <0.5 mmol/L) [17, 51]. Some cases of isolated hypoparathyroidism, in which no other cause can be identified, have been considered to be caused by autoimmune destruction of the parathyroid glands. However, formal criteria for diagnosing isolated autoimmune hypoparathyroidism have not been established and suitable autoantibody tests are not available for clinical use [1].

Complex Syndromes Associated with Hypoparathyroidism

Hypoparathyroidism may be associated with congenital developmental anomalies such as the DiGeorge and hypoparathyroidism, deafness, and renal anomalies (HDR) syndromes, and also syndromes associated with growth failure or dwarfism (Table 4.5.2). Syndromic forms of hypoparathyroidism may also be caused by mitochondrial disorders or the pluriglandular autoimmune syndrome.

DiGeorge Syndrome

Patients with the DiGeorge syndrome (DGS) typically suffer from hypoparathyroidism, immunodeficiency, cardiac outflow tract malformations; facial dysmorphia and palatal dysfunction [52]. DGS has been reported in up to 60% of children with familial or idiopathic forms of hypoparathyroidism [53], and has a wide spectrum of severity. Most commonly, hypoparathyroidism associated with DGS presents in the neonatal period with marked hypocalcaemia, which may cause laryngospasm or seizures [54]. However, the hypoparathyroidism may be transient and characterized by serum calcium concentrations that normalize during infancy and early childhood. Some individuals with DGS may only develop hypocalcaemic symptoms in adolescence or adulthood [54, 55]. Most cases of DGS are sporadic but an autosomal dominant inheritance of DGS has been observed in up to 28% of cases [52]. DGS is most commonly caused by a heterozygous 3 Mb microdeletion of chromosome 22q11.2 [52], which is referred to as DGS type 1 (DGS1). The deleted region encompasses the *TBX1* gene, which encodes a T-box transcription factor that regulates histone modification and is involved in parathyroids and thymic development (Figure 4.5.4) [52]. *TBX1* mutations have been identified in some DGS patients who did not have deletions of chromosome 22q11.2, and demonstrated to lead to all of the major phenotypes of DGS [56]. Furthermore, transgenic mice with deletion of *Tbx1* have been reported to have a phenotype that is similar to that of DGS1 patients [57].

Chromosome 10p deletions have been detected in some DGS patients [58] and this is referred to as DGS type 2 (DGS2). The nebulette (*NEBL*) gene, located on chromosome 10p, has been reported to be deleted in DGS2 patient cell lines, and thus may be the responsible gene for DGS2 (Table 4.5.2) [59]. Moreover, some DGS patients have features of the CHARGE syndrome, which is characterized by coloboma, heart abnormalities, choanal atresia, growth retardation, and genitourinary and/or ear anomalies [60]; and is caused by heterozygous mutations of the *CHD7* gene (Table 4.5.2). *CHD7* encodes the chromodomain helicase DNA binding protein 7 [60], which is expressed within the pharyngeal ectoderm [61], and may play a role in pharyngeal region development.

Hypoparathyroidism, Deafness, and Renal Anomalies (HDR) Syndrome

The combined inheritance of HDR anomalies as an autosomal dominant trait was reported in one family in 1992 [62]. Patients had asymptomatic hypocalcaemia with undetectable or inappropriately normal serum concentrations of PTH, and normal brisk increases in plasma cAMP in response to the infusion of PTH. The patients also had bilateral, symmetrical, sensorineural deafness involving all frequencies. The renal abnormalities consisted mainly of bilateral cysts that compressed the glomeruli and tubules and lead to renal impairment in some patients. Cytogenetic and deletion mapping studies involving additional HDR patients defined a critical 200-kb region on 10p14–10pter that contained the *GATA3* gene (Table 4.5.2) [63]. GATA3 belongs to a family of dual zinc-finger transcription factors that are involved in vertebrate embryonic development. DNA sequence analysis in HDR patients has identified mutations that resulted in a haploinsufficiency and loss of GATA3 function [63–65]. To date, more than 50 different heterozygous germline *GATA3* abnormalities, which comprise point-mutations and whole gene deletions have been reported [63–71]. The majority (>75%) of these HDR associated mutations are predicted to result in truncated forms of the GATA3 protein. Over 90% of patients with two or three of the major clinical features of the HDR syndrome (i.e. hypoparathyroidism, deafness, or renal abnormalities), have a *GATA3* mutation [64]. The HDR phenotype is consistent with the expression pattern of GATA3 during human and mouse embryogenesis in the developing kidney, otic vesicle, and parathyroids. However, GATA3 is also expressed in developing central nervous system (CNS) and the haematopoietic organs in man and mice, and this suggests that GATA3 may have a more complex role. Indeed, homozygous *Gata3* null mice ($Gata3^{-/-}$) have defects of the CNS and a lack of T-cell development, and die *in utero* [72]. Whereas, heterozygous *Gata3* null mice ($Gata3^{+/-}$) are viable and have hearing loss [73], in addition to having a smaller parathyroid-thymus primordia and an inadequate increase in plasma PTH in response to induced hypocalcaemia [74]. These studies of HDR patients and *Gata3* mutant mice indicate an important role for GATA3 in parathyroid development (Figure 4.5.4).

Additional familial syndromes characterized by hypoparathyroidism, deafness, and/or renal anomalies such as Barakat syndrome have been reported (Table 4.5.2) [75]. Molecular genetic studies have not been reported for these families.

Mitochondrial Disorders Associated with Hypoparathyroidism

Hypoparathyroidism has been reported to occur in three mitochondrial disorders: the Kearns–Sayre syndrome (KSS), the MELAS syndrome (mitochondrial encephalopathy, stroke-like episodes, and lactic acidosis) and the mitochondrial trifunctional protein (MTP) deficiency syndrome [76–78]. KSS is characterized by progressive external ophthalmoplegia and pigmentary retinopathy occurring at less than 20 years of age [77]. The MELAS syndrome consists of a childhood onset of mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes [76]. Mitochondrial DNA abnormalities such as deletions, duplications, and missense substitutions cause KSS and MELAS (Table 4.5.2, Figure 4.5.1) [53, 58, 76]. Whereas,

MTP deficiency syndrome, which is a disorder of fatty-acid oxidation associated with cardiomyopathy, peripheral neuropathy, pigmentary retinopathy and liver dysfunction, is caused by mutations of the *HADHB* gene on chromosome 2p23 (Table 4.5.2), which encodes the MTP β-subunit [78].

Hypoparathyroid Syndromes Associated with Growth Failure or Dwarfism

Hypoparathyroidism occurs in more than 50% of patients with Kenny-Caffey syndrome (KCS) [58], which is also characterized by short stature and osteosclerotic bone dysplasia. KCS may be inherited as an autosomal recessive (KCS type 1, KCS1) or dominant (KCS type 2, KCS2) disorder [58]. The Sanjad-Sakati syndrome (SSS), which is also known as the hypoparathyroidism-retardation-dysmorphism syndrome, affects Middle Eastern populations and has a similar phenotype to KCS [79]. SSS and KCS1 are caused by mutations of the *TBCE* gene (Table 4.5.2) [80], which encodes a chaperone protein required for the correct folding of α-tubulin subunits (Figure 4.5.1) [80], and is postulated to play a role in parathyroid gland migration [81]. KCS2 is caused by heterozygous missense mutations of the family with sequence similarity 111 member A (*FAM111A*) gene (Table 4.5.2), which modulates DNA replication and chromatin maturation (Figure 4.5.1), and may be involved in embryonic development [82, 83]. A truncating *FAM111A* mutation, p.Ser342del, has been shown to cause gracile bone dysplasia (GBD) (Figure 4.5.1), which occurs in association with hypoparathyroidism, and represents a perinatally lethal condition [83]. Hypoparathyroidism has also been reported in association with the Dubowitz syndrome (Table 4.5.2), which is characterized by multiple congenital anomalies that include microcephaly and growth retardation [84].

Pluriglandular Autoimmune Hypoparathyroidism

Hypoparathyroidism may occur in association with candidiasis and autoimmune Addison's disease, and the disorder has been referred to as either the autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED) syndrome or the autoimmune polyglandular syndrome type 1 (APS1) [85]. This disorder has a high incidence in Finland [86], and a genetic analysis of Finnish families indicated autosomal recessive inheritance of the disorder, and mapped the *APECED* gene to chromosome 21q22.3 (Table 4.5.2) [87]. Further positional cloning approaches led to the isolation of the autoimmune regulator (*AIRE)* gene from chromosome 21q22.3. This gene encodes a 545 amino acid protein that contains transcriptional factor motifs such as zinc-finger motifs, a proline-rich region and LXXLL motifs [88, 89]. Greater than 100 APECED-causing *AIRE* mutations have been reported to date, and four *AIRE* mutations have been shown to commonly occur in APECED families and these are: p.Arg257Stop in Finnish, German, Swiss, British and Northern Italian families; p.Arg139Stop in Sardinian families; p.Tyr85Cys in Iranian Jewish families; and a 13 bp deletion in exon 8 in British, Dutch, German, and Finnish families [89–91]. Occasionally, biallelic *AIRE* mutations have been reported in patients with isolated hypoparathyroidism [92, 93]. AIRE has been shown to regulate the elimination of organ-specific T cells in the thymus, and thus APECED is likely to be caused by a failure of this specialized mechanism for deleting forbidden T cells, and establishing immunologic tolerance [94].

Autosomal Dominant Hypocalcaemia

Autosomal dominant hypocalcaemia (ADH) is comprised of two genetically distinct disorders, designated as ADH types 1 and 2, which are caused by germline gain-of-function mutations of the CaSR and $G\alpha_{11}$ proteins, respectively (Table 4.5.2) [95].

CaSR and $G\alpha_{11}$

The human CaSR is a $G\alpha_{q/11}$ and $G\alpha_{i/o}$ -coupled G-protein coupled receptor (Figure 4.5.1), encoded by the *CASR* gene on chromosome 3q21.1 [95]. The CaSR is highly expressed in the parathyroid glands and kidneys, where it regulates the set-point for PTH secretion and decreases renal tubular calcium reabsorption, respectively [95]. CaSR cell-surface expression is regulated by agonist-driven insertional signalling (ADIS), which promotes anterograde trafficking of newly synthesized CaSRs to the plasma membrane [96], and also by retrograde trafficking of cell-surface CaSRs, which is mediated by the adaptor-related protein complex-2 (AP2) [97].

Autosomal Dominant Hypocalcaemia Type 1

Autosomal dominant hypocalcaemia type 1 (ADH1), which is due to gain-of-function CaSR mutations (Table 4.5.2), is characterized by hypocalcaemia, mild hypomagnesaemia, hyperphosphataemia, and serum PTH concentrations which are often detectable and within the lower half of the reference range [98]. Patients with ADH also have significantly increased urinary calcium excretion compared to hypoparathyroid patients [99]. Some patients with ADH have been reported to have ectopic calcifications affecting the basal ganglia and/or elevations in bone mineral density (BMD) [100], and some patients with severe gain-of-function CaSR mutations may also develop Bartter syndrome type 5, which is characterized by renal salt wasting leading to volume depletion, hyper-reninaemic hyperaldosteronism and hypokalaemic alkalosis [101]. Over 70 different CaSR mutations have been identified in ADH1 patients and families to date [95, 102].

Autosomal Dominant Hypocalcaemia Type 2

Mutations of the *CASR* gene are not detected in ~30% of ADH patients, and germline mutations of $G\alpha_{11}$, which is encoded by the *GNA11* gene on chromosome 19p13.3 (Table 4.5.2), have been reported in seven such ADH patients and families [98, 103–106]. *In vitro* studies of these $G\alpha_{11}$ mutations, which all comprise missense substitutions, have shown cells expressing the mutant $G\alpha_{11}$ proteins to have enhanced CaSR-mediated signalling responses, consistent with a gain-of-function [98, 103, 105]. These individuals and families with gain-of-function $G\alpha_{11}$ mutations were designated as having ADH type 2 (ADH2). ADH2 is associated with a milder urinary phenotype, with significantly reduced urinary calcium excretion compared to ADH1 [103]. Moreover, short stature caused by postnatal growth insufficiency has been reported in two ADH2 kindreds [103, 106].

Pseudohypoparathyroidism

Pseudohypoparathyroidism is caused by renal resistance to PTH, and is mainly due to abnormalities of Gαs, which mediates PTH1 receptor signalling (Figure 4.5.1) [15]. The Gαs protein is encoded by *GNAS*, which is a complex imprinted locus, and maternally

Table 4.5.3 Clinical, biochemical, and genetic features of hypoparathyroid and pseudohypoparathyroid disorders

	Hypoparathyroidism	Pseudohypoparathyroidism (PHP)				
		PHPIa	PPHP	PHPIb	PHPIc	PHPII
AHO manifestations	No	Yes	Yes	No	Yes	No
Serum calcium	↓	↓	N	↓	↓	↓
Serum PO_4	↑	↑	N	↑	↑	↑
Serum PTH	↓	↑	N	↑	↑	↑
Response to PTH:						
Urinary cAMP*a* (Chase–Aurbach test)	↑	↓	↑	↓	↓	↑
Urinary PO_4 (Ellsworth–Howard test)	↑	↓	↑	↓	↓	↓
Gsα activity	N	↓	↓	N	N	N
Inheritance	AD/AR/X	AD	AD	AD	AD	Sporadic
Molecular defect	PTH/CaSR/ GATA3/ Gcm2/ others	GNAS1	GNAS1	?GNAS1	?adenyl cyclase	?cAMP targets
Other hormonal resistance	No	Yes	No	No	Yes	No

↓ = decreased, ↑ = increased, N = normal, AD = autosomal dominant, AR = autosomal recessive, X = X-linked, AHO = Albright's hereditary osteodystrophy,? = presumed, but not proven.
*a*plasma cAMP responses are similar to those of urinary cAMP.

inherited inactivating coding-region mutations give rise to PHP type 1a (PHP1a) (Table 4.5.3), which is characterized by PTH resistance (hypocalcaemia, hyperphosphataemia, elevated serum PTH, and blunted cAMP response to exogenous PTH), together with features of Albright's hereditary osteodystrophy (AHO) such as short stature, obesity, round facies, subcutaneous calcifications, and brachydactyly [15]. Whereas, paternally inherited inactivating coding-region *GNAS* mutations cause pseudopseudohypoparathyroidism, which is characterized by AHO in the absence of PTH resistance (Table 4.5.3). Abnormalities of the upstream regions of the *GNAS* locus, or of the closely linked *STX16* and *NESP55* genes, which affect *GNAS* methylation, have been reported to cause PHP type 1b (Table 4.5.3) [107, 108], which is associated with PTH resistance in the absence of AHO [15]. Epigenetic or coding-region *GNAS* abnormalities may also cause PHP type 1c (PHP1c) (Table 4.5.3), which has a similar phenotype to PHP1a, except that altered Gαs activity is not observed in *in vitro* assays involving PHP1c patient-derived erythrocytes [109]. In contrast to PHP type 1, which has a blunted cAMP response; PHP type 2 is associated with a conserved cAMP response, and in some cases may represent an acquired condition caused by vitamin D deficiency [110].

Bones and the Kidney

The Practical Conundrum: Distinguishing Between Osteoporosis and the Bone Diseases that Accompany Chronic Renal Failure

Paul D. Miller and Michael Pazianas

Introduction

Osteoporosis may coexist with chronic kidney disease–mineral and bone disorder (CKD-MBD) and osteoporotic fractures occur in all stages of CKD (**Box 4.6.1**) [1]. Management of osteoporosis in CKD should consider the pathophysiology of both disorders. Diagnosis and management of osteoporosis in patients with stages 1–3 CKD and patients without CKD are similar, but diagnosis and management decisions differ greatly once patients have stages 4–5 CKD. Discriminating between osteoporosis and CKD-MBD is best accomplished with quantitative bone histomorphometry. Biochemical markers, especially intact parathyroid hormone and bone-specific alkaline phosphatase also may be helpful. When the diagnosis of osteoporosis is established, management in stages 4–5 CKD may include antiresorptive or anabolic agents, though evidence for efficacy is marginal in advanced CKD.

Mechanisms of Reduction in GFR: Age vs. Intrinsic Renal Disease

Glomerular filtration rate (GFR) decreases with increasing age especially after age 60 [2]. Bone strength declines with age, in part due to the decline in bone quality [3, 4], which contributes ~50% to the overall strength of bone. Bone quality is a broad term that defines the microarchitectural changes in bone (trabecular number and connectivity, cortical thinning, and increased cortical porosity) that makes an older bone more likely to break when compared with younger bone, even at the same bone density. Many of the biochemical derangements that accompany progressive CKD are contributing to the altered bone quality as well as increased fracture risk seen in CKD patients when compared to the lower risk in subjects of same age and bone mineral density (BMD) but without CKD [5].

The average rate of GFR reduction that accompanies increasing age is ~1–2 ml/min/year [6]. The mechanism for age-related reduction in renal function is multifactorial and is certainly related, in part, to vascular changes that accompany ageing. Age-related decrease in GFR is not associated with meaningful proteinuria or reduction in renal size as measured by ultrasound (US) or computerized tomography (CT) [7]. While GFR may decrease with advancing age, it is unusual that age alone is responsible for GFR reduction to levels lower than 30 ml/min. Patients with GFR values less than 30 ml/min usually have other reasons for their more severe, stage 4–5 CKD (diabetes mellitus and hypertension, for example). In all of the postmenopausal osteoporosis clinical registration trials, patients were excluded if they had a GFR under 30 ml/min.

Fractures in Patients with CKD: The Pathophysiological Origins of Skeletal Fragility

Fracture risk doubles in CKD beginning with stage 3A as compared to subjects with comparable BMD and age without CKD [8]. The

Box 4.6.1 The National Kidney Foundation (NKF) has classified chronic kidney disease (CKD) into five stages according to the estimated glomerular filtration rate (eGFR)

*Stage 3 CKD has been subdivided by the Kidney Disease Improving Global Outcome (KDIGO) into two separate stages

Stage 1 CKD: eGFR ≥ 90 ml/min with evidence of intrinsic renal damage (proteinuria or microscopic haematuria).

Stage 2 CKD: eGFR = 60–89 ml/min with evidence of intrinsic renal damage (proteinuria or microscopic haematuria).

Stage 3 CKD: eGFR = 30–59 ml/min without evidence of intrinsic renal damage (proteinuria or microscopic haematuria)*.

- **Stage 3A: eGFR 30–59 ml/min, and**
- **Stage 3B: eGFR 30–44 ml/min**

Stage 4 CKD: eGFR = 15–29 ml/min without evidence of intrinsic renal damage.

Stage 5 CKD: eGFR <15 ml/min and has also been divided into those not on dialysis and those on dialysis (stage 5D).

exact mechanism(s) of why there is greater skeletal fragility by stage 3A CKD than in persons without CKD or even in stage 1–2 CKD are not clearly delineated (Box 4.6.2) [9, 10].

Parathyroid hormone (PTH) levels rise progressively once the GFR falls to below 60 ml/min [11]. Some of the highest levels of PTH are seen in severe CKD (stage 5). PTH levels above 350 pg/ml are highly associated with quantitative bone histomorphometry features of osteitis fibrosa cystica [12]. On the opposite side of the bone histomorphometry spectrum that is seen in CKD, PTH levels below 150 pg/ml and especially below 100 pg/ml are highly correlated with very low bone turnover and often adynamic bone disease [13–15]. The latter diagnosis requires the complete absence of tetracycline labels, thin osteoid (matrix), and few or absent bone cells (osteoblasts and osteoclasts) [16].

Phosphate retention has a direct negative effect on bone mineralization [17]. It stimulates PTH secretion and reduces the production of 1,25(OH)2D and phosphate reabsorption [18] in the kidney. Phosphate retention is the stimulus for the increased secretion of osteocyte-derived fibroblast growth factor 23 (FGF-23), a phosphaturic hormone [19] which also reduces the renal production of $1,25(OH)_2D$ and rises in the serum before PTH—the other phosphaturic hormone [20]. Serum FGF-23 is inversely correlated with bone formation. Excessive production or absence of FGF-23 with normal renal function leads to defects in mineralization with accumulation of osteoid [21–23].

The active metabolite of vitamin D [$1,25(OH)D_2$] in concert with PTH and FGF-23, controls calcium and phosphorus homeostasis, and its serum concentration is a mirror image of serum phosphorus. The kidney is the main site of $1,25(OH)_2D$ production with PTH being the major stimulator. As part of the feedback loop, $1,25(OH)_2D$ suppresses PTH production. The production of $1,25(OH)_2D$ in the kidney however is decreased by FGF-23, an effect which is augmented by increased degradation as well. The reciprocal action of $1,25(OH)_2D$ is a lower PTH, increased FGF-23 production in bone, and upregulation of klotho, a cofactor for FGF-23 signalling [24].

In the intestine, $1,25(OH)_2D$ increases calcium and phosphate absorption. In the kidney, it enhances the PTH action on calcium transport and induces the synthesis of TRPV5 and the calbindins. A major indirect effect of 1,25(OH)2D on bone is calcium and phosphate absorption from the intestine. It could also have direct effects on bone formation and resorption.

Chronic metabolic acidosis has profound effects on bone [25, 26]. The retained hydrogen ions (H^+) are buffered by bone calcium carbonate ($CaCO_3$) and, as the negative ion carbonate (CO_3^-) binds to H^+ ion, calcium is released. In addition, chronic metabolic acidosis is associated with impaired bone mineralization and osteoid accumulation.

Box 4.6.2 The factors that are believed to contribute to greater bone fragility in CKD

It is very likely that the cause is multifactorial

1. Sustained secondary hyperparathyroidism
2. Phosphorus retention and impairment in bone mineralization
3. Elevated Fibroblast Growth Factor 23 (FGF 23)
4. Low renal production of 1,25 dihydroxy-vitamin D
5. Chronic metabolic acidosis (either an anion gap or non-anion gap, e.g. renal tubular acidosis)
6. Greater risk for falling (multifactorial)

Renal Bone Diseases and Osteoporosis: Partners Intertwined

The National Institutes of Health (NIH) defines osteoporosis as: 'A systemic skeletal disease characterized by low bone mass and microarchitectural deterioration of bone tissue with a consequent increase in bone fragility and susceptibility to fracture' [27]. Since all forms of renal bone disease may not always have a low BMD despite the altered microachitecture, one could make the case that the traditional renal bone diseases defined by quantitative histomorphometry (osteomalacia, hyperparathyroid bone disease, adynamic renal bone disease, and mixed renal bone disease) (Figures 4.6.1, 4.6.2, and 4.6.3) also have a form of osteoporosis by NIH criteria [28]. Recently, Professor Sharon Moe has coined the phrase 'Renal Osteodystrophy or Kidney-Induced Osteoporosis?' that recognizes the combination of traditional renal bone diseases accompanying the NIH definition of osteoporosis [29]. While scientifically correct, the clinician must decide what specific metabolic bone disease the patient has in order to implement proper treatment strategies. Are the fractures due to osteoporosis or renal osteodystrophy (defined by histomorphometry)?

The term 'Chronic Kidney Disease–Mineral and Bone Disorder (CKD-MBD)' was introduced in 2005 to describe the broader clinical syndrome encompassing mineral, bone, and calcific cardiovascular abnormalities that develop as a complication of CKD [30]. CKD-MBD defines the interactions between the kidney, bone, and parathyroid glands that lead to hyperphosphatemia and its accompanying vascular disease. Since then, the term renal osteodystrophy is used exclusively to define the bone pathology associated with CKD. Since CKD-MBD is a multisystem disease complex, it has no ICD 10 code nor any specific treatment intervention other than attempting to mitigate hyperphosphatemia with oral phosphate binders, and the magnitude of severity of secondary hyperparathyroidism. Administration of monoclonal antibodies to FGF-23, only used experimentally so far, lead to more severe hyperphosphatemia [31].

The spectrum of renal osteodystrophy consists of the predominant hyperparathyroid-mediated high-turnover bone disease

(osteitis fibrosa), osteomalacia (defined as a mineralization lag time greater than 100 days), low-turnover osteomalacia (defective mineralization in association with low osteoclast and osteoblast activities), mixed uremic osteodystrophy (hyperparathyroid bone disease with a superimposed mineralization defect), and the iatrogenic and idiopathic adynamic bone (diminished bone formation and resorption), but not osteoporosis [32, 33]. Two expert collaborative groups in the classification of renal bone diseases have suggested that renal osteodystrophy be divided into two models: low and high bone turnover [34, 35].

Idiopathic adynamic renal bone disease, more often seen in diabetic patients, could be due to an increased production of sclerostin, an inhibitor of osteoblast function [36]. Iatrogenic adynamic renal bone disease is due to oversuppression of parathyroid hormone production by therapies which inhibit parathyroid hormone synthesis (vitamin D analogues and/or Cinacalcet). Sustained lower levels of PTH below 150 pg/ml, and even more so below 100 pg/ml, have a high positive predictive value of predicting biopsy-proven adynamic bone disease [36, 37].

Discriminating Between Osteoporosis and Renal Bone Diseases

The clinician, confronted with the CKD patient who has low trauma fractures, and often a low T-score, has to decide what is the underlying metabolic bone disease in order to decide on the proper management strategy. It is also important to emphasize that both osteoporosis (defined by its highest order of criteria: fractures) as well as all forms of renal bone disease may have perfectly normal BMD (and T-score). This is because if one examines the equation for bone strength, 50% of bone strength is due to altered bone quality:

$$\text{Bone Strength} = \text{Bone Mineral Density} + \text{Bone Quality}.$$

Both osteoporosis as well as all forms of renal bone disease may have poor bone quality as a major contributor to bone fragility [38, 39]. There are no readily available office-based tools to measure bone quality. High resolution peripheral quantitative computerized tomography (HRpQCT) can provide resolution of the microstructure of bone down to levels of 70 microns. While predominantly a research tool, lower cost and smaller HRpQCT devices have recently been developed that may soon change the landscape of bone health into providing readily available office-based bone quality technologies [40].

Biochemical Markers of Bone Turnover and Quantitative Bone Histomorphometry: The Two Means of Making the Correct Diagnosis

How do we discriminate between osteoporosis and classical renal bone disease? Biochemical bone profile could be helpful but the 'gold standard' for making the correct diagnosis of the specific renal metabolic bone disease causing fragility fractures in CKD is double tetracycline labelled quantitative bone histomorphometry. The American Society for Bone and Mineral Research (ASBMR) has published a highly scientific white paper on defining both the static as well as dynamic parameters in quantitative histomorphometry [33]. Once a specific renal bone disease is excluded, then the firm

Box 4.6.3 The broad principles that may help in distinguishing between the renal bone diseases

PTH and BSAP combining the best of both worlds

- PTH "extremes" (< 100 pg/ml) or (> 600pg/ml) high specificity for adynamic/OFC.
- Bone specific alkaline phosphatase < 5 IU/L) has a high PPV (80%) for low bone turnover TINSAP <40 IU/L
- B .SAP correlate with PTH values in stage 5D CKD: both are increased on bone biopsy in established high bone turnover.
- Combining the lower quartile BSAP and PTH < 100-150 have a high PPV (90%) for adynamic bone disease.

diagnosis for a CKD patient with either low BMD or fragility fractures, is osteoporosis.

Transiliac bone biopsies in experienced operator hands can be done very safely and painlessly. The procedure is well described in previous publications [41]. However, there are fewer and fewer skilled operators that are still active in the United States and even fewer places that perform the quantitative histomorphometry. Hence, great progress has been made in the utilization of specific biochemical markers of bone turnover (BTM), especially regarding two of them: bone-specific alkaline phosphatase and intact PTH, in helping to discriminate among the various forms of renal bone disease (Box 4.6.3).

The combination of intact PTH and either total tissue non-specific alkaline phosphatase or bone-specific alkaline phosphatase provide perhaps the best means of either predicting or excluding hyperparathyroid or adynamic renal bone diseases [42–44]. These two biochemical markers are only useful in patients not receiving any medications that alter PTH or alkaline phosphatase production (e.g. vitamin D analogues, cinacalcet, and antiresorptive or anabolic osteoporosis pharmacological therapies). The combination of a lower quartile alkaline phosphatase and intact PTH less than 150 pg/ml has a very high positive predictive value (PPV) for diagnosing adynamic bone disease. Two other 'pearls' that are helpful: an intact PTH 6× or higher than the upper limit of normal for the laboratory reference range (usually 65 pg/ml) is highly predictive of hyperparathyroid bone disease, while a high alkaline phosphatase excludes adynamic renal bone disease.

The question often asked by physicians trying to discriminate between osteoporosis and a renal bone disease is: what if the bone specific Alk Phos (BSAP) is in the mid-range of the normal reference range (neither low nor high) and the serum PTH is also neither low (<150 pg/ml) nor high (>350 pg/ml) in a stage 4–5 CKD patient that has fragility fractures, and a bone biopsy is not available? In these situations, the one renal bone disease we don't want to treat with an antiresorptive therapy is renal adynamic bone disease, since it seems illogical to reduce bone turnover in situations where bone turnover is low to begin with. Additionally, since the field of osteoporosis is moving towards using anabolic agents as first line therapy in high risk patients, based on data that initiating therapy with an anabolic agent followed by an antiresorptive agent is a better sequence than the opposite, we will use anabolic therapy first line [45, 46]. In a previous study of a single patient with biopsy-proven adynamic bone disease, the anabolic agent teriparatide was capable of reversing the adynamic bone disease by paired bone biopsy [47] (Figures 4.6.4 and 4.6.5).

Conclusions

Discriminating between osteoporosis and the various forms of renal bone disease can be done. The proper utilization of a menu of bone turnover markers can very often provide good diagnostic accuracy and discriminatory capabilities. While transiliac bone biopsy is the gold standard for diagnosis, it is often not readily available for many clinicians. The one renal bone disease where antiresorptive osteoporosis therapies would be potentially unsafe

is idiopathic renal adynamic bone disease. In those patients who have fragility fractures, stage 4–5 CKD, and the biochemical profile is not as discriminatory as it can be, the initial use of an anabolic agent would be safe and certainly therapeutically beneficial in both osteoporosis as well as idiopathic renal adynamic bone disease. The two renal bone diseases where an osteoporosis pharmacological agent would not be advised are osteomalacia and hyperparathyroid bone disease. The latter two metabolic bone diseases can be excluded by defining the underlying cause of a high bone-specific alkaline phosphatase or defining the cause of an intact PTH that is also very high.

If a stage 4–5 CKD patient with fragility fractures is felt to have osteoporosis as the major underlying metabolic bone disease causing fractures, FDA approved pharmacological agents for the treatment of osteoporosis can be beneficial on or off label [48].

Hypercalcaemic and Hypocalcaemic Syndromes in Children

Laleh Ardeshirpour, Thomas O. Carpenter, and Cemre Robinson

Introduction

The calcium regulating system employs an intricate network of homeostatic signals and targets in order to meet the body's mineral demands. Mineral requirements vary considerably throughout progressive stages of development, in large part reflecting the mineral demands of *in utero* mineralization of the fetus and later skeletal growth. Features of the calcium homeostatic system during childhood years are in flux as relative rates of growth and development change throughout the life cycle. Furthermore, numerous compensatory mechanisms limit the severity of disease when an isolated insult occurs to the system. This chapter illustrates that many heritable disorders of mineral homeostasis become evident in infancy and childhood and are best recognized when viewed within the appropriate context of mineral requirements during the early stages of life. An understanding of the relevant physiology is central to formulating age-specific approaches to management of these various clinical problems, and so the disorders are reviewed in the context of physiology specific to childhood.

Features of Calcium Homeostasis Specific to Children

Perinatal Calcium Metabolism

Skeletal Development and Mineral Requirements of the Fetus

The growing fetus must be supplied with sufficient calcium for the formation and growth of a mineralizing skeleton. In addition, the physiologic milieu of the fetus must be maintained in an environment appropriate for normal cellular function. Thus, adequate extracellular calcium must be provided for normal function of the clotting factors, and avoidance of neuromuscular hyperexcitation. Yet at the same time, the supply must be appropriately limited to prevent soft tissue calcification or other toxicity to the developing fetus. A critical calcium dependent process in fetal life is skeletal accrual of mineral. Most of the skeleton is formed by the complex process referred to as endochondral ossification [1]. Cartilage templates are organized in concert with the transition of undifferentiated mesenchymal cells to differentiated chondrocytes. The cartilage templates serve as a nidus for eventual development into the skeleton. A system of chondrocyte maturation and proliferation occurs at what will become the ends of long bones, allowing for the continued linear growth of the skeleton. Regulation of this early formative process is dependent upon a variety of local and systemic factors, such as insulin-like growth factors (IGFs), fibroblast growth factors (FGFs), parathyroid hormone-related peptide (PTHrP), and Indian hedgehog protein [2]. Once mature cartilage forms, chondrocytes hypertrophy, and blood vessels penetrate the region, with the appearance of marrow stroma and osteoblasts soon to follow. Mineralization of the newly established skeleton begins, and growth results in an increasing mineral demand in order to effectively mineralize the newly formed tissue. Indeed, the fetus has substantial mineral demands: approximately 26–30 grams of calcium accumulate in the human through a term gestation, and accretion of more than three-fourths of this amount occurs in the third trimester. Calcium supply from the maternal circulation must be regulated by specific mechanisms in order to meet these demands throughout the later weeks of gestation.

The Fetal Calcium Regulating System

The maternal circulation is the source of calcium provided to the fetus. An abundance of calcium occurs in the mother primarily as a result of a pregnancy-induced doubling of maternal circulating 1,25-dihydroxyvitamin D [1,25 $(OH)_2D$] levels, which in turn increases fractional absorption of calcium at the intestine [3]. This occurs in the absence of significant increases in circulating levels of parathyroid hormone (PTH) in the mother.

The placenta is the site of nutrient transfer from the maternal circulation to the fetus. Calcium may be transported by several mechanisms across the placenta; the dominant direction of flow is from maternal to the fetal circulation, requiring active transport. A Ca^{++}-ATPase located in the fetus-directed basement membrane of the syncytial trophoblast cells appears to mediate this important function [4]. Although it is not clear exactly when in gestation active calcium transport begins, it is present by the beginning of the third trimester. The fetal circulating calcium level is maintained at a slightly higher concentration (1.2–2.0 mg/dl) than the maternal circulation as early as 15 weeks of gestation [5]. Active placental calcium transfer plays an important role in determining fetal circulating calcium level, but other factors may play a role, including PTH and PTHrP. The relative hypercalcaemia in the fetus appears to be necessary for complete skeletal growth and mineralization [6, 7].

Placental calcium transfer seems to be mainly regulated by PTHrP, and to a lesser extent by PTH [4, 8]. The mid- and carboxy-terminal portions of the PTHrP molecule are required, whereas the amino-terminus (most related to PTH in sequence) does not have activity in this regard [4, 9]. PTHrP plays an important role in embryonic growth and development of many tissues, and is produced by multiple tissues. Major sources of PTHrP production are the placenta, and to a lesser extent, the parathyroid glands. In a fetal mice model, disruption of PTHrP results in hypocalcaemia and severe chondrodysplasia [8, 10]. Fetal circulating PTH levels are low, probably due to Ca-sensing receptor (CaSR) mediated suppression of PTH secretion by fetal parathyroid glands [4]. Nevertheless, aparathyroid fetal mice develop hypocalcaemia and defective bone mineralization, pointing towards a role for PTH in maintaining normal serum calcium, and thereby perhaps supporting normal bone mineralization [11]. PTH may also exert its effect on bone formation, to some extent, via direct interaction with osteoblasts.

Fetal circulating 1,25 $(OH)_2D$ levels are low, and derived from placenta and fetal kidney, and may be related to the concurrent low PTH and high serum phosphorus levels. 1,25 $(OH)_2D$ does not play a major role in placental calcium transfer or maintenance of serum calcium level as evidenced by the fully mineralized skeleton and normal fetal serum calcium levels at term in vitamin D receptor-null (*vdr*-null) mice. In human cases of maternal vitamin D deficiency, skeletal mineralization seems to be unaffected but the newborn will be at risk of developing hypocalcaemia [4]. The presence of CaSR in both human and murine placenta suggests a possible role for this membrane receptor in fetal calcium homeostasis. Some insight has been provided by CaSR null mice: fetuses of this strain demonstrate increased PTH levels, reduced placental calcium transport, increased amniotic fluid calcium, and increased markers of bone resorption. This constellation of findings suggests that an increase in skeletal resorption can occur, when inadequate calcium levels are sensed by the fetus [11, 12]. The fetal kidneys may be involved in regulation of fetal calcium levels as well, but is of limited impact in that fetal urine is excreted into the amniotic fluid and recycled with swallowing.

Limited data regarding FGF23 levels in the human fetus suggest that intact FGF23 levels are lower than levels in adults [13] but that C-terminal levels are approximately twofold greater than in adults [14]. Circulating levels of alpha-klotho are reported as elevated in the fetus, likely reflecting a placental source [13]. Other relevant measures in the fetal circulation include relatively increased levels of phosphorus, magnesium, and relatively low concentrations of calcitonin compared to postnatal life [7].

Transition from Fetal Life to Infancy

At birth the generous supply of maternal calcium is abruptly withdrawn from the fetus, as well as the placental sources of PTHrP and 1,25 $(OH)_2D$, with a resultant acute decrease in serum calcium of approximately 1 mg/dl in term infants, and slightly more in preterm infants. One study indicates that the decrement in serum calcium and rise in PTH is greater in babies born by Caesarean section than in babies born spontaneously by the vaginal route. This decrease in calcium then stimulates secretion of PTH, suppressed during fetal life, which in turn, stimulates the kidney to generate adult normal levels of 1,25 $(OH)_2D$ within the next several days. Levels of PTHrP are reduced; this hormone likely plays a lesser role in postnatal calcium homeostasis than *in utero*. The serum calcium gradually increases to normal childhood levels within a few days of the acute postnatal decrement. The relative hypercalcaemia of the fetus likely protects the newborn infant from acute severe hypocalcaemia during the transition to the ex utero environment.

The intestine and kidney assume major roles in mineral homeostasis with this transition. The neonatal skeleton continues to accrue calcium at rates close to that attained in late gestation (averaging 100–150 mg/kg/day). Thus, the newborn infant becomes dependent upon exogenous nutritional sources of calcium. Renal excretion of calcium increases over the first few weeks of life, as glomerular filtration rate (GFR) increases. As the kidney matures, it begins to play a minor role in regulation of calcium. The newborn infant, however, becomes primarily dependent upon the *intestine* to maintain its calcium supply. In the first few days to weeks of neonatal life, passive or facilitated calcium transport (not vitamin D-mediated mechanisms) are the dominant means by which calcium is brought into the body. After several weeks, vitamin D appears to be useful in enhancing calcium absorption in term infants. Fractional calcium absorption can be relatively high in infancy particularly in very low birthweight children, who may develop hypercalcaemia during high calcium intake, as may occur with the administration of breast-milk fortifiers. This phenomenon may occur independently of vitamin D status (with normal circulating levels of 25-hydroxyvitamin D (25-OHD), and appropriately low circulating PTH and 1,25 $(OH)_2D$), implying that passive or facilitated, non-vitamin D-mediated calcium transport in the immature intestine can be remarkably efficient. The relatively low phosphate content of breast milk likely contributes to the greater bioavailability of calcium from breast milk as compared to most infant formulas. Formation of calcium-phosphate complexes in the higher phosphate containing formulas limit the availability of calcium for intestinal absorption.

Childhood Growth: A Period of Intensive Mineral Accretion

Growth and Accrual of Bone Density

Skeletal growth and mineralization continue at a very rapid pace throughout the first 2 years of life. The growth velocity on average during the first 4 months of life can be annualized to approximately 28 cm/yr. From that time on a child's growth rate asymptotically

decreases from a rate of one cm per month (approximately 12.5 cm/yr) to about 5–6 cm/yr at the time of the pubertal growth spurt, when a rate of about 10 cm/yr is transiently achieved prior to the cessation of growth. This linear growth represents the growth of the appendicular skeleton, which must be adequately mineralized; thus rapid growth in infancy places considerable mineral demands on the skeleton. Bone mineral content (BMC) and areal bone mineral density (BMD), as assessed by standard two-dimensional techniques, such as dual energy X-ray absorptiometry (DXA) proceeds at a steady pace until approximately age 11 in girls and slightly later in boys [15]. Specific guidelines for the use and interpretation of bone densitometry in children have been previously published and updated by the International Society of Clinical Densitometry [16, 17]. Bone size is a confounding variable in interpretation of DXA results, which is a particularly important issue in growing children. The BMD is an areal measurement, rather than a true volumetric measurement, since depth cannot be measured directly. Thus, DXA has been shown to underestimate the BMD in those children with smaller bone size and overestimate it in those with larger bone size. To resolve this problem, standard paediatric reference data for BMD have been established, taking into account the age, sex, ethnicity (African American or non-African American) and height of the patient, with the Bone Mineral Density in Childhood Study (BMDCS); a multicentre, longitudinal study of bone accrual in healthy children and adolescents performed at five US clinical centres [18].

Although the focus on bone activity during these years of rapid growth is primarily on formation and mineralization, there must also be extremely active turnover in general. The growing bone must be constantly modelled in order to maintain an appropriate structure. Weight-bearing forces begin to correct the physiologic bowing of childhood, as lower extremity alignment becomes more linear. As metaphyseal long bone segments accrue mineral at growth plate cartilage, extending the length of the long bone calls for an eventual narrowing of the former metaphyseal segment as it assumes a diaphyseal position. These processes require extensive bone resorptive activity. Thus, when investigating disorders of the bone and mineral system, one must recognize this relatively hyperdynamic state of bone turnover. The established normal ranges of bone activity for adults, which primarily represent bone remodelling, do not apply to children. In children and adolescents, serum markers of bone formation and resorption are released into the circulation during linear growth, bone modelling, and remodelling [19, 20]. The normal ranges of values for such markers as serum osteocalcin, alkaline phosphatase activity, or urinary excretion of deoxypyridinoline cross-links of collagen, or the N-telopeptide of type I collagen are quite wide (Table 4.7.1). Several investigators have compiled normative data on these and other biomarkers of bone turnover throughout childhood and/or adolescent age groups [3, 21] and reference curves for five bone markers in the serum; osteocalcin (OC), bone specific alkaline phosphatase (BALP), the carboxy-terminal telopeptide region of type I collagen (ICTP), the carboxy-terminal α1 chain telopeptide of type I collagen (CTX), and serum tartrate-resistant acid phosphatase 5b (TRAP5b) have been established in a large cohort of healthy children aged 2 months to 18 years, along with calculation of sex- and age-specific standard deviation scores [20, 21]. There is a consistent peak in the concentrations of most serum markers of bone formation and resorption in adolescence that decreases in adulthood, and this rise occurs approximately 2.5 years earlier in girls than in boys [21]. Circulating levels of P1NP (procollagen type I N-propeptide) has emerged as a frequently used marker of bone formation [21], and circulating CTX is often used as a marker of bone resorptive activity, and both of these markers are found to be greater in childhood than in adulthood (Table 4.7.1). Indeed, all bone markers tend to show significant variation with age whereas mainly BALP shows a significant variation with sex, with higher concentrations observed in boys [20]. Values in adolescence for the more widely used markers are shown in Table 4.7.1. It is recommended to use a set of bone turnover markers, rather than a single marker in evaluating those children with metabolic bone disorders, monitoring for disease progression or during antiresorptive therapy [20].

Puberty

In addition to the rapid growth spurt beginning in early puberty in girls, and later stages of puberty in boys, BMD accrues at an accelerated pace. The rate of increase in BMD in girls between the ages of 11 and 16 years is more rapid than at any time in late childhood or during adult life. The National Academy of Sciences (USA) has set 'adequate intake' levels for calcium by age ranges. These levels are 210 mg daily through the first 6 months of life, 270 mg/day for months 6 to 12, 500 mg/day from years 1 to 3, and 800 mg/day for ages 4 to 8. In keeping with the rapid rate of bone accretion in adolescence, calcium 'adequate intake' has been set at 1300 mg/day for the 9–18-year-old group [22]. Some have thought this number underestimates calcium requirements and have suggested that teenage girls consume 1500 mg of calcium daily.

Commensurate with the pubertal growth spurt are transient rises in the markers of bone formative activity, serum osteocalcin, and alkaline phosphatase activity. Markers of bone resorption, which decrease somewhat throughout later childhood, decrease substantially in late puberty (Tanner stages IV and V), reflecting more quiescent bone turnover than in earlier childhood, as described here and in Table 4.7.1. The postpubertal period of elevation in turnover markers persists in males longer than in females, suggesting a longer period of active mineral accrual in young men than in young women.

In addition to the changes in bone markers, geometric properties of long bones change during puberty, and appear to differ between boys and girls. These changes may be reflected in the differential changes in biomarker levels described earlier. However, the finding of wider long bones of males remains largely unexplained. Male long bones progressively grow in circumferential diameter beyond female growth in this regard, in part due to a prolonged period of generalized prepubertal growth [23]. Furthermore, recent data suggests that such sex differences in geometry are evident in prepubertal years, determined by complex genetic traits and environmental stimuli [23].

Age-Dependent Changes in Serum Minerals and Calciotropic Hormones

Appropriate diagnosis of disease or monitoring of therapy requires an understanding of changes in the biochemical parameters used to facilitate an evaluation of mineral metabolism in children.

Table 4.7.1 Normal values of biochemical markers of bone turnover in childhood

	Male	Female
Formative markers		
Serum osteocalcin (ng/ml)[1]		
<10 yrs:	6–35	6–40
10–18 yrs:	9–84	7–50
Serum alkaline phosphatase activity (IU/L)[2]		
0–14 days:	83–248	83–248
15 days <1 yr:	122–469	122–469
1–13 yrs:	135–376	135–376
13–15 yrs:	57–254	116–468
15–17 yrs:	50–117	82–331
17–19 yrs:	45–87	55–149
Serum PINP (N-terminal propeptide of type 1 procollagen) (ng/ml)[3]		
6–14 yrs:	250–1800	*6–12 yrs:* 250–1500
14–18 yrs:	80–1500	*12–16 yrs:* 80–1000
18–26 yrs:	40–300	*16–26 yrs:* 20–200
Resorptive markers		
Serum N-Tx (cross-linked N-terminal-telopeptide of type I collagen) (pmol/ml)[4]		
6–14 yrs:	20–200	*6–12 yrs:* 25–120
14–16 yrs:	14–180	*12–18 yrs:* 8–12
16–26 yrs:	7–50	*18–26 yrs:* 5–25
Urinary N-Tx (pmol equivalent of bone collagen/µmol creatinine)[5]		
<1 yr:	500–5000	870–5700
1 yr:	120–2800	475–2750
2–4 yr:	320–2100	155–2010
5–10 yr:	110–1275	115–1620
11–12 yr:	210–2600	235–2430
13–14 yr:	105–1900	45–1335
15–18 yr:	34–1146	45–400
Serum C-Tx (Cross-linked C-terminal-telopeptide of type I collagen) (pg/ml)[6, 7, 8]		
10–17 yr:	370–2560	240–1530
30–34 yr:	260–450	140–330

[1] Extrapolated from Figures 5 and 8, Calvo, M *et al.* [19]. Note that values will vary with respect to the assay employed and to the laboratory performing the test.
[2] Values rounded from table 3, Estey *et al.* [141].
[3] Extrapolated from Figure 2, van der Sluis *et al.* [21].
[4] Extrapolated from Figure 3, van der Sluis *et al.* [21].
[5] Values rounded from Bollen and Eyre [142].
[6] Extrapolated from Figure 3, Fares *et al.* [143].

[8] Adult reference from Table 4.7.2 [145].

Note the consistent peak in the concentrations of most serum markers of bone formation and resorption in adolescence that decreases in adulthood.

Figure 4.7.1 illustrates the changes in circulating minerals and related hormones during early infancy. The serum levels of calcium and magnesium do not change significantly after the first few days of life until adulthood. On the other hand, urinary excretion of calcium is much greater in infancy than in later childhood and adulthood. A convenient measure for urinary excretion of calcium is the ratio of calcium to creatinine (Ca/Cr) in a random urine sample. Urinary calcium excretion varies with type of feedings, vitamin D nutrition, and gestational age [24]. In the older child a fasting urine sample should have a Ca/Cr less than 0.21 mg/mg. For infants and younger children, age-specific normal values for spot urine samples have been reported and can range from 0.39 mg/mg for children between ages 1 and 5 years old to 0.81 mg/mg for those younger than 12 months of age [25]. A 24-hr urine collection should be confirmed

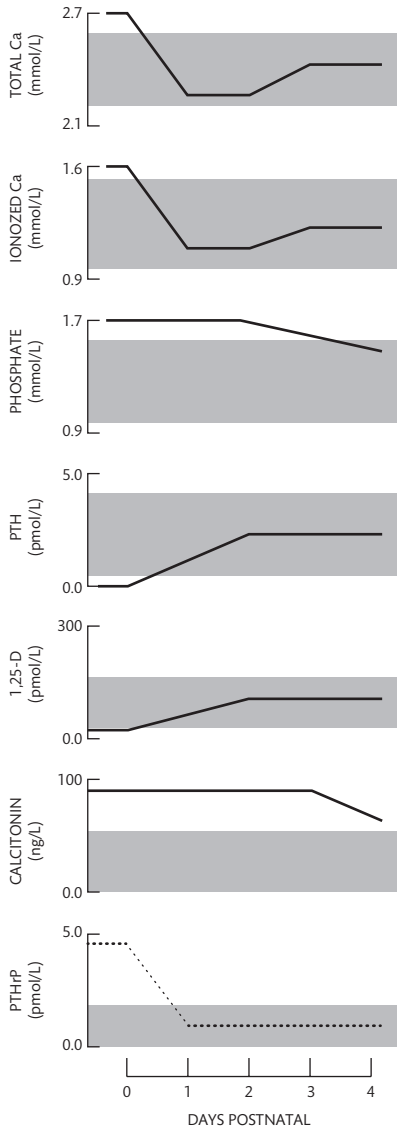

Figure 4.7.1 Longitudinal change in circulating concentrations of minerals, PTH, calcitonin, and 1,25 (OH)2 D during fetal and neonatal period in humans. Shaded areas represent the adult normal range for the parameter.

Reproduced with permission from Kovacs, C.S., Bone development and mineral homeostasis in the fetus and neonate: roles of the calciotropic and phosphotropic hormones. *Physiol Rev*, 2014. 94(4): p. 1143–218. Copyright © 2014 The American Geriatrics Society [ref 146].

by measurement of total creatinine (which should be 10–20 mg/kg/24 hr in most children), and the calcium should be less than 4 mg/kg/24hr. Circulating phosphate concentrations decrease considerably throughout the first year of life, and even further throughout later childhood. The normal ranges are substantially greater than that seen in older adults. This change is primarily due to increased reclamation of filtered phosphate in the proximal renal tubule early in life. The confusion in interpretation of age-related normal ranges has continued to result in missed diagnoses and inappropriate interpretation of mineral status. The assessment of urinary phosphate excretion should be performed on a 2-hour fasting urine specimen, with a blood sample obtained at the midpoint of the urine collection. The tubular reabsorption of phosphate (%TRP) is calculated as:

$$\%\mathbf{TRP} = \mathbf{1} - \frac{[U_P \times P_{Cr}]}{[P_P \times U_{Cr}]} \times 100,$$

where U_P refers to the urinary concentration of phosphate, P_P to plasma concentration of phosphate, U_{Cr} to urinary concentration of creatinine, and P_{Cr} to the plasma concentration of creatinine.

The %TRP can be plotted on the nomogram of Walton and Bijvoet [26] to obtain the TMP/GFR, or tubular maximum for phosphate expressed per GFR. This value reflects the value of serum P above which one will tend to stop reclaiming P in the tubule. The normal ranges vary with age and approximate the normal phosphate concentrations for age. Alternatively, a calculated method termed TP/GFR, can be used employing the formula:

$$\text{TP/GFR} = \text{Serum phosphate} - (\text{Urine phosphate} \times \text{Serum creatinine / Urine creatinine}). \quad [27]$$

Finally, values for circulating PTH do not change after early infancy throughout childhood. Circulating 25-OHD levels are relatively stable in early childhood (Figure 4.7.2), but are influenced by a variety of factors including ethnicity and season of sampling. Levels tend to be greater in children of European descent, with formula feeding, and during the summer and fall months [28]. Circulating 1,25 $(OH)_2D$ levels tend to be higher in childhood than in later life, and decline with time in early childhood, particularly during the first 3 years of life (Figure 4.7.2). Furthermore, there appears to be less stringent regulation of conversion of 25-OHD to 1,25 $(OH)_2D$ in early life. The authors have generally observed values for 1,25 $(OH)_2D$ to range up to 30% in excess of the adult normal range in normal children. Furthermore, there appears to be less stringent regulation of conversion of 25-OHD to 1,25 $(OH)_2D$ in early life.

Disorders of Hypocalcaemia

Serum Calcium

Total serum calcium is comprised of a free or ionized calcium component, a protein (primarily albumin) bound component, and a small component of filtrable calcium that is complexed to other ions such as sulphate, citrate, or phosphate. The ionized and protein bound components each represent approximately 45–50% of the total calcium. The ionized fraction is the biologically active component, and derangements in this fraction result in clinical symptoms. As discussed elsewhere, total serum calcium can be low with a simultaneously normal ionized fraction. This finding is typical of hypoalbuminaemia or acidosis. Various correction factors have been proposed, and are applicable to children as well as adults, however accurate measures of ionized calcium are preferable to calculated corrections.

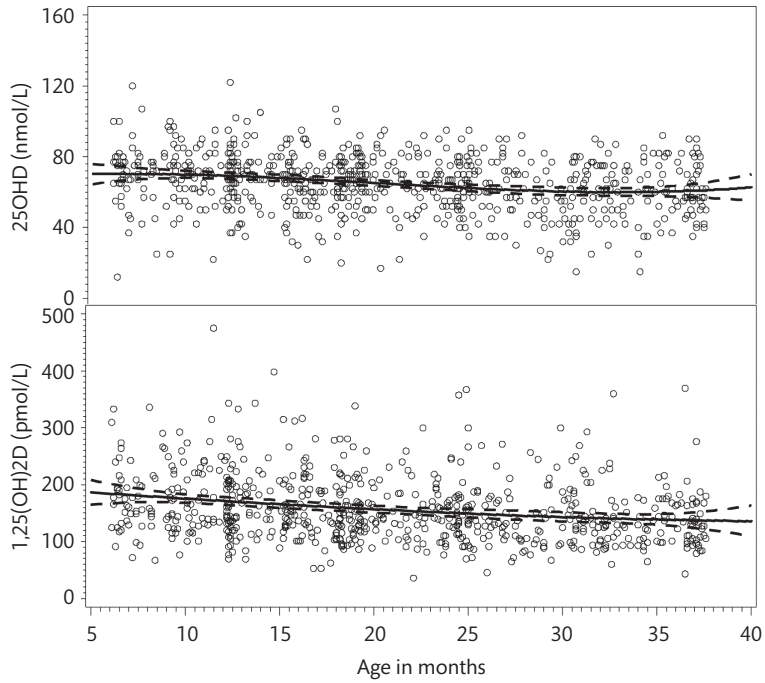

Figure 4.7.2 Scatterplot of 25(OH)D (top) or 1,25(OH)2D (bottom) related to age in months. The regression equation for the relation of 25(OH)D to age was as follows: 25(OH)D (nmol/L) = 74.9–0.44 (age in mo) (R = 0.18, *P* = 0.001). The regression equation for the relation of 1,25(OH)2D to age was as follows: 1,25(OH)2D (pmol/L) = 188.7–1.5 (age in mo) (R = 0.23, *P* = 0.001). Regression lines (solid lines) and their 95% CIs (dashed lines) are shown. 1,25(OH)2D, 1,25-dihydroxyvitamin D; 25(OH)D, 25-hydroxyvitamin D. Normal ranges of circulating 25(OH)D and 1,25(OH)2D levels in infancy. Circulating 25(OH)D and to a greater extent, circulating 1,25(OH)2D levels decrease with age over the first 3 years of life.

Hypocalcaemia in Childhood

This section discusses disorders of calcium homeostasis in childhood, with a primary focus on abnormalities in the maintenance of serum calcium. Several of these disorders, however, primarily affect the skeletal calcium compartment, and bone disease may be a more significant abnormality than perturbations in the serum concentrations. Thus, certain disorders are described in which serum calcium levels are often normal in the clinical setting, but at the expense of osteopaenic or rachitic abnormalities.

The presentation of hypocalcaemia in the newborn period typically includes facial twitching, limb jitteriness, or other features of neuromuscular irritability, occasionally progressing to focal or generalized convulsions. Poor feeding, hyperacusis, and laryngospasm mimicking croup have been described. On the other hand, non-specific findings such as apnoea, tachypnoea, tachycardia, cyanosis, or vomiting may be the only features evident. In older children tetany or perioral tingling, presentations more characteristically seen in adults, are more likely to be encountered. As with infants, focal seizures and generalized convulsions may occur. Carpo-pedal spasm in school age children has often been attributed to a writer's cramp. This phenomenon may be exacerbated by the hypomagnesaemia and alkalosis frequently encountered in states of parathyroid insufficiency. Lethargy, vomiting, and other non-specific signs have also been reported. The electrocardiogram may reveal a prolonged corrected QT interval, Q-T_c, which is determined by dividing the Q-T interval by the square root of the EKG cycle. The upper limit of normal in children is 0.44. The musculature may be affected by chronic hypocalcaemia, as witnessed by the cardinal sign of tetany. Serum creatine kinase activity (CK, or creatine phosphokinase, CPK) may be elevated in chronic hypocalcaemia; over time actual myopathic changes may occur. Severe clinical compromise with dilated cardiac myopathy has been described in infants with hypocalcaemia due to severe vitamin D deficiency [29].

Neonatal Hypocalcaemia

Neonatal hypocalcaemia seen transiently in the first few days of life is commonly referred to as **early neonatal hypocalcaemia**. This is often seen in preterm infants and has been explained as an exaggeration of the normal postnatal decrease in serum calcium levels. Early neonatal hypocalcaemia appears to occur with greater frequency in asphyxiated babies and in infants of diabetic mothers (IDM) than otherwise. The hypocalcaemia seen in IDM is probably multifactorial. Magnesium deficiency has been implicated, as well as alterations in maternal metabolism secondary to poor glucose control throughout gestation. Whether the normal postnatal increase in PTH secretion is blunted is not entirely clear.

Late neonatal hypocalcaemia occurs after 5–7 days of life and is more characteristic of the term infant. Late neonatal hypocalcaemia often presents with seizures and is less likely to be transient in nature. Hypoparathyroidism and magnesium deficiency often present in this time frame. Hypocalcaemia in babies with congenital heart disease of many types has been reported as a relatively common finding. Hypocalcaemia related to vitamin D deficiency may present at several weeks of age, however, radiographic evidence of rickets is usually not observed until over 2 months of age.

One classic situation in which prolonged neonatal hypocalcaemia occurs is in **the infant of the hyperparathyroid mother**. Presumably the maternal hypercalcaemia results in increased transport of calcium from the maternal to fetal circulation. The resultant excess calcium supply to the fetus is thought to suppress parathyroid responsivity, and prolonged hypoparathyroidism results. Symptomatic hypocalcaemia and hyperphosphataemia are typical biochemical features; hypomagnesaemia may occur as well. The disorder is usually transient, but some cases have been prolonged for months. Unrecognized maternal hyperparathyroidism should be carefully investigated in children that present with the characteristic features of the disorder. Maternal familial hypocalciuric hypercalcaemia (FHH) can result in this syndrome. We have encountered similar cases due to excessive maternal ingestion of calcium-containing antacids during pregnancy, suggesting that other causes of chronic maternal hypercalcaemia can result in a similar clinical picture.

Hypocalcaemia in the newborn setting may also occur during blood transfusions using citrated blood products. Citrate complexes with ionized calcium, reducing its circulating concentration to a level where neuromuscular hyperexcitability may occur. Total serum calcium is usually not decreased. Hypocalcaemia can occur in the **congenital nephrotic syndrome**. Persistent hypocalcaemia may present in this time frame as well. Congenital hypoparathyroidism may be present, as in the **DiGeorge syndrome**. The classic triad of this chromosome 22 deletion syndrome (hypoparathyroidism, athymia, and cono-truncal defects of the heart) typically results in long-standing hypoparathyroidism, although 'partial' hypoparathyroidism has been described. (See next for a detailed description of congenital disorders of the parathyroid glands.) Severe **osteopetrosis** may present with hypocalcaemia secondary to impaired mobilization of calcium from bone. Typically, PTH levels are elevated in order to compensate for the hypocalcaemia engendered by defective osteoclastic bone resorption in such cases. Severe **vitamin D deficiency** is generally an acquired condition manifest as hypocalcaemia as early as 2 to 3 months, but low maternal stores have rarely contributed to its development in an even younger age range.

Osteopaenia of prematurity is commonly encountered in premature infants. Poor bone mineralization is evident on radiographs or other measures of BMD. In general, the problem is more severe in children of lower birth weight. With increasing survival of children with birth weights less than 1000 grams the severity of this problem is increasing. Classical rachitic changes of flared and frayed epiphyses, craniotabes, and a rachitic rosary may develop over the first months of life. The histologic pattern of bone is thought to be a combined lesion with components of osteomalacia and osteoporosis. This disorder is a consequence of premature withdrawal of the maternal mineral supply. The enteral route, even with maximum feeding delivery, cannot provide for the mineral demands of the skeleton as it rapidly grows and mineralizes throughout the latter weeks of gestation. The problem often occurs in the setting of normocalcaemia. In preterm infants fed solely with breast milk, a phosphate deficiency syndrome may occur, as the phosphate content of breast milk is considerably less than that of commonly used in cow's milk formulas. Although breast milk phosphate is adequate for the growth of the term infant's skeleton, human breast milk fortifiers are routinely used to increase the mineral intake of the preterm infant. One caveat regarding the use of such fortifiers: calcium intake, if excessive, can result in hypercalcaemia, as its absorption is not tightly regulated in early infancy, and the fractional absorption of calcium can be very high in a low birth weight premature infant.

Treatment of Neonatal Hypocalcaemia

Symptomatic infants are treated with calcium, but there is controversy regarding treatment of hypocalcaemic infants who are asymptomatic. The emergency treatment of neonatal hypocalcaemia consists of intravenous administration of 1 ml/min of 10% calcium gluconate, which should not exceed 2.0 ml per kg body weight (which is equivalent to ~19 mg of elemental calcium per kilogram). This may be repeated three to four times in 24 hours. After acute symptoms have been managed, 5.0 ml/kg of 10% calcium gluconate may be given with intravenous fluids over 24 hours. It should be emphasized that repetitive and frequent boluses of high-dose intravenous calcium only temporarily raise the serum calcium level and an enormous renal calcium load result. Thus the favoured way of longer-term management when the parenteral route is necessary employs a constant intravenous infusion, which results in a lower calcium load per unit time to the kidneys, and maintains serum calcium at a relatively steady level. Calcium supplements may be introduced orally if tolerated. In persistent cases, the load of dietary phosphate should be lessened with a formula such as Similac PM 60/40. When hypomagnesaemia is identified, it can be treated with 0.1–0.2 ml/kg of a 50% solution of magnesium sulphate ($MgSO_4 \bullet 7H_2O$).

Hypocalcaemia of Later Onset

Disorders of Parathyroid Insufficiency

Congenital hypoparathyroidism. A wide variety of hypocalcaemic syndromes occur in children due to abnormalities in parathyroid synthesis or secretion. These syndromes provide classic examples of the critical role PTH plays in protecting the organism from acute decreases in the serum calcium level. The clinical manifestations of hypocalcaemia described earlier are the typical presenting features of hypoparathyroidism. Biochemical features usually include low blood total and ionized calcium levels, and an elevated blood phosphate level. The serum magnesium level may be low, and alkalosis may be present.

Hypoparathyroidism may result from a variety of causes. A number of genetic disorders may cause agenesis of parathyroid glands, disrupt PTH synthesis, processing, and secretion, and/or result in autoimmune destruction of parathyroid glands. As noted earlier, agenesis of the parathyroid glands occurs in the classic DiGeorge triad (OMIM #188400) of hypoparathyroidism, athymia, and cono-truncal heart defects. This syndrome is now known to be part of the larger spectrum of disease referred to as CATCH 22, a sequence of contiguous microdeletion syndromes localized to chromosome 22q11.2. These mutations are most notable in the *TBX-1* gene, a transcription factor that plays an important role in development of thymus and parathyroid glands [30]. Recently, some cases of DiGeorge syndrome have been found to harbour a deletion in 10p13-p12 (*NEBL* gene), which has been defined as DiGeorge type 2 (OMIM #601362) [31, 32]. Hypoparathyroidism usually occurs in those disorders most related to the classic DiGeorge syndrome, but has also been described in the velo-cardio-facial syndrome (OMIM #192430), another CATCH-22 pattern of anomalies.

Fluorescent *in situ* hybridization (FISH) using DNA probes which hybridize to the 22q11.2 locus is helpful in establishing the diagnosis. Not all hypocalcaemia in this microdeletion syndrome is due to parathyroid dysgenesis however; a recent description of pseudohypoparathyroidism in DiGeorge syndrome noted a deletion on chromosome 22 incorporating a G-protein locus ($G\alpha_s$)[33].

Mutations of the pre-proPTH gene, resulting in disruption of PTH secretion [34], or processing and translocation of PTH from the endoplasmic reticulum, [35] can cause **familial isolated hypoparathyroidism** (OMIM #146200) [36]. Likewise mutations of the transcription factor glial cells missing-2 (GCM2) [also referred to as glial cell missing-B (GCM-B)] on 6p24.2, resulting in loss of activity, will result in **familial isolated hypoparathyroidism** (OMIM #307700) [34, 37–39] A form of **X-linked hypoparathyroidism** has been reported in patients with mutations in the gene for the transcription factor Syr-box 3 (SOX3) [40].

A number of other patients with congenital hypoparathyroidism have concomitant involvement of other organ systems. The syndrome of hypoparathyroidism, sensorineural deafness, and renal anomalies (**HDR syndrome**; OMIM #146255) is an autosomal dominant disorder due to mutations or deletions of the gene for the transcription factor GATA3 on chromosome 10p14 [41–43]. Loss-of-function mutations in tubulin chaperone E (*TBCE*) gene on chromosome 1q42.3 cause the autosomal recessive syndrome of infantile onset hypoparathyroidism, mental retardation, intrauterine growth retardation, and dysmorphism (**Sanjad-Sakati syndrome**) (OMIM #241410) [44–46] and **Kenny-Caffey syndrome type 1** (OMIM #244460) (hypoparathyroidism, dwarfism, medullary stenosis of the long bones, and eye abnormalities) [47]. In autosomal dominant forms of Kenny-Caffey syndrome Type 2 patient has the clinical features, transient hypocalcaemia, but normal intelligence due to heterozygous mutations in *FAM111A* gene on chromosome 11q12 [48]. Mitochondrial gene defects, ranging from deletions to mutations and rearrangement, have been associated with hypoparathyroidism in patients with **Kearns-Sayre syndrome** (external ophthalmoplegia, pigmentary retinopathy, cardiomyopathy, diabetes, and hypoparathyroidism; OMIM #530000), **MELAS syndrome** (mitochondrial encephalomyopathy with lactic acidosis and stroke like syndrome, with diabetes and hypoparathyroidism; OMIM #540000), and **mitochondrial trifunctional protein deficiency (MTPDS) syndrome** manifest by peripheral neuropathy, retinopathy, and hypoparathyroidism due to mutations in *HADHA* at the 2p23.3 locus (OMIM #609015) [49, 50]. Other mitochondrial disorders associated with hypoparathyroidism include **long-chain 3-hydroxyacyl-coenzyme A dehydrogenase deficiency** (OMIM# 609016 LCHAD), and **propionic acidaemia** [51].

Gain-of-function mutations of the CaSR at chromosome 3q21.1 have been found to cause an autosomal dominant variety of hypocalcaemia. The CaSR protein, on parathyroid cell membranes, regulates PTH secretion. Mutations causing the protein to enhance its affinity for ionized calcium will allow relatively low concentrations of this ion to suppress PTH secretion, and a steady state serum calcium level in the hypocalcaemic range is established. This autosomal dominant form of hypocalcaemia has been termed ADH1 (OMIM #601198). It may be possible to distinguish **autosomal dominant hypocalcaemia** (ADH) from other forms of parathyroid insufficiency because of the relative hypercalciuria that occurs. Circulating PTH levels may not be undetectable in the untreated state [50, 52, 53]. This distinction from hypoparathyroidism has important consequences regarding long-term management. That is, the standard treatments for hypoparathyroidism, vitamin D, or its metabolites, and calcium, can further exaggerate this hypercalciuria such that nephrocalcinosis, nephrolithiasis, and renal impairment may result, particularly when serum calcium levels are kept in the usual normal range. ADH may present with features seen in **Bartter syndrome** (Bartter syndrome type 5), including hypokalaemia, metabolic alkalosis, hypomagnesaemia, hyperreninemia and hyperaldosteronaemia [54, 55]. A decrease in the distal tubular fractional chloride reabsorption rate with negative NaCl balance has been reported in some cases, with a resultant secondary hyperaldosteronism and hypokalaemia [54]. Hydrochlorothiazide and recombinant human PTH have been suggested as treatment modalities [56, 57].

Finally, heterozygous mutations in the alpha subunit of the G protein G11 (*GNA11*) on chromosome 19p13 have been identified in patients with ADH (ADH type 2; OMIM #615361) [58].

The CaSR and associated disorders are discussed in Chapter 4.4.

Acquired hypoparathyroidism. Causes of acquired hypoparathyroidism are mainly autoimmune, post-surgical, or due to infiltration of the parathyroid gland. A major cause of acquired hypoparathyroidism is due to the autoimmune polyglandular syndrome (or APS), type I. The disorder is also referred to by other names such as autoimmune polyendocrinopathy, candidiasis, and ectodermal dystrophy (APECED) [59, 60]. The primary manifestations of this disorder include hypoparathyroidism, primary adrenal insufficiency, and mucocutaneous candidiasis. A variety of other autoimmune phenomena may occur, often grouped with the endocrine, gastrointestinal, or dermatologic systems (Box 4.7.1). Defects in cellular or humoral immunity may occur. The presentation typically begins in early childhood with candidiasis. In later childhood the onset of hypocalcaemic symptoms related to hypoparathyroidism occurs, and Addison's disease often presents during adolescence. There is considerable variability, however, and often patients do not develop the classic triad. The elevation in serum calcium that may occur during an acute adrenal crisis in an undiagnosed individual may result in an increase of the serum calcium from a hypocalcaemic to a normocalcaemic value, thus masking a coexistent presentation of hypoparathyroidism. Serum calcium should be determined during the initial presentation of suspected Addison's disease, but also shortly after recovery from the acute crisis.

APS-1 syndrome is due to mutations in the gene encoding the autoimmune regulator protein AIRE [61–63]. Mutations resulting in a single amino acid substitution at position 257 (arginine –> glutamic acid) were present in more than three-quarters of the affected Finnish cases. The same mutation has been identified in the majority of cases in another series from Italy and Switzerland. Mutations in AIRE have been identified in cases of isolated hypoparathyroidism as well [64]. Autoantibodies directed to parathyroid cells have been described in patients with APS type 1, but the frequency of these findings vary greatly dependent upon the series studied [65]. Antibodies to the parathyroid CaSR have been reported in acquired hypoparathyroidism both with and without coexisting autoimmune diseases [66–70]. Yet, CaSR antibodies are not found to be specific or sensitive markers for hypoparathyroidism in APECED [71]. In addition to the usual measures taken in the management of hypoparathyroidism, treatment of this disorder may require aggressive mineral replacement, due to the often-complicating issue of malabsorption. Acute illness can be associated with such severe impairment of gastrointestinal absorption of calcium and magnesium

Box 4.7.1 Clinical features of autoimmune polyendocrinopathy syndrome type I

Major manifestations
Chronic hypoparathyroidism
Chronic candidiasis
Autoimmune Addison's disease

Other manifestations
Autoimmune hypogonadotropic hypogonadism
Alopecia
Chronic hepatitis
Chronic atrophic gastritis
Pernicious anaemia
Vitiligo
Malabsorption
Nephritis
Sjögren's syndrome
Autoimmune thyroid disease
Keratoconjunctivitis
Hypophysitis
Insulin-dependent diabetes mellitus
Exocrine pancreatic insufficiency
Pneumonitis
Vasculitis
Enamel hypoplasia
Nail dystrophy
Haemolytic anaemia
Turner syndrome

In decreasing order of incidence, adapted with permission from Betterle, C., N.A. Greggio, and M. Volpato, Clinical review 93: Autoimmune polyglandular syndrome type 1. *J Clin Endocrinol Metab*, 1998. 83(4): p. 1049–55 [59] and from Husebye, E.S., M.S. Anderson, and O. Kampe, Autoimmune Polyendocrine Syndromes. *N Engl J Med*, 2018. 378(12): p. 1132–1141 [60].

so that parenteral replacement of these minerals may be required. Continuous nocturnal nasogastric calcium supplementation may be a useful temporary measure in the affected child unable to tolerate standard bolus feeding, and where prolonged parenteral infusions are not practical.

The long-term prognosis of this condition has improved greatly over the past generation. Early cases succumbed to such problems as unrecognized adrenal crises or diabetic keto-acidosis. Although numerous complications of this disorder are recorded, including overwhelming candida sepsis, oesophageal carcinoma, and chronic active hepatitis, these severe features are rare. One review records a 50-year survival of greater than 75%.

Surgical hypoparathyroidism is rarely encountered in childhood but can be a complication of thyroid surgery. Average rates of transient or permanent hypoparathyroidism are 5–15%, respectively, following thyroidectomy [72]. Standard guidelines for thyroid surgery include identification and preservation of parathyroid tissue. The use of radioactive iodine to ablate any thyroid remnants following surgery for cancer has resulted in a less aggressive approach to thyroid surgery. Transient hypocalcaemia in the 36 hours acutely following thyroid surgery is common, although no mechanism has been clearly established which accounts for this finding. Extent of surgery correlates with the risk of hypoparathyroidism as manipulation of the parathyroid glands can result in transient or permanent hypoparathyroidism [72]. Approaches to identifying those patients at an increased risk of developing hypocalcaemia after thyroidectomy include measurement of perioperative intact PTH (iPTH), early (1 hour) postoperative iPTH measurement [73, 74], and postoperative phosphorus monitoring. A level of postoperative iPTH <10–15pg/ml has been found to correlate with an increased risk of clinically significant hypocalcaemia in adults [75, 76]. In randomized controlled trials where patients were either given oral calcium and vitamin D supplements or no supplements, fewer patients on supplements developed hypocalcaemia [77, 78]. Thus, empiric calcium with or without calcitriol replacement therapy can be considered in those patients undergoing total thyroidectomy [72].

Hypoparathyroidism may occur as a complication in disorders related to metal toxicity and infiltration of the parathyroid glands. **Thalassaemia** has been shown to result in a variety of endocrinopathies related to iron deposition. Although hypoparathyroidism was recognized as an occasional complication in most clinics managing such patients, the incidence of this complication has decreased over the past 20 years with increasing use of chelating therapies such as deferoxamine [79]. Hypoparathyroidism has been reported to occur in **Wilson's disease** presumably related to copper deposition in the parathyroid glands [80].

Functional hypoparathyroidism occurs in severe **magnesium deficiency**. Both impairment of parathyroid secretion and resistance to PTH activity at the renal tubule have been described in the setting of chronic magnesium deficiency. In classic studies by Anast *et al.* [81], the dependence of the parathyroid glands on magnesium for secretion of PTH was described in a girl with a congenital magnesium wasting syndrome. It appears that more subtle defects in PTH secretion may occur with less severe magnesium depletion. The serum magnesium level may not reflect total body magnesium status, as magnesium is predominantly an intracellular ion. However, serum magnesium level of greater than 1.3 mg/dl is unlikely to result in clinically significant changes in parathyroid secretion. In children chronic magnesium deficiency occurs in **familial hypomagnesaemia** [82]. **Familial hypomagnesaemia with secondary hypocalcaemia** is an autosomal recessive disease due to mutations in the TRPM6 ion channel, resulting in electrolyte abnormalities in the newborn period [83]. This disorder may present with hypocalcaemic/hypomagnesaemic seizures in the first 2 months of life. If diagnosed early, severe neurologic impairment may be prevented. Mutations in paracellin (encoded by *CLDN16* (OMIM #248250)), a renal tubular paracellular transport protein of the claudin family, may also cause hypomagnesaemia, hypocalcaemia, and hypercalciuria [84]. Another member of this family, *CLDN19*, (OMIM #248190) may also cause a similar syndrome [85]. **Gitelman's syndrome** (OMIM #263800) is an autosomal recessive disorder of magnesium and potassium wasting with metabolic alkalosis and hypocalciuria, due to mutations in *SLC12A3* which encodes a thiazide-sensitive NaCl cotransporter [86].

Hypomagnesaemia in children occurs more frequently with the use of chemotherapeutic agents such as cisplatin, and with aminoglycoside antibiotics such as tobramycin. Hypomagnesaemia has been reported with ibuprofen overdosage in a 21-month-old child simultaneously treated with furosemide [87], and following ingestion of ammonium bifluoride-containing automobile wheel cleaner [88]. Recent data has suggested that moderate decreases in serum magnesium levels accompany the hypocalcaemia encountered during rehabilitation from burn injuries in children [89].

Treatment of chronic hypoparathyroidism. The mainstay of the management of chronic hypoparathyroidism is replacement

with oral calcium supplements and an active metabolite of vitamin D, such as 1,25 $(OH)_2D_3$ (calcitriol) or $1\alpha-(OH)D_3$. Various liquid forms of calcium carbonate (often sold as antacids for children) are useful for the young child unable to take tablets. With conventional therapy, larger doses are often utilized but may not always achieve a physiological normalization of calcium-phosphate homeostasis. The doses are titrated to maintain the serum calcium in the slightly low to low-normal range, with care not to render the child hypercalciuric. Hypercalciuria is especially a concern in patients with ADH due to activating mutations in the CaSR that can be managed by adjunctive therapy with thiazide diuretics. Novel approaches using teriparatide [parathyroid hormone(1-34); PTH(1-34)] and calcilytic agents (antagonists of the CaSR) have recently been reported as potential therapeutics for these disorders.

Limited studies of PTH in children have shown promising results [90–95] with respect to maintenance of normal serum calcium levels [93]. Twice-daily subcutaneous injections were superior to conventional therapy with calcium and calcitriol [93]. Twice-daily dosing resulted in reduced variation in serum calcium levels compared to single daily doses, and with lower total daily doses [94]. Renal function, bone density Z-scores, bone accrual and linear growth remained normal in children over the 3-year treatment period in the study [93]. In children with severe congenital hypoparathyroidism, pump delivery of PTH(1-34) was superior to twice-daily injection therapy, maintaining even more physiologic calcium homeostasis [92].

Although PTH(1-34) tended to lower urinary calcium excretion, results did not reach statistical significance in comparison to conventional therapy [93] or were unchanged from baseline [95]. Only one adult study of pump delivered of PTH(1-34) demonstrated a statistically significant reduction in urinary calcium excretion in comparison to subcutaneous injection [96].

Effects of PTH(1-34) on different skeletal compartments have been studied in both adults and adolescents [95], showing that daily injections of PTH(1-34) stimulated bone turnover, increased bone volume, with an apparent increase in trabecular bone and trabeculation of cortical bone [95].

PTH(1-34) was used safely in a child with hypoparathyroidism due to a sporadic calcium receptor mutation [97] resulting in improved serum mineral control, increased bone mass with normal growth, but this approach did not prevent nephrocalcinosis [97].

These findings lead us to advocate that the first line of chronic therapy for children with hypoparathyroidism should be oral calcium and calcitriol. Use of PTH may be considered in those cases resistant to conventional therapy. However, as long-term effects on developing skeleton are not known, future studies in this regard will be informative.

Calcilytics, which are allosteric antagonists of CaSR, have been considered for treatment of ADH. Studies of calcilytics in mutant *CASR* knock-in mice with the ADH phenotype showed dose-dependent effects on serum calcium and phosphate levels [98]. Urinary calcium levels were improved and renal calcification prevented [98]. Although both calcilytics and PTH(1-34) resulted in improvements in serum calcium and phosphate levels, hypercalciuria and renal calcification persisted with PTH(1-34) [98]. Further studies in humans are needed to better understand the efficacy and potential side effects of calcilytics.

PTH Resistance and Pseudohypoparathyroidism

Pseudohypoparathyroidism (PHP) and pseudopseudohypoparathyroidism (PPHP) are caused by mutations and/or epigenetic changes at the complex *GNAS* locus on chromosome 20q13.3 that undergoes parent-specific methylation changes at several sites [99].

GNAS encodes the alpha subunit of the stimulatory guanine nucleotide regulatory protein ($G\alpha_s$) and several splice variants. There is less paternal $G\alpha_s$ expression in certain tissues, such as the proximal renal tubules, thyroid, and pituitary gland, thus in the presence of maternal *GNAS* mutations, the absence of this protein will lead to hormonal resistance. The syndrome represents a fascinating aspect of hormone receptor biology, and is discussed in detail in Chapter 4.5. For our purposes here, we will describe only a few of the clinical features pertinent to children with the disorder.

Heterozygous inactivating mutations involving the maternal *GNAS* exons 1–13 cause PHP type Ia (PHP1A-OMIM #103580) with PTH-resistant hypocalcaemia and hyperphosphatemia. Additional characteristics of these patients include a short stocky build, round face, early onset obesity, ectopic intramembranous calcifications, brachydactyly, and neurodevelopmental abnormalities; these clinical findings are referred to as Albright hereditary osteodystrophy (AHO). $G\alpha_s$ can be found in most tissues, thus when defective could account for PTH resistance in PHP1A patients, resistance to multiple other hormones that act by stimulating adenylate cyclase [100] including thyroid-stimulating hormone (TSH), gonadotropins, GHRH (growth hormone releasing hormone), and central nervous system (CNS) neurotransmitters can be seen. The respective hormone resistance would be manifest by thyrotrope resistance to TSH, menstrual disorder/irregularities, cryptorchidism in males, and growth hormone deficiency with short stature. Presentation in infancy may include short stature and congenital elevations in TSH, but manifestations of hypocalcaemia usually happens later in childhood.

GNAS mutations inherited on the paternal allele, cause PPHP (OMIM #612463), evidenced by the skeletal phenotype of Albright hereditary osteodystrophy, but in the absence of biochemical abnormalities associated with hormone resistance, described here earlier, in PHP1A.

PHP1B (OMIM #603233) patients demonstrate PTH-resistant, hypocalcaemia, and hyperphosphatemia without the somatic abnormalities of absence of heterozygosity (AOH). These patients have normal $G\alpha_s$ bioactivity [101]. Autosomal dominant PHP type IB (AD-PHP1B) is caused by heterozygous maternal deletions within *GNAS* or *STX16* (Syntaxin-16). *STX16* encodes a protein that is a member of the Syntaxin or t-SNARE (target-SNAP receptor) family. These proteins are found on cell membranes and permit specific synaptic vesicle docking and fusion. Loss-of-methylation at maternally methylated *GNAS* result in reducing $G\alpha_s$ expression, leading to hormonal resistance [99, 101, 102].

PHP1C (OMIM #612462) is a subgroup of PHP1A, with clinical and laboratory findings typical for PHP1A (multihormonal resistance and AHO features), but normal $G\alpha_s$ activity [99, 103, 104].

Treatment of PHP is similar to that for primary hypoparathyroidism, although there is usually little risk of hypercalciuria in the classic (PHP1A) form of the disease. Subcutaneous ectopic ossification must be monitored, which if severe may require surgical removal. Although many treat the TSH resistance with thyroxine supplementation because of the elevated TSH levels, others do not,

in view of normal thyroxine levels. No data has confirmed efficacy of the approach.

Disorders Related to Vitamin D Metabolism

Hypocalcaemia may result from a deficiency of vitamin D, usually related to limited dietary content of vitamin D or limited exposure to ultraviolet light (UV light), critical in the early steps of endogenous vitamin D production in skin. Sufficient UV light is necessary for the production of pre-vitamin D in the stratum spinosum of the dermis. UVB light of wavelength 290–315 nm provides the energy to disrupt the 9–10 C-C bond in the B ring of the steroid nucleus of 7-dehydrocholesterol (**Figure 4.7.3**). Previtamin D is then rapidly isomerized in the skin to vitamin D. Thus, vitamin D deficiency is most frequent in parts of the world where sunlight exposure is limited or exposure to sunlight is prevented. In North America, there have been numerous reports of vitamin D deficiency rickets in breastfed children not supplemented with vitamin D. Breast milk contains little vitamin D, unless the mother is taking pharmacologic doses of the vitamin D. Pigmented individuals are at higher risk for this problem, as melanin absorbs UV light external to the layer of skin where vitamin D synthesis occurs. There is a greater incidence of the problem in the late winter as compared to other times of the year. In some children vitamin D deficiency is compounded by the coincident problem of calcium deficiency. This problem may occur in lactose intolerant children avoiding dairy products, or when the diet has a very high phytate content (as with certain grains and cereals) which can limit the bioavailability of ingested calcium.

Vitamin D deficiency may often present with rachitic bone disease. Symptomatic hypocalcaemia generally occurs late in the course of development of vitamin D deficiency. The initial decreases in intestinal calcium absorption which result from vitamin D deficiency are readily compensated for by the resultant secondary elevations in PTH. When frank hypocalcaemia with tetany or seizures occurs due to vitamin D deficiency, substantial chronicity of vitamin D deficiency has usually been present.

Vitamin D is further metabolized to its most abundant circulating metabolite, 25-OHD, and its best-known active metabolite, 1,25 $(OH)_2D$. The critical mechanism of action for this involves binding to its receptor, a DNA binding protein which is part of the large superfamily of steroid/thyroid/retinoid receptors. Pathophysiology similar to vitamin D deficiency may result from defects in the 1α-hydroxylase enzyme instrumental in the synthesis of 1,25 $(OH)_2D$, or in mutations in the vitamin D receptor.

Clinical features of rickets in children include bowing of the lower extremities, craniotabes, and rachitic rosary (hypertrophy of the costochondral junctions). These syndromes are discussed in detail in Chapter 4.11. The laboratory findings of vitamin D-related hypocalcaemic disorders are compared in **Table 4.7.2**.

Establishment of an appropriate biochemical threshold for the definition of vitamin D deficiency has received considerable attention as there is no consensus on the optimal level of total serum 25-OHD. The Institute of Medicine provides extensive data suggesting that a threshold value of 20 ng/ml provides adequate vitamin D for healthy bone and mineral status in children. In high risk individuals and in individuals prone to metabolic bone disease and/or vitamin D deficiency, keeping 25-OHD above 30 ng/mL can be considered as suggested by the Endocrine Society Task Force [105]. U.S. Preventive Services Task Force issued its own recommendation in adults and concluded that the evidence on screening for vitamin D deficiency in asymptomatic adults to improve health outcomes is insufficient. Thus, current recommendations are for those individuals who are at risk for developing vitamin D deficiency to be screened.

In addition to its well-known effects on calcium/phosphate homeostasis and bone metabolism, various health benefits have been associated with vitamin D status, mostly related to a variety of associations of 25-OHD level and prevalence of certain disorders, including diabetes, multiple sclerosis, cancers (particularly colorectal), and obesity [106]. These data are epidemiologic in nature, and the possibility that vitamin D status serves as a marker for other unidentified contributors to disease remains unknown though there is a suggestion that low vitamin D levels can be an independent predictor of all-cause mortality. Studies in adults have reported associations between dyslipidaemia and cardiovascular disease (CVD) and vitamin D deficiency [107, 108]. Data are limited in children, but similarly, vitamin D deficiency has been associated with markers of CVD in children with obesity, specifically with an increase in atherogenic lipids, suggesting increased cardiovascular risk [109]. A convincing example of 'non-classical' vitamin D effects (i.e. effects apart from those influencing systemic calcium homeostasis) has been demonstrated directly in human macrophages [110]. In the presence of activated toll-like receptors 1/2, macrophages are able to express their own 1α-hydroxylase and its own vitamin D receptor (VDR). Thus, the macrophage has the capacity to metabolize 25-OHD and to use the activated product, 1,25$(OH)_2D$, in autocrine fashion, as it can produce this molecule's receptor. The stimulation of the macrophage in this way leads to the production of a unique antimicrobial peptide, cathelicidin, which is inhibitory to the growth of *M. tuberculosis*. This mechanism has been posited as a means by which vitamin D may play a role in fighting infection. Elevations in circulating PTH occur as circulating 25-OHD decreases, suggesting a mechanism by which 25-OHD deficiency might be defined. However, the threshold values of 25-OHD at which an increase in PTH levels occurs is quite variable [111] suggesting caution in using this measure as a generalizable means of establishing vitamin D deficiency. Nevertheless, these findings, in sum, raise the issue of revising the threshold for 25-OHD level as a measure of optimal vitamin D status, and toxicity information in adults appear to indicate that modest increases in supplementation is safe. Data is not yet available to establish a clear benefit to this approach, and the application of such measures to infants and children needs to be carefully examined. Indeed, the administration of vitamin D to infants and children at the increased levels recently suggested for supplementation in adults could be risky. We have observed hypercalcaemia in a newborn infant given 1400 units of supplemental vitamin D daily, with concomitant circulating 25-OHD levels over 90 ng/ml (225 nmol/L) and thus support a conservative definition of vitamin D deficiency, using threshold values for 25(OH) D of 20 ng/ml (50 nmol/L). In the normal healthy term infant, we advise adherence to current recommendations of a daily vitamin D intake of 400 IU, and 600 IU in children 1 year of age and older.

Treatment: Vitamin D in dosages of 1000–2000 IU per day is a standard approach to the initial treatment of vitamin D deficiency. As rachitic lesions heal, the dosage is decreased to 600 IU per day, the generally recognized recommended daily allowance. An assessment after 8–12 weeks of therapeutic dosing is indicated, with extension of therapeutic doses if healing is insufficient. Consideration

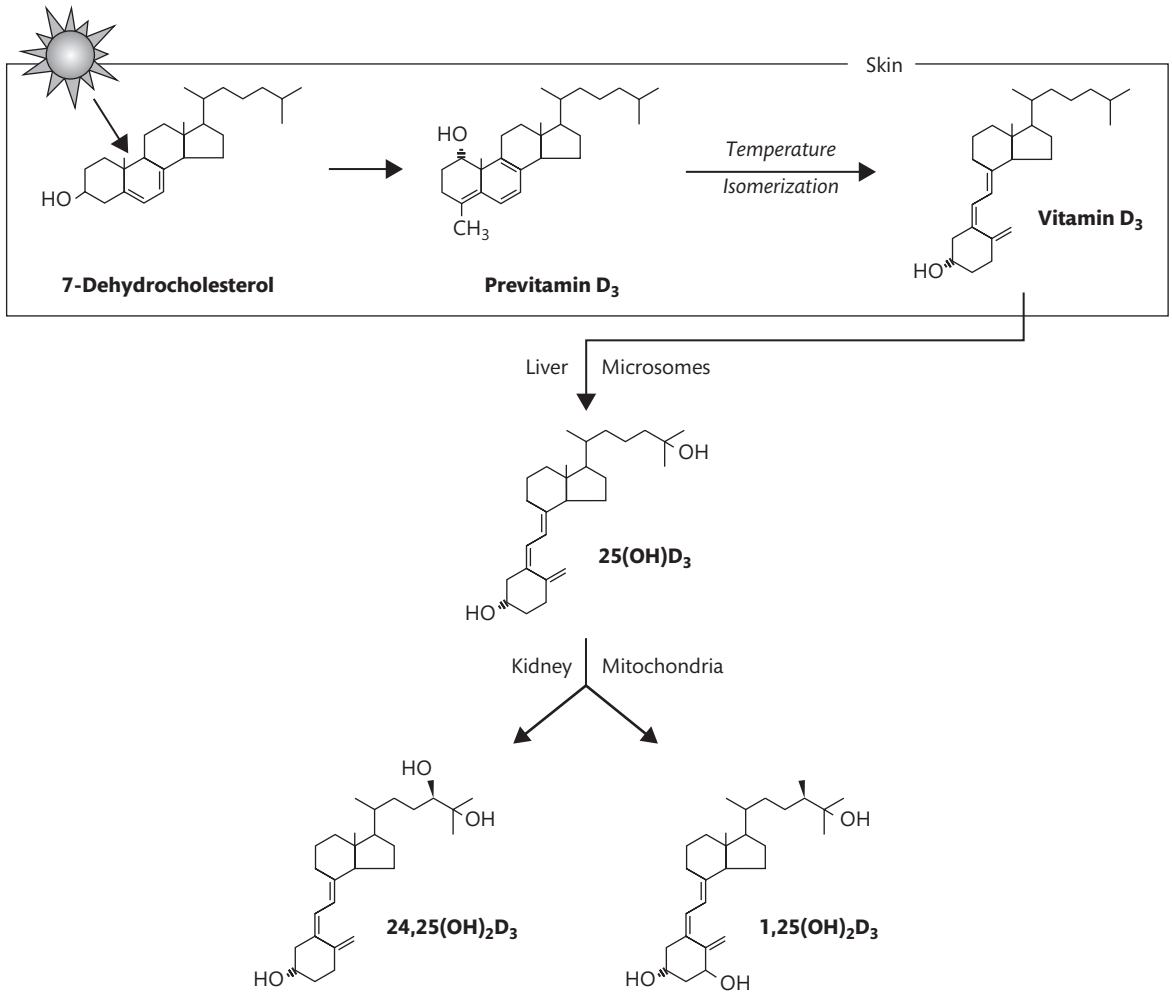

Figure 4.7.3 The vitamin D biosynthetic pathway. The steroid nucleus of 7-dehydrocholesterol is converted in skin to pre-vitamin D_3 with exposure to UVB light and rapidly isomerized to vitamin D_3, which is found in ng/ml concentrations in the circulation. This metabolite is converted to 25-OH D3 in hepatic microsomes, and is also found in ng/ml amounts in the circulation. Measurement of circulating 25-OH D_3 is a biomarker of total body vitamin D stores. 25-OH D_3 is converted in renal mitochondria to the best-known active metabolite, 1,25 (OH)2 D_3 which circulates in pg/ml concentrations in serum. Conversion of 25-OH D_3 to 24,25 (OH)2 D_3 also occurs in renal mitochondria.

of an alternative diagnosis may also be an important consideration at this stage. A single intramuscular dose of 600 000 units of vitamin D, or in two oral doses of 300 000 units each can be given in the outpatient clinic if the clinical situation would indicate that limited follow-up will occur.

The specialty clinician may happen to evaluate such a patient after a change in season, and sunlight exposure has concomitantly increased since the disease onset, or after vitamin supplementation has begun. This situation should be recognized clinically, as low-normal values of the 25(OH)D level may confuse the diagnosis.

Table 4.7.2 Laboratory findings in childhood syndromes presenting with hypocalcaemia

Serum biochemical measures[1]	Ca	P	Alk phos	PTH	25D	1,25D
Vitamin D deficiency	N,↓	N,↓	↑	↑	↓	↓,N,↑
Calcium deficiency	N,↓	N,↓	↑	↑	N	↑
Vitamin D 1-α hydroxylase defect	↓,N	↓,N	↑	↑	N	↓,N
Hereditary resistance to vitamin D	↓,N	↓,N	↑	↑	N	↑
Hypoparathyroidism	↓	↑	N	↓	N	↓N,↑
Pseudohypoparathyroidism	↓	↑	N	↑	N	↓,N

[1] Serum measures for calcium, phosphorus, alkaline phosphatase, parathyroid hormone, 25-hydroxyvitamin D, and 1,25 dihydroxyvitamin D are outlined. N, normal levels; ↓, decreased levels; ↑, increased levels.

Radiographs may demonstrate a thin dense line of opacity at the metaphyses of long bones, which indicates that recent rapid mineralization has occurred at the edge of the growth plate.

As mentioned earlier, children with vitamin D deficiency often require supplemental calcium. Some children may manifest hungry bone syndrome, in which mineralization is rapid and serum calcium levels may decrease as the bone mineralizes. Thus, supplemental calcium is given in many cases to provide a total daily intake of 30–50 mg/kg of elemental calcium. Vitamin D stores may be depleted rapidly during calcium insufficiency [112], suggesting that dietary calcium deficiency itself may be yet another risk factor for the development of vitamin D deficiency.

Deficiency of 1α-hydroxylase is best treated with physiologic doses of 1,25 $(OH)_2D_3$. Hereditary resistance to vitamin D may respond to high dosages of 1,25 $(OH)_2D_3$, but some patients require parenteral calcium infusions [113]. These heritable disorders are discussed in detail in Chapter 4.11.

Other Causes of Hypocalcaemia

Hypocalcaemia may also result from rapid loading of phosphate into the circulation. This phenomenon occurs in settings of tissue destruction, such as in **tumour lysis syndrome** observed during early phases of chemotherapy of large solid tumours. **Rhabdomyolysis** may decrease serum calcium levels for similar reasons. Several cases of hypocalcaemia and seizures have occurred following high-dose administration of phosphate either by enema or by the oral route. The use of phosphate-based cathartics in infants and small children is contraindicated. We are aware of a case in which severe hyperphosphataemia and hypocalcaemia occurred repetitively in a small child surreptitiously administered oral phosphate by her mother. Hypocalcaemia may also occur in the setting of pancreatitis due to precipitation of calcium-containing salts in the inflamed pancreatic tissue and it often correlates with the severity of the episode. Children with acute or chronic renal failure will also develop mild hypocalcaemia, which is due to a multitude of precipitating factors, such as hyperphosphataemia, and decreased 1-alpha hydroxylation of 25-hydroxyvitamin D. Hypocalcaemia has been associated with high volume (1.5 L or more per week) of soft drinks containing phosphoric acid [114]. Hypocalcaemia solely due to **low dietary calcium** intake has also been reported [115]. This syndrome has occurred in areas of South Africa in areas where food content is relatively low in calcium, and rickets is the usual presenting feature. The combination of dietary vitamin D and calcium deficiency is more commonly seen in North American children (see earlier).

Medications typically associated with the development of hypocalcaemia include bisphosphonates and aminoglycoside antibiotics. The use of intravenous bisphosphonates may precipitate hypocalcaemia in children although this is not a frequent occurrence. The effect of reduction in osteoclast activity with this class of compounds results in limitations of movement of calcium in skeletal tissue to the circulation. The practice of providing calcium supplementation for several days following an infusion is commonly used to abrogate the risk of hypocalcaemia. In small children we suggest that oral supplementation of 50 mg/kg of elemental calcium per day be provided in 2–3 dividend doses for 4–5 days following pamidronate or zoledronate infusions.

Aminoglycosides and cisplatin may affect renal tubular function and thereby result in hypocalcaemia due to renal tubular losses. Hypocalcaemia may occur in the setting of critical illness due to multiple mechanisms as described earlier. Transient hypocalcaemia often occurs post-thyroidectomy, due to manipulation of the parathyroid glands with disruption in their reverse function. Finally, the 'Hungry Bone syndrome' has been observed in the setting of treatment of severe nutritional rickets. This phenomenon is attributed to rapid uptake of calcium in the undermineralized skeleton following application of vitamin D therapy in the absence of providing concomitant calcium supplementation. Hungry Bone syndrome may also occur following parathyroidectomy when sudden removal of a parathyroid adenoma in a high bone turnover state reduces bone resorption in the setting where the remaining parathyroid glands have been chronically suppressed and unable to rapidly respond to the resultant hypocalcaemia. Continuous infusion of calcium may be necessary for several days in this clinical situation.

Disorders of Hypercalcaemia

Persistent hypercalcaemia is usually attributed to some combination of the following mechanisms: (1) excessive intestinal absorption of calcium; (2) excessive bone resorption of mineral; and (3) abnormal renal retention of calcium. Infants are usually asymptomatic with mild to moderate hypercalcaemia (11.0–13.0 mg/dl).

More severe hypercalcaemia may lead to failure to thrive, poor feeding, abdominal pain, constipation, hypotonia, vomiting, seizures, lethargy, polyuria, and hypertension. Hypercalcaemia is discussed in detail in Chapter 4.2. Congenital causes of hypercalcaemia are more frequent in children than acquired causes such as malignancy, which are more common in adults. Several syndromes with specific childhood features are described next.

Severe neonatal hyperparathyroidism is a rare condition presenting with hypercalcaemic symptoms in the first few days of life. Serum calcium levels may range as high as 15–30 mg/dl. The serum phosphate level is usually low, and serum PTH is elevated. The hypercalcaemia is predominantly due to increased bone resorption, but elevated intestinal absorption of calcium, as well as increased renal calcium retention probably occur. Radiographs of the clavicles typically reveal features of primary hyperparathyroidism. Nephrocalcinosis may be present on ultrasonographic examination. Severe neonatal hyperparathyroidism may occur in families with **FHH**. FHH is manifest by modest asymptomatic hypercalcaemia with relative hypocalciuria and normal or slightly increased serum PTH levels. FHH is an autosomal dominant, genetically heterogeneous disorder with three clinically indistinguishable variants acting in a negative manner on parathyroid cells (FHH1-FHH3) [116–118]. FHH1 (OMIM #145980) is a loss-of-function mutation in the *CASR* gene (encoding the CaSR, a G-protein-coupled receptor) on parathyroid cells. FHH2 is due to loss-of-function mutations of *GNA11* which encodes G protein family member $G\alpha_{11}$ and FHH3 (OMIM #600740) is due to loss of function of the adaptor-related protein complex 2, sigma 1 subunit (*AP2σ1*) [117, 118]. This gene product protein forms a heterotetramer with other subunits and mediates the endocytosis of the CaSR.

Severe neonatal hyperparathyroidism has been shown to result in homozygous or compound heterozygous of loss-of-function mutations in *CASR* [119]. This disorder usually requires emergency parathyroidectomy. Intravenous bisphosphonates (such as

pamidronate) has been used for treatment while waiting for surgery [120]. Another approach has employed cinacalcet, a calcimimetic, or positive allosteric modulator of CaSR, that partially restores the sensitivity of a mutant CaSR to calcium. However, this approach is not effective in the setting where homozygous null mutations of CaSR are present [116, 121]. Severe hypercalcaemia that requires surgery has also been described in infants in FHH families that have only one mutant copy of the *CaSR* gene.

In severe **Williams syndrome** (OMIM #194050) symptoms may be present from the neonatal period, but more frequently recognized later in the first few years of life. Infantile hypercalcaemia may be a presenting feature, in addition to pre- and postnatal growth failure. Characteristic unusual facies are often present, as well as cardiovascular abnormalities (usually supravalvular aortic stenosis or peripheral pulmonic stenosis), delayed psychomotor development, and selective mental deficiency. The genetic marker of the syndrome is a deletion at chromosome 7q11.23 involving elastin and LIM-Kinase genes [122]. The serum calcium levels may range as high as 12–19 mg/dl. The hypercalcaemia usually subsides spontaneously by the age of 4 years. The pathogenesis of hypercalcaemia is uncertain, although various metabolic disturbances have been described including abnormal $1,25(OH)_2D$ production, and decreased calcitonin production [123, 124]. Treatment has traditionally consisted of placing the child on a low calcium diet, free of vitamin D. Short-term therapy with corticosteroids has been applied, however a more recent approach employs intravenous bisphosphonate therapy, which has been quite effective in controlling hypercalcaemia in Williams syndrome patients in our hands. We usually use pamidronate at a dose of 0.25–0.5 mg/kg/dose, and have found that one to three doses have been sufficient to manage this problem permanently.

Jansen's metaphyseal chondrodysplasia (OMIM #156400) is an autosomal dominant disease with short limbs, severe hypercalcaemia, and hypercalciuria (despite normal or undetectable PTH and PTHrP levels) due to heterozygous mutations of the PTH/PTHrP receptor, causing ligand-independent activation of the receptor [125].

Hypophosphatemia increases circulating levels of $1,25(OH)_2D$ due to the decreased levels of the phosphate-regulating hormone, fibroblast growth factor 23 (FGF23). FGF23 regulates the genes that encode the vitamin D 1α- and 24-hydroxlyases (*CYP27B1* and *CYP24A1*, respectively) in reciprocal fashion, such that in the setting of low FGF23, 1α-hydroxylase activity increases and 24-hydroxylase decreases. This results in higher circulating levels of $1,25(OH)_2D$. This phenomenon is evident with loss-of-function mutations in *SLC34A1* (OMIM #616963), which encodes a major renal proximal tubal phosphate transporter (NaPi-IIa), as recently identified in some forms of idiopathic infantile hypercalcaemia (IIH).

Idiopathic infantile hypercalcaemia (IIH) may also result from loss-of-function mutations in the *CYP24A1* (OMIM #616963) resulting in reduced catabolism of both 25-OHD and $1,25(OH)_2D$. Most forms of this disorder result from biallelic mutations although milder phenotypes have been attributed to heterozygous mutations. The degree of hypercalcaemia can be quite variable among children with a classic phenotype [126].

Subcutaneous fat necrosis is a self-limited disorder which presents in infancy with symptoms of hypercalcaemia and erythematous or violaceous discoloration of the skin and firm indurated tissue palpable underneath. There is often a history of birth trauma or asphyxia. It is thought that the insult to the fat tissue causes cellular necrosis and infiltration of mononuclear cells and macrophages which may become granulomatous in nature. Small calcified areas may be present. Increased production of $1,25(OH)_2D$ by the inflammatory cells has been considered in some cases as the cause of hypercalcaemia [127]. Thus, a vitamin D-free, low calcium diet and glucocorticoids have traditionally been used to treat this disorder. However, like with Williams syndrome, dietary restriction of calcium intake alone may not be sufficient to correct the serum calcium level, indicating that a component of bone resorption must play a role in the development of hypercalcaemia. Therefore, we have used bisphosphonates (e.g. pamidronate) to successfully control persistent hypercalcaemia in this condition. Often a single dose is sufficient.

Intoxication with vitamin D or vitamin A should be excluded in the older infant with hypercalcaemia [128–131]. In vitamin D intoxication, it is important to measure the circulating level of 25-OHD, the most abundant circulating vitamin D metabolite. Levels of $1,25(OH)_2D$ are usually low. Toxicity may be mediated by the overwhelming large dosages of 25-OHD interacting with the VDR. Alternatively because 25-OHD has a far greater affinity than $1,25(OH)_2D$ for the circulating vitamin D binding protein (DBP), it has been proposed that the latter, more active metabolite is displaced from DBP, with toxicity resulting from the increase in free levels of $1,25(OH)_2D$. Excess intestinal absorption of calcium is present, and there may also be evidence for increased bone resorption. Elevated circulating $1,25(OH)_2D$ levels can cause hypercalcaemia but are not usually elevated in typical cases of vitamin D intoxication. Malignant and granulomatous diseases may cause extrarenal synthesis of $1,25(OH)_2D$ and resultant hypercalcaemia may ensue. Likewise, endogenous overproduction of $1,25(OH)_2D$ has been described in twins with **cat-scratch disease** induced granulomata [132]. Vitamin A intoxication results in bone pain, hypercalcaemia, headache, pseudotumor cerebri, and a characteristic erythematous skin rash with exfoliation. Alopecia and profuse ear discharge may be present. The hypercalcaemia is thought to be mediated by osteoclastic bone resorption [133]. Although toxicity is not thought to occur when less than 50 000 units of vitamin A or equivalent is ingested on a daily basis, reports of toxicity with less ingestion have been recorded in children [134]. Unrecognized liver disease may decrease the tolerance of vitamin A. In order to establish the diagnosis of vitamin A intoxication, serum retinyl ester levels should be determined in addition to the more common test for serum retinol.

Other conditions in which hypercalcaemia may be manifest in children include Down's syndrome, renal tubular acidosis, and osteogenesis imperfecta. Indeed, we have observed mild elevations in serum calcium during infancy in association with a variety of skeletal dysplasias. This appears to be a transient phenomenon. Endocrinopathies including pheochromocytoma, Addison's disease [135], thyrotoxicosis [136], and severe congenital hypothyroidism [137, 138] may be associated with development of hypercalcaemia.

Other major causes of hypercalcaemia include those commonly encountered in adults: immobilization, malignancy, and acquired hyperparathyroidism including parathyroid adenomas.

Treatment of Hypercalcaemia

Acute: The medical management of acute symptomatic hypercalcaemia consists of the administration of intravenous saline.

Intravenous infusion of bisphosphonates has also been useful in this setting. Specific long-term therapy depends on the specific hypercalcaemic disorder.

The use of bisphosphonate therapy in children has increased in recent years, both when associated with childhood cancers [139], and in the treatment of hypercalcaemia in Williams syndrome and subcutaneous fat necrosis, as noted earlier. Side effects are minimal and that the therapy appears to be safe. One should be aware of the potential complications of electrolyte disturbances, particularly hypocalcaemia, hypophosphataemia, and hypomagnesaemia.

One interesting approach in patients with IIH due to biallelic mutations of *CYP24A1* employs daily rifampin administration. The approach relies on the capacity of rifampin to induce overexpression of *CYP3A4*, which encodes an enzyme serving as an alternate mechanism for vitamin D inactivation in patients who lack *CYP24A1* function [140].

Osteoporosis

Richard Eastell

Importance

Osteoporosis affects an estimated 75 million people in Europe, the United States, and Japan combined [1]. It is a preventable and a treatable condition, yet many patients with fractures remain unrecognized and untreated.

Definition

Definitions for osteoporosis have usually been conceptual. An example was produced by a Consensus Development Conference [1] as 'a systemic skeletal disease characterized by low bone mass and microarchitectural deterioration with a consequent increase in bone fragility and susceptibility to fracture'. This definition is elegant but difficult to apply to an individual patient. An operational definition of osteoporosis has been proposed by a Working Group of the World Health Organization (WHO) [2]. This defines osteoporosis by the patient's bone mineral density (BMD) in relation to the mean value in normal, young subjects. Specifically, osteoporosis is a value for BMD level equal to or less than 2.5 standard deviation (SD) below the mean value in young subjects (T score ≤2.5) (**Figure 4.8.1**). This definition is useful as an entry criterion to a clinical trial or as a tool to study the epidemiology of osteoporosis, but it has limitations in clinical practice. It elevates a risk factor for fracture to the status of a diagnostic criterion, it ignores the importance of other determinants of bone strength [3], it ignores higher fracture risk associated with a certain level of BMD in older women, and it does not specify the technique or the site at which BMD should be measured. Bone density results can also be compared to the mean value in normal subjects of the same age (Z score). A Z score below –0.67 would indicate a value in the lowest 25% of the reference range, a level indicating a high lifetime risk of fracture. A Z score below –2 would indicate a value in the lowest 2.5% of the reference range, a level likely to be associated with a high risk factor for osteoporosis.

It is now possible to determine individuals' risk of osteoporosis using a combination of BMD and clinical risk factors as proposed by a WHO working group [4]. A prediction algorithm is available (FRAX, which allows estimation of 10-year risk) and treatment guidance may be based on this (http://www.shef.ac.uk/FRAX). In the United Kingdom, the threshold for treatment differs by age [4]. In other countries, such as the United States, treatment is recommended in a woman with osteopaenia (BMD T score –1.0 or less, and either a 10-year risk of hip fracture of 3% or 10-year risk of major osteoporotic fractures of 20% [5].

Epidemiology

The commonest osteoporosis-related fractures are the proximal femur (hip), vertebrae (spine), and distal forearm (wrist). Hip fracture rate increases exponentially with age and is three times more common in women than men. About 50% of hip fractures occur after age 80 years. There is an excess mortality of 18% following a hip fracture. Vertebral fractures are asymptomatic in over half of cases, and so their epidemiology is more difficult to define. Morphometric approaches have been applied to large population samples. Up to 25% of women over age 50 years have vertebral fractures and the prevalence in men is similar. Most vertebral fractures in women are a consequence of mild-to-moderate trauma, but in men almost half result from severe trauma. Wrist fracture incidence increases at the time of the menopause but reaches a plateau after age 70 years. There is no increase with age in men and 85% of wrist fractures occur in women. This plateau may be explained by a cessation of bone loss after age 70 years at the wrist or to a different way of falling in older people.

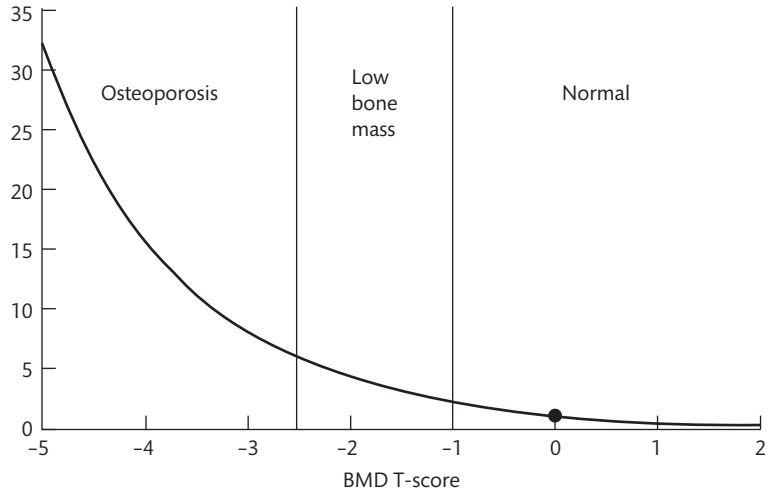

Figure 4.8.1 The risk of fracture increases by a factor of 2 for every 1–SD decrease in bone mineral density (BMD). The WHO definition of osteoporosis is based on the BMD in relation to SDs from the young normal mean (the T score). Osteoporosis is defined as a BMD that is equal to or less than 2.5 SD below the young normal mean.

These fractures carry a large cost to the Health Service, £1.7 billion in the United Kingdom. With the ageing of the population (and a secular increase in age-specific fracture incidence) the burden will increase in the future.

Pathophysiology of Postmenopausal Osteoporosis

Osteoporosis-related fractures result from a combination of decreased BMD and a deterioration in bone microarchitecture.

A BMD T score of –2.5 or less indicating osteoporosis is present in about 50% of patients presenting with wrist, spine, or hip fracture. A BMD below average for age can be considered a consequence of inadequate accumulation of bone in young adult life (low peak bone mass) or of excessive rates of bone loss. The microarchitectural changes occur in parallel with the bone loss but will be considered separately.

Determinants of Peak Bone Mass

The increase in bone mass that occurs during childhood and puberty results from a combination of growth of bone at the endplates (endochondral bone formation) and of change in bone shape (modelling) [6]. The rapid increase in bone mass at puberty is associated with an increase in sex hormone levels and the closure of the growth plates. Within 3 years of menarche, there is little further increase in bone mass. The small increase in BMD over the next 5–15 years is referred to as 'consolidation'. The resulting peak bone mass is achieved by age 20–30 years old [7].

Genetic factors are the main determinants of peak bone mass [8]. This has been shown by studies made on twins or on mother–daughter pairs. Hereditability appears to account for about 50–85% of the variance in bone mass, depending on the skeletal site. Variants in the genes encoding factors known to regulate bone mass (such as oestrogen receptor-α (ERα), vitamin D receptor, transforming growth factor-β (TGFβ), low-density lipoprotein receptor-related protein 5 (LRP5) and LRP6 (both involved in WNT signalling) and bone matrix components (e.g. collagen type I α1) were found to be associated with bone mass and fracture risk, but these variants could be used to explain only very little of the interindividual variation. The non-genetic factors include low calcium intake during childhood, low body weight at maturity and at 1 year of life, sedentary lifestyle, and delayed puberty. Each of these results in decreased bone mass.

Bone Loss

Mechanisms of Bone Loss

Bone loss occurs in the postmenopausal woman as a result of an increase in the rate of bone remodelling and an imbalance between the activity of osteoclasts and osteoblasts. Bone remodelling occurs at discrete sites within the skeleton and proceeds in an orderly fashion with bone resorption always being followed by bone formation, a phenomenon referred to as 'coupling'. In cortical and cancellous bone, the sequence of bone remodelling is similar [9]. The quiescent bone surface is converted to activity (origination) and the osteoclasts resorb bone (progression) forming a cutting cone (cortical bone) or a trench (cancellous bone). The osteoblasts synthesize bone matrix which subsequently mineralizes. The sequence takes up to 8 months. If the processes of bone resorption and bone formation are not matched then there is 'remodelling imbalance'. In postmenopausal women, this imbalance is magnified by the increase in the rate of initiation of new bone remodelling cycles (activation frequency).

Remodelling imbalance results in irreversible bone loss. There are two other causes of irreversible bone loss, referred to as 'remodelling errors'. First is excavation of overlarge haversian spaces in cortical bone [10]. Radial infilling is regulated by signals from the outermost osteocytes and is generally no more than 90 μm. Hence, large external diameters, which may simply occur randomly, lead to large central haversian canals, which then accumulate with age, leading to increased cortical porosity. In a similar way, osteoclast penetration of trabecular plates, or severing of trabecular beams, removes the scaffolding needed for osteoblastic replacement of resorbed bone. In both ways random remodelling errors tend to reduce both cancellous and cortical bone density and structural integrity.

Causes of Bone Loss

Oestrogen Deficiency

Bone loss in the postmenopausal woman occurs in two phases [11]. There is a phase of rapid bone loss that lasts for 5 years (about 3% per year in the spine). Subsequently, there is lower bone loss that is more generalized (about 0.5% per year at many sites). This slower phase of bone loss affects men, starting at about age 55 years. The rapid phase of bone loss in women is caused by oestrogen deficiency. The circulating level of oestradiol decreases by 90% at the time of the menopause. This bone loss can be prevented by the administration of oestrogen and progestins to the postmenopausal woman. It has been estimated that this rapid phase of bone loss contributes 50% to the spinal bone loss across life in women. The main effect of oestrogen deficiency is on bone, where it increases activation frequency, and may contribute to the remodelling imbalance. Oestrogen deficiency may increase bone resorption by stimulating the synthesis of *RANKL* by osteoblasts (or their precursors). *RANKL* binds to its receptor RANK on the osteoclast and promotes differentiation to osteoclasts, increases osteoclast activity, and inhibits osteoclast apoptosis. Oestrogen deficiency also increases the apoptosis of osteoblasts and osteocytes.

Oestrogen deficiency may be a determinant of bone loss in men [12]. Decreased BMD has been reported in men with an inactivating mutation of the genes for the oestrogen receptor or for aromatase (the enzyme that converts androgens to oestrogens). In older men, oestrogen levels correlate more closely with BMD than testosterone levels. In men with osteoporosis, oestradiol (but not testosterone) levels have been reported to be decreased.

Ageing

The slow phase of bone loss is attributed to age-related factors such as an increase in parathyroid hormone (PTH) levels (Figure 4.8.2) and to osteoblast senescence. An increase in PTH levels (and action) occurs in both men and women with ageing. PTH levels correlate with those of biochemical markers of bone turnover and both may be returned to those found in young adults by the intravenous infusion of calcium. The increase in PTH results from decreased renal calcium reabsorption and decreased intestinal calcium absorption. The latter may result from vitamin D deficiency (e.g. in the housebound elderly), decreased 1α-hydroxylase activity in the kidney resulting in decreased synthesis of 1,25-dihydroxyvitamin D, or resistance to vitamin D. Whatever the cause, a diet high in calcium returns both PTH and bone turnover markers to levels found in healthy young adults. It has been proposed that the age-related increase in PTH could result from indirect effects of oestrogen deficiency [11]. This proposal is based on the following evidence. In older women treated with oestrogen, [1] there is a decrease in bone turnover markers and PTH levels; [2] there is an increase in calcium absorption, possibly mediated by an increase in 1,25-dihydroxyvitamin D; [3] there is an increase in the PTH-independent calcium reabsorption in the kidney; and [4] there is a decrease in the parathyroid secretory reserve.

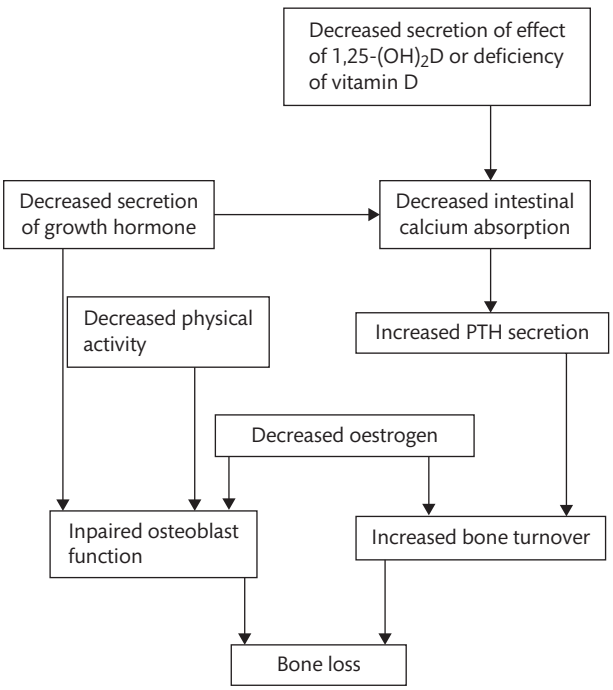

Figure 4.8.2 The causes of bone loss with ageing.

Accelerating Factors

A number of diseases and drugs are clearly related to accelerated bone loss (Box 4.8.1). Their effects are superimposed on those described just now. Thus, a patient starting on corticosteroid therapy is more likely to have an osteoporosis-related fracture if she has low BMD resulting from low peak bone mass and the accelerated bone loss of the menopause.

Identification of Mechanism of Bone Loss in an Individual

In a woman presenting with osteoporosis at age 70 years it is often possible to identify several reasons for the low BMD (Figure 4.8.3). Some of these may be identified from history taking (early menopause, drugs that accelerate bone loss), but some cannot be identified in retrospect (low peak bone mass and rapid losers).

Other Determinants of Bone Strength

Bone Geometry

Bone geometry has a major effect on fracture risk [3]. One example is hip axis length, the distance from the lateral surface of the trochanter to the inner surface of the acetabulum, along the axis of the femoral neck. Short hip axis length results in an architecturally stronger structure for any given bone density. This is probably the reason why Japanese and other Orientals have about half the hip fracture rate of Caucasians, despite similar bone density values.

Fatigue Damage

Fatigue damage consists of ultramicroscopic rents in the basic bony material, resulting from the inevitable bending that occurs when a structural member is loaded. Fatigue damage is the principal cause of failure in mechanical engineering structures; its prevention is the responsibility of the remodelling apparatus which detects and removes fatigue-damaged bone. Fractures related to fatigue damage occur whenever the damage occurs faster than remodelling can repair it or whenever the remodelling apparatus is defective. March fractures and the fractures of radiation necrosis are well-recognized examples of fractures due to these two mechanisms.

Box 4.8.1 Risk factors for osteoporosis in postmenopausal women

- Genetic factors
  - First-degree relative with low-trauma fracture (e.g. mother with hip fracture)
- Environmental factors
  - Cigarette smoking
  - Alcohol abuse
  - Physical inactivity or prolonged immobilization
  - Thin habitus (e.g. less than 57 kg)
  - Diet low in calcium (e.g. less than 500 mg/day)
  - Little exposure to sunlight (e.g. housebound elderly)
- Menstrual status
  - Early menopause, that is, before age 45 years
  - Previous amenorrhoea (e.g. anorexia nervosa, hyperprolactinaemia)
- Drug therapy
  - Glucocorticoids (e.g. 7.5 mg/day of prednisolone or more, for 6 months or more)
  - Antirejection therapy after organ transplantation (e.g. ciclosporin)
  - Antiepileptic drugs (e.g. phenytoin)
  - Excessive substitution therapy (e.g. thyroxine, hydrocortisone)
  - Anticoagulant therapy (e.g. heparin, warfarin)
  - Aromatase inhibitors and gonadotropin-releasing hormone agonist therapy for breast (and prostate) cancer
- Endocrine diseases
  - Primary hyperparathyroidism
  - Thyrotoxicosis
  - Cushing's syndrome
  - Addison's disease
- Haematological diseases
  - Multiple myeloma
  - Systemic mastocytosis
  - Lymphoma, leukaemia
  - Pernicious anaemia
- Rheumatological diseases
  - Rheumatoid arthritis
  - Ankylosing spondylitis
- Gastrointestinal diseases
  - Malabsorption states (e.g. coeliac disease, Crohn's disease, surgery for peptic ulcer)
  - Chronic liver disease (e.g. primary biliary cirrhosis)

Loss of Trabecular Connectivity

Bone structures loaded vertically, such as the vertebral bodies and femoral and tibial metaphyses, derive a substantial portion of their structural strength from a system of horizontal, cross-bracing trabeculae which support the vertical elements and limit lateral bowing and consequent snapping under vertical loading. Severance of such trabecular connections is known to occur preferentially in postmenopausal women and is considered to be an important reason for the large female/male preponderance of low-trauma vertebral fractures.

Risk Factors for Osteoporosis

A number of risk factors have been identified for osteoporosis (Box 4.8.1). Bone loss can be stopped, or reversed, if risk factors such as primary hyperparathyroidism (see Chapter 4.3) are identified and treated. The patient who presents with a vertebral fracture and low BMD is likely to have had one of four causes (Figure 4.8.3). It is impossible to know the importance of peak bone mass and the rate of bone loss in retrospect. Questions can be asked about early menopause and about the drugs and diseases known to accelerate bone loss. We usually assess risk factors by administering a questionnaire before first attendance at the clinic, by carrying out a limited biochemical work-up before the clinic visit (Box 4.8.2), and, after the clinical, evaluation exploring alternative diagnoses.

Genetic Factors

Family History

A maternal history of hip fracture increases the risk of hip fracture in an individual.

Osteogenesis Imperfecta

Late-onset forms (e.g. Sillence type I) may present with vertebral fracture. The clinical clues are the blue sclerae, hypermobile joints, lax skin, cardiac murmurs, and deafness (see Chapter 4.12).

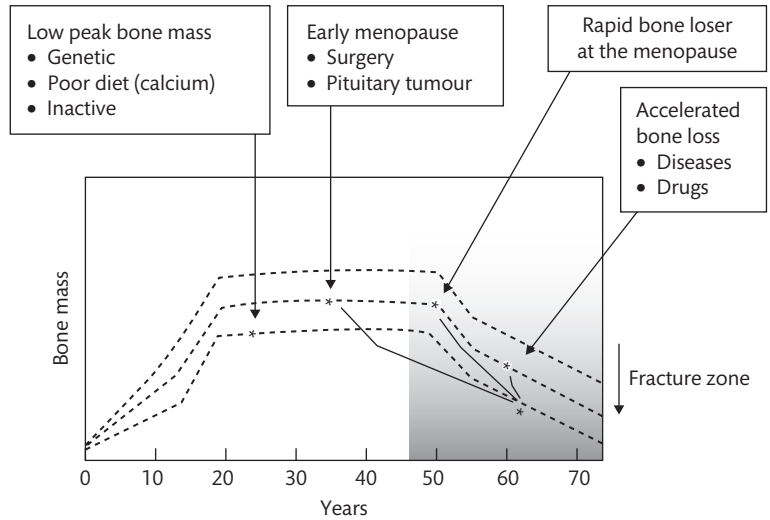

Figure 4.8.3 The possible causes of low bone mass in a 70-year-old woman. Note how peak bone mass is attained about the age of 30 years and the phase of accelerated bone loss begins at the menopause. The lower the bone density falls, the greater the risk of fracture.

Box 4.8.2 Diagnostic evaluation of osteoporosis

- Establish presence of low-trauma fracture (fall from standing height or less)
  - Spine radiographs
- Evaluate degree of bone loss
  - Bone densitometry (see Box 4.8.3)
- Laboratory tests to exclude secondary osteoporosis
  - Primary hyperparathyroidism (serum calcium)
  - Thyrotoxicosis (thyroid-stimulating hormone)
  - Multiple myeloma (erythrocyte sedimentation rate, protein electrophoresis, and urinary Bence Jones protein)
  - Osteomalacia (serum calcium, phosphate (fasting, morning), alkaline phosphatase, 24-h urinary calcium and creatinine)
  - Malabsorption syndrome (full blood count and, if necessary, red cell folate, serum vitamin B_{12}, antiendomysial antibodies, magnesium)
  - Hypogonadism in men (testosterone and, if necessary, sex hormone binding globulin, luteinizing hormone, follicle-stimulating hormone, prolactin)

Environmental Factors

Cigarette Smoking and Chronic Obstructive Pulmonary Disease

Smoking results in lower oestrogen levels and early menopause, and smokers often have a slender stature (see next). Chronic lung disease is associated with chronic respiratory acidosis and decreased physical activity.

Alcohol Abuse

The relationship between alcohol and bone loss is complex (and there may even be a protective effect at a low level of intake) [13]. Alcoholism results in low BMD because of poor nutrition and pseudo-Cushing's syndrome, and a direct suppressive effect of alcohol on osteoblasts. Fractures result from the increased propensity to fall.

Physical Inactivity and Immobilization (Neurological)

Athletes have high BMD. However, bone loss only results from complete immobilization (or space flight). The bone loss after paralysis (e.g. stroke) is regional.

Thin Habitus

This is a risk factor for fracture through decreased oestrogen production from adrenal androgens (in adipose tissue) and through decreased padding (to cushion a fall). Women with hip fracture weigh about 8 kg less than the average woman.

Diet—Low Dietary Calcium

Low dietary calcium and high dietary sodium are considered risk factors for osteoporosis. Calcium requirement increases during growth and in the postmenopausal period. A postmenopausal woman should take 1500 mg/day of calcium.

Little Exposure to Ultraviolet Light

Ultraviolet light (UVB) acts on the skin as the main source of vitamin D (see Chapter 4.11). The housebound are liable to vitamin D insufficiency. This does not result in clinical osteomalacia, but the decreased calcium absorption (see earlier) results in secondary hyperparathyroidism.

Menstrual Status

Early Menopause

A menopause before the age of 45 years is associated with increased risk of fracture. A menopause before the age of 40 years is often associated with some endocrine cause and should be investigated further.

Amenorrhoea

A late onset of the menarche and periods of amenorrhoea of any cause (e.g. exercise related, are associated with decreased bone mass later in life).

Anorexia Nervosa

This is associated with bone loss and increased risk of fracture. The bone loss is probably irreversible after 4 years of amenorrhoea. The mechanism of the bone loss is not just oestrogen deficiency. The diet is low in calcium and serum IGF-1 levels are low, and cortisol secretion may be increased.

Hyperprolactinaemia

This results in oestrogen deficiency. Not all studies have reported bone loss, and it may be that prolactin has some beneficial effects on calcium homeostasis, such as an increase in calcium absorption.

Drug Therapy

Corticosteroids

In the United Kingdom, over 250 000 patients take continuous oral glucocorticoids, yet no more than 14% receive any therapy to prevent bone loss, a serious complication of glucocorticoid treatment. Bone loss is rapid, particularly in the first year, and fracture risk may double [14]. The mechanism of the bone loss is mainly a suppression of osteoblast activity. This differs from oestrogen deficiency, in which the mechanism is mainly increased activation frequency. A treatment algorithm has been presented for adults receiving glucocorticoid doses for 6 months or more [15]. General measures (e.g. alternative glucocorticoids and routes of administration) and therapeutic interventions such as bisphosphonates, are recommended. Glucocorticoid-induced osteoporosis is discussed in greater detail in Chapter 4.12.

Antiepileptic Drugs

Phenobarbitone and phenytoin are known to affect vitamin D metabolism and result in osteomalacia. More commonly, they may cause secondary hyperparathyroidism and osteoporosis.

Excessive Substitution Therapy

Thyroxine doses sufficient to suppress thyroid-stimulating hormone, and hydrocortisone doses that result in 24-h urinary free cortisol above the reference range, have adverse effects on bone turnover and bone density (see Chapter 4.9).

Anticoagulant Drugs

Heparin stimulates bone resorption by a direct effect on osteoclasts. Its long-term use (e.g. in pregnancy) results in bone loss at the spine

and hip of 8–10% over 6 months. Warfarin may interfere with the γ-carboxylation of bone proteins, and its use is associated with an increased risk of fracture.

Endocrine Diseases

Primary Hyperparathyroidism

This is associated with an increase in bone turnover and a decrease in bone mass, particularly at sites rich in cortical bone. It is likely that there is an increase in fracture rates. These changes are reversible with surgical removal of the tumour (see Chapter 4.3).

Thyrotoxicosis

This topic is discussed in Chapter 4.9.

Cushing's Syndrome

Cushing's disease may present with vertebral fracture. The bone loss in the first few years after pituitary surgery is between 10% and 20% at the spine.

Addison's Disease

This is associated with decreased bone mass, resulting from excess substitution therapy and deficiency of adrenal androgens (precursors for oestrogen synthesis in men and postmenopausal women).

Haematological Diseases

Multiple Myeloma

This may present with vertebral fracture. It is usually identified with serum protein electrophoresis, and urinary Bence Jones testing, but occasionally the myeloma may be non-secretory and can usually be diagnosed by bone marrow examination.

Systemic Mastocytosis

This may cause decreased or increased bone density. It can be identified by urticaria pigmentosa, and mast cells are identified in the bone biopsy (see Chapter 6.15).

Pernicious Anaemia

This has been associated with low bone density and increased risk of fractures. The mechanism is unclear, as the absorption of calcium from food is normal despite the absence of gastric acid.

Rheumatological Diseases

Rheumatoid Arthritis and Ankylosing Spondylitis

The immobility may be an important cause, as may be the local (and circulating) cytokines, which promote bone resorption. The corticosteroid therapy for rheumatoid arthritis may also contribute.

Gastrointestinal Diseases

Malabsorption Syndrome

Diseases such as coeliac disease may present with osteoporosis. Other inflammatory bowel diseases, such as Crohn's disease, may require treatment with corticosteroids. Patients who have had peptic ulcer surgery have low bone density and increased risk of fracture. This may also be due to their habits—such patients are usually thin, commonly smoke, and may take excess alcohol.

Chronic Liver Disease

Chronic obstructive liver diseases, such as primary biliary cirrhosis, are associated with osteoporosis. Bilirubin has been associated with osteoblast suppression *in vitro*. Liver transplantation results in further bone loss and about one-third of patients suffer fractures [16]. This bone loss is likely to be related to the immunosuppression (corticosteroids and cyclosporine).

Clinical Presentation of Vertebral Fracture

Osteoporosis does not cause pain or deformity in the absence of fractures. Its importance lies in the fact that it greatly increases the risk of fracture, notably forearm (Colles') fracture, hip fracture, and vertebral fracture. The commonest presentation in clinical practice is vertebral fracture and so this will be described in more detail.

History of Back Pain

The back pain of vertebral fracture has some characteristic features. The pain often comes on within a day of some strain on the back, such as lifting a suitcase or a grandchild, a jolt on a bus or working in the garden. The pain soon becomes very severe and the patient may need to stay in bed for several days. The pain is usually localized to the back and it is uncommon for pain to radiate into the legs, and symptoms of cord compression such as bladder dysfunction are rare. The pain is present throughout the day and night. The pain gradually eases and goes by 4 to 6 months. If pain persists longer, or if there is a second peak of pain during the first 6 months, this usually indicates a second vertebral fracture. This is not an uncommon occurrence. Patients commonly do not complain of back pain. Indeed, it has been estimated that at least half of vertebral fractures are asymptomatic. These asymptomatic fractures appear to be particularly common in patients taking corticosteroids. Episodes of back pain may have been forgotten. The patient commonly recalls a painful episode when confronted with the appearance of a fracture on the spinal radiograph. This incontrovertible evidence prompts the recall of a painful event occurring many decades previously, often in relation to heavy manual work in a man or after pregnancy in a woman.

Loss of Height

Loss of height is an effect of ageing, resulting from the change of posture caused by degenerative changes in the intervertebral discs. Patients do not report this symptom often and it needs to be sought by asking the patient's height in early adult life. The patient may have noticed that it is more difficult to reach high shelves. It is unusual to have sudden height loss as the presenting complaint for vertebral fracture.

Kyphosis

This may have been noticed by a relative or the patient may report being 'round-shouldered'. Clothes may no longer fit. These symptoms are not specific to vertebral fracture and are more commonly caused by disc degeneration. In a young person, kyphosis may be caused by Scheuermann's disease (see next).

Other Symptoms of Vertebral Fracture

Vertebral fractures in the lumbar region result in decreased abdominal volume. This causes the abdomen to protrude. Patients with osteoporosis are commonly slender, so this appearance is new. They may also result in impingement of the costal margin on the iliac crest. This 'iliocostal friction syndrome' causes pain and a grating sensation. This pain is postural, occurring on sitting. Vertebral fractures in the thoracic spine result in reduced lung volume. This may result in respiratory symptoms, such as dyspnoea, or in delayed recovery from chest infections.

Clinical Examination

Two aspects of the clinical examination are useful in the patient with suspected vertebral fracture. The first relates to the location of the pain. It is often assumed that the deformity on the radiograph and the patient's back pain are associated. However, a careful palpation of the spinal processes counting down from vertebra prominens (seventh cervical vertebra) often reveals that the site of the pain does not correspond with the level of the deformity on the radiograph. It is helpful to evaluate the size of the gap between the costal margin and the iliac crest. This is normally three finger's breadths (as measured by the patient's fingers).

Diagnostic Evaluation

Spinal Radiographs

See Box 4.8.2. Plain radiographs are required of the thoracic and lumbar spine in the anteroposterior and lateral position. It is a common mistake to take the radiograph only of the painful area. This would miss asymptomatic fractures in other parts of the spine. It is common only to take lateral radiographs. The anteroposterior radiograph is useful to identify the vertebral level of the fracture and to exclude other causes of deformity, such a malignancy (associated with absent pedicles). The critical feature of an osteoporosis-related vertebral fractures is fracture of the vertebral endplate.

Types of Deformity

Vertebral deformities may be wedge, endplate ('biconcave', when both endplates are affected), and compression (also called 'crush') [17]. Wedge deformities are particularly common in the thoracic spine, because the normal kyphosis in this region results in the main force running anteriorly. Biconcavity deformities are particularly common in the lumbar spine, because the normal lordosis results in the main force running through the middle of the vertebra. There appears to be no association between the type of deformity and the severity of pain or with the level of BMD. The level of the deformities should be recorded to allow comparison at follow-up visits.

Deformities that Mimic Fractures

The most common deformity to mimic fracture is Scheuermann's disease. This is a form of epiphysitis that occurs during adolescence ('juvenile epiphysitis') and gives the appearance of wedging and elongation of the vertebral bodies. The characteristic feature is the wavy appearance of the superior and inferior borders.

Malignancy may cause vertebral deformity. The isotope bone scan is particularly useful in this situation as it is unusual to have a single bone lesion. Increased uptake in multiple sites in the skeleton is typical of malignancy. This may occur in prostate cancer, which affects the sacrum, lumbar spine, and ribs (via Batson's venous plexus). Malignancy may cause erosion of the pedicle, a typical appearance not found with osteoporotic vertebral fractures.

Paget's disease of bone commonly affects the spine (see Chapter 4.10). The bone may appear sclerotic, but it is weak and can fracture. The bone texture has a disorganized appearance and the vertebra may be enlarged.

Osteomalacia may result in vertebral deformities (see Chapter 4.11). Often adjacent vertebrae are affected and the endplates are deformed. This gives rise to a 'cod-fish' appearance. There may be other radiological clues, such as the ground-glass appearance of the vertebral body bone and the presence of pseudofractures (Looser's zones) in the pelvis, long bones, or ribs.

Use of Vertebral Morphometry in the Clinic

Dual-energy X-ray absorptiometry (DXA) can be used to image the spine as well as to obtain a measurement of bone density (see next). Vertebral fractures may be identified by careful focus on the appearance of the vertebral endplate [17]. Fracture is likely if the endplate is deformed and should be confirmed with a radiograph.

Isotope Bone Scan

This can be a useful diagnostic tool in certain cases. There is increased isotope uptake in a vertebra for at least 6 months after it has fractured and typically has a uniform distribution in the vertebral body. This can be useful if the radiological appearances are borderline and yet the symptoms are characteristic. In patients with a suspicion of malignancy (previous breast cancer and history of weight loss) the scan is helpful in that metastases often affect many bones. The scan is helpful in a patient with corticosteroid-induced osteoporosis with pelvic pain. These patients commonly develop insufficiency fractures and these show up as symmetrical appearance affecting the sacral alae and the pubic rami. Single photon emission computed tomography is a variant of the isotope bone scan and is particularly useful in identifying the cause of back pain. If the facet joints show increased uptake then the patient may benefit from an injection of local anaesthetic into the facet joint.

Magnetic Resonance Imaging

This approach can be useful in identifying a recent deformity and distinguishing a fracture from a malignant deposit. It is very useful in identifying cord compression. It is an essential test before kyphoplasty or vertebroplasty are considered (see next); only recent fractures clearly benefit from these procedures.

Bone Density Measurement

See Table 4.8.1. DXA is precise, accurate, involves exposure to only low doses of X-rays, and allows measurement of sites of clinical interest (that is, lumbar spine and proximal femur). In DXA, two energy peaks of X-rays are absorbed to different extents by bone and soft tissue, and the density of bone is calculated, in g/cm^2, using simultaneous equations. The measurement is compared with two reference ranges—one for young adults (age 30 years) to give T scores

Table 4.8.1 Techniques for the non-invasive measurement of bone mass

Technique	Site	Comments
Single (or dual) energy X-ray absorptiometry	Forearm and heel	Inexpensive, precise, uses low doses of radiation, measures sites unresponsive to therapy
Dual-energy X-ray absorptiometry	Lumbar spine	Fairly expensive, precise, uses low doses of radiation, measures site responsive to therapy, needs skilled operator, subject to artefacts (spondylosis)
	Proximal femur	Fairly expensive, less precise, uses low doses of radiation, measures site best for fracture prediction, needs skilled operator
	Total body	Expensive, precise, uses low doses of radiation, measures sites unresponsive to therapy, needs skilled operator, allows assessment of body composition
Quantitative computed tomography	Spine	Expensive, less precise, uses high doses of radiation, measures sites responsive to therapy, needs skilled operator, allows assessment of trabecular bone alone
	Forearm and ankle	Inexpensive, precise, uses low doses of radiation, measures sites unresponsive to therapy, does not need skilled operator
Ultrasonometry	Heel, fingers, etc.	Inexpensive, less precise, uses no radiation, measures sites unresponsive to therapy, does not need skilled operator, fairly portable

and one for age-matched adults to give Z scores. This has become the standard technique for bone density assessment and guidelines have been proposed (Box 4.8.3). The two sites most commonly used in practice are lumbar spine and total hip. Low BMD at the total hip is a strong predictor of hip fracture [18].

Single energy X-ray (or photon) absorptiometry has similar advantages to DXA, and the equipment is less expensive. However, the sites in which bone density can be measured (distal forearm and calcaneum) may not be of clinical interest.

Quantitative computed tomography (CT) allows three-dimensional measurements of the bone density of the lumbar spine. This technique also allows measurement of trabecular bone alone (i.e. the type of bone usually lost first in the development of osteoporosis). In the research setting, finite element modelling can be applied to the information provided by this technique to estimate bone strength. However, quantitative CT is more expensive, less precise, and involves a higher radiation dose then DXA. Reformatting of routine CT scans of chest and abdomen can help identify vertebral fractures.

Quantitative ultrasound measurements are usually made on the calcaneum. The ultrasound signal has a lower frequency (200–600 kHz) than that used in obstetrics (more than 1 MHz). The attenuation of the signal (broad-band ultrasound attenuation) may reflect both the density and the architecture of bone, and the velocity of the signal reflects the density and biomechanical properties (elasticity). Quantitative ultrasonometry is currently used only in research but, if recent studies of its predictive ability in osteoporosis are confirmed, it could become an established technique.

Investigating Secondary Osteoporosis

A secondary cause is present in approximately 40% of women and 60% of men with osteoporosis. The most commonly found abnormalities are those of low vitamin D and either high or low urinary calcium [19]. Investigations to identify a secondary cause are recommended if the BMD is more than 2 SD below the age-matched mean or if the patient has low-trauma vertebral fractures (Box 4.8.2).

Bone Biopsy

This may be useful in unusual forms of osteoporosis (e.g. idiopathic osteoporosis in young adults). It provides information about the rate of bone turnover and the presence of secondary forms of osteoporosis (e.g. systemic mastocytosis). Patients with high bone turnover usually respond better to antiresorptive drugs.

Biochemical Markers of Bone Turnover

These reflect the processes of bone resorption and bone formation (Box 4.8.4). Markers that are specific to bone (e.g. osteocalcin and deoxypyridinoline) may be useful for monitoring the effect of drugs used in the treatment of osteoporosis [20]. Biochemical markers of bone resorption (such as chest X-ray) may be particularly useful because they are maximally suppressed by 3 months' treatment with oestrogens or bisphosphonates (see next and Chapter 4.10). They could be more useful than bone density for monitoring treatment because changes in bone density may not be detected for 2 years and not all patients have access to bone densitometry.

Box 4.8.3 Clinical indications for bone densitometry

- Presence of strong risk factors (see Box 4.8.1)
- Radiological evidence of vertebral fracture or osteopaenia
- Previous fragility fracture of the spine, hip, or wrist (after age 40 years)
- Monitoring of therapy

Box 4.8.4 Biochemical markers of bone turnover

- Bone formation markers (products of the osteoblast)
  - Serum alkaline phosphatase (bone isoform)
  - Serum osteocalcin
  - Serum C- and N-propeptides of type I collagen
- Bone resorption markers (degradation products of type I collagen or enzymes)
  - Urinary excretion of pyridinium cross-links of collagen (e.g. deoxypyridinoline)
  - Serum or urinary excretion of C- and N-telopeptides of type I collagen
  - Serum or urinary excretion of galactosyl hydroxylysine
  - Urinary excretion of hydroxyproline
  - Serum tartrate-resistant acid phosphatase

Treatment

General Measures

The treatment of acute back pain due to a recent vertebral fracture includes:

- bed rest (as short as possible), back support
- analgesics/non-steroidal anti-inflammatory drugs (NSAIDs)
- heat and gentle massage
- insertion of cement into the vertebral body (balloon kyphoplasty or percutaneous vertebroplasty; https://www.nice.org.uk/guidance/ta279/chapter/1-Guidance)

The treatment of chronic back pain due to vertebral fractures is difficult but includes:

- analgesics/NSAIDs
- physiotherapy
- intermittent use of spinal support for some activities
- exercise programme to maintain muscle strength and flexibility of the spine
- injection of local anaesthetic into the facet joints of the spine

In all patients (with or without fractures), it is important to treat diseases that can increase bone loss and contribute to osteoporosis (Box 4.8.1). An important part of the management of patients with osteoporosis, especially those following hip fracture or other frail patients, consists of attention to their general health status, such as ensuring adequate dietary protein intake, and measures to decrease the risk of falls or the degree of trauma that results from falling. These included better lighting, provision of handrails, removal of obstacles, attention to drugs such as sedatives and antihypertensives that may predispose to falls, or carpeted surfaces rather than hard floors. Regular exercise may be of value in maintaining mobility and improving muscle mass, thus reducing the risk of falling. Heavy weight-bearing and vigorous exercise programmes should be avoided by patients with osteoporosis as they may trigger the occurrence of a new fracture.

Calcium and Vitamin D

Low calcium intake and vitamin D deficiency should be prevented or effectively treated in all patients. As many hip fractures occur in patients over age 80 years and this population is particularly prone to low calcium intake and vitamin D deficiency (see Chapter 4.11), it is particularly important to ensure that these patients receive adequate calcium and vitamin D as part of their management. Ambulatory patients who receive periodic sunlight exposure generally produce sufficient vitamin D through skin photoconversion, but others should receive a supplement containing at least 800 IU of vitamin D daily. It is best to avoid high dose, infrequent dosing as this may increase the risk of falls. Total intake of calcium, including supplements if necessary, should be at least 1000 mg. It is best to obtain this with diet, as there has been an association described of high dose calcium supplements and myocardial infarction. Despite the necessity of adequate calcium and vitamin D for bone health, it should be appreciated that treatment with calcium and vitamin D alone is insufficient to prevent postmenopausal bone loss or to markedly reduce fracture risk in patients with osteoporosis.

Pharmacological Intervention

Drugs to increase bone mass inhibit bone resorption or stimulate bone formation. Most drugs approved for use in osteoporosis inhibit bone resorption, but some of these (e.g. hormone replacement therapy (HRT), bisphosphonates) increase BMD by 5–10% over the first 2 years of treatment [21].

Antiresorptive drugs—bisphosphonates—are considered the treatment of choice (Table 4.8.2). Their strict dosing instructions may reduce compliance in older people. In the United Kingdom, five agents are currently approved for use in osteoporosis: etidronate, alendronate, risedronate, ibandronate, zoledronic acid, and raloxifene. The most effective alternative treatments are raloxifene and HRT.

- Calcium, 1000 mg/day, and vitamin D, 500 IU/day, have been shown to prevent hip fracture in housebound, elderly patients. This treatment is safe and inexpensive, and does not require

Table 4.8.2 Antifracture efficacy of approved treatments for postmenopausal women with osteoporosis when given with calcium and vitamin D

Intervention	Vertebral fracture	Non-vertebral fracture	Hip fracture
Alendronate	A	A	A
Risedronate	A	A	A
Ibandronate	A	A*	NAE
Zoledronic acid	A	A	A
Denosumab	A	A	A
Raloxifene	A	NAE	NAE
HRT	A	A	A
Calcitriol	A	NAE	NAE
Teriparatide	A	A	NAE
Abaloparatide	A	A	NAE

A, grade A recommendation; NAE, not adequately evaluated; HRT, hormone replacement therapy; A*, in subset of patients only (post hoc analysis).

UK clinical guideline for the prevention and treatment of osteoporosis. *Arch Osteoporos.* 2017 Dec;12(1):43.

monitoring. It is commonly given with other treatments for osteoporosis.

- Alendronate is given in a dose of 10 mg/day continuously or 70 mg once weekly. Alendronate must be taken at least 30 minutes before breakfast (to help absorption) with a full glass of water, and the patient must not lie down after taking the tablet (to avoid oesophagitis). Alendronate is equally effective on the hip, forearm, and spine, and has been shown to prevent fracture at all of these sites.
- Risedronate is given in a dose of 5 mg/day continuously or 35 mg once weekly. Risedronate can be taken at least 30 min before breakfast or 2 h after a meal. It has been shown to prevent spine, hip, and other fractures.
- Ibandronate is given in a dose of 150 mg once monthly; calcium recommendations and instructions for use are as for risedronate. Ibandronate reduces the risk of vertebral fracture (and other fractures, if the BMD T score is ≤3). This treatment can also be given by intravenous injection (3 mg) given every 3 months.
- Zoledronic acid is given by intravenous infusion (5 mg over 15 min) given every 12 months. It reduces fractures at the spine and hip and all other fracture sites; it has been shown to reduce further fractures in patients presenting with hip fractures.
- Denosumab is given by subcutaneous injection (60 mg) every 6 months. It reduces fractures at the spine and hip and all other fracture sites for up to 10 years on treatment.
- Raloxifene is given in a dose of 60 mg/day continuously. Raloxifene has been shown to reduce the risk of spine (but not other) fracture, and may reduce the risk of breast cancer. It may increase the risk of deep vein thrombosis and does not prevent hot flushes.
- HRT is no longer recommended for the first-line prevention of osteoporosis because the risks outweigh the benefits. Risks with HRT include breast cancer (50% increase in risk after 10 years' treatment) and deep vein thrombosis (threefold increase in risk, particularly in patients with previous deep vein thrombosis); it is associated with increased risk of stroke and ischaemic heart disease. The benefits of HRT include relief of hot flushes and vaginal dryness. Tibolone has the advantage that it reduces fractures (spine and non-vertebral) and the risk of breast cancer, but it does increase the risk of stroke.
- Testosterone therapy is effective in men with hypogonadism. It is not currently used in eugonadal men, because of concerns about the increased risk of prostate cancer and ischaemic heart disease (via lowering of high-density lipoprotein).

One other agent can be useful in special circumstances:

- Calcitriol stimulates calcium absorption and may stimulate osteoblasts directly. It appears to be effective in corticosteroid-induced osteoporosis, in which it can be considered an alternative to HRT or bisphosphonates, particularly in younger patients and in patients with chronic kidney disease. Regular monitoring of serum calcium is required because hypercalcaemia is a common adverse effect.

Formation-stimulating drugs have been licensed for osteoporosis:

- Use of a recombinant fragment of PTH (teriparatide) may be advised by specialists in osteoporosis for patients who have failed to respond to antiresorptive therapy or are intolerant of it and have severe osteoporosis. Teriparatide treatment increases the thickness of cortical bone and the connectivity of trabecular bone. These improvements in bone quality (and in quantity—spine BMD is increased by about 9% on average at 1 year) are associated with reductions in fractures of the spine and elsewhere. The treatment is given by daily subcutaneous injection (20 μg/day), with calcium supplementation for a period of 2 years. Abaloparatide is an analogue of PTH-related protein and is licensed in some countries as an anabolic treatment.
- An antibody to sclerostin (romosozumab) has recently become available in some countries for the treatment of osteoporosis. It is more effective in preventing fractures than alendronate alone [22]. The treatment is given as a subcutaneous injection (210 mg) every month for a year and then is followed by an antiresorptive treatment such as alendronate or denosumab. It should not be used in patients at high risk of myocardial infarction or stroke.

Follow-up

Once patients have been identified and treatment initiated, it is important to ensure adequate follow-up to reinforce the importance of compliance to treatment and evaluate response. At a minimum, all treated patients should be seen initially after 3 to 6 months and thereafter at least annually. The importance of adherence to treatment should be stressed. After several years of therapy, the potent antiresorptive therapies (alendronate, risedronate, ibandronate, zoledronic acid, and denosumab) have been associated with an increased risk of atypical femur fracture and osteonecrosis of the jaw. Thus, if the risk of fracture is low after five years (e.g. femoral neck T score is above –2.5) then treatment is stopped for bisphosphonates (a drug holiday) or switched for denosumab (e.g. zoledronic acid); if the risk of fracture is high then treatment is continued for ten years and then stopped [23].

Monitoring of response to therapy can be achieved with the use of biochemical markers or repeated BMD measurements, and may be of value in assessing compliance and providing feedback to patients. Although not required, treatment response to oral antiresorptive treatments, such as bisphosphonates, can be evaluated after 3 to 6 months by assessing the change in biochemical markers of bone turnover, such as N-terminal or C-terminal cross-links of type I collagen, serum osteocalcin or serum procollagen I N-propeptide (Box 4.8.4). In most patients these markers decrease by more than 30% relative to pretreatment baseline measurements, and/or are reduced to within the premenopausal reference range, providing evidence that the treatment is having its desired effect to decrease bone turnover. Amino-terminal propeptide (PINP) has proven to be particularly useful in clinical practice as it has little diurnal rhythm and is stable. Changes in BMD occur over a longer time frame, and it is generally not useful to repeat the BMD measurement before the end of 1 to 2 years of therapy, and every 2 years thereafter (Figure 4.8.4). Most patients receiving efficacious therapy can be expected to have a measurable increase in BMD at the spine and total hip after 2 years of treatment. The increases in BMD are small at the peripheral sites of measurement, such as the heel or forearm, in relation to the precision of these measurements. Therefore, peripheral sites are unreliable for assessing response in individual patients.

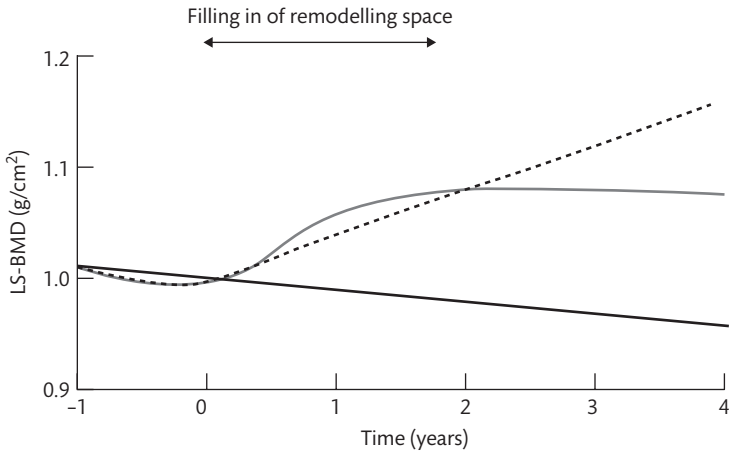

Figure 4.8.4 Changes in bone mineral density (BMD) with treatment. If no treatment is given (solid line) to someone with osteoporosis there is progressive bone loss. Antiresorptive treatments (stippled line) prevent this bone loss and result in bone gain because of filling in of the remodelling space (over a period of about 2 years). Formation-simulating treatments result in a year-on-year increase in BMD (broken line).

Other Forms of Primary Osteoporosis–Male Osteoporosis

Although osteoporosis is generally regarded as a disease of women, up to 30% of hip fractures and 20% of vertebral fractures occur in men [12]. The risk factors for osteoporotic fractures in men include low body mass index, smoking, high alcohol consumption, corticosteroid therapy, physical inactivity, diseases that predispose to low bone mass, and conditions increasing the risk of falls. The key drugs and diseases that definitely produce a decrease in BMD and/or an increase in fracture rate in men are long-term corticosteroid use, hypogonadism, alcoholism, and transplantation. Age-related bone loss may be a result of declining renal function, vitamin D deficiency, increased PTH levels, low serum testosterone levels, low calcium intake, and absorption. Osteoporosis can be diagnosed on the basis of radiological assessments of bone mass or clinically when it becomes symptomatic. Various biochemical markers have been related to bone loss in healthy and osteoporotic men. Their use as diagnostic tools, however, needs further investigation. A practical approach would be to consider a bone density more than 2.5 SD below the young normal mean value (T ≤–2.5) as an indication for therapy [18]. The treatment options for men with osteoporosis include agents to influence bone resorption or formation and specific therapy for any underlying pathological condition. Testosterone treatment increases BMD in hypogonadal men and is most effective in those whose epiphyses have not closed completely. Bisphosphonates (such as alendronate and risedronate) are the treatment of choice in idiopathic osteoporosis [24, 25], with teriparatide in more severe cases [26].

Thyroid Disorders and Bone Disease

Laura M. Watts, Bernard Freudenthal, J.H. Duncan Bassett, and Graham R. Williams

Introduction

Osteoporosis is defined as a bone mineral density (BMD) of 2.5 or more standard deviations below that of a young adult (T-score ≤ −2.5). It is characterized by reduced bone mass, low BMD, deterioration of bone microarchitecture, and an increased susceptibility to fragility fracture. The prevalence of postmenopausal osteoporosis increases with age from 6% at 50 years of age to over 50% at age 80 and the lifetime incidence of fracture for a 50-year-old in the United Kingdom is 50% for women and 20% for men [1]. Osteoporosis is a worldwide public health burden that costs an estimated $16 billion in the United States and €37 billion in Europe per annum [2, 3].

Bone strength and fracture susceptibility are determined by the acquisition of peak bone mass and the rate of bone loss in adulthood. Risk factors for osteoporosis and fracture include low BMD, a prior or parental history of fracture, low body mass index (BMI), use of glucocorticoids, smoking, and excessive alcohol consumption. Euthyroid status is essential for skeletal development, bone mineralization, acquisition of peak bone mass, and the regulation of bone maintenance in adults. Accordingly, large population studies have shown that hypothyroidism, thyrotoxicosis, and even subclinical hyperthyroidism are associated with an increased risk of fracture.

Thyroid disease is common and, similar to osteoporosis, is more prevalent in women and with increasing age. The prevalence of hypothyroidism is between 1 and 2% while 0.5–2% of women have thyrotoxicosis. As a result, thyroid replacement is very common for either primary hypothyroidism or the consequences of surgical or radioiodine treatment for thyrotoxicosis. Subclinical hypothyroidism (defined by the presence of an increased circulating thyroid-stimulating hormone (TSH) but normal thyroid hormone concentrations) may affect up to 10% of women over 55 and such patients may be overtreated [4, 5].

In children, hypothyroidism results in delayed bone age and growth arrest. Treatment with thyroxine (T_4) reverses these changes by inducing rapid 'catch-up' growth. Juvenile Graves' disease, the commonest cause of thyrotoxicosis in children, is characterized by advanced bone age and accelerated growth that results in short stature due to premature fusion of the growth plates [6]. In adults, histomorphometry studies reveal that hypothyroidism results in reduced bone turnover, however a prolonged remodelling cycle may cause a net gain in bone mass. Thyrotoxicosis increases bone resorption and formation but induces a net 10% loss of bone per remodelling cycle [7].

Thyroid Hormone Action

Circulating thyroid hormone levels are maintained in the euthyroid range by a classical negative feedback loop. Thyrotropin releasing hormone (TRH) is synthesized in the paraventricular nucleus of the hypothalamus and stimulates synthesis and secretion of TSH by the anterior pituitary gland. TSH, acting via the G-protein coupled TSH receptor, stimulates growth of thyroid follicular cells and the synthesis and release of thyroid hormones. Thyroid hormones act via thyroid hormone receptors in the hypothalamus and pituitary to inhibit TRH and TSH synthesis and secretion. This feedback loop maintains circulating thyroid hormones and TSH in a physiological inverse relationship that defines the hypothalamic-pituitary-thyroid (HPT) axis set point [6].

The thyroid gland secretes the pro-hormone T_4 and a small amount of the active hormone 3,5,3′-L-triiodothyronine (T_3). Circulating T_4 levels are maintained at approximately 3–4-fold higher concentrations than T_3. Intracellular availability of T_3 is determined by active uptake by specific cell membrane transporters including monocarboxylate transporter-8 (MCT8), MCT10 and organic acid transporter protein-1c1 (OATP1c1), and by the activities of the type 2 and 3 deiodinase enzymes (D2 and D3). D2 converts T_4 to T_3 by catalysing removal of a 5′-iodine atom. By contrast,

D3 prevents activation of T_4 and inactivates T_3 by removal of a 5-iodine atom to generate the metabolites 3,3′,5′-L-triiodothyronine (reverse T_3) and 3,3′-diiodothyronine (T_2), respectively. Thus, the relative levels of D2 and D3 determine the concentration of intracellular T_3 available to the nuclear receptors (TRs) [8].

TRs act as hormone inducible transcription factors that regulate expression of T_3-responsive target genes. The *THRA* and *THRB* genes encode three functional TRs, TRα1, TRβ1, and TRβ2. TRα1 and TRβ1 are widely expressed but with developmental and tissue specific regulation of their relative levels. Expression of TRβ2 is mainly restricted to the hypothalamus and pituitary where it mediates inhibition of TRH and TSH expression [7].

Skeletal Development and Bone Maintenance

Long bones form by endochondral ossification, in which a cartilage anlage develops from mesenchyme condensations to form a scaffold for subsequent bone formation. Mesenchyme progenitor cells differentiate into chondrocyte precursors, which undergo a sequence of clonal expansion, proliferation, hypertrophic differentiation, and apoptosis. Chondrocytes secrete a cartilage matrix that mineralizes and is subsequently remodelled by bone-resorbing osteoclasts and bone-forming osteoblasts to form the diaphysis. Linear growth occurs by a similar process within the epiphyseal growth plates, located at the proximal and distal ends of long bones. By contrast, the skull vertex forms by intramembranous ossification, in which mesenchymal cells differentiate directly into osteoblasts resulting in bone formation in the absence of a cartilage scaffold. Linear growth continues until fusion of the growth plates during puberty but bone mineralization and consolidation of bone mass accrual continues into early adulthood when peak bone mass is achieved [9].

Functional integrity of the skeleton is maintained by the process of bone remodelling, which is achieved by the integrated activities of osteocytes, osteoclasts, and osteoblasts. Osteocytes derive from differentiated osteoblasts that have become embedded in bone matrix and comprise 90–95% of all adult bone cells. The osteocyte network senses changes in mechanical load and regulates bone remodelling by the release of cytokines and chemotactic signals that stimulate differentiation and recruitment of osteoclasts to sites of altered mechanical load or microdamage. Osteoclasts excavate a resorption cavity until this process is terminated by apoptosis. Subsequently, osteoblasts mature, secrete, and mineralize osteoid to replace the resorbed bone. Signalling between osteoclasts and osteoblasts couples their activities to result in skeletal homeostasis with preservation of bone strength [10].

Thyroid Hormone Action in Bone

TRα1 and TRβ1 are expressed in growth plate chondrocytes, bone marrow stromal cells, and osteoblasts but it is uncertain whether they are present in osteoclasts [6, 11]. Expression of TRα1 is around ten times higher than TRβ1 in bone, suggesting the major T3 actions in bone are mediated via TRα1 [12]. Osteoblasts, osteoclasts, and chondrocytes also express thyroid hormone transporters to regulate local availability of thyroid hormone within bone [13].

In vivo and *in vitro* studies have shown that T_3 acts to inhibit growth plate chondrocyte proliferation and stimulate hypertrophic chondrocyte differentiation. In childhood hypothyroidism, growth arrest and delayed bone formation are consequences of gross disruption of growth plate architecture (epiphyseal dysgenesis) and a failure of hypertrophic chondrocyte differentiation. By contrast thyroid hormone excess accelerates chondrocyte differentiation resulting in advanced bone formation [6, 11].

In osteoblasts, T_3 increases proliferation and differentiation via complex cytokine and growth factor signalling pathways. For example, T_3 induces *FGFR1* in osteoblasts. Consistent with this, activating mutations of *FGFR1* cause Pfeiffer's craniosynostosis syndrome, and craniosynostosis is a recognized manifestation of severe juvenile thyrotoxicosis [14]. Thyroid hormone also stimulates osteoclast proliferation and activity, but it is uncertain whether this is a direct cellular response to T_3 [7].

The TSH receptor is expressed on osteoblasts, chondrocytes, and osteoclasts, however TSHα/β expression has not been detected within bone [15–17]. Direct actions of TSH on bone are uncertain. TSH may either inhibit or have no effect upon osteoclast differentiation, promote or have no effect upon osteoblast differentiation [17, 18] and promote chondrocyte differentiation [16, 19].

Studies in Genetically Modified Mice

Studies in mutant mice have demonstrated that TRα1 mediates T_3 action in bone. Mutation or deletion of TRα causes skeletal hypothyroidism due to disrupted T_3 action resulting in transient growth retardation, impaired ossification, and reduced bone mineralization during growth (Table 4.9.1). In adults there is a defect in bone remodelling, a marked increase in bone mass and increased bone mineralization [7, 20]. By contrast, mutation or deletion of TRβ disrupts the HPT axis leading to elevated levels of thyroid hormone which act upon TRα in bone causing skeletal hyperthyroidism. Mice display accelerated growth, advanced ossification with increased mineralization during growth but short stature from premature quiescence of the growth plates (Table 4.9.1). In adults increased bone remodelling results in osteoporosis and reduced bone mineralization [7, 12]. Together, these features indicate that thyroid hormones exert anabolic actions during skeletal growth but catabolic responses in adult bone [7, 21].

Control of T_3 availability is also required for normal postnatal skeletal development and strength. Mice lacking D2 have brittle bones with increased bone mineral content as reduced T_3 production within osteoblasts leads to decreased thyroid hormone action in bone [22]. Mice lacking the thyroid hormone transporter MCT8 have normal prenatal skeletal development but delayed endochondral ossification due to impaired T_3 transport into chondrocytes [23].

Mouse models, however, have been less clear regarding direct effects of TSH on bone. TSH receptor (TSHR) knockout mice have congenital hypothyroidism with undetectable T_3 and T_4 and elevated TSH. They show decreased BMD and increased bone turnover only partially normalized by thyroid supplementation from three weeks [15]. However, the extent to which this is due to TSH acting as a direct negative regulator of bone turnover or whether it results from thyroid hormone deficiency at a critical early period of

Table 4.9.1 Skeletal phenotypes of thyroid hormone receptor mutant mice

	TRα mutant mice	TRβ mutant mice
Systemic thyroid status	Euthyroid	Elevated T_4, T_3, and TSH
Skeletal thyroid status	Hypothyroid	Thyrotoxic
Juvenile skeleton	Transient growth delay Delayed endochondral and intramembranous ossification Impaired chondrocyte differentiation Reduced calcified bone	Persistent short stature Advanced endochondral and intramembranous ossification Enhanced chondrocyte differentiation Increased calcified bone
Adult skeleton	Osteosclerosis Increased bone volume Increased mineralization Reduced osteoclastic bone resorption	Osteoporosis Reduced bone volume Reduced mineralization Increased osteoclastic bone resorption

See review [7].

development followed by catch-up growth remains uncertain [7]. However, intermittent administration of TSH to ovariectomized animals has been shown to prevent bone loss associated with the hypogonadal state [18, 24]. Nevertheless, comparison of two mouse models of congenital hypothyroidism, suggests that the effects of thyroid hormone may predominate over those of TSHR signalling during skeletal development. Pax8 knockout mice lack a transcription factor that is essential for thyroid follicular cell development and have undetectable thyroid hormone levels, a 2000-fold elevation of TSH and a fully functional TSHR. By contrast, hyt/hyt mice have congenital hypothyroidism also accompanied by a 2000-fold increase in TSH but they harbour a loss-of-function point mutation in the *Tshr* gene leading to complete loss of TSHR protein function. Both mutants display a similar phenotype of growth retardation and delayed ossification typical of hypothyroidism despite the divergence in TSH signalling [7].

Skeletal Consequences of Altered Thyroid Status in Humans

Children

Childhood Hypothyroidism

Congenital hypothyroidism results in growth arrest, epiphyseal dysgenesis, delayed bone age, and short stature. Thyroxine replacement induces rapid catch-up growth and children that are treated early reach their predicted adult height and achieve normal BMD after 8.5 years follow-up [25, 26]. Nevertheless, a single study suggested that adult BMD may be reduced despite treatment from the neonatal period [27]. Children with juvenile acquired hypothyroidism also display growth arrest, delayed bone maturation and short stature [28]. T_4 replacement induces rapid catch-up growth, but these individuals may fail to achieve final predicted height and the resulting permanent height deficit is related to the duration of thyroid hormone deficiency prior to replacement [28]. A study of 25 children and adolescents with untreated subclinical hypothyroidism for over 3 years showed no significant effect of moderately raised TSH (4.58–8.88 IU/L) on BMD [29].

Childhood Hyperthyroidism

Juvenile thyrotoxicosis results in accelerated growth, advanced bone age, and short stature due to accelerated skeletal maturation. In severe cases in young children, early closure of the cranial sutures may result in craniosynostosis [30]. Thyrotoxicosis in children causes increased bone resorption, reduced BMD with major effects on cortical bone, and increased urinary N-terminal telopeptide of type I collagen (NTX) [31, 32]. After 1–2 years of antithyroid treatment, BMD and bone turnover markers return to normal [32–34].

Impaired Sensitivity to Thyroid Hormone

Impaired sensitivity to thyroid hormone can be caused by mutations affecting thyroid hormone action (thyroid hormone action defects (THAD), including RTHα and RTHβ), transporters (thyroid hormone cell membrane transporter defects, THCMTD) or generation of T_3 from T_4 (Thyroid hormone metabolism defects: THMD) [35]. Resistance to thyroid hormone (RTH) β is an autosomal dominant condition caused by a dominant negative mutation of *THRB* [36]. The mutant TRβ disrupts negative feedback in the HPT axis leading to increased circulating thyroid hormone concentrations in the presence of inappropriately normal or elevated TSH levels. The syndrome results in a complex mixed phenotype of hyperthyroidism and hypothyroidism depending on the target tissue studied and the specific mutation. Thus, an individual patient can have features of both thyroid hormone deficiency and excess with skeletal abnormalities similar to both hyper and hypothyroidism. These include craniofacial abnormalities, craniosynostosis, delayed or advanced bone age, short stature, increased bone turnover, osteoporosis, and fracture [7].

RTHα results from dominant negative mutations in *THRA*. Affected individuals have features of congenital hypothyroidism due to lack of response in TRα expressing tissues. Unlike RTHβ, there is no disruption to the negative feedback mechanisms of the HPT axis: serum TSH is normal, T_4 is normal/low and T_3 is normal/high resulting in a reduced T_4:T_3 ratio [7]. Skeletal features include disproportionate short stature due to short lower limbs, delayed tooth eruption, delayed closure of fontanelles, delayed bone age, epiphyseal dysgenesis and a thickened calvarium [7, 37, 38].

Sec insertion sequence binding protein 2 (SBP2) is a key factor mediating selenocysteine incorporation into thyroid hormone deiodinases, essential for their normal function. *SBP2* mutations result in defective conversion of T_4 to T_3, resulting in low T_3 despite high T_4 levels. Skeletal consequences include prepubertal growth retardation, transient delayed bone age and craniofacial dysmorphism [39, 40].

Mutations in the thyroid transporter *MCT8* result in low T_4, variable TSH, and elevated total T_3 levels, with a neurological phenotype of dystonia and hypotonia and severe developmental delay [41, 42]. The bone phenotype of these individuals has not been studied in detail.

Adults

Many studies have investigated the skeletal consequences of altered thyroid function in adults. Early studies frequently lacked statistical power because of small numbers of patients and the absence of long-term follow-up. Some were further confounded by inclusion of patients with a variety of thyroid diseases and by comparison of mixed cohorts of patients that included pre- and postmenopausal women or men. Other unadjusted confounders included prior or family history of fracture, BMI, physical activity, use of oestrogens, glucocorticoids, bisphosphonates, and vitamin D, smoking, or alcohol intake. Nevertheless, a number of meta-analyses have attempted to reconcile this heterogenous literature (Table 4.9.2).

Normal Individuals

Bone Turnover Markers

A study of 60 euthyroid postmenopausal women reported that high circulating TSH correlated with low urinary deoxypyridinoline concentrations but not with serum procollagen type I C propeptide (PICP) levels [43]. However, the number of subjects was small and included patients with treated hypothyroidism, subclinical hyperthyroidism, and secondary hyperparathyroidism. Two larger studies of euthyroid postmenopausal women [44] and euthyroid men over 70 years of age [45] showed no association between TSH and serum osteocalcin, procollagen type 1 N-terminal propeptide (P1NP), β-C-terminal telopeptide (CTX), and urinary NTX.

BMD and Fracture

A variety of mainly cross-sectional population studies have investigated the relationship between thyroid status and BMD (Table 4.9.3). With the exception of one prospective study of 4936 men and women over 65 years of age that showed no significant association with BMD [46], the others all reported an association between TSH or T_4 levels and BMD in either hip or lumbar spine.

Other studies have investigated the association of thyroid status with fracture risk, including longitudinal cohort studies (Table 4.9.4). The majority demonstrated an association between hyperthyroidism and fracture risk that was related to disease duration, although several large studies found no association between thyroid status and fracture risk.

Patients with Hypothyroidism

Bone Turnover Markers and BMD

Histomorphometry analyses have demonstrated that bone turnover is decreased in hypothyroidism [47] and the bone resorption markers urinary pyridinoline and deoxypyridinoline are lower in patients newly diagnosed with severe hypothyroidism [48]. Consistent with histomorphometric data showing normal bone volume in hypothyroidism, BMD was normal in newly diagnosed patients [49].

Fracture

Large population studies have mostly demonstrated an association between hypothyroidism and long-term fracture risk (Table 4.9.4). Patients with a prior history of hypothyroidism have been shown to have a 2–3-fold increased risk of fracture, which persists for 10 years following initial diagnosis [49–51]. In a recent study of 8414 hypothyroid adults, though elevated baseline TSH was not associated with hip fracture or major osteoporotic fracture, in post-hoc analysis, fracture risk was increased in postmenopausal women relative to the cumulative time they were over-replaced with levothyroxine, and was increased in all hypothyroid men below 75 years of age [52].

Patients with Thyrotoxicosis

The severe bone disease associated with uncontrolled thyrotoxicosis in now rare because of early diagnosis and treatment, although several studies have investigated the skeleton in thyrotoxic patients either prior to treatment, or by observing epidemiological data.

Table 4.9.2 Meta-analyses and literature reviews

Reference	Population	Studies (n)	Type	Conclusions
Vestergaard 2003 [56]	Thyrotoxicosis	20 BMD 5 Fracture	Meta-analysis	Spine and hip BMD reduced in untreated thyrotoxicosis. Fracture risk increases with age at diagnosis

Lin 2011 [119]	Cross-sectional	1343 men 1614 women	Men and women >45 years of age	No association with TSH, but T_4 correlated with BMD in older females
van Rijn 2014 [120]	Cross-sectional	2584 women	Perimenopausal women with no history of thyroid disease	High-normal T_4 levels associated with decreased BMD, but no association with TSH
Hwangbo 2016 [121]	Cross-sectional	648 women 728 men	Postmenopausal women and age-matched men	High-normal T_4 associated with higher trabecular bone score in women
No association with BMD				
Garin 2014 [46]	Prospective cohort	598 men and 719 women	Men and women >65 years of age	No association of TSH with BMD

Bone Turnover Markers and BMD

The effect of thyrotoxicosis on bone turnover markers is consistent with histomorphometric data that shows high turnover of trabecular bone with net increase in bone resorption [53]. Levels of resorption markers such as carboxy terminal telopeptide of type 1 collagen, urinary pyridinoline and deoxypyridinoline are increased, and formation markers including bone specific alkaline phosphatase and osteocalcin are also elevated [54]. Studies have shown that BMD at the time of diagnosis of thyrotoxicosis is reduced compared to age-matched controls [54–56].

Fracture

Various observational studies have identified an association between fracture and a prior history of thyrotoxicosis (Table 4.9.4). Most studies did not determine whether the increased fracture risk could be accounted for by reduced BMD. Nevertheless, other studies failed to demonstrate an association between thyrotoxicosis and fracture, though they may have lacked statistical power (Table 4.9.4).

Individuals with Subclinical Hyperthyroidism

Bone Turnover Markers and BMD

Elevated levels of urinary deoxypyridinoline, pyridinoline, osteocalcin and alkaline phosphatase have been reported in patients with subclinical hyperthyroidism [57–59]. Subclinical hyperthyroidism has also been associated with reduced BMD at the femoral neck and other sites (Table 4.9.3), although other studies have been negative [46, 60]. Meta-analyses have supported an association with reduced BMD that is strongest in postmenopausal women (Table 4.9.2).

Fracture

Prospective studies have suggested that suppressed TSH levels may be associated with an increased risk of hip fracture (Table 4.9.4), and this has been corroborated by meta-analyses (Table 4.9.2). A subanalysis of the Fracture Intervention Trial demonstrated that TSH suppressed below 0.5 mU/L was associated with increased risk of vertebral fracture [61], though some subjects may have had untreated thyrotoxicosis. A minority of smaller

Negative studies				
Van den Eeden 2003 [77]	Cross-sectional case controlled	501 women hospitalized for hip fracture 533 controls	Women >65 years of age	No association of T_4 replacement with fracture risk
Van der Deure 2008 [97]	Prospective cohort	479 men 672 women	>55 years of age	No association of TSH or T_4 with fracture risk
Svare 2013 [126]	Prospective cohort	25 205 normal individuals	16 610 women and 8595 men aged 40 years or more	No association of TSH with fracture risk
Garin 2014 [46]	Cross-sectional	2765 women 2171 men	>65 years of age	No association of TSH with fracture risk
Siru 2018 [45]	Prospective cohort	4248 men	>70 years of age	No association of TSH or T_4 with fracture risk

studies failed to show a significant association with fracture risk, as did one meta-analysis that included only seven population-based studies [62].

Patients Treated with Suppressive Doses of Thyroxine

The long-term management of patients with differentiated thyroid cancer involves treatment with doses of thyroxine that suppress TSH and which may have detrimental effects on the skeleton [63].

Bone Turnover Markers and BMD

Small studies have investigated the effect of suppressive doses of T_4 on bone turnover, reporting increased levels of markers of bone resorption [64, 65] and bone formation [66–68]. Most studies of BMD show an association of TSH suppression therapy with reduced BMD at the lumbar spine, femur, or radius only in postmenopausal women [65, 69], and studies have shown no effect in men [70]. The reduction in BMD also correlates with duration of TSH suppression [71]. These findings are supported by

meta-analyses (Table 4.9.2). Of several cross-sectional studies that included male patients, only one reported a reduction in lumbar spine and femur BMD in subjects receiving suppressive doses of T_4 [72].

With the long-term effects of suppressive doses of T_4 on BMD most severe in postmenopausal women, monitoring of BMD in such patients has been recommended [73]. In addition, international thyroid cancer guidelines now recommend risk-stratifying patients and limiting the use and severity of TSH suppression in low-risk differentiated thyroid cancer [63].

Fracture

There are no studies with sufficient statistical power to determine the effect of treatment with suppressive dose of T_4 on fracture risk, except for one study showing markedly increased risk of radiological vertebral fracture [74].

Patients Treated for Hypothyroidism

Bone Turnover Markers and BMD

Histomorphometric studies have suggested an increase in bone turnover in response to T_4 replacement in hypothyroidism [47] and studies of bone turnover markers have shown that low levels of urinary pyridinoline and deoxypyridinoline in hypothyroidism normalize with treatment [48]. Once stabilized on treatment, bone turnover markers are comparable with normal controls [75], but plasma CTX correlates with the T_4 replacement dose [76]. Observational studies that include patients receiving long-term T_4 replacement for hypothyroidism have not identified any significant effect on BMD, particularly when adjusted for circulating thyroid hormone levels.

Fracture

Population studies have not identified an overall association between T_4 replacement therapy and fracture risk [77]. In one large prospective study investigating the effects of T_4 replacement, increased fracture risk was found to be associated with cumulative time of T_4 overreplacement in postmenopausal women [52]. In another observational cohort, fracture risk was increased in patients with suppressed (≤0.03 mU/L) or high TSH, but not low TSH (0.04–0.4 mU/L) [78]. One study showed an association of T_4 treatment with fracture only in males, but thyroid hormone levels were neither measured nor adjusted for [79]. Overall, fracture risk appears not to be affected in patients receiving physiological T_4 replacement, and this conclusion is consistent with studies of patients treated for subclinical hypothyroidism [80].

Patients Treated for Thyrotoxicosis

Studies of patients with thyrotoxicosis have shown that elevated resorption and formation markers return to normal two months after initiation of antithyroid medication [81–83]. A meta-analysis investigating the effect of treatment for thyrotoxicosis on BMD [56] demonstrated that the low BMD at diagnosis returned to normal within one to four years, and subsequent studies have shown treatment for thyrotoxicosis results in a 4% increase in BMD within one year [84–86]. Nevertheless, one large population study reported that an increased risk of fracture persisted for 5 years following diagnosis [50].

Human Genetics

BMD is a highly heritable trait, and genome-wide association studies have identified numerous genes associated with BMD. However, no thyroid related genes have yet been identified in these studies [87–93]. Thyroid status is also a complex genetic trait. In healthy individuals, T_3, T_4, and TSH levels fluctuate over a range that is less than 50% of the normal reference range and each individual has their own HPT axis set point [94]. Heritability of T_3 concentration is 23–64%, T_4 is 39–65%, and TSH is 64–65% [95, 96].

Candidate gene studies have shown variable but contradictory association of thyroid pathway genes with bone parameters. The D727E polymorphism in *TSHR* has been associated with increased femoral neck BMD [68, 97] but has been reported at increased frequency in those with osteoporosis [98]. A recent large study found no association between polymorphisms at the *TSHR* locus and femoral neck or lumbar spine BMD. Using Mendelian randomization to avoid confounding and reverse causation, this study also found no evidence for a causal relationship between circulating TSH concentrations and BMD [99].

Polymorphisms in *THRB* have been associated with trabecular but not cortical BMD at the hip [100], but no studies have associated *THRA* variants with BMD or fracture [101–103]. A polymorphism in *DIO2* has been linked to reduced femoral neck BMD and increased markers of bone turnover in a small study. However, the significance of this is unclear as no such association was found in a study of a larger group of individuals and no *DIO2* mutations were identified in 100 women with high BMD [103, 104]. The clinical significance of genetic variants in thyroid hormone metabolism and receptors is currently unclear and studies in very large populations will be required.

Conclusions

- A negative feedback loop maintains circulating thyroid hormones and TSH in an inverse relationship that defines the HPT axis set point.
- The skeleton is exquisitely sensitive to thyroid status. T_3 exerts anabolic responses during skeletal growth and has catabolic effects on adult bone.
- Bone strength and fracture susceptibility are determined by peak bone mass acquisition during growth and the rate of bone loss in adulthood.
- Population studies indicate that thyroid status in the upper normal range is associated with decreased BMD and fracture.
- Untreated hyperthyroidism results in increased bone turnover, reduced BMD, and an increased risk of fracture. A prior history of thyrotoxicosis may be associated with reduced BMD and a long-term increased risk of fracture.
- Subclinical hyperthyroidism is associated with increased bone loss, decreased BMD, and an increased risk of fracture.
- Treatment with suppressive dose of T_4 results in decreased BMD especially in postmenopausal women.
- Physiological T_4 replacement in hypothyroidism does not affect BMD or fracture risk.
- Overreplacement of patients with hypothyroidism is associated with an increased risk of fracture.
