Testicular steroidogenesis takes place in Leydig cells, and the most important hormone produced is T. LH is the key regulator of testicular steroidogenesis, but its action can be modulated by numerous other endocrine, paracrine, and autocrine factors. Most details of the synthesis, secretion, and metabolism of testicular steroid hormones were unravelled in the 1950s and 1960s. More recent studies on androgens have concerned identification and characterization of the steroidogenic enzymes at genome and protein level, mechanisms of cholesterol supply for steroid biosynthesis, and mechanisms of androgen action (see Chapter 10.1.2, 'Sex Steroid Actions in the Male').

Androgens are essential for all masculine functions of the body, including sexual differentiation, development of secondary sex characteristics, growth of sex organs, spermatogenesis, the masculine features of the musculo–skeletal apparatus, and sexual behaviour (**Box 10.1.1.1**) [18]. Essential for all of them is a single regulatory step, the binding of androgen to its receptor, which then evokes the variety of structural and functional responses specific to each target tissue.

The synthesis of all steroid hormones starts from cholesterol, for which the Leydig cells have multiple sources: (a) *de novo* synthesis from acetyl coenzyme A; (b) stored cholesteryl esters; (c) exogenous lipoprotein-supplied cholesterol; and (d) plasma membrane-derived cholesterol following hormonal stimulation [19]. The most utilized source are the plasma low- and/or high-density lipoprotein–cholesterol complexes, endocytosed by receptor-mediated mechanisms. Cholesterol is thereafter esterified and stored in intracellular lipid droplets.

The next step is the transcytoplasmic transport of cholesterol from lipid droplets to the outer mitochondrial membrane by still poorly understood mechanisms. More is known about the subsequent transfer of cholesterol from the outer to the inner mitochondrial membrane, a rapid step (within minutes), which in the testis is critically dependent on gonadotrophin stimulation. A crucial role therein is played by the functional interplay of at least two recently discovered molecules, the steroidogenic acute regulator protein (stAR) and the translocator protein (TSPO) [19] (see also Chapter 5.8.1, 'Genetics of Adrenal Insufficiency').

  - Distribution of adipose tissue
  - Haematopoiesis
  - Thickening of skin
  - Function of sebaceous gland

The first and rate-limiting step of steroid biosynthesis [19] at the mitochondrial inner membrane is the conversion of cholesterol to pregnenolone, catalysed by the cytochrome P450 cholesterol side chain cleavage enzyme (P450scc, CYP11A1) and auxiliary electron transferring proteins (**Figure 10.1.1.4**). For the following steps, from pregnenolone onwards, the steroid molecule is translocated to the smooth endoplasmic reticulum. Depending on the order of enzymatic reactions, two alternative pathways, Δ^5 or Δ^4, are employed (**Figure 10.1.1.4**), the former being more important in the human testis. Hence, pregnenolone is first converted by the bifunctional CYP17A1 enzyme to 17-hydroxypregnenolone (17-hydroxylation step) and further to dehydroepiandrosterone (17, 20 lyase step). The following steps, in alternative order, are *either* the conversion of the 3β-hydroxy-5-ene structure of dehydroepiandrosterone by 3β-hydroxysteroid dehydrogenase/$\Delta^{5\text{-}4}$ isomerase (3β-HSD) to the 3-keto-4-ene structure of androstenedione, *or* the reduction of dehydroepiandrosterone by 17β-hydroxysteroid dehydrogenase (17β-HSD; mainly type III) to 5-androstene-3β,17β-diol, with final formation of T after the two reactions taking place in alternate order. In the alternative Δ^4 pathway, the first metabolic step after pregnenolone is its 3β-HSD-catalysed conversion to progesterone, after which the

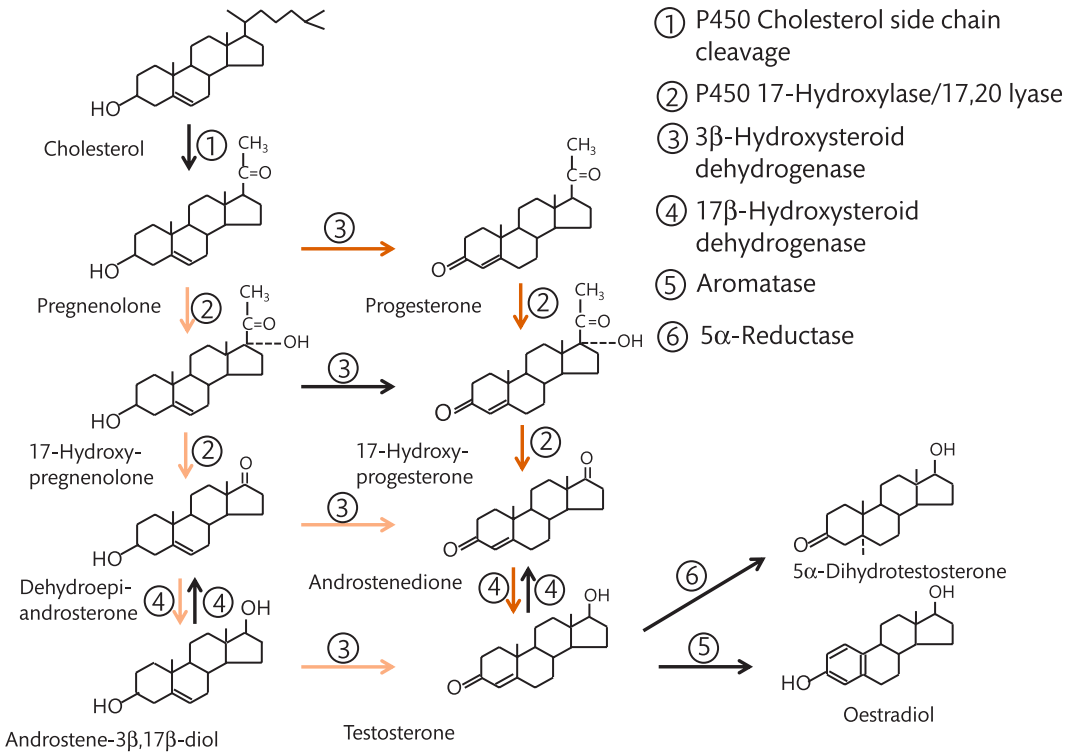

Figure 10.1.1.4 The key steroid metabolic steps in the testis leading to formation of T, 5α-DHT and oestradiol. The Δ5 pathway, used by the human testis, is marked with light orange arrows, and the Δ4 pathway, more important in rodents, with dark orange arrows. The same enzyme with dual function, P450 17-hydroxylase/17,20-lyase (enzyme 2) catalyses both 17-hydroxylation and ring D side chain cleavage in pregnenolone and progesterone. Apart from the interconversion of 17-keto and 17-hydroxy steroids all other reaction in the steroid metabolic pathway are irreversible. Multiple isoform of 17β-hydroxysteroid dehydrogenase (enzyme 4), with differing substrate specificities, catalyse these reactions. *For a colour version of this figure, please see colour plate section.*

metabolism proceeds further through 3-keto-4-ene intermediates to T (Figure 10.1.1.4).

The daily T production in a male is 6–7 mg; about 95% of it originates from the testes and the rest through peripheral metabolism of adrenal androgenic precursors (mainly dehydroepiandrosterone (DHEA) and its sulphate conjugate). A number of other steroid hormones are also secreted, of which many are Δ^4 and Δ^5 intermediates of T synthesis (Table 10.1.1.1). Some of them are weak androgens themselves (e.g. androsterone) or are metabolized further to more active androgens or oestrogens in peripheral tissues (androstenedione). Some steroids are stored in the testis and secreted as sulphate conjugates (Table 10.1.1.1) [20]. Steroid sulphates have no known hormonal function, and apparently represent storage and secretory forms.

T serves as a precursor for two important steroid hormones, 5α-DHT and oestradiol [21, 22] (Figure 10.1.1.4). Although these two T metabolites are secreted by the testis (Table 10.1.1.1), the major proportion of them is formed in peripheral tissues. 5α-DHT is 5–10-fold more potent than T due to its higher affinity for androgen receptor (AR), and it is also the main active molecule in some androgen target tissues, such as hair follicle and prostate, where a large proportion of circulating 5α-DHT is formed [23]. 5α-Reductase, converting T to 5α-DHT, exists as two isoenzymes [22]. Type 1 is expressed in sebaceous glands and liver, and type 2 in male urogenital tract, genital skin, and liver. In prostate, 5α-reductase is upregulated by androgen, in liver by thyroid hormone, and in skin fibroblasts by insulin-like growth factor (IGF) -I. Disturbances of male-type differentiation and sexual functions in connection with *5α-reductase* mutations demonstrate the physiological significance of this metabolic step in androgen physiology (see also Chapter 10.1.2, 'Sex Steroid Actions in the Male').

Oestradiol, either alone or in combination with androgens, participates in some important physiological functions of testicular steroids. About 25% of circulating oestradiol originates from the testes,

Table 10.1.1.1 The mean testicular, spermatic vein and peripheral vein concentrations (in nmol/L) of the key testicular steroids in man (Leinonen *et al.*, 1981).

Steroid	Testis	Spermatic vein	Peripheral vein
Pregnenolone sulphate	2600	430	90
Progesterone	130	23	0.8
17-Hydroxyprogesterone	690	45	3.2
Dehydroepiandrosterone	680	35	8.2
Dehydroepiandrosterone sulphate	2000	1400	1000
5-Androstene-3β,17β-diol	820	590	500
Androstenedione	740	45	2.5
Testosterone	2600	720	20
Testosterone sulphate	1400	150	13
5α-Dihydrotestosterone	50	14	1.5
Oestradiol	15	0.4	0.1

and the rest is formed through peripheral aromatization of androgenic precursors, mainly in adipose tissue and liver [21]. Human males with inactivating mutations of the *aromatase* (*CYP19*) or *oestrogen receptor-α* (*ESR1*) genes, as well as the corresponding knockout mouse models [24], have emphasized the physiological significance of oestrogen action in the male. Deficient oestrogen action in the male is associated with incomplete long bone epiphyseal closure, osteoporosis, insulin resistance, abnormalities in plasma lipids, and body fat deposition (see also Chapter 10.1.2, 'Sex Steroid Actions in the Male').

In the catabolism of T [25] the first step is its conversion to androstenedione through an interconvertible reaction catalysed by a specific oxidative isoenzyme of 17β-HSD (type 2) present in the liver. Androstenedione is then the preferential substrate for further reduction and hydroxylation reactions. The major metabolism involves 5α- and 5β-reduction of the Δ^4 double bond in ring A of the steroid nucleus, which is followed mainly by 3α- and 3β-hydroxylation of the 3-keto group. Thereafter, the 3α-metabolites are mainly conjugated with glucuronic acid, the 3β-metabolites with sulphate. About 90% of the androgen metabolites are excreted into urine and 10% into faeces. Of the urinary steroid metabolites, 20–40% occur as glucuronides, 40% as sulphates and the rest in free form.

Steroid Hormone Secretion and Transport

The secretion of steroid hormones into the circulation is assumed to be a passive diffusion process due to their lipid solubility and ease of transit through cell membranes. The main steroids produced and secreted by the human testis are listed in Table 10.1.1.1. T and the sulphate conjugates of pregnenolone, dehydroepiandrosterone, and 5-androstene-3β,17β-diol are quantitatively most abundant. There is no intratesticular storage of bioactive steroid hormones, with the exception of their sulphate conjugates, and the regulation of circulating steroid hormone concentrations occurs mainly at the level of their biosynthesis and variation of testicular blood flow. Since only about 30 μg of T is stored in the normal testes, the total content must turn over 200 times per day to achieve the daily production of 6 mg. Testicular steroid secretion has diurnal variation due to the night-time accentuation of LH secretion. Secretion pulses of serum T after the LH secretion peaks (average interval of 2 h) are inconsistent, apparently due to the relatively slow response of human testicular steroidogenesis to gonadotrophin stimulation, and to the buffering effect of steroid binding to plasma transport proteins (see next). Whereas animal experiments show dramatic (over 10-fold) responses of serum T to LH/human chorionic gonadotrophin (hCG) stimulation, the acute response of human testicular T release, within 1–2 hours, is only in the order of 30–50%.

In circulation, only 1–2% of T appears in free (i.e. non-protein-bound) form, 44% is bound to sex-hormone-binding globulin (SHBG), and 54% to albumin and other proteins [26]. SHBG is a dimeric β-globulin with a molecular weight of about 95 kDa, its carbohydrate content is 30%, and each of its monomers binds one androgen or oestrogen molecule. The affinity of albumin for T is only about 0.1% of that of SHBG, but its high concentration in circulation explains its overall importance in androgen transport.

Due to the avid binding of T to SHBG, their complexes do not enter androgen target cells. However, they may have some, as yet incompletely characterized, functions at the cell membrane [26]. T dissociates from the binding proteins in capillaries, where their interaction with endothelial glycocalyx reduces the affinity for T, allowing free T to diffuse into target cells. In contrast, the binding of T to albumin is easily dissociable, and this fraction, together with free T, forming about half of total plasma T, is considered to form the so-called bioavailable fraction of androgen.

The plasma level of SHBG is under endocrine and metabolic regulation [26], increasing clearly by oestrogen and ageing, and decreasing somewhat by androgen, and clearly by obesity. Consequently, the SHBG level in men is about half of that of women, and it increases in hypogonadism. If the HPT axis functions normally, changes in SHBG levels do not affect the balance of bioactive androgens, since they are quickly compensated for by changes in the feedback regulation.

For reading on mechanism of androgen action, see Chapter 10.1.2 'Sex Steroid Actions in the Male').

Physiological Effects of Androgens

The physiological effects of androgens are listed in Box 10.1.1.1. The major androgenic functions include the feedback regulation of gonadotrophin secretion by the hypothalamic–pituitary system, regulation of initiation and maintenance of spermatogenesis, male-type differentiation of the sexual organs during embryogenesis, stimulation of secondary sexual differentiation during puberty and control of male sexual behaviour. An alternative way of grouping the androgen effects is to define them as androgenic, psychological, and anabolic (Box 10.1.1.1). Besides the classical androgen target organs, low levels of AR are present in almost every tissue. T is the prohormone for some androgen actions, which, at target tissue level, are exerted by 5α-DHT or oestradiol. The anabolic androgen actions on muscle are predominantly due to T action, whereas its effects on bone, at least partly, require aromatization to oestrogens. The androgen effects on the central nervous system are mediated both through oestrogen (following aromatization of T) and ARs.

Testicular Protein and Peptide Hormones: Inhibin, Activin, and Follistatin

The testis produces a number of bioactive proteins and peptides (Table 10.1.1.1) and various autocrine and paracrine functions have been proposed for most of them [27–29]. Some of these hormones are functional in fetal life: the Leydig cell product insulin-like 3 (INSL3) regulates testicular descent, and the Sertoli cell product anti-Müllerian hormone (AMH) induces the regression of Müllerian ducts in the male fetus. Endocrine effects outside the adult testes have clearly been demonstrated only for inhibins, whereas the other members of the same family, activins, and their binding protein, follistatin, mainly exert their actions as paracrine or autocrine growth factors within the testis and several other tissues. The endocrine role of inhibins is to mediate the negative feedback regulation of pituitary FSH secretion.

Inhibin and activin are dimeric gonadal proteins, members of the transforming growth factor (TGF)–β family [1, 29]. In addition, there are specific transport proteins for activin, follistatin and α_2-macroglobulin. A plethora of studies have described the regulatory functions of these molecules in different tissues and their potential clinical significance.

Inhibin is a dimeric glycoprotein hormone of 32 kDa size, consisting of two dissimilar subunits, connected by disulphide bonds: a 18 kDa α-subunit and a 14 kDa β-subunit of type βA or βB, forming

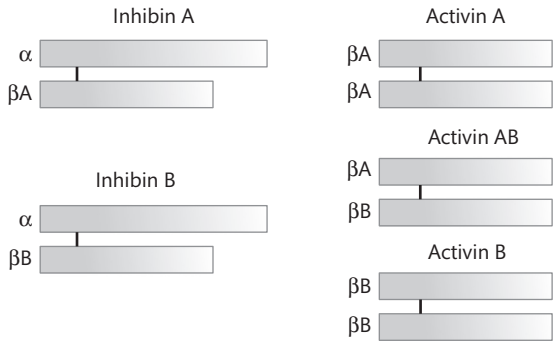

Figure 10.1.1.5 Schematic representation of inhibins and activins. The different subunits (α, βA and βB) can heterodimerize to form inhibins A (α/βA) and B (α/βB) or homodimerize to form activins A (βA/βA), AB (βA/βB) or B (βB/βB).

inhibin A and B (Figure 10.1.1.5). Homodimers of two β-subunits (βA/βA, βA/βB, βB/βB), have opposite biological action to inhibin, that is, para/autocrine stimulation of pituitary FSH secretion, hence the name activin. Activins bind to two types of receptors, I and II, which are single transmembrane-domain serine/threonine kinase molecules. Inhibin together with its coreceptor betaglycal blocks activin binding to its receptors. Follistatin, a glycoprotein of 31–42-kDa molecular size, bioneutralizes peptides of the TGFβ family, including activin.

In the human adult testis Sertoli cells strongly express inhibin α and βB mRNA, but βA mRNA very weakly. Hence, Sertoli cell-derived inhibin B is the main circulating inhibin with endocrine action [30, 31]. The Leydig cells express inhibin-α subunit and βB. βA is also expressed by peritubular myoid cells, and βB by spermatogenic cells. Follistatin is expressed by Sertoli and germ cells.

FSH stimulates inhibin α subunit expression in Sertoli cells, whereas the β subunits are under paracrine regulation. Serum FSH and inhibin B levels are inversely correlated, in support of the physiological role of inhibin (in concert with T) as a negative feedback regulator of FSH synthesis and release at the pituitary level. The expression of βA- or βB-subunits (that is, activin synthesis) is largely independent of FSH. The role of activin in FSH regulation is auto/paracrine locally in pituitary gland, and it is modulated by neutralizing action of follistatin. The inhibin peptides participate within the testis in the regulation of spermatogenesis.

Circulating inhibin B levels closely reflect the number and function of Sertoli cells. Inhibin B measurements offer a tool for monitoring Sertoli cell function in individual patients with infertility, in clinical and toxicological studies on male fertility, as well as in studies of developmental deficiencies of testicular function [31]. Low levels of inhibin B occur in men with non-obstructive azoospermia, in untreated men with hypo- or hypergonadotropic hypogonadism, in infertile men with elevated FSH, in men with Klinefelter syndrome and in orchidectomized men [32, 33]. Men with inactivating mutation of the *FSH receptor* gene also have very low level of this peptide [34]. Inhibin B is an early marker of male puberty, increasing about threefold between stages I and II [35]. The negative correlation between inhibin B and FSH is attained in late puberty. The levels of activin A are similar in men and women, and follistatin levels are somewhat lower in men.

Local Regulation of Testicular Function

Besides gonadotrophins and other hormones reaching the testis from circulation, there is a complex network of local paracrine, autocrine, and intracrine regulatory interactions within the testis (Box 10.1.1.2). This type of regulation is easy to demonstrate *in vitro* in cell coculture experiments, and numerous such interactions

are known today [27, 28]. However, their physiological significance remains uncertain in the absence of conclusive *in vivo* data.

One explanation for the local regulatory network is biological redundancy. To assure a vital physiological process, such as spermatogenesis, partly overlapping mechanisms are needed; if one fails the others take over. The other explanation relates to the complex testicular anatomy where different cell types may have dynamic interactions through paracrine coordination between cells at different functional and developmental stages. A perplexing feature is the wide expression, without apparent function, of a multitude of genes in germ cells during their maturation process. The main types of testicular local regulation are described next, and those most likely of physiological significance are elaborated.

Besides being the main testicular hormone, T is also the best example of a physiologically significant paracrine factor within the testis [27, 28]. Being formed by Leydig cells, it plays a key role in the local regulation of spermatogenesis. The Sertoli cells produce, under the influence of T, nutrients and other paracrine signals for the maintenance of spermatogenesis; hence the role of T is essential but indirect. AR are also present in the peritubular myoid cells, and T also has an autocrine or intracrine role in regulating Leydig cell function.

Almost all classes of regulatory peptides have been shown *in vitro* either to be produced in the testis or to have receptors in this organ, and a concept has been put forward that these peptides form an intratesticular network of paracrine and autocrine signalling (Box 10.1.1.2). Testis-specific knockout animal models can inform the possible physiological relevance of the paracrine or autocrine regulation. However, it may not apply to the human testis, since vast species differences exist in testicular cell-to-cell interactions. Conspicuously, experimental disruption of function of many peptides with putative intratesticular function has turned out to have only marginal effects on testicular function in rodents. There are a few exceptions; the disruption of the inhibin-α subunit has demonstrated that inhibin is an intragonadal tumour suppressor molecule, and general or testicular overexpression of enkephalin, interleukin-2 and TGF-β genes impair spermatogenesis and fertility [28]. In addition, impaired spermatogenesis is a non-specific finding in a number of genetically modified animal models with no apparent relationship to testicular function.

The best example of a physiologically significant paracrine effect within the testis, apart from T, is provided by the transgenic experiments with the insulin-like growth factor genes [36]. Overexpression of insulin-like growth factor-II increases testicular size. Mice with disrupted insulin-like growth factor-I gene have impaired Leydig cell maturation and suppressed spermatogenesis. However, since both the endocrine and paracrine component of testicular insulin-like growth factor-I actions are eliminated in this model, the final evidence for the significance of intratesticular insulin-like growth factor-I awaits testis-specific disruption of its gene. Altogether, it remains a conundrum why almost every biologically active regulatory molecule is expressed in the testis and can be shown to have direct effects (usually *in vitro*) on some aspects of testicular function.

Spermatogenesis

Testis Development and Germ Cells

Differentiation of germ cells from spermatogonia to spermatozoa is called spermatogenesis. See Figure 10.1.1.6. It takes place in the seminiferous tubules in the testis. It includes three phases: mitotic proliferation of spermatogonia, meiosis of spermatocytes, and morphogenesis of haploid spermatids to mature spermatozoa (spermiogenesis). Kinetics of germ cell differentiation is tightly regulated, and complete spermatogenesis takes 74 days in humans. Quantity of sperm production is highly variable, and World Health Organization (WHO) has lowered the reference limits for normal semen quality over decades. The current lower reference limit for total sperm number per ejaculate is 39 million and for sperm concentration 15 million per millilitre (WHO 2010). The median sperm concentration in young men of the general population varies between 40 and 60 million per millilitre, whereas men with proven fertility have much higher sperm concentrations [37]. Even in healthy, fertile men, most spermatozoa are structurally abnormal, and according to WHO reference limits, semen is considered normal if more than 4% of spermatozoa are morphologically normal [38]. See Chapter 10.2.3 Semen Analysis.

Germ cell specification occurs early in embryonic development. Primordial germ cells migrate from the yolk sac via hind gut to the bipotential gonadal primordium which differentiates to a testis in the presence of the sex-determining region of Y (*SRY*) gene. Several other genes are necessary for a male specific gonadal differentiation, such as *SOX9*, but they are not discussed further here (for review, see [39] for further details). Germ cells are called gonocytes in the fetal testis. They become surrounded by Sertoli cells and these form the seminiferous cords. The gonocytes undergo epigenetic reprogramming when the whole genome is demethylated and then methylated again, except for few gene areas that remain outside reprogramming. When the gonocytes migrate from the centre of the seminiferous cord to the

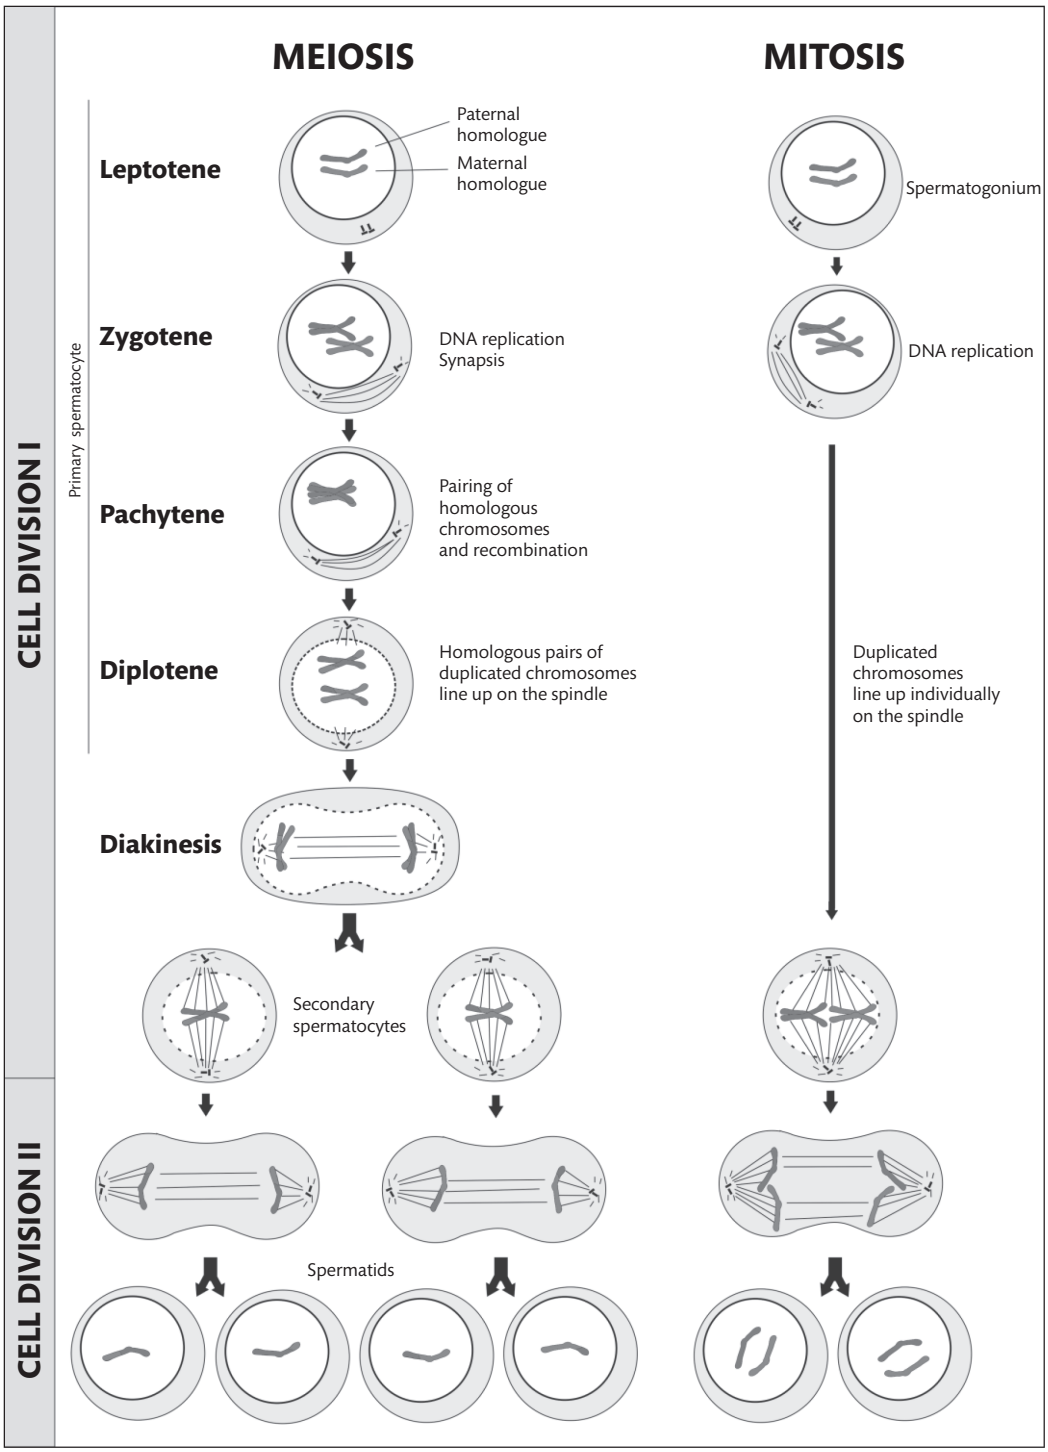

Figure 10.1.1.6 Schematic presentation of mitosis and meiosis. Spermatogonia multiply by mitosis like somatic cells, whereas spermatocytes undergo meiosis where genetic material is exchanged between chromosomes by homologous recombination. Chromosomes separate from each other in the first meiotic division when haploid secondary spermatocytes are formed. These divide rapidly again when chromatids separate and haploid spermatids are formed.

Sheyla Cisneros Montalvo is acknowledged for drawing the figure.

basement membrane in the periphery they form the spermatogonial stem cell pool. In rodents these cells proceed immediately to the first spermatogenic cycle, whereas the human spermatogonial stem cell pool is held in an undifferentiated stage for more than ten years until puberty. Survival of spermatogonia is critically dependent on optimal temperatures lower than core body temperature. Testes have to descend into the scrotum to be able to create a countercurrent heat exchange system between the testicular veins and arteries. Spermatogonia undergo apoptosis in an undescended testis (cryptorchidism) causing infertility in bilateral cryptorchidism, unless the testes are brought to the scrotum early in childhood [40].

Spermatogonia

Before puberty only the spermatogonial stem cell pool is maintained and spermatogonia do not enter meiosis. Spermatogenesis beyond meiosis starts in puberty in response to increasing FSH stimulation and continues through adult life. The balance between renewal of the spermatogonial stem cell pool and commitment to differentiation is critical for maintenance of lifelong fertility. If the spermatogonial stem cell pool is depleted, sperm production will cease when all differentiating spermatogonia have developed into spermatozoa. On the other hand, accumulation of stem cells leads to tumour-like development and reduction of sperm production. Glial cell-derived neurotrophic factor (GDNF) promotes the self-renewal of stem cell spermatogonia [41], and when their retinoic acid receptor gamma (RARγ) expression increases, retinoic acid drives cohorts of these cells to differentiation [42].

Mitoses of spermatogonial stem cells increase with ageing, which is considered as a possible reason for mutations to accumulate, particularly in some hot spots, such as genes for fibroblast growth factor receptors. Approximately two novel point mutations per year appear leading to doubling of mutations every 20 years. As a consequence, several genetic diseases occur more often in children of old men than in those of young fathers. Achondroplasia, Apert syndrome, and Costello syndrome are examples of such diseases [43]. Other diseases, such as autism spectrum disorders, the genetics of which is not known, are also more common in children of old men than in young men's offspring.

Spermatogonial proliferation differs between rodents and men. Mice and rats have several generations of spermatogonia due to many rounds of overlapping mitotic proliferation, whereas men have only three types of spermatogonia: A_{dark}, A_{pale}, and B. They are located on the basement membrane of the seminiferous tubules surrounded by Sertoli cells. After mitotic division of type B spermatogonia, the first meiotic cells, preleptotene spermatocytes appear. DNA is replicated and the cells are moved through the blood–testis barrier to the adluminal side of the seminiferous epithelium where the extracellular milieu is very different from normal, mimicking intracellular space with high potassium and low sodium concentration. The adluminal space is also immune-privileged protecting unique germ cells from immune surveillance.

Testes start to grow at the onset of puberty when the Sertoli cells proliferate first, and then spermatogonia are committed to differentiation and enter meiosis. The rapid multiplication of spermatogenic cells makes the testes grow. This first visible sign of puberty in boys occurs at the median age of 11.5 years, while the age range spans from 9.5 to 13.5 years [44].

A_{dark} spermatogonia divide actively and maintain the spermatogonial pool before puberty, whereas in adult testes these cells serve as reserve stem cells and stay mostly quiescent [45, 46]. In adult testes A_{pale} spermatogonia proliferate either to renew themselves (self-renewal) or give rise to type B spermatogonia (differentiation commitment). A_{dark} spermatogonia are needed to replenish the pool of A_{pale} spermatogonia when these become depleted. Thus, A_{pale} spermatogonia are transit-amplifying progenitor cells rather than true stem cells. Difficulty in studies of human spermatogonia is the subtlety of morphological differences between A_{dark} and A_{pale} spermatogonia. Rarefaction in the nucleus of A_{dark} spermatogonia is used to recognize this cell type.

Proliferation and differentiation of rodent spermatogonia have been well-characterized, and despite apparent differences between rodent and human spermatogenesis, regulatory mechanisms appear to be similar. Retinoic acid signalling commits the spermatogonia from self-renewal to differentiation and meiosis [47]. Quiescent stem cell spermatogonia do not express KIT, the receptor for stem cell factor (KIT ligand), that appears in differentiating spermatogonia [48]. Stem cell factor is important for germ cell survival and KIT is expressed also in fetal gonocytes, spermatocytes, and in a truncated form in spermatids. Differentiation of spermatogonia is accompanied with an epigenetic change, since these cells express DNA methyltransferases (DNMT) and possess altered histone modifications compared to undifferentiated spermatogonia [49]. This may prevent the differentiating spermatogonia to switch back to stem cells.

Meiosis

Meiosis is a long process taking 2–3 weeks depending on species. It starts with DNA replication in preleptotene spermatocytes that transit from the basal compartment via a transitory space to the adluminal compartment of the seminiferous tubules [50]. Meiosis proceeds through leptonema, zygonema, pachynema and diplonema (one can also use terms leptotene, zygotene, pachytene, and diplotene phases) to diakinesis. In leptotene spermatocytes chromosomes that consist of two sister chromatids start to condense and the synaptonemal complex starts to form between DNA strands. In zygonema, pairing of the homologous chromosomes takes place. Crossing-over occurs in pachytene spermatocytes when non-sister chromatids of homologous chromosomes switch DNA with each other. The sites of crossing-over, chiasmata, become apparent in diplotene spermatocytes when the synaptonemal complex disintegrates and the chromosomes separate from each other. In diakinesis, meiotic spindle starts to form and nuclear membrane disintegrates. In the first meiotic division chromosomes are divided into two haploid secondary spermatocytes (with 2C amount of DNA). They do not replicate DNA but rapidly undergo another division giving rise to haploid spermatids (with 1C amount of DNA).

Spermiogenesis

Spermatids undergo a remarkable metamorphosis from a conventional round cell to a highly differentiated carrier of the genome that can move rapidly and fertilize an egg. Spermatids develop an acrosomal structure to cover nucleus that condenses and polarizes to form the head of the sperm. Condensation of the nucleus requires the changing of histones to protamines in the chromosomes, which allows a toroid structure, packing the chromosomes very tightly. Transition proteins appear in between the exchange process. Some histone proteins are also left and their methylation status is considered important. A flagellum is built behind the head, and the midpiece at the proximal end of the tail is loaded with mitochondria that are like rocket motors for the space craft. The whole process takes 2–3 weeks, like meiosis, depending on species. Spermiogenesis

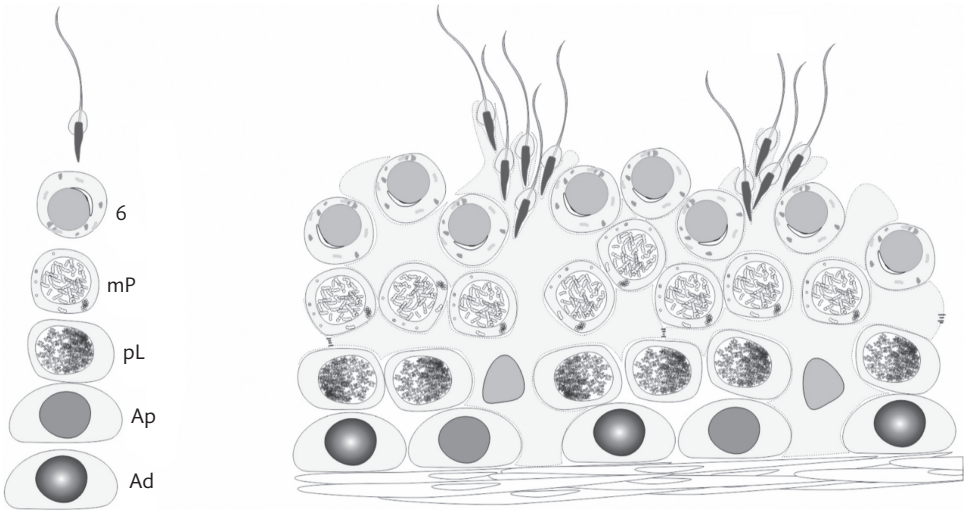

Figure 10.1.1.7 Schematic presentation of a section of human seminiferous epithelium at stage VI of the cycle. Sertoli cells envelope all spermatogenic cells. The blood–testis barrier is formed by Sertoli cells between spermatogonia and spermatocytes, isolating spermatogonia to basal compartment and spermatocytes together with spermatids to the adluminal compartment of the seminiferous epithelium. Preleptotene spermatocytes reside briefly in the intermediate compartment when transferred from the basal lamina to the adluminal area.
Sheyla Cisneros Montalvo is acknowledged for drawing the figure.

ends at spermiation when mature spermatids are released from the seminiferous epithelium to the lumen of the seminiferous tubules.

Transcription stops when the nuclear condensation occurs. However, many new proteins are needed after that, and the cells have to store RNA for later translation. Spermatids have a special ribonucleoprotein structure, called chromatoid body that is a platform for RNA storage and post-transcriptional modification [51, 52]. Components of the chromatoid body can be seen already in intermitochondrial cement of pachytene spermatocytes, but it becomes conspicuous in round spermatids where its movements around the nucleus can be followed in live cell microscopy [53].

Stages of the Seminiferous Epithelial Cycle

Different phases of spermiogenesis are easy to recognize, because the morphology of the cells change rapidly and the cellular features are very distinct. This has helped to understand also the whole organization of the spermatogenic cells in the testis. Yves Clermont and Charles Leblond introduced a staging system on the basis of spermatid morphology in 1952 [54]. In the seminiferous epithelium, spermatogonia, spermatocytes, and spermatids form layers where distinct cell types are always found together and they differentiate synchronously to the next developmental phases. These distinct cell associations characterize different stages of the seminiferous epithelium. They proceed in the seminiferous tubules in a wave-like fashion, and in time, in a cyclic fashion. In rodent seminiferous tubules these are easy to follow, because the stages occupy whole segments of the tubules and they can be microdissected separately from each other. In human seminiferous tubules the structure is more complex, since one cross-sectional segment of the tubule can contain pieces of several stages. This can be explained by the helical arrangement of succeeding stages. Clermont (1963) originally described six stages of the human seminiferous epithelium [55], whereas more recently, 12 stages were characterized [56], which makes comparison to e.g. the mouse easier. Sertoli cells nurture the spermatogenic cells and modify their functions according to the needs of different stages. This makes spermatogenic function cyclical, and the length of the cycle reflects the species-specific characteristics of spermatogenesis. The length of the cycle in human is 16 days [57], and the whole spermatogenesis takes around 4.5 epithelial cycles (see Figures 10.1.1.7 and 10.1.1.8).

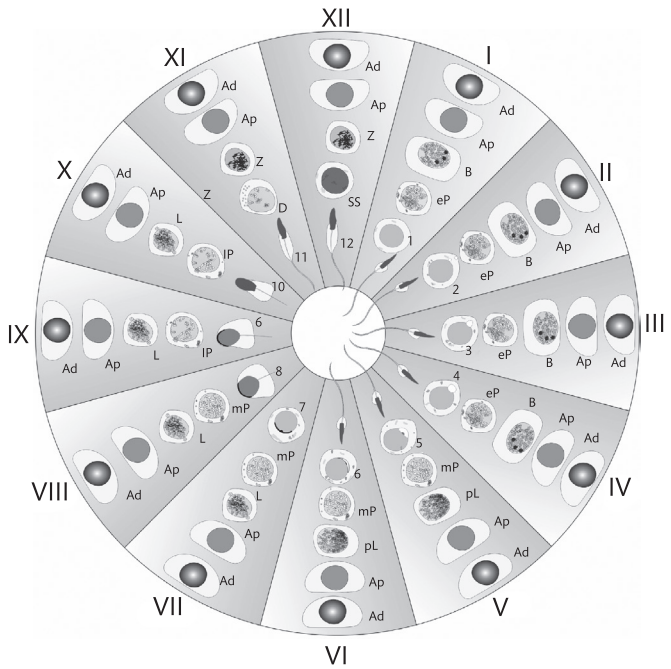

Figure 10.1.1.8 Spermatogenic cells form distinct associations, called stages of the seminiferous epithelial cycle, that follow each other in a cyclic fashion and germ cells differentiate through the cycle up to mature spermatid that is released to the lumen after stage VI in human seminiferous epithelium.
Sheyla Cisneros Montalvo is acknowledged for drawing the figure.

LH/T and FSH Actions in the Regulation of Spermatogenesis

It is generally held that FSH action is needed in the early stages of spermatogenesis, whereas the progression of postmeiotic round spermatids to elongated spermatids is the quintessential step needing androgen action [58, 59]. To what extent the actions of LH-stimulated T and FSH are needed for completion of spermatogenesis remains a contentious topic. The hormonal requirements for initiation of the first spermatogenic wave at puberty, for its maintenance in adult age, and for the re-initiation after transient suppression are apparently different. Androgen alone may not be able to drive spermatogenesis to completion beyond the early spermatid stage in the immature testis, and if a prepubertal animal is hypophysectomized, LH only partially prevents germ cell loss. On the other hand, full spermatogenesis can be initiated in various gonadotrophin-deficient rodent models by T treatment alone, and in man, prolonged hCG treatment alone, through stimulation of T production, is able to initiate spermatogenesis [60]. However, these patients may not have been totally deficient in FSH.

Treatment of healthy men with T enanthate (200 mg/week i.m.) suppresses both gonadotrophins and intratesticular T while maintaining peripheral T action. As a result, spermatogenesis is severely suppressed—to the extent that this provides a successful means of male contraception (see Chapter 10.3.6, 'Hormonal Male Contraception'). If these men receive injections of LH or hCG, their spermatogenesis recovers **qualitatively**, due to the restoration of high intratesticular T [61], although their FSH level remains suppressed. However, the sperm counts remain at only 50% of the pretreatment levels. This has been considered evidence that the re-initiation of spermatogenesis is possible with T alone, but its **quantitative** recovery also needs FSH. When FSH was added to the above treatment regimen, spermatogenesis was fully restored. The T-suppressed men were also treated with purified FSH alone [61], which was able to stimulate spermatogenesis, though not quantitatively. Hence, it appears that neither LH/T nor FSH is absolutely required for qualitatively normal spermatogenesis if either of the other hormone is available at sufficient levels.

Human inactivating *FSHR* mutations, as well as animal models with disrupted *Fshb* or *Fshr* gene function, have shed more light on the role of FSH in spermatogenesis [62]. Men with inactivating mutation in *FSHR* are normally masculinized, but subfertile with reduced testicular size and poor sperm quality. However, sporadic men with inactivating *FSHB* mutation have been found to be azoospermic. The reason for the discrepancy between phenotypes of the hormone and receptor inactivation remains unclear. Both the *Fshb* and *Fshr* knockout mouse data are in agreement with phenotype of the FSHR deficient men, indicating that spermatogenesis, though quantitatively and qualitatively compromised, may proceed without FSH action. Apparently, T is the 'master switch' of spermatogenesis and other factors, including FSH, are needed to maintain it qualitatively and quantitatively normal.

One of the remaining enigmas of androgen action is why the regulation of spermatogenesis seems to require about 100-fold higher concentrations of T than is needed for extragonadal androgen actions, despite the fact that apparently the same AR is mediating these effects. A simple explanation may be that such high intratesticular levels of T are in fact not needed—the T levels are high only because this organ is the site of T production. Recent animal data are in support of this explanation [63].

10.1.2 Sex Steroid Actions in the Male

Dirk Vanderschueren, Leen Antonio, Na Ri Kim, and Frank Claessens

Introduction

Sex hormones are steroids synthesized from cholesterol, predominantly in the gonads and adrenal glands. Testosterone (T) represents the main circulating androgen and oestradiol (E2) the main circulating oestrogen. Leydig cells in the testis of an adult man produce 5–7 mg testosterone daily (see Figure 10.1.2.1), regulated by luteinizing hormone (LH) from the anterior pituitary gland. Around 5–10% of circulating testosterone is converted to the more potent androgen dihydrotestosterone (DHT) by the 5-alpha-reductase enzymes, thereby amplifying specific androgen actions in specific androgen responsive tissues such as prostate and skin (Figure 10.1.2.1). E2 is converted from androgens (T and androstenedione) via aromatization by the aromatase enzyme; 15–25% of the aromatization occurs in, and is secreted into the circulation, by the testis, and the rest in extragonadal tissues such as adipose tissue. Conversion to E2 accounts for the diversified 'dual mode' of action of androgens. Although only 0.1% of testosterone is converted into E2 and circulating concentrations of E2 are about 100 times lower than those of T, this diversification pathway of androgens is of major physiological importance in males. Sex steroids exert their effect by binding to intracellular nuclear receptors that are present in many tissues and act as ligand-dependent transcription factors. Androgens and oestrogens bind to the ligand-binding domain of the androgen receptor (AR) and oestrogen receptor α or β (ERα/ERβ), respectively. In this chapter, we discuss the physiological role of AR and ER mediated androgen actions throughout life.

Sex Steroid Metabolism and Transport

Conversion of Testosterone to Dihydrotestosterone and Oestradiol

Testosterone has a direct androgenic effect following activation of the AR. This is the most important pathway in muscle (Figure 10.1.2.1) [1]. In other androgen-sensitive tissues such as the prostate, intracellular androgen action is amplified by local enzymatic conversion of T to DHT by the 5-alpha-reductase enzymes (mainly 5ARD 1,2) [2–4]. The higher potency of DHT is believed to be due to higher binding affinity for the AR and more efficient coactivator recruitment. It is likely that this amplification system has evolved to selectively expose tissues requiring high local AR activity (such as prostate or hair follicle) while sparing other tissues in whom such high activities are not necessary or could be harmful. Furthermore, T also functions as a prohormone for E2 in reproductive organs, bone, brain, and adipose tissue, where the aromatase enzyme (CYP19A1) is highly expressed [3, 5].

Other enzymes are also involved in sex steroid synthesis and metabolism in peripheral target tissues. In this tissue-specific sex steroid synthesis, also called intracrinology, adrenal sex steroid precursors with weak androgenic potency, such as dehydroepiandrosterone (DHEA), are converted to more potent androgens as well as oestrogens. While some tissues depend on androgens delivered from the bloodstream, others are more reliant on this intracrine hormone metabolism [4]. In addition, the enzyme activities that inactivate sex steroids through catabolism or conjugation vary considerably even between cell types within the same tissue. Taken together, this implies that sex steroid concentrations measured in serum may not always represent the full gamut of androgen and oestrogen activities at the tissue/cellular level due to the differential local synthesis and metabolism of sex steroids.

Transport of Sex Steroids in Circulation

In the circulation, sex steroids are mainly bound to sex hormone-binding globulin (SHBG) and albumin. Albumin, the most abundant protein in human serum, binds sex steroids with a relatively low affinity (10^{-4}M range), whereas SHBG specifically binds sex steroids, mainly T and E2, with a high affinity (10^{-9}M range), with the affinity of SHBG for T being three times higher than for E2. In normal men, about 55% of T and 30% of E2 is bound to SHBG. Only a small fraction (1–3%) of T and E2 circulates in a non-protein bound or free form [6, 7].

According to the 'free hormone hypothesis', the free fraction is responsible for the biological activities of sex steroids, as only the free unbound hormone can enter the cell and activate its nuclear receptor. However, because sex steroids are only loosely bound to albumin, it is hypothesized that the bound hormone can dissociate from albumin, enter the cell, and may also activate the receptor. Together with the free fraction, the albumin-bound hormone

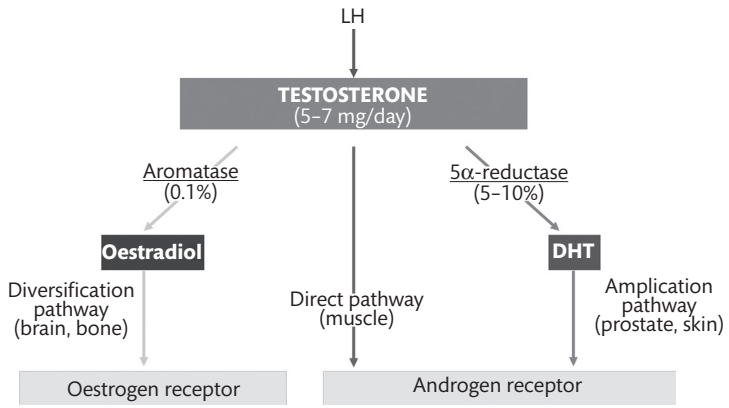

Figure 10.1.2.1 Pathways of testosterone action. The physiological responses to testosterone are either direct via activation of the AR or are modulated via reduction into the more potent DHT (amplification pathway) or via aromatization into oestrogens that act via ERs (diversification pathway).

Adapted and reproduced from PY Liu *et al*: Androgens and Cardiovascular Disease. *Endocr. Rev 2003*. 24: 313–40.

fraction is therefore considered the biologically available (bioavailable) fraction, while the fraction that actually binds to the receptor is called the biologically active (bioactive) fraction (Figure 10.1.2.2) [5]. However, it remains unclear to what extent the bioavailable fraction equates or equilibrates with the bioactive fraction, as intracellular metabolism of the steroid hormone and rate of blood flow in the target tissue also have to be taken into account.

Molecular Mechanisms of Androgen and Oestrogen Actions

Androgens (mainly T and DHT) are highly selective steroid ligands for the AR. The AR (also known as NR3C4) is a member of the nuclear receptor superfamily. The AR is composed of three different functional domains (Figure 10.1.2.3): the central DNA-binding domain (DBD) recognizes androgen response elements (ARE) via two zinc finger modules, the N-terminal domain (NTD) has transactivating properties (AF-1) and the C-terminal ligand-binding domain (LBD) has a ligand-binding pocket and a second activation function (AF-2) [8, 9].

Unliganded AR is primarily located in the cytoplasm. Once ligands, androgens, bind to the AR, the LBD undergoes a conformational change resulting in the dissociation of heat shock proteins (HSPs) from the cytoplasmic AR. This triggers dimerization of the receptor, the exposure of a nuclear localization signal inducing translocation to the nucleus and the induction of the AF-2 surface that is recognized by a number of coactivators (Figure 10.1.2.4). The androgen/AR complex will then recruit these coactivators to AREs located near the androgen target genes in the genome.

The coactivators of the AR function as pioneering factors, histone modifiers, chromatin modifiers, or general transcription factors. Along with AR, actions of coactivators will lead to the upregulation of the expression levels of the target genes, whereas corepressors suppress AR transactivation, resulting in downregulation of certain target genes [10–12]. How the same transcription factor can trigger diverse responses in different tissues can at least in part be explained by the tissue-specific concentration of the ligands and the expression levels of the receptors themselves, but also by the chromatin architecture and the cooperativity of the AR with tissue-specific transcription factors [13].

Apart from the classical, sex steroid-induced gene transcription, androgen and oestrogen actions can also be mediated through non-genomic mechanisms. In such non-genomic actions, the ligand binds to the cytoplasmic receptor, which is then translocated to the plasma membrane, where it can activate other signal transduction pathways (Figure 10.1.2.4) [14]. In contrast to the slow classical nuclear receptor actions, requiring hours to days, these non-genomic actions result in rapid effects, occurring within seconds or minutes of ligand binding. The best-documented event is the triggering of the release of intracellular calcium, which can lead to activation of kinases such as mitogen-activated protein kinase (MAPK), protein kinase A (PKA), Akt and protein kinase C (PKC). Ultimately, this process indirectly affects gene transcription through phosphorylation and subsequent protein synthesis. The exact role of the membrane-initiated events in androgen-related physiology and pathologies still needs to be established.

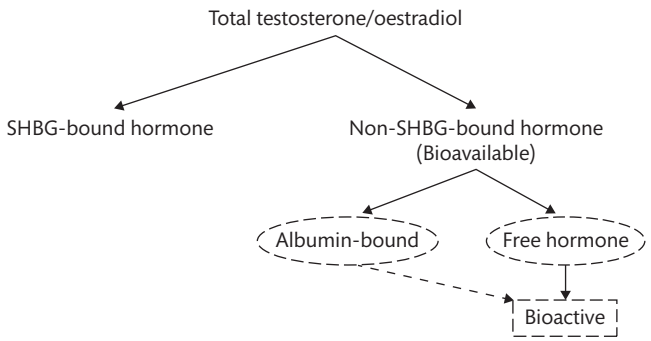

Figure 10.1.2.2 Sex steroid fractions in human serum.

Ontogeny of Androgen Action

Testosterone levels change considerably during the male life span (Figure 10.1.2.5).

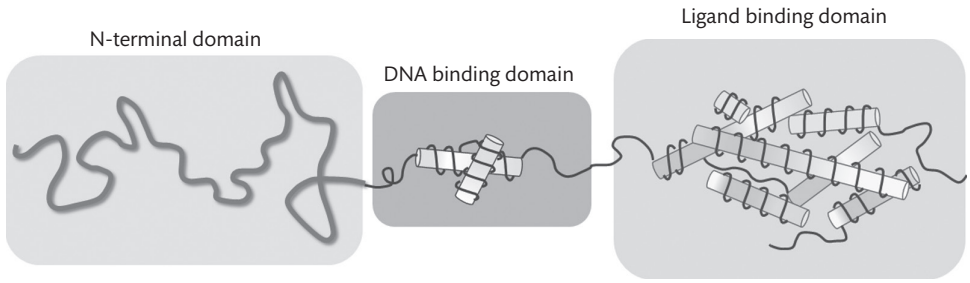

Figure 10.1.2.3 Schematic model of the modular structure of the AR, with an unstructured NTD, a central DBD, and a carboxyterminal ligand-binding domain.

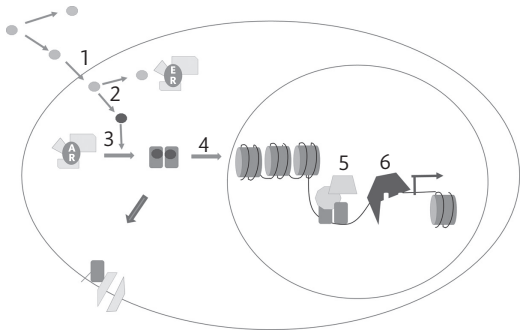

Figure 10.1.2.4 Multiple steps in the nuclear and membrane-initiated actions of androgen receptor: (1) Testosterone (orange) enters the cell where it can be converted to DHT (2) (red) or oestrogen (green). When T or DHT bind to AR, HSPs (light blue) dissociate, the receptor is dimerizing (3) and enters the nucleus (4), where it will bind AREs (5), recruiting coactivators (grey) ultimately leading to increased transcription of androgen target genes by RNA polymerase II (dark blue). *For a colour version of this figure, please see colour plate section.*

Antenatal

Around the sixth week of embryogenesis, the undifferentiated gonads develop into testes (see also Chapter 7.2.1 and 10.1.1). This is regulated by testis-determining factor, a transcription factor encoded by the sex-determining region of the Y chromosome. Around week 8, the fetal Leydig cells start producing T. This prenatal T exposure determines further differential sex development in the fetus. T induces differentiation of the Wolffian ducts into male reproductive organs such as epididymis, vas deferens, and seminal vesicles. Additionally, immature Sertoli cells produce anti-Müllerian hormone (AMH). This triggers the regression of Müllerian ducts, eventually inhibiting the formation of uterus and fallopian tubes in the male fetus [15–17].

DHT is important for differentiation and development of male external genitalia during embryogenesis [18, 19]. This is illustrated by individuals with mutations in the gene encoding 5α-reductase, resulting in absent or very low levels of DHT. Although these patients have a 46, XY-karyotype, they are born with female external genitalia. As the testes can produce normal levels of T, internal male urogenital structures develop normally in these individuals. Moreover, increase of T at the onset of puberty leads to development of typical male features, such as an increase in muscle mass and voice deepening [20].

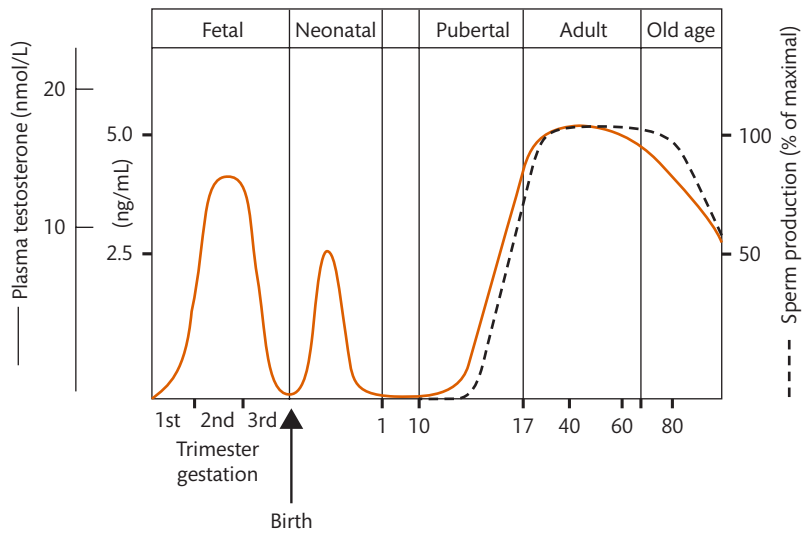

Figure 10.1.2.5 Concentrations of testosterone and appearance of spermatogenesis across the male lifespan.
Reproduced from JE Griffin *et al*: The Testis. In: Bondy PK, Rosenberg LE (eds). *Metabolic control and disease*, 8th edition. Philadelphia, Pa: WB Saunders, 1980:1535–78.

Individuals with inactivating mutations in the AR also have a 46, XY-karyotype, but are born with a female external phenotype due to abrogation of both DHT and T mediated effects antenatally. In these patients with the complete androgen insensitivity syndrome (CAIS), T levels are normal or even high, but the Wolffian ducts do not differentiate into epididymis and vas deferens. As AMH action is normal, a uterus and fallopian tubes are absent. For a detailed discussion on disorders of sex development, see Chapter 7.2.2.

Neonatal and Childhood

At birth, hypothalamic gonadotropin-releasing hormone (GnRH) neurons are transiently activated, probably due to cessation of the negative feedback by placental oestrogens. This triggers transient activation of the hypothalamic–pituitary–gonadal (HPG) axis, resulting in a second peak of T levels (mini-puberty). Androgen exposure in the neonatal period is important for growth in childhood and reproductive function in later life [21, 22].

After these two peaks in early development, circulating T remains low until puberty. Moreover, SHBG levels are very high in childhood, resulting in even lower free sex steroid concentrations in prepubertal children.

Puberty

Upon entry into puberty, T secretion resumes and SHBG levels gradually decrease, contributing to a progressive increase in free sex steroids. High androgen levels induce development of secondary sexual characteristics and axial skeleton growth. Increased testicular size, thinning of the scrotum, and growth of pubic hair are the most obvious physical signs of pubertal sexual development. In addition, increasing levels of T lead to an increase in muscle mass and deepening of voice. T deficiency during puberty leads to absence of or insufficient secondary sexual development as well as infertility (i.e. hypogonadism in adulthood if persistent). This is covered in more detail in Chapter 7.3.2.

Puberty is a critical period for peak bone mass acquisition and establishment of sexual dimorphism in bone mass and geometry and overall physique. Together with T, oestrogens play an important role in bone development during male puberty. This became evident from case reports of men with aromatase deficiency. Aromatase deficiency is caused by a loss-of-function mutation in the *CYP19A1* gene, resulting in impaired oestrogen synthesis and very low or undetectable E2 levels [23]. Without oestrogen action, the long bone epiphyses do not close and the growth termination from epiphyseal fusion expected at the end of puberty is lacking. This results in continuous linear bone growth and men with aromatase deficiency therefore present with tall stature and eunuchoid body proportions. Furthermore, these men fail to achieve adult peak bone mass leading to osteopenia or osteoporosis and skeletal deformities such as scoliosis and genu valgum. Oestrogen treatment results in a rapid completion of bone maturation, epiphyseal closure, and growth cessation. Furthermore, oestrogens can increase bone mineral density. Other features of the syndrome include impaired spermatogenesis as well as the metabolic syndrome with abdominal obesity, insulin resistance, and dyslipidaemia [23].

One case report of a man with a mutation in ERα reports a similar phenotype [24], which confirms animal data that the major receptor for oestrogen action in the male is ERα. Thus far, no men with ERβ mutations have been described.

Adulthood

Circulating T levels reach their peak in early adulthood. This is then followed by a gradual decline in T levels in subsequent decades, with a concomitant increase of SHBG concentrations [25–27]. This age-related decline in T is gradual and lacks a sharp inflection point akin to the menopause in females. The extent to which the age-related decline in T is due to chronological ageing alone or to the accumulation of age-related comorbidities remains however incompletely understood (see Chapter 10.3.5).

Obesity is an important contributor to low T levels in adult men. Severely obese men (body mass index (BMI) > 40 kg/m^2) have lower serum total and free T levels compared to men with normal BMI [28] and their T concentrations drop more quickly [29]. Also chronic illnesses, such as cardiovascular disease and type 2 diabetes, are associated with lower testosterone levels in adult men. Similarly, SHBG levels can be affected by multiple hormonal and metabolic factors (see Chapter 10.2.2).

Androgens play a key role in the physiology of the adult male. However, recent studies with experimentally induced androgen and oestrogen deficiency in healthy young men made it clear that oestrogens also play a fundamental role in several target organs, responsible for effects that were traditionally attributed to androgens [30]. Androgen and oestrogen mediated effects are summarized in **Table 10.1.2.1**.

High intratesticular testosterone levels are essential for normal spermatogenesis [31]. On the other hand, sexual function is mediated by both androgens and oestrogens. Experimentally induced short-term sex steroid deficiency in healthy young men resulted in a decrease in sexual desire and erectile function. When these men were treated with T replacement therapy together with an aromatase inhibitor, thereby normalizing T levels but maintaining E2 deficiency, sexual desire and erectile function remained decreased compared to men treated with T only [30]. Furthermore, androgen deficiency also induced a decrease in lean mass and muscle strength [30], whereas E2 deficiency induced a decrease in bone mineral density [32].

E2 is not only important for sexual/reproductive function and skeletal development, but it also regulates hypothalamic–pituitary–thyroid (HPT) axis activity, both at hypothalamic and pituitary level. In humans, the relevance of androgen aromatization to E2 for normal gonadotropin feedback has been studied in men with idiopathic hypothalamic hypogonadism (IHH) who were treated with pulsatile GnRH to normalize gonadotropin levels [33]. Not only T but also E2 infusion resulted in decreased levels of LH and follicle-stimulating hormone (FSH), which indicates that E2 plays a role in mediating negative feedback actions on gonadotrophin secretion. It is known that E2 exerts feedback regulation via ERα expressing KNDy (Kisspeptin/Neurokinin B/Dynorphin) neurons in arcuate nucleus of hypothalamus [34]. Furthermore, transdermal E2 treatment decreased LH pulse frequency, LH pulse amplitude, and GnRH-stimulated LH secretion in men suffering from aromatase deficiency, again illustrating the importance of oestrogens for hypothalamic-pituitary feedback in men [35].

Table 10.1.2.1 The differential role of androgens and oestrogens in male physiology

Sex steroid target organ	Androgens		Oestrogens E2	Remarks	Ref
	T	DHT			
Reproduction					
Spermatogenesis	+		+	Intratesticular T levels are crucial for normal spermatogenesis. Impaired spermatogenesis is also observed in men with aromatase deficiency.	[23, 31]
Sexual desire Erection	+		+	Experimentally induced short-term sex steroid deficiency in healthy young men resulted in a decrease in sexual desire and erectile function. When these men were treated with T replacement therapy together with an aromatase inhibitor, thereby normalizing T levels but maintaining E2 deficiency, sexual desire, and erectile function remained decreased compared to men treated with T only.	[30]
Prostate		+		DHT mediates prostate growth and the development of benign prostate hyperplasia. Treatment with a 5α-reductase inhibitor results in a decrease of prostate volume.	[36]
Bone and body composition					
Maintenance of bone mass	+		++	Severe oestrogen deficiency leads to a decline in bone mineral density. In patients with aromatase deficiency, oestrogen treatment restores bone mineral density. Murine models with osteoblasts and osteocytes specific knockouts of AR also revealed a direct role for androgens on trabecular bone, independent of aromatization.	[23, 32, 37] [38, 39]
Maintenance of muscle mass and strength	+			Androgen deficiency leads to a decrease in lean mass, muscle strength, and muscle size.	[30]
Body fat			+	Oestrogen deficiency results in an increase in body fat.	[30]
Hypothalamic-pituitary feedback	+		+	Both T and E2 provide hypothalamic-pituitary feedback.	[40]
Central nervous system					
Gender-related behaviour	+		+	Early prenatal androgen exposure contributes to the development of gender-related behaviour. Murine models suggest neonatal oestrogen exposure is important for sexually dimorphic behaviour in adult life.	[41–43]
Aggression	+			Serum T levels showed a low, but positive correlation with aggressive behaviour and higher correlation with dominance.	[44]
Skin and hair					
Sebum production	+	+		Androgens stimulate sebum production and are a contributing factor in the development of acne vulgaris.	[45]
Pubic and axillary hair growth	+			Due to the rise of androgen levels in puberty, axillary, and pubic hair starts growing. Patients with CAIS have no pubic and axillary hair.	[45]
Facial hair growth	+	++		Due to the rise of androgen levels in puberty, facial hair starts growing. Patients with CAIS or 5α-reductase deficiency have absent or sparse facial hair.	[45]
Male balding		+		Androgens suppress hair growth on the frontal and vertex scalp, leading to male balding. Patients with CAIS or 5α-reductase deficiency do not develop male balding.	[45]
Erythropoiesis	+		?	Androgens stimulate haemoglobin synthesis and erythropoietin synthesis. Exogenous testosterone suppresses hepcidin, resulting in a higher haematocrit.	[46] [47]

10.2

Evaluation of the Male Patient with Suspected Hypogonadism and/or Infertility

10.2.1 Clinical Evaluation

Bradley D. Anawalt

Clinical Evaluation

Although male hypogonadism (androgen deficiency and/or infertility due to a defect in spermatogenesis) are common in men, there is no value in screening for these disorders [1]. There are a number of questionnaires available for screening or case-finding, but these instruments should be reserved for research purposes [1]. The clinician should evaluate men for androgen deficiency when they present with suggestive symptoms such as low or decreased libido, new onset of erectile dysfunction or gynaecomastia, infertility (attempting to conceive with at least weekly vaginal intercourse without contraception for at least 12 months), or unexplained muscular weakness (**Box 10.2.1.1**). Male androgen deficiency is associated with many vague and non-specific symptoms that overlap with depression, anxiety, and psychosomatic disorders; sexual symptoms (e.g. decreased libido, decreased morning erections, and decreased penile tumescence) appear to be most specific for androgen deficiency [2]. Men with signs of androgen deficiency such as lack of full pubertal development (e.g. small testes), osteoporosis, or unexplained anaemia should be evaluated for hypogonadism even in the absence of suggestive symptoms [3–5].

When androgen deficiency or infertility is suspected or confirmed in a man, the remainder of the history and the physical examination should be focused on determination of the following: (1) the onset and duration of androgen deficiency or infertility; (2) the cause of androgen deficiency or infertility; (3) and determination of the likely benefit and risk of hormonal therapy (testosterone or gonadotropin replacement therapy).

The timing of onset of male hypogonadism has important diagnostic and therapeutic implications. For adult men who present with prepubertal or congenital onset of hypogonadism, hormonal therapy may cause dramatic changes in facial appearance, musculature, and bone density, but it is unlikely to fully restore all end-organ function to normal compared to age-matched peers. For example, testosterone replacement therapy will not increase bone mineral density in men who are diagnosed as adults with congenital hypogonadism to that of age-matched peers who are eugonadal [6, 7]. Likewise, gonadotropin therapy is more likely to be rapidly effective for men with acquired, postpubertal hypogonadotropic hypogonadism than for men with congenital hypogonadotropic hypogonadism (e.g. Kallmann syndrome) [8]. In addition, men with congenital hypergonadotropic or hypogonadotropic hypogonadism often have syndromes with extragonadal sequelae (e.g. increased risk of diabetes mellitus type 1 and 2 and autoimmune thyroid disease in Klinefelter syndrome or anosmia and single 'horseshoe' kidney in Kallmann syndrome associated with *ANOS1* [*KAL1*] mutation) [9, 10].

The cause of hypogonadism is either primary (testicular) or secondary (dysfunction or disease of the hypothalamus and pituitary). The distinction between primary and secondary hypogonadism

Box 10.2.1.1 Symptoms and signs of adult male hypogonadism

Specific, but uncommon, symptoms and signs
- Incomplete or delayed sexual development
- Inability to conceive after ≥12 months of frequent intercourse without contraception
- Loss or decreased growth of androgen-dependent body hair
  Small testes (<10 ml)

Suggestive symptoms and signs
- Decreased libido, spontaneous erections, and sexual activity
- New onset of breast growth and tenderness
- Low trauma fracture or significant height loss
- Hot flashes

is important diagnostically; men with primary hypogonadism might benefit from karyotyping for Klinefelter syndrome whereas men with secondary hypogonadism must have an evaluation for diseases and medications that affect hypothalamic and pituitary function [1]. Determination of the cause of hypogonadism is also important therapeutically; infertility due to primary hypogonadism cannot be treated medically whereas the majority of men with hypogonadotropic hypogonadism can have fertility restored or improved with gonadotropin therapy [8].

The history and physical examination can be useful in determining the onset and cause of hypogonadism. The history and examination are also indispensable in determining the potential benefits and risks of testosterone or gonadotropin replacement therapy. For example, a man who presents during adulthood with congenital hypogonadism is likely to have decreased spermatogenesis that will increase but not normalize with gonadotropin replacement therapy. On the other hand, a man who presents with recent onset of postpubertal hypogonadism is less likely to have evidence of end-organ harm from androgen deficiency; for this man, testosterone replacement might not cause measurable changes in androgen-dependent tissues, but it will maintain androgen-dependent organ function within the normal range. The history and physical examination might also identify specific risks of androgen therapy. For example, testosterone therapy might cause accelerated male pattern balding in men with a family history of androgenic alopecia or increased risk of prostate cancer in men with risk factors for prostate cancer.

Specific Elements of the History and Physical Examination for All Men Suspected of Having Androgen Deficiency or Infertility

All adult men with suspected androgen deficiency or male infertility should be queried about the following:

To determine the onset of hypogonadism: The man should be asked about the onset and achievement of pubertal milestones—were they are at normal age milestones compared to peers? How long have symptoms and signs of hypogonadism been present? Did the man have a decline in libido? (Men with untreated prepubertal hypogonadism have never had a normal libido and will not report a decline.) Did the man ever father a child? (It is true that such history would not prove previous normal fertility as the man might not be the biological father, but the information is still useful.)

To determine the cause of hypogonadism or male infertility: The man should be asked about exposure to testicular toxins (e.g. alkylating chemotherapeutics), testicular trauma or infection (e.g. mumps orchitis). The man should also be asked about symptoms or signs of sellar masses (new onset of blurry vision or headaches; symptoms of other pituitary hormone hypo- or hyperfunction) and risk factors for iron overload syndromes (family history of hemochromatosis or personal history of blood transfusions). Finally, the man should be queried about exogenous prescription or nonprescription use of corticosteroids, opioids, anabolic androgenic steroids, or medications that cause hyperprolactinemia and about symptoms suggestive of corticosteroid excess (easy bruisability or muscle weakness).

Men with suspected male hypogonadism should have a physical examination that includes the following:

Genital examination: The most important part of the physical examination in man with suspected male hypogonadism is the genitourinary examination. The penis should be examined for normal location of the urethra opening. The vasa deferens should be palpated. Absence of one or both of the vasa suggests cystic fibrosis, a cause of male infertility [4]. The testes should be measured with a Prader orchidometer; Prader orchidometry correlates well with ultrasonographic measurements although ultrasonographic measurements are usually slightly smaller [11]. Testes that are each 3 ml or smaller (by Prader orchidometry) indicate that the onset of hypogonadism occurred before the onset of puberty and usually indicates primary hypogonadism due to Klinefelter syndrome or congenital hypogonadotropic hypogonadism due to a genetic mutation.

The remainder of the exam should be focused on evidence of androgen effects. The skin should be examined for acne and hair in androgen-dependent areas (e.g. face, chest, and below the umbilicus). Acne suggests that the skin has recently been exposed to androgens. Hair in androgen-dependent areas indicates that the skin has had some lifetime exposure to androgens. It takes several months of androgen exposure to cause hair growth, but several years of hypogonadism to decrease hair in androgen-dependent areas. The chest should be examined for breast tissue (see Chapter 10.3.7, 'Gynaecomastia'). Breast tissue is firm and rubbery and discoid around the areolae; it can be discriminated by the firm edge of the breast tissue that can flipped up from surrounding fat that is soft. The muscles should be examined for strength and mass; profound, longstanding hypogonadism may cause decreased muscle mass and strength. A man who is infertile and has well-developed musculature but low serum testosterone and gonadotropin concentration might be using androgenic anabolic steroids.

In specific settings, the clinician should examine for unusual physical findings. In men with small testes and suspected congenital hypogonadotropic hypogonadism, the man should be examined for eunuchoidal proportions that is most easily detected as arm span that is at least 5 cm greater than the height of the man. In addition, men with congenital hypogonadotropic hypogonadism should be queried or tested for decreased sense of smell, coloboma, or dysdiadokinesis; these findings suggest specific heritable genetic mutations (e.g. Kallmann syndrome due to *ANOS1* mutation or CHARGE syndrome). Men with postpubertal onset of hypogonadotropic hypogonadism should be examined for signs of Cushing syndrome including thin skin with diffuse ecchymoses or broad purple striae and proximal muscle weakness (e.g., inability to rise from the seated postion without using arms to push or pull up).

Conclusions

A history and physical examination is useful for helping determine the onset of hypogonadism and may be useful in determining specific causes of hypogonadism or infertility. For example, a man who presents with small testes, decreased or absent sense of smell, and a coloboma likely has a genetic mutation causing congenital hypogonadotropic hypogonadism. A man with infertility and absence of one or both vasa deferentia has cystic fibrosis. Finally, the history and exam provide important clues about the likelihood of therapeutic benefit and adverse effects of testosterone or gonadotropin therapy. For example, an infertile man with hypogonadotropic

hypogonadism, testes that each measure 6 ml, and a family history of androgenic balding is likely to have improved fertility with gonadotropin therapy but might experience male pattern baldness with any form of androgen replacement therapy. Thus, a careful history and physical examination is an important component of the evaluation of a man suspected of having hypogonadism or infertility.

10.2.2 Endocrine Evaluation

Jean-Marc Kaufman

Men Evaluated for Suspected of Hypogonadism

Making the diagnosis of hypogonadism requires the documentation of deficient testosterone (T) production as reflected by low T blood concentrations [1]. After having established that the patient is T deficient, further hormonal evaluation is needed to determine the underlying cause of hypogonadism with measurement of serum gonadotropins to differentiate secondary hypogonadism of hypothalamic-pituitary origin from primary testicular failure as the next step. Additional hormonal measurements may be of help to refine the diagnosis. Optimally, planning of the endocrine investigations is guided by the findings of the clinical evaluation. The clinical and hormonal findings jointly provide guidance as to the need of additional investigations such as imaging and genetic testing. In general, there is a rather straight forward logic sequence of hormonal investigations in men with suspected hypogonadism. The approach is summarized in Figure 10.2.2.1.

Hormonal Diagnosis of Hypogonadism

The diagnosis of hypogonadism is based on the presence of symptoms and signs of hypogonadism and a consistently and unequivocally low serum total T and/or free T [1]. Some conditions to be fulfilled to reliably demonstrate a low serum T concentration and thus deficient T production, are summarized in Box 10.2.2.1.

Measurement of Serum T Level

In order to account for the physiologic circadian variation of serum T levels in healthy men, with usually ≥ 40% difference between peak T levels in the morning compared to nadir T levels in late afternoon to early evening [2], blood sampling to confirm a clinical suspicion of hypogonadism should be performed in the morning, ideally between 7:00 and 10:00 a.m. Although the circadian variations of serum T concentrations tend to be blunted in ageing men, this effect nevertheless persists partially and variably so that sampling in older men should also be performed in the morning. Sampling should be performed in fasting state because of reported decreases in blood T concentrations of around 25–30% after food intake [3, 4]. Because T is secreted episodically with resulting within and between-day variations in T levels, the finding of a low T should be confirmed by demonstration of low T in a second blood sample. Acute stress (e.g. surgery) and disease can result in transient marked suppression of T levels, so that blood sampling for diagnosis of hypogonadism should not be performed during or soon after such events (i.e. preferably not earlier than 2–4 weeks following full recovery). Moreover, to account for possible transient T decrease of any cause, the second blood sample for confirmation of low T should be obtained on a separate occasion, ideally with an interval of at least 2 weeks after the initial sampling. Conversely, a single clearly normal serum T generally excludes significant hypogonadism. Only occasionally, e.g. in symptomatic men with borderline low-normal serum T and evidence for a disorder of the gonadal axis (e.g. elevated gonadotropins), one may want to confirm the normal T in a second sample.

To measure T levels in serum, mass-spectrometry-based methods which include serum extraction and a chromatography step, i.e. gas chromatography-mass spectrometry (GC-MS) and mainly liquid

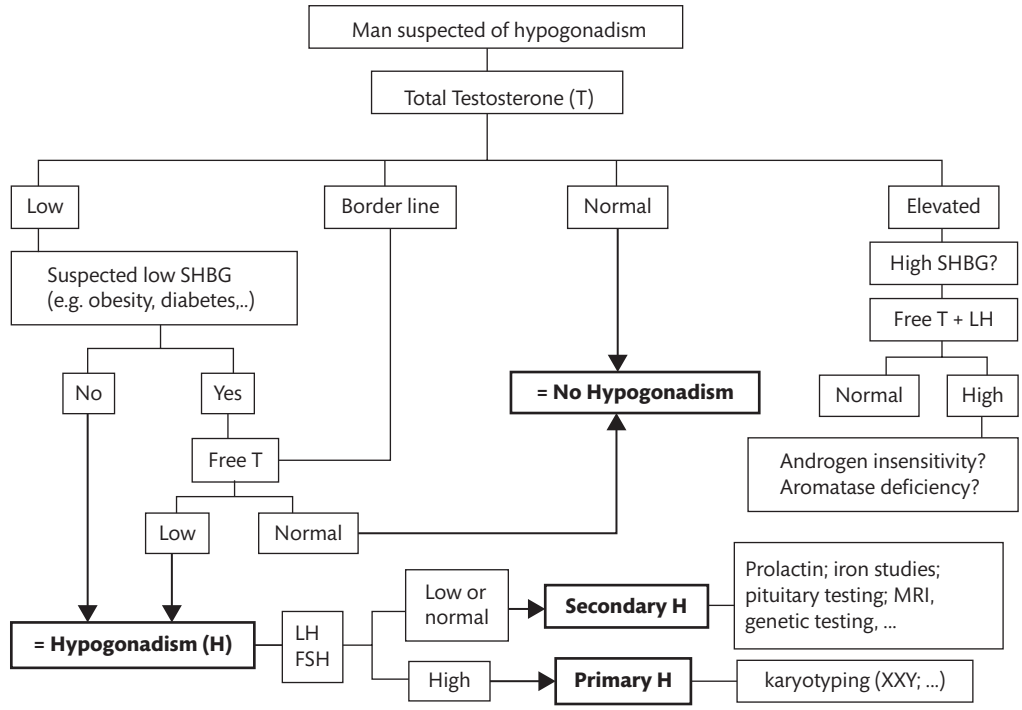

Figure 10.2.2.1 Flow-chart for hormonal evaluation of men suspected of hypogonadism.

chromatography-tandem mass spectrometry (LC-MS/MS), are now considered the preferred state-of-the-art methods, whereas automated immunoassay platforms are the most commonly used methods by clinical chemistry laboratories. The radioimmunoassay methods for T introduced in the early 1970s included serum or plasma extraction and chromatographic purification steps before immunoassay, which improved specificity by removing potentially cross-reacting steroids and allowed increased sensitivity by extracting larger volumes of serum. Evolutions in the past decades have seen radio-immunoassays mostly replaced by alternative immunoassay techniques (e.g. chemiluminescence-immunoassays), and the extraction and chromatography steps have been omitted with resultant diminished specificity as a trade-off for gains in time, costs, and suitability for automation in multianalysers. These automated platform immunoassays have been criticized for poor assay performance [5, 6]. Clinically, this is particularly an issue in children and women, where these immunoassays cannot reliably quantify the low serum T concentrations. By contrast, most T immunoassays in commonly used automated platforms perform reasonably well for routine diagnosis of hypogonadism in men [7, 8], even if there are some issues of calibration and accuracy. Irrespective of whether immunoassay or LC-MS/MS is used, proper assay validation and ongoing quality control in individual clinical laboratories is essential and should include the use of a reference range validated for the particular laboratory conditions.

Poor standardization of T assays limiting comparison of results across assay platforms has been an issue of concern. In response the USA Centers for Disease Control and Prevention (CDC) Clinical Reference Laboratory developed a reference method calibrated with higher order reference material and implemented a standardization and certification programme for T assays open to subscription by external laboratories.

There is no consensus on what is considered a subnormal T level, with proposed cut-off levels varying from 8 to 12 nmol/L (230–350 ng/dl) according to different recommendations and guidelines from scientific societies [1, 9, 10]. Moreover, reference ranges for serum T levels vary between laboratories due to methodological issues related to both T assay calibration and how the reference data

Box 10.2.2.1 Points to consider when assessing serum testosterone (T) for diagnosis of hypogonadism

Pre-analytical conditions

- Blood sampling performed in the morning (preferably between 7 and 10 a.m.)
- Blood sampling after overnight fast
- No sampling during- and earlier than 2–4 weeks after full recovery from acute physically stressful event or disease
- No sampling after night work shift

Analysis and interpretation

- Measurement of serum total T with a well validated assay: LC-MS/MS (ideal) or immunoassay
- Use of a valid reference range (laboratory-validated or through cross-calibration with external assay)
- Assessment of serum-free T if total T borderline low/normal (e.g. 200–400 ng/dl or 7–14 nmol/L) in particular in clinical situations with altered SHBG (see Box 10.2.2.2)
- Free T ideally measured by a validated equilibrium dialysis- or ultrafiltration-based technique, but limited access
- Free T estimated by calculation from total T, SHBG (and albumin) using a validated equation (see text): acceptable practical alternative but with limitations
- Low (free) T to be confirmed in repeat sample, preferably after an interval (weeks) allowing for recovery of possible transient cause of low (free)T
- Single clearly normal (free) T generally excludes significant hypogonadism
- Occasionally, borderline low-normal (free)T may deserve confirmation in repeat sample if clinic suggestive of deficiency and other indications of disorder of gonadal axis (e.g. elevated gonadotropins)

was generated. In the 2018 update of the US Endocrine Society clinical practice guideline on T therapy in men with hypogonadism (1), the only lower T cut-off level put forward is 9.2 nmol/L (264 ng/dl) for T assays calibrated against the CDC reference method. This 9.2 nmol/L cut-off corresponds to the 2.5th percentile for T in non-obese men 19–39 years of age, according to harmonized T reference ranges generated from cross-calibrated data from US- and Europe-based cohorts of community-dwelling men [11]. Although there is no universally accepted T cut-off for diagnosis of hypogonadism, there is broad agreement that men with T below 8 nmol/L are likely to be hypogonadal, whereas men with T above 12 nmol/L are not [9].

When serum T is measured with the purpose to monitor T treatment in a hypogonadal men, interpretation of T levels can be difficult as there may be very large fluctuations in measured levels depending on the timing of sampling relative to administration of the last T dose and on the route of administration (e.g. transdermal versus intramuscular) and the pharmacokinetics of the T preparation being used. Blood sampling is often performed shortly before administration of the next dose, in order to capture the trough T level. However, for most preparations there can be significant within- and/or between-day variations of T levels such that single time point measurement may not be fully representative. These issues are important for clinicians to bear in mind when considering T dose adjustments in patients being started or maintained on T therapy and when assessing efficacy or compliance to treatment.

Assessment of Serum-Free T Level

Testosterone in the circulation is mostly bound to plasma proteins, i.e. in part specifically and with high affinity to SHBG (about 40–60%; variable according to SHBG concentration), in part more loosely bound to albumin (about 40–50%), and minor fractions bound to cortisol-binding globulin and orosomucoid. In men, only 1 to 3% (median 1.5%) of T circulates as free hormone [12]. According to the free hormone hypothesis, only this small fraction can freely access the target tissues and is directly available for biological action [13]. At least part of T loosely bound to albumin might dissociate in the capillary circulation and thus also become available for diffusion into the tissues. The combined free and albumin-bound fractions of T are often referred to as 'bioavailable T'. The relation between free T and bioavailable T serum concentration is fairly constant, unless there are large deviations of serum albumin levels from normal [14].

In conditions which markedly affect SHBG levels (**Box 10.2.2.2**) free T is a more accurate index of testicular function than total T. As an example, obesity results in decreased SHBG and consequently also decreased total T levels, whereas free T is still maintained in many obese men with low total T, who are not in fact hypogonadal. Thus, to rely solely on total T will lead to overdiagnosis of hypogonadism in obese men. However, if free T is also decreased in addition to total T, usually encountered in severe obesity, these men are likely to be truly and symptomatically hypogonadal. On the other hand, SHBG increases with age so that gonadal function in older men may be lower than suggested by the total T level and more accurately reflected by the free T level. Moreover, men with markedly increased SHBG concentrations (e.g. due to HIV/AIDS, antiepileptic medication, or liver disease) may have a low free T and be hypogonadal despite a total T in the normal range. All current guidelines recommend total T as the first-line diagnostic test for diagnosis of hypogonadism [1, 9, 10, 15–17]. Generally they recommend assessment of free T only as a supplementary diagnostic test in those symptomatic men with a condition known to affect SHBG concentrations, where total T is a less reliable index of gonadal status, and in those with borderline total T result at the lower limit of the reference range. However, not all recommendations support the use of free T assessment [10, 17]. Nevertheless, several studies have illustrated the usefulness of free T assessment (e.g. [18, 19]).

Box 10.2.2.2 Clinical situations associated with altered serum SHBG levels

Low SHBG
- Obesity
- Type 2 diabetes mellitus
- Hypothyroidism
- Cushing syndrome
- Glucocorticoid treatment
- Acromegaly
- Growth hormone therapy
- Nephrotic syndrome

High SHBG
- Ageing
- Low BMI
- Thyrotoxicosis
- Chronic liver disease (cirrhosis; hepatitis)
- HIV infection
- Growth hormone deficiency
- Anticonvulsant drugs (some, e.g. phenytoin)
- Oestrogen, tamoxifen, clomiphene citrate use

There are methodological issues as to the clinical implementation of free T assessment. The reference range for free T is even less well established than that for total T and there is again no generally accepted lower cut-off level indicating T deficiency. A level around 225 pmol/L (6.5 ng/dl), but ranging from 170 to 240 pmol/L (5.0–7.0 ng/dl) has been suggested [5, 9, 16, 20–22]. Measurement of free T is based on dialysis or ultrafiltration techniques. In the indirect dialysis and ultrafiltration methods a tracer is added (usually tritium-labelled T), percentage free T is measured after dialysis or ultrafiltration and free T concentration is calculated from percentage free T and separately determined total T level. In state-of-the-art direct methods the actual concentration free T is measured directly in the dialysate or ultrafiltrate using a highly sensitive LC-MS/MS assay [12, 14]. Implementation of these reference methods are technically challenging, cumbersome, expensive, and thus not well suited for routine clinical use. Consequently, free T measured by a dialysis (or ultrafiltration) method is not available in most clinical chemistry laboratories and thus not accessible to clinicians. As an alternative for routine clinical purposes, an estimate of free T can be calculated from total T and SHBG (and albumin) concentrations. Different equations for calculation of free T have been proposed: they all have limitations and do not perform equally well when validated against actually measured free T [12]. Best established are calculations based on the law of mass action with the version proposed by Vermeulen *et al.* [14] being the most widely used in clinical practice and research. Even this equation has limitations: although the calculated estimate correlates strongly with the

actual measured free T over the full range of clinically encountered SHBG levels and performs reasonably well for routine clinical purpose, it tends to systematically overestimate the actual measured free T by about 15–20% [12]. Importantly, the calculated estimates of free T are critically dependent on the reliability of the assays used for determination of total T and SHBG concentrations. There are possible pitfalls which can occasionally affect the reliability of the calculated free T estimates: e.g. very rare SHBG variants with altered affinity for T; use of drugs competing with the binding of T to SHBG (e.g. methyltestosterone, fluoxymesterone); states of disequilibrium between free and bound T (e.g. sampling shortly following parenteral T administration). Moreover, calculations should not be used in case of serum concentrations of SHBG far outside the reference range at the extremes of highs and lows, which is not rare in women (e.g. very high SHBG under use of oral contraceptives) but is uncommon in men, or in case of unusually high T concentrations clearly above the upper normal range (e.g. shortly following parenteral T administration).

The non-SHBG –bound or 'bioavailable' T is measured by an ammonium sulphate precipitation technique, which involves addition of tritium-labelled T tracer and precipitation of SHBG-bound T with ammonium sulphate. The unprecipitated tracer remaining in the supernatant is albumin-bound or free and represents the bioavailable fraction. Bioavailable T can then be calculated from separately measured total T and the percentage tracer in the supernatant. An estimate of bioavailable T can also be calculated from total T, SHBG, and albumin (e.g. using the equation based on the law of mass action according to Vermeulen *et al.*) [14]. The ammonium sulphate precipitation method is technically challenging, with results from different labs difficult to compare and there is no evidence that determination of bioavailable T offers added value compared to free T for diagnosis of male hypogonadism [1, 5, 14]. Finally, T concentration in saliva reflects closely serum-free T concentration if measured reliably, which requires the use of an LC-MS/MS-based assay [23]. Although this approach has potential, there are pitfalls (e.g. contamination of the saliva with blood), reliable assay of saliva T is not generally available in clinical chemistry labs and experience with use of saliva T as diagnostic tool is presently lacking.

Differentiation Between Causes of Hypogonadism

Gonadotropins

Luteinizing hormone (LH) and follicle-stimulating hormone (FSH) secretion increases when negative feedback exerted at the hypothalamic-pituitary level is diminished in the presence of low circulating levels of sex steroids (T and oestradiol) and inhibin B, respectively, unless this expected response is prevented by hypothalamic-pituitary malfunction. In a hypogonadal man, low or inappropriately normal gonadotropin levels therefore indicate secondary hypogonadism due to functional or organic hypothalamic-pituitary dysfunction with the low T secondary to inadequate LH stimulation of the testicular Leydig cells. Conversely, in a hypogonadal man elevated gonadotropin levels indicates primary hypogonadism with diminished negative feedback on gonadotropin secretion resulting from primary testicular failure. Measurement of serum levels of LH and FSH is the primary step in the search for the cause of hypogonadism and orientates further investigations. As an example, elevated gonadotropins in absence of another manifest cause of primary hypogonadism will direct towards performing karyotyping for possible Klinefelter's syndrome. On the other hand, low gonadotropins in absence of a manifest functional cause of hypogonadism will direct towards investigating for possible organic hypothalamic-pituitary disease (e.g. determination of serum prolactin and iron load, MRI imaging, possibly testing of other pituitary hormonal axes, or search for genetic defects affecting gonadotropin-releasing hormone (GnRH) secretion or action or directly the LH gene).

Serum LH and FSH are measured by immunoassay. Even if there are differences in sensitivity and accuracy between assays, most are sufficiently robust to perform satisfactorily for clinical purposes. The secretion of gonadotropins is pulsatile and this is reflected in moment to moment variations and a pulsatile pattern of serum LH levels, whereas the pulsatile pattern is less prominent and serum levels are less variable for FSH. In most instances this variability of LH levels does not cause diagnostic problems because in primary hypogonadism LH and FSH levels are usually substantially elevated and clearly distinct from the low to normal levels characteristic of secondary hypogonadism. Only in rare instances with borderline findings is repeated measurement of LH in a separate sample needed to account for variability of LH levels. At the lower end of gonadotropin levels, there is overlap between low and normal levels and assays differ in their ability to distinguish between both. Again, this is rarely a problem in clinical practice as in men with secondary hypogonadism the prevailing low, low-normal, or normal gonadotropin levels are generally clearly distinct from the elevated levels seen in primary hypogonadism.

In the GnRH-stimulation test, the pituitary response of LH and FSH to stimulation with GnRH is assessed as a measure of the pituitary gonadotropin secretory capacity. Protocol details may vary, but commonly LH and FSH levels are measured before and 30 to 45 minutes following intravenous injection of 100 μg GnRH. In healthy men, the increase of LH in response to GnRH tends to be proportional to the baseline LH level and the response of FSH, although much lower, is proportional to that of LH. The GnRH test has been used mainly to differentiate between normal and decreased gonadotropin secretion. However, there is no general agreement on criteria for normal response and although the discrimination between the response in healthy men and men suspected of disorders of the hypothalamic-pituitary-gonadal axis may be better for absolute than for relative LH increase, overall neither can reliably discriminate [24]. With the currently available improved immunoassays for gonadotropins, the GnRH test offers little added value above assessment of basal levels in the evaluation of hypogonadal men and indications for performing a GnRH test are now limited (e.g. in some instances for differential diagnosis of precocious puberty). In particular, the GnRH test does not reliably differentiate between delayed puberty and hypogonadotropic hypogonadism (HH) or in men with HH between a hypothalamic and pituitary defect.

A major component of the negative feedback inhibition of LH secretion by sex steroids is exerted by circulating oestradiol, which is in part of testicular origin but originates mainly from aromatization of T in peripheral tissues (e.g. in fat tissues) [25]. Patients with a functional hypothalamic disorder of GnRH secretion as cause of HH will usually respond with augmentation of both gonadotropin

and T levels in response to reduced hypothalamic oestradiol negative feedback by treatment either with a compound with (partial) antagonistic action on hypothalamic oestrogen receptors (e.g. clomiphene citrate or tamoxifen) or with an aromatase inhibitor (e.g. letrozole). However, there are no formally established or validated protocols for diagnostic purposes.

Prolactin

In men with secondary hypogonadism serum prolactin level should be measured. Prolactin is measured in serum by immunoassay. A prolactin concentration above the reference range in a single serum sample obtained randomly during the day infers the presence of hyperprolactinemia if excessive venipuncture stress has been avoided. High levels, more than tenfold the upper reference range (>250 μg/L or 5300 mIU/L), usually indicate the presence of a prolactinoma. However, more modest elevations of prolactin levels may also indicate the presence of a prolactinoma even though other possible causes of hyperprolactinemia should be considered [26]. Modest hyperprolactinemia may result from lesions of hypothalamus or pituitary stalk (e.g. hypothalamic or pituitary tumour, trauma, surgery, lymphocytic hypophysitis, infiltrative disease such as sarcoidosis) which interfere with the hypothalamic tonic inhibitory control of prolactin secretion by dopamine. Further, modest elevations of prolactin can be due to (psychological and physical) stress at time of blood sampling. Several medications stimulate prolactin secretion, sometimes to markedly elevated serum levels (up to >200μg/L). This is in particular the case for psychotropic drugs such as risperidone and gastroprokinetic drugs such as metoclopramide and domperidone with antidopaminergic activity. Several other drugs can cause hyperprolactinemia, among which verapamil, morphine, and other opiates, and amoxapine. Prolactin levels can be increased in hypothyroidism, renal failure, cirrhosis of the liver, and by chest wall stimulation. Finding of an elevated serum prolactin in asymptomatic men may result from presence of circulating macro-prolactin with absent or only low bioactivity, which can be tested by assay of the serum for prolactin after precipitation of possible macroprolactin by sample pretreatment with polyethylene glycol (PEG). Some clinical laboratories check all serum samples with markedly high prolactin concentration for presence of macro-prolactin.

Insulin-Like Peptide 3

Insulin-like peptide 3 (INSL3), a member of the relaxin-insulin hormone family, is produced by testicular Leydig cells. It acts via the Relaxin Family Peptide Receptor2 (RXFP2), which is expressed on testis germ cells and in lower concentrations on the Leydig cells, suggesting a paracrine and autocrine role. It indirectly facilitates testicular descend by promoting the development of the gubernaculum. In adults it may have a role in germ cells survival. Its concentration in serum increases at puberty in response to increased LH levels. In adults, INSL3 concentrations reflect Leydig cells maturation and number [27]. INSL3 was reported not to differentiate between boys with delayed puberty and HH [28]. In HH INSL3 are low, remain low under treatment with T or FSH monotherapy, but the INSL3 levels do increase with hCG or hCG-FSH treatment. However, the INSL3 rise in response to hCG (or hCG-FSH) was reported to be less pronounced in HH patients with history of cryptorchidism [29]. There is presently no established clinical role for INSL3 measurements in the work-up of adult men suspected of hypogonadism.

Sex Steroid Hormones Other Than T

Through action of 5α-reductase (type 1 and 2) T can be metabolized to its 5α-reduced, more potent androgenic metabolite 5α-dihydrotestosterone (DHT). Only small amounts of DHT are secreted by the testes, most DHT in the circulation (≥80%) derives from 5α-reduction of T by 5α-reductase type2 in peripheral target tissues. Therefore, serum DHT is not a representative measure of testicular function and its measurement, which is of interest in rare cases of suspected 5α-reductase deficiency, does not contribute to the work-up of adult men with suspected hypogonadism [30].

Androstenedione is secreted by both the testes and adrenal cortex. Its androgenic action is dependent on its biotransformation to T (blood conversion rate around 15%). This contribution is marginal relative to the testicular T production and measurement of serum androstenedione levels does not contribute to the work-up of men suspected of hypogonadism. This is also the case for measurement of serum levels of the androgen precursor dehydroepiandrosterone (DHEA), which originate mainly from secretion by the adrenal cortex and peripheral desulphatation of DHEA-sulphate (DHEAS), and for no more than 10% from testicular secretion. Androstanediol glucuronide, which has been proposed as an important marker of androgenic activity in women, is derived in men from T by up to 70% and the remaining from DHEAS, thus offering no useful information in addition to the assessment of serum T in the work-up of male hypogonadism [30].

Oestradiol is a physiologically important sex steroid in men [31, 32]. Most circulating oestradiol is derived from aromatization of T in peripheral tissues and only ≤ 20% is directly secreted by the testes. Measurement of oestradiol may potentially be informative in specific clinical situations such as in patients with gynaecomastia (possible relative or absolute oestrogen excess), morbid obesity (inconsistent reports of oestrogen excess), osteoporosis (increased bone loss and fracture risk associated with low oestradiol), or rare cases of severely delayed skeletal maturation (possible oestradiol deficiency in aromatase deficiency). The oestradiol serum levels in healthy men before age 65 years lie around 10–53 pg/mL (38–196pmol/L) [33]. To reliably measure the low oestradiol levels in men may require a well validated LC-MS/MS-based method as many immunoassays lack the required sensitivity. Moreover, there are no established consensus cut-off levels for either oestradiol excess or deficiency.

Inhibin B

Inhibin B is a testicular glycoprotein hormone which belongs to the TGF-β superfamily. It is a heterodimer composed of disulphide-bound alpha and beta B subunits. Inhibin B is apparently secreted by the Sertoli cells which, however, requires the presence of germ cells in the adult testis. Following transiently elevated serum levels during the neonatal activation of the gonadal axis ('mini-puberty'), its concentration in serum is low in prepubertal boys to rise again during puberty under influence of increased FSH secretion and initiation of spermatogenesis. In early pubertal stages there is a positive association between serum levels of FSH and inhibin B. In later puberty (from Tanner stages G3 and G4 on) and in adult men, there is a close inverse relationship between serum levels of FSH

and inhibin B. This reflects that in adult men inhibin B production is primarily regulated by germ cells with only a secondary role for FSH and that serum inhibin B is the principal negative feedback regulator of FSH secretion as long as spermatogenesis is not severely deteriorated with ensuing markedly low serum inhibin B. Serum levels are measured by immunoassay, which requires high specificity for inhibin B and low cross-reactivity with other inhibin subtypes, activins, and their respective subunits. Inhibin B levels display a significant circadian rhythm, which closely parallels that of serum T [34, 35]. In adult men, serum inhibin B levels reflect global testicular spermatogenesis and are strongly positively associated with both testis volume and sperm count [36]. In subfertile men, there is a generally close relationship between degree of impairment of spermatogenesis and inhibin B secretion, with arrest of spermatogenesis at earlier stages accompanied by the lowest inhibin B levels [32]. The basal serum inhibin B level has been shown to offer excellent discrimination (better than LH) between HH (idiopathic HH or combined pituitary hormone deficiency) and constitutional delay of puberty in boys with Tanner genital stage G1 (i.e. testis volume <3 ml) with 100% sensitivity and specificity for an inhibin B of ≤35 pg/ml [37]. In boys with early genital stage G2 (testis volume 3–6 ml) discrimination was still fair and better than serum LH with sensitivities of 86% and 80% and specificities of 92% and 88% in boys with idiopathic HH and combined pituitary hormone deficiencies, respectively, for a serum inhibin B of ≤65 pg/ml [37]. In men with HH, inhibin B increases under FSH or pulsatile GnRH therapy with a lesser response in men with history of cryptorchidism and a more rapid response in men with acquired HH compared to men with congenital HH. A higher baseline inhibin B level, greater than 60pg/ml has been reported to be a favourable predictor for achieving adult testicular size and optimizing spermatogenesis during long-term GnRH therapy in men with idiopathic HH [38]. Besides in the differentiation between HH and constitutional delayed puberty, measurement of inhibin B does not play a contributory role in the work-up of adult men suspected of hypogonadism.

Anti-Müllerian Hormone

Anti-Müllerian hormone (AMH), a testicular homodimeric glycoprotein hormone belonging to the TGF-β superfamily, is a marker of prepubertal Sertoli cell function. Its production is stimulated by FSH and downregulated by T. Serum levels are measured by immunoassay. In boys before puberty, serum levels reflect the number, integrity, and immature state of Sertoli cells. The AMH levels are high in prepubertal boys (55–250 ng/ml; 400–1800 pmol/L) and decline during puberty (Tanner stage 2: 70–1000 pmol/L: Tanner stage 4: 30–400 pmol/L), when Sertoli cells express the androgen receptor (AR) and are exposed to increasing intratesticular T concentrations, to reach low levels (3–18 ng/ml; 25–130 pmol/L) in healthy adult men [39, 40]. In untreated men with congenital HH, serum AMH levels are generally high compared to eugonadal men, reflecting the immature state of their Sertoli cells. Treatment with FSH results in further increase of AMH levels, whereas the levels decrease markedly towards normal low adult levels during combined FSH—hCG treatment in response to exposure of the Sertoli cells to hCG-induced rise of intratesticular T concentrations [41].

AMH has no prominent role in the diagnostic hormonal work-up of adult men suspected of hypogonadism. However, AMH is more contributory as diagnostic tool in prepubertal boys [38, 39]. Low serum AMH can be an early marker of (central or gonadotropin-independent) precocious puberty. Conversely, AMH levels remain elevated in boys with delayed puberty. In boys with prepubertal testes (stage 1), serum AMH can help differentiate between adolescents with constitutional delayed puberty and adolescents with HH as the latter have lower AMH levels due to the lower FSH exposure and/or a smaller pool of Sertoli cells. However, for this indication inhibin B levels are more discriminative [37]. AMH levels are also lower in some children with cryptorchidism, monorchidism, and partial gonadal dysgenesis [39, 40]. In boys with non-palpable gonads, serum AMH is highly predictive for presence of (intra-abdominal) testis tissue; undetectable AMH is suggestive of congenital or acquired anorchidism or complete gonadal dysgenesis [39, 40]. In this context, the information obtained by dosage of serum AMH largely limits the indications for performing an hCG-stimulation test (measurement of serum T before and following intramuscular hCG injection(s); applied protocols for hCG-stimulation test vary by duration, hCG dosage, single or repeated injections).

Genetic Markers

Polymorphisms of the promotor of the *SHBG* gene can affect SHBG concentration and thus serum total T levels. However, this should not raise major diagnostic problems as the magnitude of these effects is not large relative to the considerable native between subject variations of SHBG concentrations seen in community-dwelling men. Moreover, these polymorphisms are not expected to affect serum-free T levels. Polymorphisms of SHBG affecting the affinity for T have also been reported. These also should not affect measured free T levels, although they may invalidate calculated estimates of free T in carriers of these very rare polymorphisms [42–45].

Polymorphisms of the androgen receptor can affect androgen sensitivity. This has in particular been documented for the polyglutamine tract polymorphism encoded by a highly polymorphic CAG repeat sequence in exon 1 of the androgen receptor gene, with longer repeat associated with lower receptor transactivation upon binding with its ligand. In theory, taking into account such genetic polymorphisms can refine the interpretation of T levels. However, the effect of this and other reported polymorphisms that can affect T levels is quantitatively too marginal to be clinically relevant in the context of the diagnostic work-up of men suspected of hypogonadism [45–47].

Rare mutations in the androgen receptor gene can cause partial androgen insensitivity and rare mutations in the aromatase gene can cause oestrogen deficiency. Because of diminished negative feedback exerted by T and oestradiol, respectively, hormonally both conditions are characterized by elevated LH and T levels, whereas oestradiol levels tend to be elevated in androgen insensitivity and low in aromatase deficiency.

Men Evaluated for Subfertility

Semen analysis according to World Health Organization (WHO) criteria is the gold standard for evaluation of men with suspected subfertility. Hormonal investigations provide mainly corroborating evidence. The clinical context will usually indicate whether or not the fertility problem may be part of a broader problem of

hypogonadism affecting also testicular hormonal function, which can be ascertained by measurement of serum T and gonadotropin levels.

Elevated serum FSH levels indicate testicular dysfunction with deficient spermatogenesis and consequent diminished inhibin B secretion. Serum FSH and inhibin B levels are strongly inversely correlated and both rise of FSH and decrease of inhibin B levels are to some extent proportional to the severity of impaired spermatogenesis. However, in individual cases findings for hormonal levels and spermatogenesis may be discordant. Both FSH and inhibin B are expected to be within normal range in men with obstructive azoospermia, which can be further documented by analysis of the seminal plasma. However, both FSH and inhibin B may also be within normal range in non-obstructive azoospermia with arrest of spermatogenesis in a late stage, in some men with azoospermia and focal Sertoli-cell-only, and in some men with hypospermatogenesis [34–36]. Findings of decreased serum AMH in men with impaired spermatogenesis have been inconsistent and serum AMH has not been found to be a clinically useful marker of spermatogenesis [35, 48]. Furthermore, measurement of inhibin B and AMH after stimulation with recombinant FSH does not appear to offer added diagnostic value compared to basal levels of these hormones and, similarly, limited available data on measurement of inhibin B and AMH in seminal plasma does not indicate added value compared to serum levels [35].

Although in some studies diagnostic accuracy of inhibin B and of inhibin B and FSH combined was slightly greater than that of FSH, this is not of practical significance for evaluation of individual patients with subfertility, for which measurement of inhibin B offers no clear added value above FSH dosage [34–36, 49]. Importantly, in men with non-obstructive azoospermia neither the levels of FSH, inhibin B, or AMH, nor their combination can reliably predict the outcome of procedures to retrieve sperm from the testis either by fine-needle aspiration (FNA) or by open biopsy (testicular sperm extraction—TESE) [34, 35].

10.2.3 Diagnostic Semen Analysis

Jackson C. Kirkman-Brown and Sarah J. Conner

Introduction

Human semen is comprised of spermatozoa (commonly referred to as sperm) produced during spermatogenesis in the testes, matured in the epididymis, and seminal plasma produced by the accessory sex glands: the prostate and the seminal vesicles. Prior to ejaculation, during the arousal phase, the alkaline pre-ejaculate, a clear and colourless viscous fluid, is released from the bulbourethral gland. This neutralizes any urine left in the urethra prior to the passage of semen. Pre-ejaculate fluid emission is very variable in amounts between men, from not noticeable through to several millilitres; it may contain sperm from prior ejaculations and occasionally patients may erroneously believe that this is, in fact, their ejaculate. Although the focus is often on the sperm, the epididymal environment and seminal plasma are also important for reproductive function providing protection from the acidic environment of the vagina and from oxidative damage as well as supplying compounds, essential for optimal sperm function. Secretions into the epididymal lumen include L-carnitine, α-glucosidase, and glycerylphosphorylcholine, a pump mechanism selectively moving L-carnitine from circulating blood at the epididymal level. The fluid secreted by the seminal vesicles has an alkaline pH and makes up more than 60% of the ejaculate volume. Fructose, produced in the seminal vesicles under the stimulation of androgens, plays an important role in energy metabolism and motility of spermatozoa. Prostatic secretion, with an acidic pH between 6.4 and 6.8, comprises about 15–20% of the ejaculate volume; it is rich in citric acid, zinc, acid phosphatase, magnesium, and polyamines. Citric acid is important in the maintenance of osmotic equilibrium of the seminal plasma and coagulation/liquefaction of semen after ejaculation.

During ejaculation, the secretions of various accessory glands and the testicular fraction are released in a precise sequence. The first fraction is predominantly prostatic with an epididymal and testicular fraction (rich in sperm), and is followed by fractions that derive from the seminal vesicles.

Mixing of the fluids from the prostate and seminal vesicles leads to coagulation of the ejaculate which increases retention of the semen within the upper vagina to facilitate sperm passage into the cervix. In humans, the ejaculate liquefies after approximately 30 minutes under the action of prostatic proteolytic enzymes.

Guidelines for Initial Assessment

Basic semen analysis is the primary diagnostic tool in the male fertility assessment pathway. The complete pathway, as recommended by a recent World Health Organization (WHO) working group should initially include '*a physical examination performed by an examiner with appropriate training and expertise, a reproductive history and at least one properly performed (high quality) semen analyses. A full evaluation by a urologist or other specialist in male reproduction should be done if the initial screening evaluation demonstrates an abnormal physical examination, an abnormal male reproductive or sexual history, or an abnormal semen analysis is found*' [1] (see Chapter 10.3.3, 'Management of Idiopathic Male Infertility').

During semen analysis an assessment is made of the number, viability, motility, and morphology of the sperm cells as well as the quality of the seminal plasma and the presence of non-sperm cells. It is very important to note that the diagnostic reliability of semen analysis depends crucially on the quality control of the entire system, alongside experience and ability of the laboratory staff. Therefore laboratories participating in an external quality assurance (EQA) scheme should always be used, in countries where this is possible they should also be accredited to the relevant local standards (see next). A serious confounder of any results is the application of different criteria to the evaluation of sperm parameters, making it difficult to compare tests carried out in different laboratories [2].

To ensure consistent and comparable results, since 1980, the WHO has produced a regularly updated manual of guidelines for semen analysis. The current version, published in 2010 [3], is the 5th edition and, in addition to detailed laboratory protocols, provides a set of reference ranges and limits based on analysis of semen samples from several thousand recent fathers in eight countries on three continents. Other semen analysis protocols, designed to meet or exceed requirements of the WHO recommendations, such as those from The European Society for Human Reproduction and Embryology—Special Interest Group in Andrology (ESHRE-SIGA) recommendations [4] and the Practical Guide to Basic Laboratory Andrology [5], have been adapted to suit the needs of modern Assisted Reproductive Treatment (ART) laboratories. Results received from ISO15189 accredited laboratories working to either the WHO or ESHRE-SIGA standards can be considered reliable as long as the laboratory is participating in an EQA scheme.

Guidelines for Collecting Semen Samples

It is well recognized that there can be a high level of variability in the parameters of semen samples from a single individual due to biological and analytical reasons [6] and caution should therefore be exercised in drawing firm conclusions based on the analysis of a single sample, a single abnormal result does not necessarily mean any problem is present. The process of spermatogenesis takes 64 days in humans. Therefore, a second test after 2–3 months should be considered when abnormal results are returned but there is no need to repeat a normal first analysis [1]. Febrile illnesses cause significant sperm abnormalities which become apparent within 7–10 days, and can persist for up to 10–12 weeks.

Some of the variations in semen analysis may be minimized by following certain rules prior to sample collection. The period of sexual abstinence before taking a sample should be between 2 and 7 days, which serves to match the criteria used by WHO to set the reference ranges [3, 7]. This period includes any ejaculation, not only sexual intercourse, a detail often overlooked by patients and staff. Various studies have shown a positive correlation between semen volume, sperm concentration, and length of abstinence. Effects on sperm quality are less clear for abstinences under 2 days, longer abstinences correlate with decreased sperm quality due to prolonged storage in the epididymis/vas deferens [7]. It is worth discussion with patients that regular ejaculation is likely to provide optimal sperm quality.

Masturbation with ejaculation of the sample into a sterile container, such as those used for urine, is the recommended procedure for collection of semen samples. Where masturbation proves difficult, coitus, using specialized 'sperm safe' condoms developed and marketed specifically for this purpose, is recommended. Coitus

interruptus should not be considered, as this method tends to lose part of the ejaculate and makes it difficult to distinguish between the man and his partner's epithelial cells, white cells, and red blood cells; and can moreover cause bacterial contamination. It is notable that some patients will expect or require using a lubricant for masturbation, generally these are toxic to sperm, even those marketed as 'sperm friendly' intimate lubricants may have adverse effects. Good diagnostic laboratories will usually provide the same mineral oil used in *in vitro* fertilization (IVF) processes for masturbation as it is assured at a relevant medical grade and will have passed sperm toxicity testing. It is similarly worth discussion with patients to check that these lubricants are not being used at home during intercourse attempting conception [8, 9].

The sample should by default be obtained at the site of the laboratory for a number of reasons: to examine the ejaculate within the first 30 minutes; to control the environment and handling of the ejaculate; and finally, if subsequent samples are to be produced for treatment or storage, they will usually have to be produced on site for legal traceability.

Semen samples may sometimes have to be collected offsite for psychological, or practical reasons. These should still be collected in a designated provided container, with accurate record the time of ejaculation, the sample kept at 20–37°C and delivered to the laboratory within 1 hour of collection. The patient should also be asked to provide information regarding any pathologies from which he may have suffered during the three preceding months including the use of medication, fevers, viral or bacterial infections, antibiotic therapy, and local or general anaesthetic. Any of these factors may influence semen characteristics.

Macroscopic and Microscopic Evaluation of the Ejaculate

The semen sample should be processed within 1 hour of ejaculation in order to evaluate the time and nature of liquefaction. Microscopic evaluation must be carried out after a complete liquefaction of the sample. A normal sample usually liquefies within 15–30 minutes at room temperature, so processing should occur within 60 minutes after ejaculation. Failure to liquefy, either partially or completely, within 1 hour should be noted.

Volume

The normal semen volume is ≥1.5 ml [3]. Reduced semen volume (<1.0 ml) may indicate obstructive pathologies of the ejaculatory ducts or of a secretory defect of the seminal vesicles for functional or anatomical reasons. Rarely, and usually accompanied by other clinical evidence, it may suggest reduced production of testosterone [10]. A total absence of ejaculated semen is termed aspermia (as opposed to azoospermia—which is absence of spermatozoa in an ejaculate). In cases of low volume or aspermia, postejaculatory urine analysis should always be performed to consider for the possibility of retrograde ejaculation, prevalent in diabetics with autonomic neuropathy and men using certain medications (e.g. alpha-adrenergic antagonists). It is worth noting that retrograde ejaculation in some patients has been treated successfully by a number of medications, including alpha agonists [11, 12] without need for recourse to ART treatment.

Hyperspermia (elevated ejaculate volume) (>6.0 ml, represents the upper 90 Centile and >6.8 ml the 95 Centile of 'normal' [3]) can be associated with inflammatory pathologies and/or infections of the seminal vesicle and/or the prostate.

pH and Appearance

Seminal plasma has an alkaline pH (normal variation 7.2–8.0) reflecting the predominant contribution of the seminal vesicles. pH (≥8.0) may indicate inflammatory pathologies and dysfunction of the prostate. Acidic pH (<7.0) is more informative, and is often associated with obstructive pathologies of the ejaculatory ducts, or with congenital (agenesis) or acquired hypotrophy or atrophy of the seminal vesicles and vas deferens (if associated with azoospermia).

The physiological appearance of semen is opalescent ivory. This becomes milky when the ejaculate derives exclusively from the prostate, as occurs in some cases of genital tract obstruction. A yellowish appearance can indicate a high number of white blood cells (pyospermia) [13], and is often associated with acute or subacute infections of the male genital tract. Pink, intense red, or red-brown colours indicate the presence of blood (haematospermia). Haematospermia can be caused by trauma (such as following prostate biopsy), inflammations, and infections of the male genital tract, duct obstructions, cysts (bladder or accessory sex glands), and neoplastic pathologies [14].

Liquefaction and Viscosity

Immediately after ejaculation, human seminal fluid undergoes a process of coagulation which transforms the liquid into a gelatinous coagulate. Immediately after coagulation, the process of liquefaction begins and should be completed within 60 minutes. The assessment process ascertains whether liquefaction is complete or not and whether it occurs within an appropriate physiological time span. Liquefaction is the process of the ejaculate becoming homogenous liquid and not having 'jelly-like' parts, it must not be confused with viscosity.

When incomplete liquefaction occurs, it becomes more difficult to analyse sperm parameters (concentration and motility) accurately. Since coagulation and liquefaction depend on factors of seminal vesicular and prostatic origin, an alteration of these processes can indicate pathologies of these structures. Perturbed liquefaction is often found in infection or inflammation of the accessory glands, and may explain infertility, if only in part.

The evaluation of seminal viscosity provides information on rheological characteristics common to all biological fluids. The viscosity is assessed by measuring the elasticity of the semen post-liquefaction with a normal semen sample forming threads of less than 2 cm [3]. An increase in viscosity makes microscopic analysis difficult and hinders the assessment of sperm parameters. Hyperviscosity can indicate pathologies of the accessory glands, while reduced viscosity often occurs in cases of serious oligozoospermia or in azoospermia.

Sperm Concentration

An accurate sperm count concentration is essential for the evaluation of fertility and determination of treatment options. WHO or ESHRE methods should be followed including: initial assessment of a 10 µl aliquot from well mixed semen on a slide; subsequent dilution to immobilize all cells according to protocols using a positive displacement pipette for accurate volume of the viscous semen;

a duplicate count on an improved Neubauer Haemocytometer chamber counting >200 sperm per side; and assessment of acceptability of the result from the variance of the two counts as per described methods [3, 5].

Fertile men between the ages of 20 and 40, who are normal from anatomical, urological, andrological, and endocrinological standpoints, may show great variation in the number of spermatozoa between ejaculates. However, this intraindividual variation can be minimized provided that sample collection is carried out properly, and the physical and psychological conditions of the subject do not vary. The lowest 'normal' threshold concentration for potential natural fertilization is 15 million/ml (with >39 million sperm in the entire ejaculate). This figure is based on the fifth centile for fertile men who get partners pregnant within 1 year [3]. Concentrations below this number are indicative of oligozoospermia. The absence of spermatozoa in the ejaculate is termed azoospermia. Semen samples without spermatozoa in a first examination should be centrifuged at 200 g for 15 minutes and the supernatant recentrifuged at 3000 g for 10 minutes; both pellets should be evaluated to confirm the absence of sperm.

Sperm Motility

Sperm motility should be measured after liquefaction or at fixed time points after ejaculation (1–2 h), again according to set WHO/ESHRE protocols [3, 5, 15]. It is important to consider not only the percentage of motile cells, but also the grades of motility [5]. Sperm motilities should be classified as: rapid progressive, with a velocity of at least 25 μm per second (grade A); slow or sluggish progressive (grade B); non-progressive (grade C); or absent (grade D). In normal subjects, 1 hour after ejaculation, the percentage of sperm with motility of grades A + B should be at least 32%, with at least 25% grade A. Values below these are indicative of asthenozoospermia. The importance of characterizing grade A from B sperm motility is because rapid sperm are recognized as those capable of fertilization naturally and in IVF.

Sperm Morphology

Human sperm morphology is classified according to the Tygerberg Strict Criteria approach [3, 5, 16]. Although commonly referred to as '% normal sperm', they are better thought of as 'typical' or ideal sperm, as the classification is based upon the morphology of those which can penetrate through cervical mucus and are found at the site of fertilization. Sperm morphology is evaluated using stained smears. The Sperm-Papanicolau and Quick-Diff techniques are those most commonly used. They have differing fixation effects upon the sperm such that standard morphology classification ranges for parameters such as head size must be specific to the stain employed.

Morphology defects are classified into those of the head; neck/midpiece; tail and abnormally retained cytoplasmic material (often referred to as cytoplasmic droplet). According to the strict criteria classification, any sample having <4% 'typical' or 'normal' forms is considered teratozoospermic [3, 5].

The Teratozoospermia Index, or TZI, combines the four separate morphology assessments of head, midpiece, tail and retained cytoplasm to provide a single number that represents the average number of defects per abnormal morphology sperm. ESHRE recommends multiparametric assessment which allows the calculation of the TZI [5].

Elements Other Than Spermatozoa

Scrutiny of untreated semen or stained smears allows non-sperm cells in the ejaculate to be identified, both in physiological and pathological conditions. The most important cells to identify are leucocytes, of which there should be less than 1 million/ml [3]. Staining (by Sperm-Papanicolau or immunohistochemistry) should be specific for leucocytes to allow differentiation from other spherical cells in semen. Raised leukocyte count in semen is indicative of genital tract infection, should be investigated further and treated, if appropriate, with antibiotics.

Semen may also contain immature germ cells, red blood cells, epithelial cells (released from accessory glands, ducts, and luminal surfaces of the genitourinary tract), prostatic corpuscles, and various other debris. It is normal to observe small amounts of debris in samples. If bacteria are present, then a sample should be sent for microbiological analysis. This requires centrifugation to remove the bacteria from seminal plasma which usually supresses the bacterial culture growth if conventionally streaked on an agar plate.

Vitality Tests

These tests are used in cases where less than 40% of sperm are motile, in order to differentiate spermatozoa that are immotile but alive from those that are dead [5].

The most frequently employed tests are the eosin-nigrosin test and the hypo-osmotic swelling (HOS) test. The eosin test utilizes a vital staining system (eosin Y alone or in combination with nigrosin) which distinguishes between the live (unstained) spermatozoa and the dead (stained) cells. The dead cells, with damaged plasma membranes, are permeable to the dye.

The HOS test evaluates the percentage of spermatozoa with swelling of the tail after incubation in a hypo-osmotic solution. This test is based on the fact that spermatozoa with an intact membrane, when suspended in a hypo-osmotic solution (below 150 mOsm/L), allow the passage of water molecules across the plasma membrane to achieve osmotic equilibrium. They consequently swell, especially at the level of the tail, and show specific morphologic changes. Conversely, dead cells allow the passage of water freely in both directions, and do not show any swelling. Since the HOS test can distinguish dead from vital cells, it has garnered renewed interest in identifying vital sperm for intracytoplasmic injection (ICSI) for *in vitro* fertilization.

Antisperm Antibodies

Seminal antisperm antibodies are auto-antibodies directed against sperm-surface antigens. Their presence is usually suggested by motile sperm being adherent to each other in clumps. Antisperm antibodies are thought to indicate that the blood–testis barrier has been compromised at some stage by illness or trauma. There are a number of different *in vitro* tests available, though they are not routinely used due to difficulties with standardization [3, 5].

Reporting Basic Semen Analysis Results

Results of a basic semen analysis are reported in many different ways. It is important to understand that the WHO reference

ranges are not absolute cut-offs for diagnosis; they are statistical limits below which natural conception may be less likely or take longer. Many patients with hypogonadotropic hypogonadism on gonadotropin treatment can achieve spontaneous pregnancies with sperm densities below 15 or 10 M/ml (for more information see Chapter 10.3.2.3, 'Gonadotrophin Induction of Spermatogenesis').

Secondly, uncertainty of the result related to the limited number of cells examined in any assessment means that absolute value cut-offs are not meaningful in practice [17]. The following table (Table 10.2.3.1), which takes into account accuracy of the result, is suggested as a useful alternative aide to interpretation when WHO methods are followed (taken from [17]).

Genetic Testing After Basic Semen Analysis

If severe oligozoospermia (<5×10^6/ml) or non-obstructive azoospermia are found and assisted conception therapies are planned, then further genetic tests should always be undertaken. These would include karyotype and Y-chromosome microdeletions, and cystic fibrosis transmembrane conductance regulator (CFTR) gene mutation analysis should be offered to all males with congenital bilateral absence of the vas deferens or cystic fibrosis [7] (see Chapter 10.3.3).

Advanced Semen Analysis Methods

Beyond a 'basic semen analysis' there are a multitude of further fertility analyses that can optionally be performed on patients or their samples. These tests are often not widely available as they are not a required part of a standard WHO semen analysis, and often the evidence for their use or interpretation is limited. These more complex and costly analytical tools should be considered of secondary or tertiary importance, and are to be carried out in specific cases only after standard semen analyses have been performed. For some men, results from basic semen analysis may indicate the need for more advanced tests looking in more detail at the seminal plasma and sperm functionality.

Biochemical Study of Seminal Plasma

Biochemical analysis of the seminal fluid can make a notable contribution to the differential diagnosis of azoospermia. Thus, in primary hypospermatogenic azoospermia, with normal androgenic production, there are no abnormalities in the secretions of the accessory glands and seminal plasma biochemistry is normal. In contrast, subjects with azoospermia due to congenital absence of the vas deference and seminal vesicle or bilateral obstruction of the ejaculatory ducts, there is a relatively high concentration of citric acid and very low or undetectable fructose. Subjects with obstruction of the efferent ducts have extremely low levels of free carnitine and α-glucosidase, while fructose and citric acid levels remain normal [18].

Sperm Function Tests

Many sperm function tests can be used in parallel with sperm analysis to establish a complete picture of the fertilizing capacity of sperm and perhaps guide further management including assisted reproduction [19, 20].

Sperm Migration and Interaction with the Female Genital Tract

Sperm–cervical mucous interaction tests (the *in vivo* postcoital test, or PCT) and the *in vitro* assay of sperm migration in cervical mucous provide valuable information about the condition of cervical mucous, and related hormonal functions in the female partner, and also sperm survival after intercourse. However, these tests are difficult to standardize and so have fallen out of routine use.

Sperm Kinetics and CASA

Many endeavours have been made to find an objective method to read sperm kinetics. Computer Assisted Semen Analysis (CASA) methods employ digital image acquisition and analysis to analyse sperm kinetic parameters such as velocity, linearity, lateral head displacement, and beat cross frequency. Although CASA may provide objective data on sperm motility, it is essentially still a research tool at the time of writing [21].

Table 10.2.3.1 Basic semen analysis results

Parameter		Pathological	Borderline	Normal	Unit
Concentration		**<10**	10–20	**20–250**	10^6/ml
Volume		**<1.5**	1.5–1.9	**2.0–6.0**	ml
Total sperm count		**<20**	20–79	>**80**	10^6/ejaculate
Motility	Motile	**<40**	40–59	>**60**	%
	Progressive	**<35**	35–49	>**50**	%
	Rapid			>**25**	%
Vitality		**<40**	40–59	>**60**	%
Morphology: typical forms		**<4**	4–13	>**14**	%
TZI*		**>1.80**	1.61–1.80	<**1.60**	

* TZI—the Teratozoospermia Index or TZI, combines the four separate morphology assessments of head, midpiece, tail and retained cytoplasm to provide a single number that represents the average number of defects per abnormal morphology sperm.

Other Advanced Sperm Function Tests

There are many other tests to investigate different aspects sperm functions, including sperm intracellular calcium signalling in response to progesterone challenge, sperm capacitation, acrosome reaction, sperm-oocyte interaction, and oocyte activation assays. Currently these are research methods without proven clinical application. The interested reader can refer to [22–28] for more details.

Sperm Nuclear Function

In recent years there has been great interest in the value of assessing sperm DNA packaging and DNA fragmentation/damage as a predictor of both natural conception and the assisted reproduction outcomes. Currently there is no standardization in different tests of sperm chromatin structure and sperm DNA quality. Current evidence does not support the routine use of sperm DNA testing [29–31]. It is also worth noting that there appears to be a relationship between sperm DNA and miscarriage for certain assays [31, 32]. With a number of assays in use in different laboratories and no clearly defined clinically relevant thresholds, the situation for these tests is rapidly evolving and routine use widely debated [30, 33–35].

Quality Control

Clinicians rely on accurate and well-standardized semen analysis results from the diagnostic andrology laboratory that can be used to inform the diagnosis and treatment of patients with fertility disorders. Unfortunately, evaluations of sperm parameters continue to demonstrate marked differences both within and between laboratories [36–38], a point usually not appreciated by clinicians outside Reproductive Medicine. Effective quality control is therefore mandatory in identifying random and systematic laboratory errors and to ensure that all analytical and non-analytical procedures are sufficient to ensure the most accurate results. The WHO manual and ESHRE recommendations both recommend strict quality control procedures and that all laboratories providing a semen diagnostic service should participate in an accredited EQA scheme [3, 5]. To implement these recommendations in practice, clinicians should only request and accept results from EQA-accredited andrology laboratories.

Klinefelter's Syndrome

Claus H. Gravholt

Introduction

Klinefelter syndrome (KS) is the most common sex chromosome aneuploidy and was first described by HF Klinefelter in 1942, publishing nine cases of a syndrome characterized by gynaecomastia, azoospermia, hyalinized small testes, elevated levels of follicle-stimulating hormone (FSH), and hypogonadism [1]. Jacobs and Strong demonstrated in 1959 the extra X chromosome in the karyotype of KS [2].

Knowledge concerning KS expanded through chromosome surveys on large number of unselected newborns, with follow-up through childhood and adolescence performed in the seventies and eighties [3–5]. These studies on newborns focused mainly on development in infancy, childhood, and adolescence, leaving the natural history of KS in adulthood less well described. The typical man suffering from KS is described as tall, with narrow shoulders, broad hips, sparse body and facial hair, gynaecomastia, small testes, androgen deficiency and reduced intelligence [6], but a less severe phenotype is present in many patients [7]. Typical features are listed in **Table 10.3.1**. However, this current clinical picture may only represent a 'tip of the iceberg' glimpse of the full phenotypic spectrum, since only about 25% of all KS males are ever diagnosed [8]. If and when all KS males are diagnosed, the entire literature on KS may well have to be re-written.

Genetic Background

KS is characterized by the presence of one Y chromosome and two X chromosomes in a phenotypical male. In the diagnosed Danish population of KS patients 90% had the 47,XXY karyotype, while mosaic forms are also seen [9, 10]. Non-mosaic 47,XXY most often occurs due to non-disjunction of the sex chromosomes during the first or second meiotic division of gametogenesis in either parent. There is evidence that failure of the paternal XY or maternal XX chromosomes to pair and recombine in the usual way is a causative factor, as is also the case for autosomal trisomies [7, 11]. Paternal meiosis I errors account for approximately 50% of 47,XXY karyotypes, while meiosis II errors does not lead to 47,XXY karyotypes [11]. Of the remaining maternally derived karyotypes, 22% to 48% are due to meiosis I errors, 9% to 29% to meiosis II errors, 7% to unknown meiotic errors, and 3% to 16% to postzygotic mitotic non-disjunction [7, 11, 12]. In prenatally ascertained cases, 54% are paternally derived and 46% are maternally derived [12]. The phenotype does not appear to be influenced by the parental origin of the extra X chromosome, though few studies have specifically addressed this issue [13]. The molecular basis of KS remains poorly understood, although new studies point towards complex genotype-phenotype relations dependent on both changes in DNA methylation profile and RNA expression, likely tissue dependent [14–16] (see online **Figure 10.3.1**). The expression of X-linked genes in the pseudoautosomal regions of the X and Y chromosomes that escape inactivation may also be involved [7], but the identity and function of the critical genes have not been determined. Presence of an extra copy of the short stature homeobox-containing gene on chromosome X (*SHOX*) is probably the basis for the increased height in KS [17]. *SHOX* is a homeodomain transcription factor and brain natriuretic peptide and fibroblast growth factor receptor 3 are transcriptional targets of *SHOX*, and it has been shown that extra copies lead to excessive height gain [17].

A KS diagnosis should always be based on clinical findings combined with a confirmatory cytogenetic evaluation. On the other hand, a phenotypically normal man with very low-grade mosaicism (probably below 5–10%) should not have the diagnosis of KS.

Table 10.3.1 Abnormalities and diseases associated with Klinefelter syndrome

Feature	Frequency (%) or increased risks
Infertility [92]	>99
Azoospermia [92]	>95
Decreased bitesticular testis volume (4–8 ml; normal range: 25–60 ml)) [18, 35, 93]	>95
Spermatozoa retrievable after TESE	30–50
Decreased beard growth and pubic hair# [92]	30–80
Abdominal adiposity [43]	~50
Decreased muscle mass and strength [35, 45]	~40
The metabolic syndrome [43]	46
Type 2 diabetes [43]	10–39
Osteopenia [45, 93]	~40
Osteoporosis [45, 94]	5–10
Mitral valve prolapse [95, 96]	0–50
Ischaemic heart disease [41, 42]	~1.5 fold*
Deep venous thrombosis and pulmonary embolism [41, 48, 97]	3–6-fold*
Autoimmunity [98–100]	Increased risk of several autoimmune diseases
Tremor (Parkinson-like symptoms) [101, 102]	>25
Breast cancer [103–105]	~4 fold*
Osteoarthritis [41]	4-fold increased risk*
Learning disability [81]	>75
Delayed speech development [81]	>40
Decreased penile size [81, 106, 107] incl. micropenis neonatally?	10–25
Mediastinal cancer [108]	Increased risk
Gynaecomastia [35, 81, 109]	28–75
Cryptorchidism [18, 41, 81]	27–37
Increased gonadotropin levels# [18, 92, 93]	>75
Decreased testosterone levels# [18, 92, 93]	>75
Increased height [35, 81]	>30
Psychiatric disturbances [81, 110]	>25
Congenital malformations (heart, cleft palate, and inguinal hernia) [41, 96, 111]	Increased risk
Fractures [41, 97]	Increased risk (2–40-fold)*
Autism spectrum disorder [112, 113]	30–50

TESE, testicular sperm extraction; * above normal male frequency; # in the untreated condition.

Underdiagnosis and delayed diagnosis of KS is a major problem [8]. Importantly, early diagnosis permits identification of speech problems and scholastic difficulties that require special measures during childhood and adolescence to improve educational outcomes. Moreover, early diagnosis facilitates prevention or amelioration of the long-term consequences of gonadal insufficiency.

Summarizing epidemiological data across countries and ethnicities yields a prevalence estimate of 152 per 100 000 [8], but with a major discrepancy between the prenatal and postnatal prevalence, with only 25% of the expected number of KS being diagnosed postnatally and less than 10% of these being diagnosed before puberty. Prenatal diagnosis of a fetus with 47,XXY karyotype requires professional genetic counselling to inform the pregnant couple about the relatively good prognosis, but at the moment in Europe 75% of couples expecting a child with KS choose termination [8]. Since only 25% of the expected number of men with KS are diagnosed, ascertainment bias is a major problem when interpreting data from different studies on different populations of KS patients.

Congenital Malformations

There are no specific stigmata at birth, but an increased incidence of congenital malformations has been reported [18]. Minor congenital abnormalities were found in 26%, with clinodactyly of the fifth finger as the most frequent [19] and major congenital abnormalities were found in 18% of KS boys, with cleft palate, inguinal hernia and cryptorchidism being the most frequent [19]. In a large clinical study 27% of KS patients had a history of maldescent of testes compared to 8% of the total number of patients attending the same clinic [18].

Testicular Development

The typical testicular histology includes hyalinization of seminiferous tubules, loss of germ cells, and Leydig cell hyperplasia. In about 40–50% of KS patients, occasional focal spermatogenesis may be found with the possibility of surgically retrieved spermatozoa being used for intracytoplasmic sperm injection (ICSI) into oocytes to achieve *in vitro* fertilization [20]. The cause of the hyalinization of the testes with subsequent hypogonadism and infertility is unknown. There is a progressive loss of spermatogonia from infancy [21] while hyalinization of the seminiferous tubules probably does not occur until mid-puberty [22]. At the beginning of puberty [23], testes enlarge to approximately 4 ml and thereafter shrink in adulthood [24, 25]. Testes may be malfunctioning already during intrauterine life, since micropenis seen in some newborn males with KS may be a result of decreased testosterone production *in utero* [26]. Some find the normal surge in testosterone seen in the first 1 to 6 months of life (minipuberty) attenuated in KS boys [26, 27], while others find it similar to controls [28]. The levels of FSH, luteinizing hormone (LH) and testosterone are normal during the prepubertal period, but after the onset of puberty a rise in FSH and LH and a decline in testosterone occur, compared to normal boys [24], along with a decline in insulin-like factor 3 (INSL3), a marker of Leydig cell function [29], while 17β-oestradiol is normal despite the relatively lower levels of testosterone [30]. Even though levels of testosterone for many patients are within the normal range, levels of gonadotrophins are usually elevated [6, 30, 31], indicating a relative or compensated hypogonadism that is reflected by the increased pituitary drive, and hence may be one of the causes of Leydig cell hyperplasia.

Fertility

KS patients are usually considered infertile, but with the recent development of the testicular sperm extraction (TESE) and intracytoplasmic sperm injection (ICSI) methodologies, it is now possible to extract viable sperm from the testes by surgical biopsy and inject it directly into an extracted ovum. Successful extraction rates of sperm in clinical practice are around 30–45% [32], and about half of these experience a pregnancy [33] with fewer live childbirths [34] (also see Chapter 10.3.3, 'Management of Idiopathic Male Infertility'). Specialized genetic counselling and options of prenatal diagnosis or even preimplantation genetic diagnosis should be offered to couples seeking infertility treatment where the male is suffering from KS, although so far, there does not seem to be an increased risk of KS in the offspring.

Hypogonadism

Currently it is thought that all KS males will develop hypogonadism, some already in puberty, while others develop hypogonadism later in adult life [18, 35–37]. Hypogonadism may delay or reduce the development of normal male secondary sexual characteristics with less growth of beard, muscle bulk, and secondary body hair [6]. Sexuality may be affected—fewer 47,XXY men are married, experience greater sexual dissatisfaction in general, while more acknowledge unconventional sexual experiences and demonstrate a less masculine gender role compared to a control group [38, 39].

Hypogonadism may also contribute to the neuro-cognitive phenotype seen in KS. The long-term consequences of hypogonadism in KS are difficult to separate from the gene-dose effects of having an extra X chromosome, because studies on comparable hypogonadal conditions (e.g. hypogonadotropic hypogonadism) are lacking due to their infrequency.

Gynaecomastia

In KS the prevalence of gynaecomastia is markedly increased, up to 50% [6] in some series, although the true prevalence probably is lower [40]. The decreased testosterone level in concert with a normal level of oestradiol may cause gynaecomastia [24], because of an altered oestradiol/testosterone ratio. Testosterone treatment seldom leads to a regression of gynaecomastia, but most KS patients will need to have the breast tissue removed surgically.

Diabetes and the Metabolic Syndrome

Epidemiological studies on both morbidity [41] and mortality [42] show a fourfold increased risk of diabetes, and clinical studies describe a strikingly high frequency of the metabolic syndrome and insulin resistance in KS [43, 44], with increased cholesterol levels. KS subjects accumulate excessive amounts of body fat, especially truncal fat, and typically have a low level of physical fitness [30, 45].

Cardiovascular Disease

Mortality from cardiovascular diseases is increased in KS [10, 46], even though the mortality from ischaemic heart disease is reduced [10]. The risk of hypostatic leg ulcers may be significantly increased [47]. In addition, the risk of deep venous thrombosis and pulmonary embolism is 4–6-fold higher than in control males [41, 48]. Dysfunction of the fibrinolytic system has been proposed as a reason for this and increased activity of plasminogen activator inhibitor 1(PAI-1) in KS patients was described in one study [49], but further studies are needed.

Osteoporosis

Hypogonadism is a known cause of secondary osteoporosis in both females and males [50]. A majority of studies show a significant reduction in bone mineral density (BMD) in KS males compared to normal men [51–54]. Although fragility fractures is not as commonly reported in the few clinical studies of adults with KS as would be expected from the BMD deficits, nevertheless epidemiological data consistently show increased risks of hospital admissions with osteoporotic fractures (forearm, hip, and spinal fractures) [55] and increased mortality from hip fractures [10]. Hence, the reported reduction in BMD is likely to signal an important and potentially preventable clinical problem in KS patients.

Cancer

The overall risk of cancer is not increased in KS, but the specific risk of breast cancer is increased compared to the general male population [56, 57]. In addition, there is a significantly increased risk of mediastinal germ cell tumours [58, 59], an increased mortality from lung cancer, and non-Hodgkin lymphoma, but a significantly reduced mortality from prostate cancer.

Cognitive Disturbances

Global intelligence is somewhat lower in KS [4, 5, 60, 61], with decreased verbal intelligence, delayed development of speech, and with a high proportion of dyslexia and educational problems in many, but not all KS [62–65]. One study on adults with sex chromosome abnormalities, including KS and 47,XYY syndrome, detected at birth, showed that the decreased verbal IQ and reading impairment persisted in adulthood [66], but also that a large variability in educational and vocational achievement was present. The reason for the delay in speech and decreased verbal intelligence is unclear, but MRI studies have shown consistent changes in different nuclei of the brain [67–69] (see online Figure 10.3.2), although these changes have not been linked with specific changes in the neuropsychologic profile [70–72].

Psychiatric Diseases

Increased incidence of psychiatric illness were reported in KS primarily based on screening for sex chromosome abnormalities in penal institutions, psychiatric hospitals and institutions for the mentally retarded [73]. In a long-term follow-up study of KS males identified in a chromosome survey in Edinburgh, an increased frequency of referral to psychiatric treatment was seen [5]. A multinational survey for sex chromosome aberrations among patients

with schizophrenia found a four- to fivefold excess of KS compared with general population data [74]. An epidemiological study on hospital admissions in KS showed a significantly increased risk of discharge with a psychiatric diagnosis [55], and patients may show an increase in schizophrenia-spectrum pathology [75]. Overexpression of X-linked genes escaping X-inactivation is thought to be involved in some of the psychiatric disturbances seen in KS [76].

Criminality

One study found no increased frequency of criminal behaviour in KS judged by self-reported penalties [77]. Another study following 34 KS patients for 10 and 20 years showed increased criminal behaviour at 10 years follow-up, compared with both hypogonadal men (from other causes than KS) and with a eugonadal control group [60] but after 20 years of follow-up there was no significant difference in criminality [78]. Recently published data on 32 KS patients diagnosed prepubertally or during puberty showed a large proportion of patients with severe psychosocial problems, with 69% having problems with controlling aggression, 28% offending the law and 18% having convictions [79]. A recent large epidemiological study (n = 934) showed increased criminality specifically related to arson, sexual abuse and burglary compared to a large background population (n = 88 979) [80].

Treatment

Optimal treatment and care of patients with KS involves a multidisciplinary team including speech therapists, psychologists, general practitioners, paediatricians, endocrinologists, urologists, and infertility specialists. Although most clinicians believe that testosterone treatment has a positive impact, both physically and psychologically, no randomized controlled trials on the efficacy and safety of testosterone replacement therapy have been performed in KS, mainly due to small sample sizes in most clinics and lack of research funding support. Current practice is largely based on observational data from KS patients and evidence extrapolated from other hypogonadal conditions, so that some areas of management remain controversial and without clear consensus.

Infants with KS are rarely diagnosed because they lack KS-specific stigmata. However, some KS boys have micro penis, which anecdotally can respond to treatment with topical testosterone cream or single injections of intramuscular testosterone in some cases. The most serious problem in early childhood is the delay of speech development affecting perhaps half of the boys with KS [5]. Careful observation for speech delay is needed in order to refer these boys to speech therapists promptly. The same holds true for learning disabilities, which were observed in 77% of boys with KS followed from birth to adulthood [81].

At puberty, if **both** LH and FSH rise above normal, some centres recommend initiating testosterone treatment with the aim of promoting a full development of male secondary sexual characteristics and ensuring sufficient increase in muscle bulk and BMD [82], although such recommendations are not based on high level evidence. Testosterone treatment in pubertal KS boys has also been reported to increase energy, endurance, better mood and concentration and relations to others [83]. Retrospective chart data on a group of KS boys diagnosed before and during puberty (n = 32, whereof 17 received testosterone treatment) showed increased psychosocial problems in periods without testosterone treatment [84]. In a minority of KS adolescents with particular behavioural issues, (such as aggression, socialization, and communication problems), initiation of testosterone treatment should proceed cautiously and preferably with supports from psychologists with neurocognitive therapy experience.

Treatment in a large group of young hypogonadal men of mixed origins (wherein some had KS) has been shown to have a positive impact on fat mass, muscle mass, and muscle strength, as well as sexual function, with some improvements in positive aspects of mood [85].

There is general agreement that KS patients with testosterone levels at the lower end of the normal range, and with elevated FSH and LH levels, indicating hypogonadism to be present [37], should be treated if they complain of hypogonadal symptoms (lack of libido, erectile problems, decreased energy, etc.) [86–88]. Based on our own experience, we believe that all KS patients (asymptomatic as well as symptomatic) should receive testosterone treatment if their gonadotrophins are elevated, even if their testosterone levels are within the lower end of the normal range. Most, if not all, KS patients, who at first sight may seem asymptomatic, but after a more comprehensive assessment (see Table 10.3.1) using a combination of questionnaires with focus on quality of life [89], body composition, sleep quality [113], and biochemistry, will be found to have some features related to hypogonadism. In this context it is important to remember that many KS patients are not good rapporteurs concerning their own health, and that physicians should take due care to cover all relevant areas when interviewing these patients. This is supported by the frequent finding of excessive truncal fat, low muscle mass, decreased bone mass and microarchitectural bone changes [43, 87], reduced haemoglobin [35], presence of gynaecomastia [35], decreased sexual function [88], and depressive symptoms [89] in untreated KS patients. However, while there is good evidence that testosterone treatment improves these features in hypogonadal men (including KS) with low testosterone, there is currently no evidence from randomized controlled trials (RCTs) that testosterone treatment can reverse or improve these features in KS men with low or low-normal testosterone and elevated LH (see Chapter 10.4.4, 'Benefits of Testosterone Treatment'). More data are required before our practice outlined earlier is more widely adopted. Interestingly, only 48.6% of 1155 KS patients in the national Danish registry were ever prescribed testosterone, starting only at the age of 30.4 years [90].

We believe that testosterone treatment should aim for normalization in LH and testosterone levels in the mid-normal range by transdermal treatment and low-normal preinjection nadir values of testosterone when treatment is by injection therapy. In the authors' experience, LH and testosterone can be normalized in virtually all KS patients if the testosterone dose is carefully titrated, using recommended regimes for physiological replacement of testosterone. It may be inferred that many KS patients are not sufficiently treated, because LH often remain elevated. However, concerns have been raised that this approach (aim to normalize LH) may lead to excessive T exposure in some patients, especially from injectable therapy.

As with other forms of hypogonadism, improvements in subjective symptoms and other patient important outcomes should be key goals of testosterone replacement therapy in KS (in addition to normalization of biochemical endpoints). Treatment is recommended to be continued lifelong in order to prevent osteoporosis, obesity, metabolic syndrome and diabetes, and to ensure optimal cognitive development.

Temporary discontinuation of exogenous testosterone as well as treatment with human chorionic gonadotrophin (hCG) and aromatase inhibitors to increase intratesticular testosterone, are empirical approaches commonly employed to increase the chance of sperm recovery by TESE [91], although they have not been proven to be efficacious. These practices should be carefully audited and confirmed by evidence, preferably in a randomized trial setting and should not be extrapolated to influence the imperative of regular testosterone replacement therapy in KS. Currently, there is no evidence to support withholding testosterone treatment to young men with KS that have still not attempted TESE and may not do so for years.

Conclusions

Klinefelter syndrome is a frequent cause of hypogonadism and infertility. It is the most common sex chromosome disorder in man, with 47,XXY being the most common karyotype. The syndrome affects one in every 660 males but is severely underdiagnosed; only 25–50% of the expected number of cases is diagnosed and only a minority of them before puberty.

In children the main clinical findings are delayed speech development and learning disabilities as well as increased height and cryptorchidism. In adults the main reasons for diagnosing KS are infertility and hypogonadism. KS is associated with a significant increase in mortality and morbidity from a number of diseases.

In accordance with accepted practice for hypogonadism, there is general agreement that **symptomatic** KS men with unequivocally low testosterone should receive testosterone replacement. However, the exact indications for testosterone treatment in apparently **asymptomatic** KS men with low-normal testosterone and elevated FSH and LH remain uncertain. While some clinicians (including the authors) routinely initiate testosterone treatment in all KS men with elevated LH and FSH, aiming to counter the presumptive harmful effects of compensated hypogonadism, not all authorities agree with this approach due to the current lack of high level evidence from RCTs.

Male Adult Hypogonadism

10.4.1 Aetiology

Alvin M. Matsumoto and Radhika Narla

Introduction

Once the diagnosis of hypogonadism is suspected in a man with signs and symptoms of androgen deficiency and confirmed with consistently low early morning total and/or free testosterone concentrations drawn in the fasted state on at least two separate occasions, the aetiology of hypogonadism should be determined [1].

Measurements of circulating gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are usually performed in same blood sample as a confirmatory testosterone, to ascertain whether low testosterone is due a primary disorder of the testes or secondary to a defect in the hypothalamus and/or pituitary gland. Subsequently, a working diagnosis of the aetiology of the hypogonadism should be based on the patient's past medical history, clinical presentation, and further laboratory testing.

Aetiologies of hypogonadism can be classified into two broad categories: **primary hypogonadism** and **secondary hypogonadism**. Primary hypogonadism is usually caused by an intrinsic structural or congenital defect within the testes, resulting in impaired testosterone and sperm production and elevated LH and FSH concentrations (as a result of reduced negative feedback suppression; FSH concentrations are usually more elevated than LH concentrations because active cell-division during spermatogenesis is more sensitive to damage than testosterone production) [1, 2].

Secondary hypogonadism is caused by disease or dysfunction leading to inadequate hypothalamic gonadotropin-releasing hormone and/or pituitary gonadotropin secretion and stimulation of the testes [3], resulting in reduced testosterone and spermatogenesis, and low or inappropriately normal LH and FSH concentrations Key differences between the categories are highlighted in Table 10.4.1.1.

In addition to identifying the level of the HPT axis deficit, it is important to determine whether the cause of hypogonadism is organic or functional [1, 4]. Table 10.4.1.2 summarizes all the categories of hypogonadism. Organic hypogonadism, or classical hypogonadism, is caused by a congenital, structural, or infiltrative disorder that results in permanent hypothalamic, pituitary, or testicular damage. In contrast, functional hypogonadism is caused by conditions that suppress gonadotropin and testosterone concentrations that are potentially reversible with treatment of the underlying cause(s) (e.g. with weight loss or discontinuation of opioid medications) [4]. Finally, some aetiologies of hypogonadism are caused by defects both in the testes and hypothalamus and/or pituitary (i.e. combined primary and secondary hypogonadism).

Prior to initiating testosterone treatment, it is important determine whether a patient has secondary hypogonadism as some hypothalamic–pituitary causes require specific management besides testosterone therapy. In contrast to men with primary hypogonadism

Table 10.4.1.1 Differences between primary and secondary hypogonadism

	Primary hypogonadism	Secondary hypogonadism
Condition	Testicular failure	Hypothalamus–pituitary failure
Gonadotropin levels	Elevated	Low or normal
Frequency observed	Less common	More common
Spermatogenesis	Usually impaired	Impaired if severe
Organic or functional aetiology	Usually organic (structural or intrinsic testicular defect), permanent	Usually functional (extrinsic gonadotropin suppression of a structurally intact hypothalamus and pituitary), potentially reversible

Table 10.4.1.2 Aetiology of Male Hypogonadism

Primary hypogonadism	Secondary hypogonadism
Organic	
Congenital	
Klinefelter syndrome and variants	Congenital hypogonadotropic hypogonadism
Cryptorchidism (uncorrected bilateral)	Complex genetic syndromes*
Congenital anorchia	Inactivating LH beta mutations
Myotonic dystrophy	
Noonan syndrome	
Testicular adrenal rest tumours (congenital adrenal hyperplasia)	
Testosterone biosynthetic defects	
Complex genetic syndromes	
Inactivating mutations of LH receptor	
Acquired	
Bilateral orchidectomy testicular damage, torsion, radiation	Hypothalamic/pituitary or parasellar tumours
Cancer chemotherapy (alkylating agents)	Hypothalamic/pituitary radiation
Orchitis (mumps)	Pituitary apoplexy
Autoimmune testicular failure	Severe head trauma, pituitary stalk injury/section
Advanced older age*	Infiltrative disorders
Hodgkin's disease*	Hypothalamic/pituitary infection (tuberculosis, fungal)
Testicular cancer*	Immune check point inhibitors, hypophysitis, hypophysectomy
	Hemochromatosis*—that of primary hypogonadism, transfusion-related iron overload
	Sickle cell disease*
Functional	
Hepatic cirrhosis*	Constitutional delayed puberty
Renal failure (CKD 4–5)*	Diabetes mellitus
	Obesity
	Obstructive sleep apnoea
	Opioid use
	Hyperprolactinemia
	Malnutrition
	Excessive exercise (energy expenditure > intake)
	Glucocorticoid excess (Cushing syndrome)*
	Sex steroid use (anabolic steroids, progestins, oestrogens)*
	Chronic systemic illness, organ failure (liver, lung, heart)*
	Alcohol abuse*
	Severe acute illness or surgery*

* Combined primary and secondary hypogonadism.

who have permanent impairment of spermatogenesis, men with secondary hypogonadism can respond to gonadotropin therapy to stimulate testosterone and sperm production, and treat the infertility (see Chapter 10.5, 'Management of Idiopathic Male Infertility'). Also, although uncommon, secondary hypogonadism from a pituitary or hypothalamic tumour can be associated with deficiency and/or excessive secretion of other anterior pituitary hormones or pituitary mass effects (e.g. visual field defects or headaches) that require management in addition to testosterone treatment [1–3]. Finally, the cause of secondary hypogonadism is often functional and potentially reversible so that testosterone treatment may not always be required (e.g. weight loss with diet or bariatric surgery can improve testosterone concentrations in obesity-related hypogonadism) [1, 4].

Causes of Primary Hypogonadism

Organic Congenital Aetiologies

Klinefelter Syndrome

Klinefelter syndrome (KS) results from one or more extra X chromosomes, most commonly by a 47,XXY karyotype; or mosaicism in most of the remainder (a 47,XXY karyotype present in some tissues or cells and a normal 46,XY karyotype in others). KS occurs in approximately 150 per 100 000 males and is the most common cause of primary hypogonadism [5]. Men with KS have classical phenotypic characteristics: very small firm testes (less than 2.5 cm or 6 ml), varying degrees of testosterone deficiency, gynaecomastia, long legs relative to arms, azoospermia, and infertility. Some men may have milder signs and symptoms. A karyotype confirms the diagnosis [1–3, 5, 6] (see Chapter 10.3, 'Klinefelter's Syndrome').

Men with classical KS have azoospermia, but both mosaic and classical KS men been shown to be capable of conceiving children through testicular sperm extraction. KS men also have a higher incidence of male breast cancer, extragonadal germ cell tumours, and non-Hodgkin's lymphoma, decreased bone mass, higher degree of insulin resistance, and autoimmune disorders [2, 5, 6].

Cryptorchidism

Cryptorchidism is failure of one or both testes to descend through the inguinal canal into the scrotum. Most commonly, it is associated with selective impairment of sperm production and increased FSH with normal testosterone production [1–3]. However, rarely (e.g. in men with uncorrected bilateral cryptorchidism), both testosterone and sperm production are impaired with elevated FSH and LH concentrations, consistent with primary hypogonadism. Bilateral cryptorchidism may be present in other causes of both primary hypogonadism (e.g. Klinefelter syndrome) and secondary hypogonadism (e.g. Kallmann syndrome) or other complex congenital genetic syndromes (e.g. Prader–Willi syndrome). Patients with cryptorchidism have an approximately 5–10-fold increased testicular cancer risk, especially within an undescended testes; increased risk persists despite surgical relocation of the testis in the scrotum (orchiopexy) [2].

Congenital Anorchia

Congenital anorchia, also known as vanishing testes syndrome, is a rare disorder characterized by the absence of one or both testes in

a phenotypic male (suggesting that functioning testes were present during fetal genital development). It is believed to be caused by testicular torsion during fetal life after sufficient testosterone exposure to produce masculinization of the reproductive tract. Males with congenital anorchia present with primary hypogonadism, delayed puberty, and on physical exam, testes are not palpable. In contrast to bilateral cryptorchidism (discussed earlier), in congenital anorchia, testosterone concentrations do not increase with hCG stimulation and anti-Müllerian hormone concentrations are very low or undetectable. A response to hCG stimulation would raise the possibility of intra-abdominal testes and cryptorchidism [2].

Myotonic Dystrophy

Myotonic dystrophy is an autosomal dominant disorder that presents with progressive muscle weakness and wasting, myotonia (involuntary sustained muscle contraction), male pattern balding, and other congenital anomalies. There are two types of myotonic dystrophy, type 1, and type 2. Type 1 myotonic dystrophy is more prevalent and results from an expansion of trinucleotide cardiotocography (CTG) repeats in the *DMPK* gene. Type 2 myotonic dystrophy is a neurologically milder form caused by expansion of CTG repeats in *CNBP* gene. In both types, the pathogenesis is a disruption of the normal mRNA metabolism and this affects many genes and causes multisystem effects including hypogonadism. While the exact mechanism is unknown, testicular atrophy and primary hypogonadism is observed in both types [2, 3].

Noonan Syndrome

Noonan syndrome, previously referred to as the male Turner syndrome, is an autosomal dominant or occasionally sporadic genetic disorder that is caused by mutations of genes that are part of the Ras-MAPK signalling pathway, such as PTPN11, SOS1, BRAF, and others. While the exact mechanism is unknown, alterations in encoded proteins leads to multisystem dysregulation including hypogonadism. The clinical features of Noonan syndrome include short stature, certain facial features (low set ears, downward slanting eyes, strabismus, high arched palate), short web neck, skeletal abnormalities (shield-like chest, pectus excavatum or carinatum, cubitis valgus, and joint laxity), intellectual disability, congenital heart defects (pulmonic stenosis and hypertrophic cardiomyopathy), and primary hypogonadism [2].

Congenital Adrenal Hyperplasia (CAH)

Men with CAH have mutations in genes coding for enzymes essential for steroid biosynthesis. The most common form of CAH is autosomal recessive 21α-hydroxylase deficiency caused by a mutation of the *CYP21* gene leading to low cortisol and aldosterone concentrations that increase adrenocorticotrophic hormone (ACTH) concentrations (due to reduced cortisol negative feedback) and cause adrenal hyperplasia with accumulation of proximal steroid hormone precursors (17-hydroxyprogesterone and progesterone, and adrenal androgens (androstenedione and DHEA) [2, 7]. Men with CAH may develop testicular adrenal rest tumours (TARTs) that can cause compression of surrounding testicular tissue and primary hypogonadism. TARTs are palpable on examination or identified by ultrasound and decrease in size with adequate glucocorticoid treatment to suppress ACTH stimulation. Also, if glucocorticoid suppression is inadequate, men with CAH can then present with secondary hypogonadism. Due to oversecretion of adrenal androgens, these men maintain virilization but increased progesterone as well as testosterone and oestradiol concentrations from conversion of adrenal androgen precursors can suppress LH and FSH concentrations leading to impaired spermatogenesis and secondary hypogonadism [2, 3, 7].

Testosterone Biosynthetic Defects

Rare testosterone biosynthetic enzyme defects, including 17α-hydroxylase/17,20-lyase, 17β-hydroxysteroid dehydrogenase type 3/17-ketoreductase and 3β-hydroxysteroid dehydrogenase type 2 deficiencies caused by mutations in the *CYP17, HSD17B3*, and *HSD3B2* genes, respectively, usually present at birth with a partial virilized near-female phenotype, or ambiguous genitalia, i.e. 46,XY disorder of sex development (DSD). However, males with incomplete deficiencies in these biosynthetic enzymes may present as a near-male phenotype with delayed puberty, hypospadias, gynaecomastia, and primary hypogonadism [7].

Complex Genetic Syndromes

Numerous complex genetic syndromes associated with distinct morphological developmental manifestations and congenital anomalies, may also present with primary hypogonadism.

While the mechanism is unknown, Prader–Willi can present with either primary or secondary hypogonadism and can have either unilateral or bilateral cryptorchidism and obesity that may contribute to hypogonadism [8]. Men with Down's syndrome (trisomy 21) usually present with isolated impairment of sperm production with normal or selective high FSH, but occasionally, they may present with elevated FSH and LH concentrations [2].

Luteinizing Hormone Receptor Mutations

Patients with inactivating mutations of LH receptors resulting in Leydig cell aplasia or hypoplasia usually present with a near-female phenotype or ambiguous genitalia and cryptorchidism (46,XY DSD). Men with milder forms have micropenis, hypospadias, undervirilization, delayed puberty, or primary hypogonadism.

Organic Acquired Aetiologies

Bilateral Orchiectomy, Testicular Damage, or Torsion and Radiation

Bilateral orchiectomy results in rapid and severe primary hypogonadism often associated with hot flushes [1–3]. Direct blunt trauma or torsion to one or both testicles may be associated with vascular compromise that can lead to development of testicular atrophy. Exposure of the testes to the large amounts of ionizing radiation (>600–800 cGy) that is used in treatment for certain types of leukaemia can also result in testicular damage (especially spermatogenesis) and primary hypogonadism [9].

Cancer Chemotherapy

Combination cancer chemotherapy regimens that contain alkylating agents (e.g. cyclophosphamide) used in the treatment of Hodgkin's or non-Hodgkin's lymphoma; cyclophosphamide therapy for systemic rheumatic disorders; or platinum drugs (e.g. cisplatin) used in the treatment of testicular cancer can cause testicular atrophy, impaired spermatogenesis, and testosterone production with elevated gonadotropin concentrations [10].

Orchitis

Viral infections of the testes, such as mumps orchitis, most commonly result in testicular atrophy and isolated impairment of spermatogenesis and elevated FSH concentrations, but if severe, can cause primary hypogonadism. Orchitis is the most common complication of mumps in pubertal boys and men. Testis pain and swelling usually occurs 1–2 weeks after the initial painful swelling of the parotid glands; however, orchitis is subclinical in half the cases [1–3]. HIV infection, and/or associated opportunistic infections may involve the testes directly leading to primary hypogonadism [2, 3].

Autoimmune Polyglandular Syndrome

Autoimmune polyglandular syndrome type 1 is a rare autosomal recessive disorder that is caused by a mutation in the autoimmune regulator (*AIRE*) gene, characterized by autoimmune hypoparathyroidism, primary adrenal insufficiency, mucocutaneous candidiasis and, rarely, primary hypogonadism. Autoimmune polyglandular syndrome type 2 is a polygenic disorder associated with HLA-DR3 and DR4 that is characterized by autoimmune primary adrenal insufficiency, thyroid disease (Hashimoto's or Graves' disease), type 1 diabetes mellitus and rarely, primary hypogonadism associated with steroid cell autoantibodies (SCA) [11].

Advanced Older Age

In men, there is a gradual decline in testosterone concentrations with ageing, at a rate of approximately 1% per year after age 30 years [1, 2, 4, 12]. Sex-hormone-binding globulin (SHBG) concentrations increase with ageing, resulting in a greater decrease in free testosterone concentrations and an increasing prevalence of testosterone concentrations in the hypogonadal range in older men [4, 12]. However, the prevalence of clinical hypogonadism (low testosterone concentrations with clinical manifestations of androgen deficiency) is lower, 2% (with only sexual symptoms) to 9% [4].

With ageing, there is also a progressive increase in LH and FSH concentrations. However, in large part because of age-related comorbidities, gonadotropin concentrations do not increase to above normal until advanced age (70 years or older). Therefore, healthy advanced age men usually manifest primary hypogonadism, while older men with poorer health status and comorbid illness(es) have hormone pattern of secondary hypogonadism. There is evidence of both testicular failure (reduced testosterone response to hCG stimulation and histologically reduced Leydig cell numbers) and hypothalamic dysfunction (disordered LH pulses) with ageing [12].

Recently, The Testosterone Trials demonstrated that short-term testosterone treatment in older men with symptomatic hypogonadism (but without recognizable organic HPT axis pathology) improved sexual function (sexual activity, libido, and erectile dysfunction), anaemia, bone density; slightly improved walking distance, mood, and depressive symptoms; but did not improve cognitive function and vitality. However, testosterone did increase non-calcified coronary artery plaque volume with no differences in cardiovascular adverse events [1]. The significance of this last finding is not known and there is a need for longer term, larger randomized trials. Meanwhile, in older men, it is important to consider functional causes of low testosterone concentrations that are potentially reversible during work-up for hypogonadism aetiology before considering starting testosterone [1, 4, 12].

Cancer

Advanced Hodgkin's disease or testicular cancer can also present with primary hypogonadism before chemotherapy or radiation therapy; the cause is unknown. While the pattern is that of primary hypogonadism, secondary hypogonadism can also be observed [2, 3].

Functional Acquired Aetiologies

Hepatic Cirrhosis and Chronic Kidney Disease

In alcoholic cirrhosis, direct toxic effects of alcohol may lead to testicular atrophy and elevated FSH and LH concentrations; however, gonadotropin suppression can also be observed. Patients with cirrhosis are often treated with spironolactone that acts primarily as an androgen receptor antagonist, but also may reduce testosterone production. Furthermore, oestradiol and estrone concentrations may be elevated due to reduced hepatic clearance and contribute to secondary hypogonadism by suppressing LH and FSH concentrations. In severe cirrhosis and liver failure, reduced hepatic protein production, protein-calorie malnutrition, and complicating infections may also lead to gonadotropin suppression. Hepatic cirrhosis is considered a functional cause of hypogonadism because gonadal function may recover after liver transplant, at least partially, depending on the chronic immunosuppression regimen used [2, 3].

Chronic kidney disease may also produce both primary and secondary hypogonadism. However, in late stage chronic kidney disease (CKD), the LH, and FSH concentrations are high in large part, due to reduced renal clearance of gonadotropins [1, 2]. Primary testicular failure in CKD as evidenced by reduced Leydig cell testosterone response to hCG is due to numerous factors, including direct toxic effects of uraemia, systemic inflammation, and chronic nutritional deficiency. These factors, in addition to hyperprolactinaemia (from reduced prolactin clearance), contribute to alterations in pulsatile gonadotropin secretion. Renal transplantation usually reverses hypogonadism, depending on the presence of comorbid conditions and use of certain medications such as glucocorticoid immunosuppression [1–3]. See Chapter 10.6 'Hypothalamo–Pituitary–Testicular Axis Function in Systemic Diseases and Effects of Medications'.

Causes of Secondary Hypogonadism

Organic Congenital Aetiologies

Congenital hypogonadotropic hypogonadism (CHH) is a relatively rare condition that causes severe secondary hypogonadism with estimated prevalence 1/4000 to 1/10 000 males. Males with CHH present with delayed puberty or incomplete sexual maturation (eunuchoidism), severe androgen deficiency with prepubertal testosterone concentrations, impairment of sperm production, and varying but usually severe degrees of gonadotropin deficiency.

Gonadotropin deficiency is caused by gonadotropin-releasing hormone (GnRH) deficiency (as evidenced most commonly by absent or less commonly by deficient pulsatile LH secretion) or rarely, GnRH receptor defects. CHH can be divided into three subgroups: Kallmann syndrome, normosmic CHH, and CHH associated with complex genetic syndromes forms [13].

Approximately 60% of CHH men have anosmia or hyposmia due to defective development of the olfactory bulbs known as Kallmann syndrome (e.g., due to KAL1, FGFR1/FGF8, PROKR2/PROK2 mutations). Kallmann syndrome patients may have other developmental midline defects, such as cleft lip or palate, or other craniofacial defects, sensorineural hearing loss, digital skeletal anomalies, unilateral renal agenesis, and neurological defects such synkinesia or mirror movements [14].

Individuals with normosmic CHH have normal olfaction and are difficult to differentiate from those with constitutional delay of puberty (CDP) which is much more common. Presence of micropenis, cryptorchidism, careful history, and signs from family members would make the clinician favour normosmic CHH rather than CDP. Certain gene mutations that typically cause isolated CHH include KISS1R (kisspeptin 1 receptor gene), KISS1 ligand, and GnRH receptor. When the diagnosis of CHH is suspected, it is recommended to refer to a clinical geneticist for further evaluation [2, 14, 15].

CHH can also occur in a number of complex genetic syndromes that are characterized by a constellation of developmental and/or hormonal abnormalities. The CHARGE (**C**oloboma or central nervous system (CNS) anomalies, **H**eart anomalies, choanal **A**tresia, growth **R**etardation, **G**enital defect (cryptorchidism and hypospadias), and **E**ar anomalies) that is caused by a mutation in the *CHD7* gene may present with either Kallmann syndrome or normosmic CHH [15]. CHH is part of numerous congenital dysmorphology syndromes, many of which are associated with neurological abnormalities and obesity that may contribute to secondary hypogonadism, such as Prader–Willi syndrome that can manifest either with primary or secondary hypogonadism [2].

Although rare, inactivating mutations of the LHβ subunit gene result in prepubertal secondary hypogonadism manifested by failure to undergo puberty with severe androgen deficiency [16].

Organic Acquired Aetiologies

Hypothalamic, Pituitary, or Parasellar Tumours and Radiation

Tumours of the hypothalamus, pituitary, or parasellar area including pituitary macroadenomas, pituitary cysts, meningiomas, craniopharyngiomas can decrease GnRH and/or LH and FSH secretion. Hypopituitarism following treatment for these or other tumours with surgery or radiation therapy can also result in secondary hypogonadism. Although secondary hypogonadism associated with some pituitary macroadenomas may be reversed after surgical resection, more commonly, gonadotropin deficiency is irreversible. In addition, microprolactinomas can suppress GnRH secretion and reduce LH pulsatility independent of its mass effect (see later section on hyperprolactinaemia).

Depending on the neuroanatomical location, size, and associated destruction and functional state, hypothalamic or pituitary tumours may be associated with anterior pituitary hormone deficiencies (e.g. secondary adrenal insufficiency and hypothyroidism) or hypersecretion (e.g. hyperprolactinaemia, Cushing syndrome, or acromegaly); diabetes insipidus or hypothalamic dysfunction; tumour mass effects (e.g. headache, visual field defects, or cerebrospinal fluid rhinorrhoea) that require evaluation and management independent of testosterone treatment for secondary hypogonadism.

Pituitary Apoplexy/Severe Head Trauma/Pituitary Stalk Injury/Hypopituitarism

Pituitary apoplexy is sudden haemorrhage or infarction within a pituitary tumour that can lead to compression and destruction of the pituitary gland, manifested by sudden onset of headache, nausea, visual defects, and acute hypopituitarism [2]. It is rare and occurs in only 2–12% of patients with pituitary adenomas. The acute impairment of pituitary function usually persists after the acute event particularly if surgery is required [17].

Infiltrative Disorders

Hypopituitarism leading to decreased anterior pituitary hormone secretion, including LH and FSH, can be caused by infiltrative inflammatory or granulomatous disorders of the pituitary. The typical diseases are lymphocytic hypophysitis, sarcoidosis, and Langerhans cell histiocytosis. Tuberculosis and fungal infections causing basilar meningitis can affect hypothalamic and pituitary function that results in secondary hypogonadism [1–3].

Immune Checkpoint Inhibitors and Hypophysitis

Recently, immune checkpoint inhibitors have become a mainstay in cancer treatment especially for metastatic melanoma and lung cancer. However, these can cause autoimmune effects and lead to endocrinopathies including hypophysitis and secondary hypogonadism. One new class of immunomodulating antibodies directed against CTLA4 (anti-CTLA4-mAbs) has been shown to have an incidence of hypophysitis ranging up to 17%. While most often secondary adrenal insufficiency and hypothyroidism occur, the incidence of hypogonadotropic hypogonadism with this type of hypophysitis was approximately 7.5% [18].

Haemochromatosis and Transfusion-Related Iron Overload

Iron overload caused either by hereditary hemochromatosis, a genetic disorder of excessive gastrointestinal iron absorption caused by mutations in the *HFE* gene, or due to chronic blood transfusions for haematologic conditions (e.g. β-thalassemia major, sickle cell disease) may involve excessive iron deposition in both the pituitary gonadotrope and testes, but more commonly presents with secondary hypogonadism [2, 3]. In more recent studies, the prevalence of secondary hypogonadism associated with haemochromatosis is approximately 6% and hypogonadism is more likely in men who have hepatic cirrhosis, ferritin concentrations exceeding 1500 ng/ml and complications of iron deposition such as diabetes mellitus [19]. Early treatment of iron overload with therapeutic phlebotomy or chelation therapy may reverse hypogonadism however, pituitary dysfunction is more commonly irreversible.

Functional Aetiologies

Constitutional Delayed Puberty (CPD)

As discussed, CPD is the most common cause of delayed puberty, affecting approximately 3% of adolescents. Also often referred to as 'late bloomers', this is thought to be a transient delay in production of GnRH from hypothalamus leading to decreased LH and FSH secretions that resolves eventually with older age [2].

Diabetes Mellitus

Low free testosterone and inappropriately normal or low LH and FSH concentrations occur in 30–40% of men with type 2 diabetes mellitus. The mechanisms contributing to secondary hypogonadism are likely to be multifactorial and include obesity, poor glycaemic control, systemic inflammation, and diabetic complications (e.g. CKD) [2–4]. Some of the mechanisms that have been observed with poorly controlled diabetes mellitus and hypogonadism include higher glucose values decreasing LH pulses, increase in inflammatory markers such as C-reactive protein (CPR), tumour necrosis factor-α (TNF-α) and interleukin-1β (IL-1β) suppressing GnRH release in hypothalamus and LH secretion [4].

Obesity

In men with mild to moderate obesity (body mass index, BMI, 30–40), SHBG concentrations are usually suppressed, resulting in low total testosterone concentrations; however, free testosterone concentrations are usually normal unless obesity is associated with comorbid illness such as diabetes or obstructive sleep apnoea in which case, free testosterone concentrations are low and gonadotropin concentrations are inappropriately normal or low, consistent with secondary hypogonadism [1–4]. Men with severe or morbid obesity (BMI >40) have more consistently low free testosterone concentrations and secondary hypogonadism. Gonadotropin suppression is likely due to increases in pro-inflammatory cytokines (e.g. tumour necrosis factor-α or interleukin-1) and dysregulated leptin signalling [4]. Because obesity associated with insulin resistance suppresses SHBG concentrations by reducing hepatic SHBG production, it is critical to measure free testosterone in the work-up of an obese man with hypogonadism [1]. Substantial weight loss following bariatric surgery increases free testosterone and gonadotropins [4].

Obstructive Sleep Apnoea (OSA)

Men with untreated or inadequately treated obstructive sleep apnoea are also more likely to have reduced testosterone and gonadotropin concentrations as well as symptoms of low energy, low libido, and fatigue [1–4]. Secondary hypogonadism is likely due in part to obesity and age, but also to the significant stress associated with nocturnal oxygen desaturation that results in arousal and sleep fragmentation [4].

Opioid Use

Use of opioid medications, especially long-acting opioids, for the treatment of chronic pain or opioid use disorder may cause secondary hypogonadism by inhibiting pulsatile hypothalamic GnRH secretion (primarily via interaction with μ-opioid receptors). Opioid-induced hypogonadism usually occurs in men taking high dosages of opioids (e.g. 100–200 mg of oral morphine equivalents daily, intrathecal morphine sulphate, oral methadone greater than 30 mg daily or with transdermal fentanyl patches) [20]. Tapering off opioids may reverse secondary hypogonadism, although this may not always be possible.

Hyperprolactinaemia

Hyperprolactinaemia can suppress pulsatile GnRH secretion that can be corrected with D_2 dopamine receptor agonist treatment. The most common causes of hyperprolactinaemia are: prolactinoma (most commonly, prolactin-secreting macroadenomas in men); pituitary stalk interruption (preventing endogenous hypothalamic dopamine-induced inhibition of prolactin secretion); hypothalamic disease; central nervous system-active medications (D_2 dopamine receptor antagonists, e.g. older antipsychotics such as phenothiazines, some atypical antipsychotics such as risperidone, and gastrointestinal promotility agents such as metoclopramide); CKD (as a result of decreased prolactin clearance). Treatment of the prolactinoma with normalization of serum prolactin concentrations is generally associated with an increase in serum testosterone concentrations unless there is tissue destruction or vascular compromise from very large macroprolactinomas. Discontinuation or switching of a medication that causes hyperprolactinaemia or treatment with D2 dopamine receptor agonists (e.g. cabergoline or bromocriptine) if possible, can reverse secondary hypogonadism [1–3].

Malnutrition/Excessive Exercise

Severe energy deficit due to starvation, protein-calorie malnutrition, and eating disorders (e.g. anorexia nervosa) where there is substantial weight loss can suppress hypothalamic pulsatile GnRH secretion. Refeeding, nutritional resuscitation, or treatment of eating disorders, respectively, restores HPT function. High intensity training or exercise seen in athletes or in the military that results in very high energy expenditure, usually associated with inadequate energy intake can also cause a state of energy deficit that decreases LH, FSH, and testosterone concentrations. Once excessive exercising is stopped or reduced and/or energy intake is increased, the HPT recovers usually in several weeks to months [2, 3].

Glucocorticoid Excess (Cushing Syndrome)

Glucocorticoid excess caused by either by exogenous glucocorticoid treatment or endogenous Cushing syndrome predominantly suppresses hypothalamic GnRH secretion; but also has direct inhibitory effects on the testes, inducing apoptosis in Leydig cells [2, 3]. Glucocorticoid-induced hypogonadism typically occurs with chronic high-dose glucocorticoid treatment, but testosterone suppression can occur in men taking doses as low as prednisone 7.5 mg daily [1, 2]. Restoration of normal HPT axis function and reversal of hypogonadism occurs with discontinuation of glucocorticoid administration or treatment of Cushing syndrome.

Sex Steroids

Androgens, progestins or oestrogens can suppress gonadotropin concentrations by negative feedback on the hypothalamus and/or

pituitary. Androgenic anabolic steroids (AASs, synthetic androgens) are taken in various combinations by athletes to enhance performance and non-athletes to enhance muscle bulk and strength. Because AASs do not cross-react in testosterone assays, testosterone levels are suppressed while taking these steroids. Patients taking AASs often present normal virilization but small testes on physical exam and have profoundly suppressed gonadotropins and testosterone that may persist with symptoms of androgen deficiency for months to years after discontinuation [21]. Progestins (e.g. megestrol acetate), an appetite stimulant that is used in patients with wasting syndromes such as cancer cachexia and HIV/AIDS wasting also cause severe suppression of gonadotropins and testosterone. Exposure to oestrogen-containing substances or oestrogen-secreting tumours of the testes or adrenal gland also induce secondary hypogonadism that is reversible with discontinuation of the offending substance or resection of the tumour, respectively [2].

Chronic Systemic Illness, Organ Failure

As previously discussed, chronic illnesses, especially hepatic cirrhosis, chronic kidney disease, congestive heart failure or chronic obstructive pulmonary disease (COPD) can cause combined primary and secondary hypogonadism. In severe late- or end-stage organ failure, secondary hypogonadism is predominant, and the degree of hypogonadism depends on the severity of illness and multiple other factors, such as malnutrition, systemic inflammation, medication exposure (e.g. prednisone use in COPD patients) [1–3].

Predominantly secondary more than primary hypogonadism also occurs in other chronic systemic illnesses such as, chronic active alcohol use disorder, HIV disease, and sickle cell disease [2].

Acute Illness or Surgery

Acute or critical illness or surgery requiring hospitalization often causes a hormonal pattern where secondary hypogonadism predominates with suppressed pulsatile GnRH secretion [1–3]. Testosterone and gonadotropin suppression improve once the acute illness is resolved; however, the duration of recovery is dependent on the severity of the acute illness, underlying chronic comorbid illness, age, and medications used during the illness and recovery (e.g. opioids or glucocorticoids) [22]. Therefore, evaluation for hypogonadism should not be performed until a patient is fully recovered, which may take several months.

10.4.2 Types of Treatment

Giulia Rastrelli, Mario Maggi, and Giovanni Corona

Introduction

This chapter will present the medications specifically approved for treatment of male hypogonadism (testosterone preparations and gonadotropins) and those not yet approved but currently under investigation as possible new therapeutic options.

Pharmacologic Treatments

Testosterone Preparations

In 1935, Karoly Gyula David and Ernst Laqueur extracted and purified an androgenic steroid from bull testes, which was named **testosterone** (T). In the same year, Butenandt's group in Gottingen and Ruzicka and Wettstein in Basel simultaneously described the chemical synthesis of T [1]. It soon became apparent that native T could not be given effectively by oral or parenteral routes, because of a prompt hepatic metabolism. Hence, a series of chemical modifications were developed to improve T bioavailability and pharmacokinetics, essentially by retarding the rate of liver catabolism [2, 3].

Nowadays many T formulations are available including oral, injectable(intramuscular or subcutaneous implantation), transdermal (gels, axillary solution, and patches) or transmucosal (buccal and nasal systems) formulations. In the following sections, the specific characteristics of the T preparations available on the market will be analysed in detail (Table 10.4.2.1). It should be noted that available T preparations have been approved for clinical use based only on their efficacy in raising T levels into the physiological range [4–7], rather than achieving clinical benefits. The efficacy of T preparations in improving the clinical features of hypogonadism has only been properly evaluated in more recent post-marketing randomized clinical trials (RCTs).

Oral Testosterone Preparations

Alkylation in 17-α position in ring A of the T molecule prevents rapid breakdown in the liver, hence, 17α-methyl-T was synthesized for oral use in 1935. However, this compound, along with all other 17α methyl T derivates, is associated with liver toxicity and are now no longer in clinical use [2, 3]. Unfortunately, these products are still available on the black market and continue to be abused as anabolic steroids [8]. In contrast, alkylation at the 1-α position as well as esterification of the 17α-hydroxyl group also reduce hepatic first-pass effect, but these modifications are not associated with hepatotoxicity. Hence, oral T formulation based on these chemical modifications are can be prescribed for clinical use (Table 10.4.2.1).

Testosterone Undecanoate

In the late 1970s, a new orally effective T formulation, based on 17β-esterification of native T with a long aliphatic side chain, undecanoic acid (oral T undecanoate, TU), was introduced to the market (Table 10.4.2.1). This lipophilic T ester allows absorption via the intestinal lymphatic system, avoiding the first-pass effect in the liver [2, 3]. Recently, this preparation has been reformulated, in a mixture of castor oil and propylene glycol laureate (*T undecanoate caps*), to increase stability of the product at ambient temperature [3]. Oral TU is formulated in 40 mg gel capsules. However, its bioavailability is poor on an empty stomach and the absorption is dependent on the dietary fat content [2, 3, 9]. A minimal amount of 20 mg of dietary fat is required for optimal oral TU absorption [2, 3, 9]. One or two 40 mg capsules should be taken thrice daily during meals, limiting its acceptability for compliant T treatment [2, 3, 9].

Parenteral Testosterone Preparations

Subdermal Implantation of T Pellets

T pellets are currently available only in a limited number of countries, including the United States and the United Kingdom. The pellets consist of pure crystals of 100 mg and 200 mg of T compressed into short rods and are placed, under local anaesthesia, into the subdermal fat layer of the skin usually in the lower abdominal wall or upper buttock area [2, 3, 9] (Table 10.4.2.1). The recommended dosage includes the implantation of 3 to 6 pellets (600–1200 mg) subcutaneously every 4 to 6 months. T pellet implantation provides the longest and the most stable form of T release, but possible adverse side effects include implant site infections and/or pellet extrusion occurring in 5–10% of cases.

Intramuscular Injectable Preparations

Injectable formulations of T are based on 17β-esterification of native T with fatty acids of variable aliphatic or aromatic chain lengths, and are administered in an oily base. Following intramuscular injection, the oily base acts as a depot, because it serves to retard the release of the T ester. Following release, the esters are rapidly hydrolysed to release native T into the circulation. Therefore, the duration of action of esterified T esters is largely dependent on the length of the ester side chain (which determines the lipophilic property/fat solubility of the T ester), as well as on the volume of the oily base.

T propionate (TP) has a short side chain ester and a short duration of action, requiring the administration of at least two to three injections per week (usually 50 mg every 2 or 3 days). **T cypionate (TC)** and **enanthate (TE)** have longer side chain esters and a longer duration of action, and can be injected every 10–14 days at doses of 200–250 mg.

The relatively short half-life of these T esters can lead to wide fluctuations in T plasma concentrations across the injection interval, in so-called peaks and troughs. Circulating T concentrations are commonly supraphysiological in the first few days after administration and then decline to subphysiological levels in the days prior to the next scheduled injection. This can be perceived as unpleasant variations in mood or energy by patients and represents a risk factor for erythrocytosis [10]. However, due to due to their long-established usage and relatively low cost compared to other formulations, these shorter-acting T esters continue to be prescribed widely in some countries.

In 2004, a **long-lasting injectable formulation of TU** was introduced to the market [2, 3, 9] (Table 10.4.2.1). The greater fat solubility rendered by the longer fatty acid side chain and the relatively large volume of oily base in the formulation increases the duration of action compared to other T esters [11] (Table 10.4.2.1). In most countries, injectable TU is available as a 1000 mg dose in 4 ml castor oil. This formulation maintains relatively stable circulating T concentrations when injected at 12 weekly intervals, following a week 6 loading dose. Once steady-state T concentrations have been achieved, usually after the third dose, the injection interval may need to be adjusted to every 10–14 weeks to achieve therapeutic serum T trough concentrations of 10–15 nmol/L. In the United States, TU is marketed as 750 mg is 3 ml castor oil. This formulation requires 10-weekly injections, following an initial week 4 loading dose. Injectable TU preparations result in lower plasma T fluctuations compared to other intramuscular T preparations with shorter half-lives, reducing the risk of polycythemia and improving patient compliance [11].

An uncommon adverse effect specific to injectable T formulations in oily base reported in post-marketing studies is pulmonary oil microembolisms due to leakage of the oil-based depot into the systemic circulation [2, 3, 9]. This can manifest with transient cough and respiratory distress immediately after the injection which generally does not require any intervention apart from reassurance. In addition, along with other parenteral preparations, injectable TU should be avoided in men at increased bleeding risk, due to, for example, coagulopathies or thrombocytopaenia.

Transdermal Testosterone Preparations

Testosterone Patches

Transdermal T formulations have been available since the mid-1990s, initially as self-adherent T patches designed to be applied to the relatively thin, highly vascularized scrotal skin. Scrotal patches gained limited acceptance given they are relatively large, require shaving, and have relatively poor adherence to the skin. Moreover, scrotal systems tend to disproportionally increase dihydrotestosterone (DHT) due to the relatively high expression of 5α-reductase in scrotal skin. Subsequently, patches for application on non-scrotal skin were developed [2, 3, 9] (Table 10.4.2.1). Non-scrotal patches require alcohol-based absorption enhancers which not uncommonly leads to skin irritation at the application site which, in addition to the requirement of daily application, may limit compliance [2, 3, 9].

Testosterone Gels

Given drawbacks associated with T patches, transdermal T formulations in hydroalcoholic gels with less irritative penetration enhancers have become available in the early 2000s. Transdermal gels are available in different concentrations (1%, 1.62%, and 2%) either as sachets (usually containing 50 mg of T) or as metered-dose pumps to allow dose titrations. Worldwide, transdermal gels constitute the largest market share of T prescriptions [2, 3, 9] (Table 10.4.2.1). Like patches, T gels require daily administration usually to upper arms or shoulders. Once applied, T gel is rapidly absorbed by the stratum corneum and subcutaneous tissues which serve as a reservoir from which T is gradually released into systemic circulation, leading to relatively stable circulating T concentrations over the subsequent 24 hours (for dosing regimens see Table 10.4.2.1). However, T levels can be variable from day to day and dose adjustment is frequently required. To ensure optimal absorption, the skin should be kept dry for 4–6 hours following gel application [2, 3, 9]. Due to the potential risk of T transfer, men are instructed to avoid close skin contact with others for the first few hours following gel application. To try and reduce transference risk, an alcohol-based T solution (2%) developed for axillary application is available in some countries, but its acceptability has been relatively low [2, 3, 9] (Table 10.4.2.1)

Transmucosal Testosterone Preparations

Transbuccal Testosterone Preparations

In some countries, a buccal preparation in tablet form is available, designed to adhere to the gum or inner cheek to provide a controlled and sustained release of T through the buccal mucosa. The tablet does not dissolve completely and must be removed and replaced every 12 hours. Each buccal system contains 30 mg of T. This formulation can maintain physiological T concentrations, but local irritation (such as gum oedema, ulceration, and gingivitis) can occur [2, 3, 9] (Table 10.4.2.1).

Transnasal Testosterone Preparations

A gel containing 5.5 mg of T in 122.5 mg of gel for nasal administration is available in some countries, including the United States and Canada. The recommended dose is 11 mg of T (corresponding to two pump actuations, one per nostril) administered three times daily [2, 3, 9] (Table 10.4.2.1).

Monitoring Testosterone Treatment

International guidelines [12, 13], recommend that patients receiving T treatment should be reviewed 3–6 months after initiation of therapy and yearly thereafter. Clinical assessment includes monitoring for improvement in hypogonadal symptoms and evaluation for side effects of T treatment (Table 10.4.2.1). Serum T should be measured to assess adequacy of T dosing, noting that timing of the blood draw and circulating T targets vary depending on the T formulation used (Table 10.4.2.1). Haematocrit should be monitored and if above 0.54, T therapy should be withheld until it declines to the normal range (see Chapter 10.4.5, 'Risks of T Treatment'). For men of more than 55 years of age who, following individualized discussion regarding advantages and disadvantages, opt for prostate monitoring, digital rectal exam, and prostate-specific antigen testing can be performed at regular intervals. In hypogonadal men at high risk of osteoporotic fracture, bone mineral density is measured at baseline, while subsequent measurements are individualized.

Androgens Other Than Testosterone

Dehydroepiandrosterone

Dehydroepiandrosterone (DHEA) is produced by the adrenal glands and circulates as a sulphated form (DHEAS). DHEA is a weak androgen receptor agonist and largely serves a steroid precursor of T. A meta-analysis of 25 RCTs including 1353 older men treated with DHEA at a dose varying from 25 to 100 mg per day for a mean of 36 weeks found that DHEA did not improve sexual function, quality of life, bone health or metabolic profile [14]. Therefore, use of DHEA for treatment of male hypogonadism is not recommended.

Table 10.4.2.1 Available testosterone preparations for the treatment of adulthood hypogonadism. NA = not available

Formulation	Trade names	Chemical structure	Half-life	Standard dosage	Monitoring T concentrations		Side effects
					When to measure	When to adjust the dose or frequency	
Testosterone preparations							
Oral							
Testosterone undecanoate	Andriol® Andriol Testocaps®	17-α-hydroxyl-ester	4 h	120–240 mg 2–3 times daily	3–5 h after ingestion	NA	Need for multiple assumptions per day with fatty meals
Mesterolone	Proviron®	1α-methyl-4,5α-dihydrotestosterone	12 h	50–100 mg 2–3 times daily	NA	NA	NA
Parental							
Testosterone enanthate	Testoviron Depot® Delatestryl® Testoenant®	17-α-hydroxyl-ester	4–5 days	250 mg every 2–3 weeks	Midway between injections	TT<14 nmol/L TT>25 nmol/L	Pain at injection site Cough after injection Fluctuation in symptoms
Testosterone cypionathe	Delatestril®	17-α-hydroxyl-ester	8 days	200 mg every 2–3 weeks	Midway between injections	TT<14 nmol/L TT>25 nmol/L	
Testosterone propionate	Testovis®	17-α-hydroxyl-ester	20 h	100 mg every 2 days	NA	NA	
Testosterone undecanoate in castor oil	Nebido® Aveed ®(US)*	17-α-hydroxyl-ester	34 days	1000 mg every 10–14 weeks *750 mg every 10 weeks	The week prior the next injection	TT nadir below or above the low-mid normal range	
Surgical implants	Testopel® Testoimplant®	Native testosterone	–	4–6 200 mg implants lasting up to 6 months	At the end of dosing interval	TT nadir below or above the low-mid normal range	Infection Expulsion of implant
Transdermal							
Testosterone patches	*Not scrotal:* Androderm® Andropatch® Testopatch®	Native testosterone	10 h	50–100 mg/day	3–12 h after application	TT below or above the low-mid normal range	Itching and skin irritation at application site
Testosterone gel 1–2%	*1% gel:* Androgel® Testogel® Testim® *2% gel:* Testostop® Tostrex® (also known as Fortesta®, Tostran® and Itnogen®, available only in Europe) *1.6% gel* Androgel (available only in US)	Native testosterone	6 h	50–100 mg/day	2–8 h after application	TT below or above the low-mid normal range	Skin irritation at application site Stickiness or slow drying Potential risk of transfer to person in close contact
Underarm testosterone (testosterone solution 2%)	Axiron®	Native testosterone	NA	60–120 mg/day	2–8 h after application	TT below or above the low-mid normal range	
Dihydrotestosterone	Andractim ®	Native dihydrotestosterone	NA	5 or 10 g/day	NA	NA	NA

Transmucosal							
Testosterone buccal	Striant®	Native testosterone	12 h	30 mg/twice daily	Immediately before or after application	NA	Gum Irritation Taste alterations
Testosterone nasal	Natesto®	Native testosterone	10–100 minutes	11 mg three times/daily	NA	NA	Nasal discomfort Rhinorrhoea Epistaxis Nasal congestion Parosmia
Androgens other than testosterone							
Oral							
Dehydroepiandrosterone	Galenic preparation	Native dehydroepiandrosterone	12 h	25–100 mg daily	NA	NA	NA
Mesterolone	Proviron®	1α-methyl-4,5α-dihydrotestosterone	12 h	50–100 mg 2–3 times daily	NA	NA	NA
Transdermal							
Dihydrotestosterone	Andractim ®	Native dihydrotestosterone	NA	5 or 10 g/day	NA	NA	NA

Dihydrotestosterone (DHT) Gels

In some European countries, DHT is available as a hydroalcoholic 2.5% gel with a dosage of 5 or 10 g/day [2, 3, 9] (Table 10.4.2.1). It has been used in the context of gynaecomastia or microphallus, but evidence for benefit is limited [2, 3, 9] (Table 10.4.2.1). Moreover, DHT cannot be aromatized to oestradiol. This limits DHT use, given increasing evidence that some of the biological actions attributed to T (e.g. maintenance of bone mass, prevention of adipose tissue accumulation, and possibly maintenance of libido) are dependent on its conversion to oestradiol [15]. Moreover, evidence regarding benefits and risks of DHT is limited, due to the paucity of RCTs. In one RCT of 120 men aged 50–70 years with borderline-low T levels, DHT treatment (125–250 mg daily for 6 months) was associated with a modest improvement in sexual function, but no effects on body weight or lipid parameters [16]. In an RCT of 114 healthy (not hypogonadal) men DHT gel (70 mg/daily) modestly improved body composition and measures of muscle performance, without evidence of adverse prostate effects [17, 18]. However, bone mineral density and sexual desire decreased, likely due to the relative lack of oestrogenic action.

Mesterolone

Mesterolone (1α-methyl-4,5α-dihydrotestosterone) is a 1α-methylated derivative of 5α-dihydrotestosterone (DHT) available for oral administration (Table 10.4.2.1) [2, 3]. However, similar to DHT, Mesterolone cannot be aromatized to oestradiol, limiting its clinical use.

Alternative Treatments to Testosterone

GnRH/Gonadotrophin Therapy

Gonadotropin-releasing hormone (GnRH) and gonadotrophin therapy is most commonly used to stimulate spermatogenesis (see Chapter 10.4.3, 'Gonadotrophin Induction of Spermatogenesis'). These agents require testicular responsiveness, and are therefore only effective in hypogonadotropic hypogonadism. Due to cost and need for parental therapy, they are generally not a practical treatment option for T replacement in hypogonadism. with limited evidence supporting their clinical use in this context.

Only two studies have evaluated the efficacy of luteotropic hormone (LTH) stimulation in adult men [19–21]. These RCTs have used human chorionic gonadotrophin (hCG) due to its longer half-life compared to LTH in doses used to induce spermatogenesis. In a placebo-controlled RCT, hCG modestly increased lean mass and decreased fat mass and modestly improved lipid parameters, but had no effect on sexual function [20, 21]. A very small study (including ten men receiving hCG) reported improvements in sexual function comparable to T treatment, but this study lacked a control group [22].

Antioestrogens

This category includes the selective oestrogen receptor (ER) modulators (SERMs) and the aromatase inhibitors (AIs). These orally active agents antagonize the oestradiol-mediated negative feedback that normally supresses GnRH and gonadotrophin section and lead to a reflex rise in circulating LTH, FSH, and T. However, the agents require an intact gonadal axis and are not effective in organic hypogonadotropic hypogonadism due to established hypothalamic–pituitary disease. In addition, as discussed next, they may interfere with oestrogenic signalling and to date, there are limited clinical data supporting their use. It should be noted that both SERMs and AIs are not approved for use in male hypogonadism. For all these reasons, their use should be considered experimental and restricted to clinical trials.

SERMs

SERMs are non-steroidal compounds that bind to the oestrogen receptor and exert both agonistic and/or antagonist actions, depending on the target tissue.

SERMs are classified into three generations. The first generation includes the triphenylethylene derivatives, clomiphene citrate (CC), tamoxifen, and toremifene. The second generation includes the benzothiophene derivatives, of which only raloxifene is available for clinical use. More recently, third generation compounds such as basedoxifene, ospemifene, and lasofoxifene have become available, but have not been evaluated in men.

CC is a non-racemic mixture composed of two stereoisomers: the trans-isomer enclomiphene (ECC), representing 62% and the cis-isomer zuclomiphene representing 38% of the mixture [3]. ECC has a pure antioestrogen effect with a half-life of 10 hours. Zuclomiphene has mixed oestrogenic and antioestrogenic actions and a longer half-life of 30 days. CC is approved for use in female infertility to induce ovulation. Due to its antioestrogenic actions, CC antagonizes the oestradiol-mediated negative central gonadal axis feedback resulting in increased gonadotropin secretion, which stimulates oocyte development. The same mechanism can be exploited in men, whose endogenous T levels significantly increase after using CC, ECC, or other SERMs [3].

Besides CC and ECC, tamoxifen, toremifene, and raloxifene have been evaluated in clinical studies using doses listed in Table 10.4.2.2 [3]. A meta-analysis of available studies has reported that in men with low to borderline T concentrations who do not have organic gonadal axis pathology, SERMs increase gonadotropins and circulating T, generally into the mid-normal range for healthy young men. However, so far, high-quality studies assessing their effects on androgen deficiency symptoms and end organ effects are lacking and currently available reports do not provide conclusive evidence of efficacy [3]. One placebo-controlled 8-week RCT in 17 men with lowered T concentration (less than 9.4 nmol/L) and erectile dysfunction (ED) [23] reported that CC at a dose of 50 mg daily had no effect on erectile function, despite a marked increase in T (+10.0 nmol/L vs. baseline and +7.7 nmol/L vs. placebo). Another 12-week RCT in 26 men with lowered serum T (less than 10.4 nmol/L) [24] compared CC 25 mg daily with anastrozole 1 mg similarly found no improvement in hypogonadal symptoms, including ED, were observed. In contrast to exogenous T, which suppresses gonadotropins and spermatogenesis, SERMs increase gonadotropins and may stimulate/preserve spermatogenesis in patients with functional secondary hypogonadism. To date, the largest RCT involving a SERM randomized 256 obese men with low serum T to either enclomiphene, T, or placebo. As expected ECC increased, but T therapy decreased, gonadotropins, while both ECC and T therapy increased serum T concentrations compared to placebo [25]. ECC maintained, whereas T modestly reduced sperm counts from a normal baseline [25]. However, to date, robust data on symptomatic improvements and fertility are

Table 10.4.2.2 Available preparations alternative to testosterone for the treatment of adulthood hypogonadism. NA= not available

Formulation	Trade names	Chemical structure	Half-life	Standard dosage
GnRH				
Gonadotropin-releasing hormone (GnRH)	Lutrelef® Factrel® Lutrepulse®	Native GnRH	10–40 minutes	100–400 ng/kg every 90–120 min
Gonadotropins				
Human chorionic gonadotropin (hCG) *Extractive* *Recombinant* Luteotropic hormone (LTH) *Recombinant*	Novarel® Chorex® Gonic® Choron® Chorigon® Pregnyl® Gonasi® Prophasi® Ovidrel® Ovitrelle®	hCG purified from the urine of pregnant women Human recombinant hCG Human recombinant LTH	23–38 h 29 h 4.5 h	1000–2000 IU 3 times/week NA NA
Follicular stimulating hormone (FSH) *Extractive* *Recombinant* *Follitropin alfa* *Follitropin beta* *Follitropin delta*	Menogon® Meropur® Fostimon® Fertinorm® Bravelle® Gonal-f® Cinnal-f® Fertilex® Ovaleap® Bemfola® Follistim® Puregon® Follitropin (generic)	FSH purified from the urine of pregnant women Human recombinant FSH Human recombinant FSH	NA	75–150 IU 3 times/week 75–150 IU 3 times/week 75–150 IU 3 times/week

not available. ECC has not been approved for clinical use and is not commercially available.

Raloxifene and toremifene, both SERMs with partial agonistic activity in bone, have been evaluated for their effect on skeletal endpoints. In a 6 month RCT of older men with serum bioavailable T less than 4.5 nmol/L, treatment with raloxifene 60 mg daily was associated with an improvement in markers of bone remodelling compared to placebo, but only in the subgroup of men with the lowest oestradiol and T concentrations [26]. Similar results were reported in a 6 months RCT of 43 healthy older men treated with raloxifene 120 mg daily [27]. Effects of SERMs on bone have also been assessed in men receiving androgen deprivation therapy (ADT) for prostate cancer, who have castrate concentrations of both T and oestradiol. In a large (n = 646 men receiving ADT) RCT, toremifene 80 mg daily for 2 years was associated with a significantly lower incidence of morphometric (according to the Genant semiquantitative scoring method) vertebral fractures than placebo (relative risk reduction of −50 ([−1.5; −75]%; p <0.05) [28]. However, men receiving toremifene had higher incidence of venous thromboembolic events (VTE; 2.6% vs. 1.1%) that was significant among older men (80 years old or older), which led the manufacturer to discontinue further evaluation of toremifene in men with prostate cancer receiving ADT [2, 29]. While an increased risk of VTE has not been reported in younger men without prostate cancer, existing studies have not been designed or powered to evaluate such risks. However, SERMs should be avoided in men at risk for VTE until more definitive data are available.

Aromatase Inhibitors

AIs inhibit aromatase, an enzyme whose physiologic function is to convert T into oestradiol. Based on their structure, AIs are classified into steroidal (testolactone and exemestane) and non-steroidal (anastrozole and letrozole) compounds. Exemestane, anastrozole, and letrozole are approved for the treatment of oestrogen receptor positive breast cancer in women. AIs profoundly reduce serum oestradiol (by >98%), and hence, in a mechanism similar to SERMs, remove oestradiol-mediated central gonadal feedback with consequent increase in gonadotropin secretion in turn stimulating testicular T production and possibly spermatogenesis. However, to date beneficial effects of AIs on spermatogenesis and fertility have not been reported. Similar to SERMs AIs increase circulating T into the mid-normal range, with an average difference of 7 nmol/L compared to placebo arm [3]. Effect in clinical outcomes such as sexual function, bone parameters, muscle strength, and metabolic outcomes have not been adequately evaluated to date. Effects of AIs on sexual function have been evaluated by three small short-term placebo-controlled RCTs [30–32]. None of the studies reported an improvement in sexual function. While this may have been due to lack of power, the findings are consistent with evidence that oestradiol plays a role in sexual function in men. Three RCTs [32–34] evaluated the effect of AIs on body composition, lipids, and muscle strength. None of them showed any difference in fat or lean mass and lipids in the AI arm as compared with placebo. Given the profound reduction of circulating oestradiol, detrimental effects of AIs on bone health are a potential concern. While two small RCTs did not report an effect on bone density [32, 35] the largest RCT (n = 69) using anastrozole reported a significant reduction in lumbar spine bone mineral density (BMD) at 52 weeks compared to placebo (change from baseline BMD: −0.020 ± 0.005 vs. 0.009 ± 0.006 for anastrozole and placebo group, respectively; $P = 0.0014$) [34]. At present, the available data do not support a role for AIs in the treatment of men with lowered T, despite their ability to increase circulating T levels [3]. However, the limited available evidence is not sufficient for drawing conclusions on their clinical utility, and further studies are required.

Conclusions

The optimal treatment of adult hypogonadism should be based on the clinical context, treatment availability, and individual patient needs and expectations. In the majority of cases, T substitution represents the best treatment. The use of transdermal T preparations and long-acting injectable T undecanoate have become the most popular forms of the replacement, providing assured efficacy and safety. When fertility is required, in the case of secondary hypogonadism, the use of gonadotrophins is appropriate and quite successful. The unlicensed use of antioestrogens in the management of male hypogonadism is not supported by good evidence on efficacy and carries concerns regarding long-term safety.

10.4.3 Induction of Spermatogenesis by Gonadotrophin Treatment

Michael Zitzmann

Introduction—General Principles

Testicular dysfunction often compromises both production of testosterone and spermatogenesis. These functions are dependent on

gonadotropin action in men, with luteinizing hormone (LH) stimulating testosterone production in Leydig cells and follicle-stimulating hormone (FSH) supporting spermatogenesis by stimulating Sertoli cell function (see Chapter 10.1.1). Testicular disorders, causing primary hypogonadism, do not present a condition in which a therapy with gonadotropin-releasing hormone (GnRH) or gonadotropins is an option to induce spermatogenesis. Rather, morbidities with impaired secretion of GnRH (tertiary hypogonadism) or lack of production of gonadotropins (secondary hypogonadism) in the presence of an intact, yet unstimulated testis, present an option for the therapy with these hormones [1–4].

Mutations in a large set of genes causing the secondary and tertiary hypogonadism have been reported [5, 6], but also other, prepubertal or postpubertally acquired pathologies of the pituitary and hypothalamus can give rise to a similar a clinical picture (see Section 2, 'Pituitary and Hypothalamic Diseases').

Hypogonadism is usually treated with replacement of testosterone to correct androgen deficiency. However, in hypogonadotropic hypogonadism (HH), it is also possible to achieve fertility as well, by temporarily switching testosterone treatment to gonadotropins: human chorionic gonadotropin (hCG) in combination with FSH (purified urinary FSH or recombinant human FSH [rhFSH]) or, alternatively, pulsatile GnRH in case of tertiary hypogonadism [7–13]. Once paternity has been achieved, men should switch back to more convenient and cost-effective testosterone replacement, unless men wishing to father a second child within a short time frame.

Hormonal treatment designed to achieve fertility in hypogonadotropic hypogonadal men usually do not increase sperm counts into the normal range (sperm concentration ≥15 mill/ml or a total sperm count ≥38 mill/ejaculate as per current World Health Organization definitions). Normalization of sperm counts is not necessary to achieve fertility. In a study of 24 men with IHH receiving gonadotropin therapy, 71% of a total of 40 initiated pregnancies were conceived with sperm concentrations ranging from 1 to 20 mill/ml [14]. Similar results were seen in men with IHH receiving pulsatile GnRH combined hCG/hMG therapy [15, 16]. The length of treatment required to induce spermatogenesis and achieve fertility (ranging from a few months to several years) depends on cofactors discussed next [17].

Spermatogenesis can be induced even in hypogonadotropic patients with a very small testicular volume (of less than 3 ml), but this may require treatment for 18–24 months [15, 16, 18]. During therapy, testicular volume can be monitored carefully by ultrasound sonography, in order to detect subtle increases, which precede the first appearance of sperm [19].

A review of 42 patients with HH reported that a history of surgically corrected testicular maldescent (uni- or bilateral) hampers spermatogenesis and requires a longer course of treatment, but again, this does not preclude fertility. This is especially the case in unilateral maldescent, but there are also reports of men with previous bilateral cryptorchidism achieving paternity with gonadotrophin treatment. On average, patients with unilateral maldescent required 5 months (range 1–16 months) and patients with bilateral maldescent required 13 months (12–22 months) of treatment until induction of spermatogenesis, that is appearance of sperm in the ejaculate. In comparison patients without a history of maldescent required 4.5 months of treatment (2–18 months) [16, 17]. Similar findings have been reported in other studies [20–24]. Since induction of spermatogenesis may take 2 years or occasionally even longer, men with HH desiring paternity should plan well in advance to initiate timely treatment. In repeatedly treated patients, stimulation of spermatogenesis tended to be faster, leading to a reduced time to pregnancy [16]. In one study [25], 75 men with idiopathic hypogonadotropic hypogonadism (IHH) (with 72 desiring fertility) were treated at two academic andrology centres for a total of 116 courses of therapy from 1981–2008; semen analysis and testicular examination were performed every 3 months. A total of 38 men became fathers, including five through assisted reproduction. The median time to achieve first sperm appearance was 7.1 months (95% confidence interval [CI] 6.3–10.1) and for conception was 28.2 months (95% CI 21.6–38.5). The median sperm concentration at conception for unassisted pregnancies was 8.0 m/ml (95% CI 0.2–59.5). Multivariate correlated time-to-event analyses showed that larger testis volume predicted faster induction of spermatogenesis and unassisted pregnancy. In general, advanced age was a negative predictor, but a definitive threshold in terms of 'too old age' does not seem to exist.

It has been recently shown that the underlying pathology strongly influences the treatment response in HH. A history of puberty was a predictive marker for successful of gonadotropin substitution, while, for example patients with Kallmann syndrome had lower chances for testicular growth and they also had lower sperm output [17].

The induction of fertility in men with secondary or tertiary hypogonadism is highly effective but obviously needs patience in subgroups with unfavourable confounders [17, 19, 26]. Of note, recent evidence suggests that central hypogonadism may be a reversible condition in up to 10% men [27], and should be considered in men experiencing testicular growth despite testosterone treatment. In such men, gonadotropin treatment to induce spermatogenesis or testosterone replacement may no longer be necessary; however, these men require periodic clinical monitoring, as the gonadal axis recovery may only be temporary.

Gonadotropin Therapy

Gonadotrophin therapy is effective in promoting fertility in patients with secondary as well as tertiary hypogonadism. Historical hCG and hMG, both purified extractions from urine was used. In contemporary practice, however, purified urinary FSH and recombinant human FSH have replaced hMG in most countries [19, 28].

Pulsatile GnRH Therapy

In general, GnRH therapy is not frequently used since gonadotrophin therapy (see next) is successful in both secondary and tertiary hypogonadism. Pulsatile GnRH delivery is more expensive and demanding and not generally available except in the few centres with a research interest in GnRH physiology [29].

Treatment with GnRH requires subcutaneous pulsatile application using a portable pump via a butterfly needle placed in the abdominal wall and changed every 2 days. The dose usually ranges from 5 to 20 μg/120 min (corresponding to 100–400 ng/kg body weight/120 min). Low-dose pulsatile GnRH therapy (2 μg/150 min) may

be tried but is commonly not sufficient to elicit a pituitary response [30]. The induction of spermatogenesis is evidenced by the appearance of sperm in the ejaculate. Spermatogenesis (with counts ranging from 1.2–15.3 mill/ml) was achieved after an average of 4 months of treatment, as shown during GnRH substitution in patients with idiopathic (i.e. tertiary) HH or Kallmann's syndrome [16].

Similar results have been demonstrated in other studies [21, 31–33]. Despite low sperm counts, pregnancies can be achieved, the duration until conception being on average 6–7 months. During pulsatile GnRH treatment testicular size increased significantly, from an initial mean size of 6.8 ± 2.2 ml to 14.9 ± 3.2 ml after 5–12 months of treatment [16].

Generally, GnRH therapy is successful in inducing virilization and spermatogenesis in tertiary hypogonadism. However, a small subset of tertiary IHH men usually those who showed a complete absence of prior pubertal development (presumed GnRH receptor gene defects), does not achieve a satisfactory response to GnRH [34].

Treatment with hCG/Highly Purified Urinary Human FSH (Urinary-hFSH)

Improved purification methods have provided highly purified urinary FSH with enhanced specific activity in comparison to hMG (10 000 IU/mg of protein vs. 150 IU/mg of protein for hMG) [35].

In 14 prepubertal males with isolated HH or panhypopituitarism (i.e. secondary hypogonadism), complete virilization was achieved in all patients; in seven of eight patients willing to provide ejaculates spermatogenesis was achieved [36]. The subcutaneous application makes self-administration feasible: in 60 men with different forms of HH (16 with Kallmann syndrome, 19 with IHH, 25 with hypopituitarism) highly purified urinary FSH (150 IU thrice/week) and hCG (2500 IU twice/week) were administered. Results were comparable to other studies and the treatment was well tolerated [19, 37].

Treatment with hCG/Recombinant Human FSH (rhFSH)

rhFSH has advantages over urinary preparations in terms of purity, specific activity, consistent composition, and constant supply. Multiple dose pharmacokinetics showed an elimination half-life of 48 ± 5 h and demonstrated that serum FSH increases in a dose-dependent fashion. No intrinsic LH activity was detected [38–40].

Early case reports suggested rhFSH effectiveness in inducing spermatogenesis in HH [15, 41] in combination with hCG-treatment.

In a study of ten men with HH due to hypothalamic or pituitary disorders, combined therapy with recombinant FSH (150 IU s.c. thrice/week) and hCG (2000 IU 2–3 times/week), seven had evidence of spermatogenesis after a median of 6 months. Five achieved a sperm output of more than 1.5 mill/ml. Mean testicular volume increased by 4.2 ml. Three pregnancies were achieved during FSH treatment. Its efficacy is comparable to urinary FSH in restoring normal fertility in men with gonadotropin deficiency [19, 42].

A combined analysis of data from four studies using rhFSH/hCG to induce spermatogenesis in men with HH (n = 100) revealed that spermatogenesis could be achieved in 68 men after a maximal duration of treatment of 18 months [43].

Table 10.4.3. Modern modalities of gonadotropin substitution therapy in men to achieve spermatogenesis and maintain androgenicity

Substance	Form of application	Dosage
GnRH pulsatile	Subcutaneous by minipump	5–20 µg/Pulse every 2 h
or alternatively		
Human chorion-gonadotropin (hCG)	Subcutaneous or intramuscular	1500–3000 IE 2 2 to 3 times per week depending on testosterone levels achieved
in combination with		
Highly purified or recombinant FSH	Subcutaneous or intramuscular	150 IE 3 ml 3 times per week

hCG preparations are only approved for i.m. application, however, it long clinical experience that a s.c. administration of hCG-preparations is therapeutically very effective and safe. But this is, strictly speaking, an off-label use.

There is no evidence of any significant difference in terms of various clinical outcomes between GnRH and gonadotrophin therapy in hypogonadotropic patients seeking fertility. A study with 36 patients with tertiary hypogonadism (IHH or Kallmann syndrome), comparing GnRH (n = 18) with gonadotrophin (n = 18) therapy, reported no significant difference in effectiveness with respect to sperm counts. A 2-year comparison including 16 patients showed no advantage of either therapy concerning acceleration and/or enhancement of testicular growth, onset of spermatogenesis or increment of sperm output [31].

Conclusion

Gonadotropin substitution therapy is highly effective in men with HH in achieving fertility. See Table 10.4.3.

Practical Relevance

- In tertiary or secondary hypogonadism, fertility and androgenization of patients can be achieved by administration of gonadotropins. A rarely used alternative method is pulsatile GnRH application in tertiary hypogonadism.

10.4.4 Benefits of Testosterone Treatment

Shehzad Basaria and Thiago Gagliano-Jucá

Introduction

Male hypogonadism is a clinical syndrome that arises from disruption of the hypothalamic–pituitary–testicular axis resulting in failure to produce physiological concentrations of

testosterone and/or normal production of sperm [1]. Primary hypogonadism results from testicular dysfunction, while secondary hypogonadism arises due to disease or dysfunction of the hypothalamus and/or the pituitary. In primary hypogonadism, serum concentrations of gonadotropins are increased, testosterone concentrations are decreased (hypergonadotropic hypogonadism), and spermatogenesis is impaired, with impairment of spermatogenesis generally greater than that of testosterone production. In secondary hypogonadism, testicular testosterone secretion and spermatogenesis are similarly impaired, but concentrations of gonadotropins are low or inappropriately normal (hypogonadotropic hypogonadism) [2].

Men seek consultation in the clinics typically as a result of symptoms and signs related to low serum testosterone levels, although some men might present with infertility as their chief complaint. Testosterone is produced by the Leydig cells of the testes and is the predominant androgen in men; it is essential for virilization and maintenance of the male phenotype. As a result, prepubertal onset of androgen deficiency results in small testes and micropenis, high-pitched voice, eunuchoidal habitus, gynaecomastia, decreased body hair, and low libido [2]. If the onset is post-pubertal, size of the phallus, body proportions, and voice remain normal; these patients may present with gynaecomastia, reduced hair growth, low libido, and erectile dysfunction [1, 2]. Additionally, as testosterone has several non-reproductive functions, which include impact on bone mass, body composition, muscle strength, erythropoiesis, and mood, men with low testosterone may present with low bone mass, reduced muscle strength, unexplained anaemia, and decreased energy [1, 2].

Even though randomized trials of testosterone replacement in men with organic hypogonadism are few (it is unethical for these patients with profound androgen deficiency to be randomized to a placebo arm), agreement exists—on the basis of clinical experience and open-label trials—that testosterone replacement therapy (TRT) is associated with beneficial effects. This statement on accepted efficacy of TRT applies only to classic/organic hypogonadism, and must not be extrapolated to the age-related decline in testosterone levels, also known as 'late-onset hypogonadism' or 'age-related low testosterone'. Testosterone levels peak in the second and third decade of life and then gradually decline (in some men) with advancing age without a clear inflection point [3–6]. The age-related decline in testosterone levels has been associated with defects at all levels of the hypothalamic–pituitary–testicular axis, and the trajectory of this decline is influenced by body mass index (BMI), comorbid conditions, medications and genetic factors [7–9]. In the European Male Ageing Study (EMAS), three sexual symptoms (poor morning erection, low sexual desire, and erectile dysfunction) were associated with testosterone levels below 11 nmol/L (317 ng/dl) or free testosterone levels below 220 pmol/L (63 pg/ml) [6]. Men defined as having late-onset hypogonadism by these criteria tended to be older and have a higher BMI, lower muscle mass, lower bone mineral density (BMD), lower haemoglobin levels, and slower gait speed, which suggests that men with late-onset hypogonadism have end-organ deficits similar to those observed in patients with organic androgen deficiency [9, 10]. Nonetheless, randomized trials of TRT in men with late-onset hypogonadism have shown modest benefits at best. Furthermore, long-term safety of TRT, particularly its impact on cardiovascular disease and prostate cancer risk, remains unknown. Therefore, testosterone treatment for age-related low testosterone is not approved by the American Food and Drug Administration (FDA) and remains 'off-label'. Here we discuss the data on the efficacy of testosterone treatment in both organic hypogonadism (most studies included younger men but some also included middle-aged and older men with organic hypogonadism) and in men with purely age-related low testosterone (Figure 10.4.4.1 Online-only).

Benefits of Testosterone Replacement

Sexual Function

Hypogonadal men experience fewer sexual thoughts and spontaneous erections, and have lower overall sexual activity than eugonadal men [11]. However, hypogonadal and eugonadal men have similar erectile responses to visual erotic stimuli [11]. These observations have led to the generally accepted view that testosterone influences spontaneous but not sexually aroused erections, whereas its association with libido remains its most consistent effect.

Testosterone therapy in young hypogonadal men improves many aspects of sexual function, including overall sexual activity, sexual desire, intensity of sexual feelings, sexual fantasies, as well as the number and duration of night-time and spontaneous erections [11–15]. However, TRT does not improve ejaculatory function in hypogonadal men with ejaculatory dysfunction [16]. A meta-analysis of randomized trials showed that TRT improved sexual motivation, number of successful intercourses, erectile function scores, and overall sexual satisfaction in men with baseline serum testosterone concentrations lower than 12.0 nmol/L (356 ng/dl), whereas no effect was seen in men with higher (>12 nmol/L) serum testosterone concentrations [17].

Even though sexual symptoms are consistently associated with low serum testosterone levels in older men, intervention trials have reported inconsistent efficacy in this population. This might be because some trials enrolled men with low-normal or normal serum testosterone levels, and only a few studies investigated the effects of TRT in older men with sexual dysfunction and unequivocally low testosterone levels. Additionally, most earlier trials did not enrol participants based on rigorously defined criteria for sexual dysfunction, thus making it difficult to draw firm conclusions regarding the efficacy of TRT on sexual function. Nevertheless, positive effects of TRT on libido have been reported more consistently than those on erectile function in randomized trials in older men. Indeed, in men older than 60 years with age-related low testosterone, serum testosterone concentrations do not correlate strongly with erectile function, which suggests aetiologies other than testosterone deficiency may be responsible for erectile dysfunction [2]. More recently, however, the Testosterone Trials (TTrials), a coordinated set of seven trials involving 790 men aged 65 years or older with unequivocally low testosterone concentration at baseline (below 9.54 nmol/L (275 ng/dL)), randomized men with at least one manifestation of hypogonadism (decreased libido, difficulty walking, or low vitality) to transdermal testosterone gel or placebo gel treatment for 12 months [18]. The therapy-induced increase in serum testosterone concentration was associated with modest increases in sexual activity (Figure 10.4.4.2a), sexual desire and erectile function [18]. These findings were further confirmed in a recent meta-analysis of randomized, placebo-controlled testosterone trials in adult men with morning

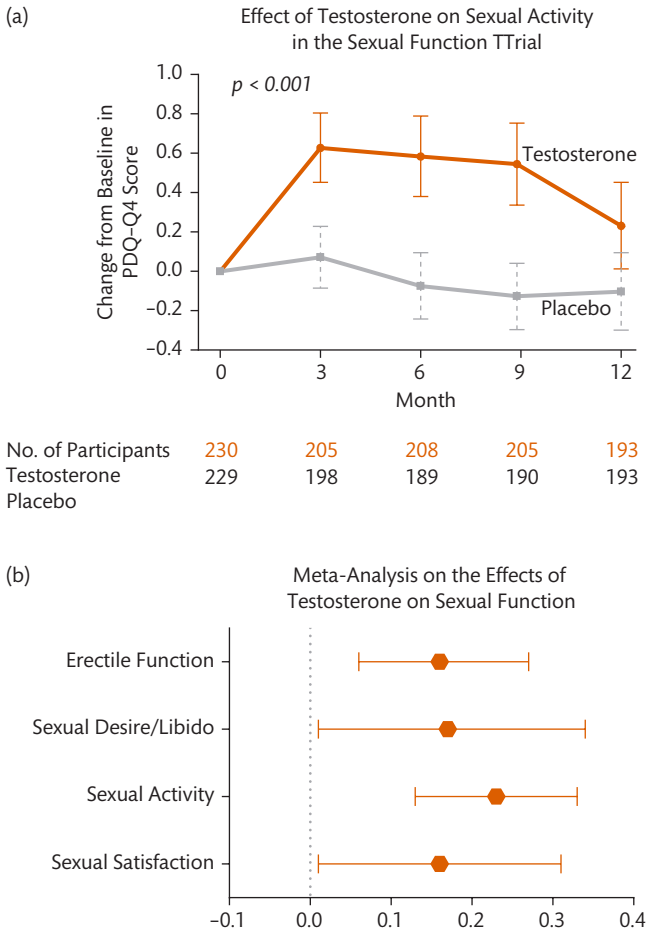

Figure 10.4.4.2 Effects of testosterone replacement on sexual function in hypogonadal men. Panel A shows change from baseline in overall sexual activity with testosterone treatment in older men assessed by the Psychosexual Daily Questionnaire (data presented as means; error bars are 95%CI). Panel B shows the effects of testosterone replacement on various aspects of sexual function summarized in a meta-analysis of randomized testosterone trials in men with low serum testosterone concentrations (≤300 ng/dl) and one or more symptoms of androgen deficiency (data displayed as standardized mean difference and 95%CI).

Panel A Source data from Snyder PJ *et al*. Effects of Testosterone Treatment in Older Men. *N Engl J Med*. 2016;374(7):611–24. Copyright © 2016, Massachusetts Medical Society. Panel B Source data from Ponce *et al., J Clin Endocrinol Metab*. 2018;103(5):1745–54.

testosterone levels below 10.4 nmol/L (300 ng/dl) and one or more symptoms or signs of hypogonadism [19] (Figure 10.4.4.2b).

When men present with predominant complaint of erectile dysfunction and their serum testosterone concentrations are only mildly reduced (generally from a non-organic aetiology), phosphodiesterase-5 inhibitors (PDE-5 inhibitors) might be the first line of therapy as they are more efficacious than TRT based on the magnitude of improvement as assessed by validated questionnaires. In small clinical trials, patients with erectile dysfunction and low serum testosterone concentrations who do not respond to monotherapy with PDE-5 inhibitors, addition of testosterone to PDE-5 inhibitors have shown some benefit [20]. However, in a large randomized, controlled trial, no additional benefit was seen when TRT was added to participants after their dose of sildenafil was carefully optimized [21] (Figure 10.4.4.3 Online-only).

Muscle Mass, Muscle Strength, and Physical Function

Testosterone is a potent anabolic hormone which plays a major role in regulating body composition, maximal voluntary muscle strength and muscle power [22, 23]. In epidemiological studies, low testosterone concentrations are associated with higher fat mass, lower lean body mass, and lower muscle strength [24]. Additionally, men with low testosterone levels are more prone to having worse physical performance than men with normal testosterone levels [24, 25], and are more predisposed to become frail and experience falls [5, 26].

The most noticeable and consistent effect of TRT in hypogonadal men is the increase in muscle mass and maximal voluntary strength [27–29]. In a trial in young hypogonadal men, TRT for 10 weeks induced a mean increase in lean mass of 5.0 kg (8.9%), as well as improvements in chest press (22%) and leg press strength (45%) [27] (Figure 10.4.4.4a). In studies that included adult men of all ages (including older men), modest increments in lean mass (1–3 kg) and muscle strength have been observed [29–31]. Similarly, modest increases in lean mass and muscle strength were seen in trials of TRT in intermediate-frail and frail older men as well as in older men with mobility limitations [32–34].

Despite the consistent observation of improvements in lean mass and maximal voluntary muscle strength, improvements in measures of physical function have been inconsistent or of a small magnitude [30, 32–35]. In a large trial of community-dwelling older men with low to low-normal serum testosterone, TRT for 3 years improved loaded and unloaded stair climbing power [30]. Loaded stair climbing power also improved in a 6-month trial of TRT in older men with mobility limitation and low testosterone [34] (Figure 10.4.4.4b), with a greater proportion of men receiving testosterone (compared with placebo) demonstrating improvement that was considered to be clinically meaningful [33]. However, there was no significant improvement in gait speed [34]. Similarly, clinical trials in older men have also not demonstrated improvements in other measures of physical function, such as the sit-to-stand test, the get up and go test, the 6-minute walk test and the Short Physical Performance Battery score [32].

The conflicting findings relating to the efficacy of TRT in improving measures of physical function in older men were further highlighted by the findings of the TTrials. In the pre-determined analysis of the cohort enrolled in the *Physical Function Trial* of the TTrials (387 men with self-reported difficulty walking or climbing stairs ***plus*** a gait speed <1.2 m/s on the 6-minute walk test), TRT did not result in significant improvements in the primary endpoint of walking distance in men treated with testosterone for 12 months compared to placebo [18, 35] (Figure 10.4.4.4c). In other words, in carefully selected men who had both unequivocal low serum testosterone concentrations and physical dysfunction, TRT was not beneficial. However, a sub-analysis that included all randomized men (including those who did not have physical dysfunction) demonstrated significant improvements in the 6-minute walk test [18]. Additionally, men treated with testosterone were more likely to report that their walking ability had improved [18].

Another functional parameter that has been evaluated in some testosterone trials is aerobic capacity (VO_2peak). In the TEAAM trial, TRT for 3 years in men 60 years and older with low to low-normal serum testosterone concentrations (below 13.9 nmol/L; 400 ng/dl) attenuated the expected age-related decline in aerobic

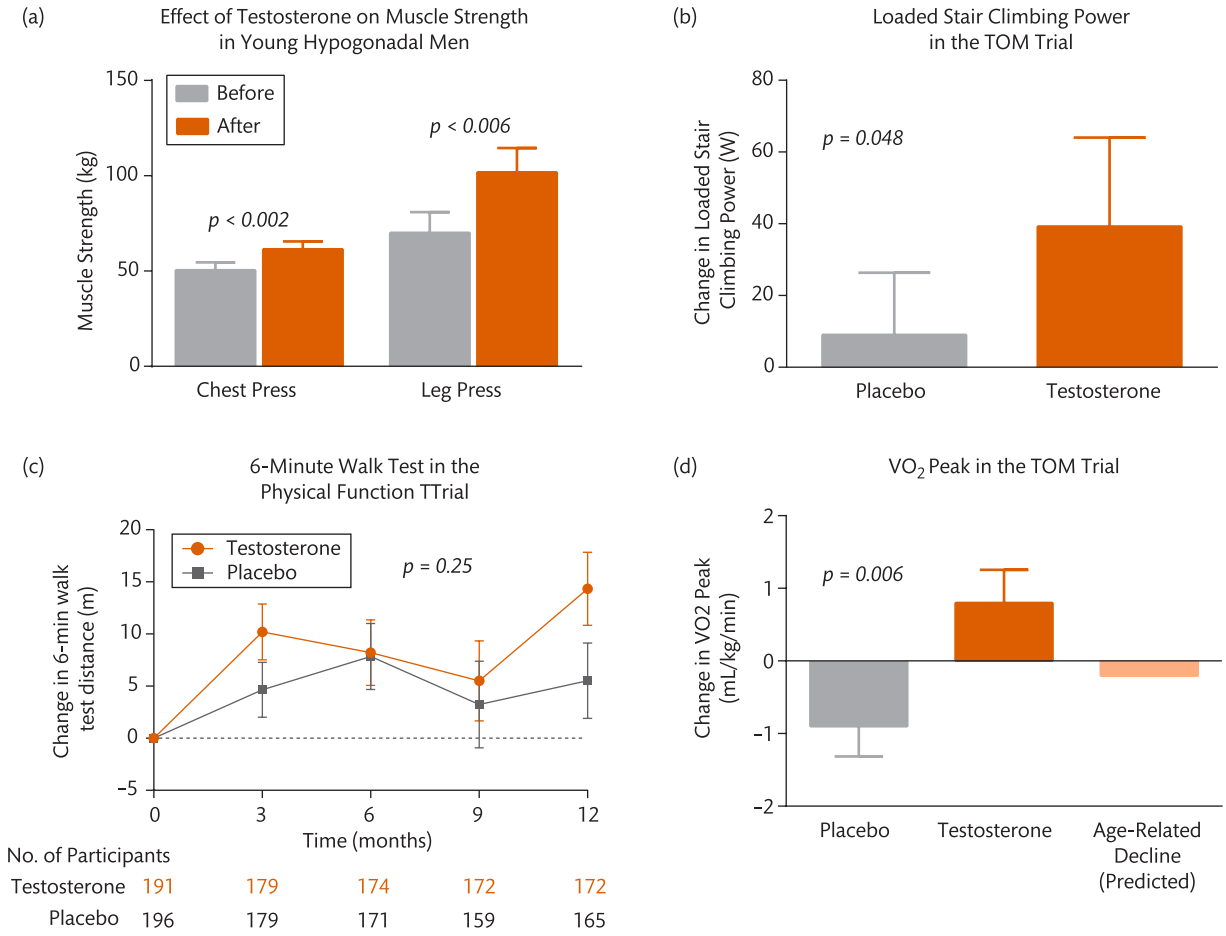

Figure 10.4.4.4 Effects of testosterone administration on measures of muscle performance and physical function in interventional trials. Panel A shows the effects of testosterone replacement for 12 weeks on voluntary maximum strength in the chest press and leg press exercises in young hypogonadal men (bars are means and error bars SEM). Panel B shows the effects of testosterone treatment for 6 months on loaded stair climbing power in older men with mobility limitations (data displayed as means and error bars are 95% CI). Panel C shows the change in walk distance in the 6-minute walk test in older men with mobility limitations participating in the Physical Function Trial of the TTrials (data displayed as means and error bars are 95% CI). Panel D shows mean changes in VO_2peak after 6 months of testosterone treatment or placebo in mobility-limited older men (error bars are SEM). The anticipated age-related decline in the VO_2peak for the 6-month period is shown for reference.

Data in Panel A derived from Bhasin *et al., J Clin Endocrinol Metab*. 1997;82(2):407–13. Data in Panel B derived from Basaria *et al. N Engl J Med*. 2010;363(2):109–22. Panel C adapted with permission from Bhasin *et al., Lancet Diabetes Endocrinol*. 2018;6(11):879–890. Panel D adapted with permission from Storer *et al., J Clin Endocrinol Metab*. 2016;101(6):2562–9.

capacity [36]. However, this effect was modest (a 0.91 ml/kg/min difference from placebo) and its clinical meaningfulness remains uncertain. Similar findings were also seen in older men with mobility limitations [37] (Figure 10.4.4.4d).

The reasons why the gains in muscle mass and muscle power consistently demonstrated in clinical trials of TRT have not translated into improvements in physical function remain unclear. It is conceivable that adjunctive physical exercise training, together with TRT may be necessary to achieve more meaningful improvements in functional performance; this avenue deserves further investigation. In the interim, TRT for the sole purpose of improving physical performance is not recommended.

Bone Mineral Density and Bone Quality

Testosterone has anabolic effects on the male skeleton; it increases bone mass and strength via its direct action on the androgen receptor and indirectly through its conversion to oestradiol [38, 39]. During puberty, increase in the secretion of gonadal steroids stimulate osteoblast activity, markedly increasing BMD [40]. Pre-pubertal androgen deficiency is associated with reduced cortical and trabecular bone mass [40, 41]; similarly, compared to eugonadal men, hypogonadal men also have lower cortical and trabecular bone mass [41]. Additionally, lower bioavailable testosterone levels have also been associated with lower volumetric BMD, bone geometry and bone quality in older men [42]. Indeed, suppression of testosterone production with androgen deprivation therapy for prostate cancer is associated with a rapid loss of bone mass [43, 44].

Testosterone therapy in young, hypogonadal men is associated with improvement in vertebral BMD [31, 45–47]. Small trials in men with unequivocal organic hypogonadism have shown that TRT is associated with an increase of 5–8% in spinal and 4% in hip BMD, with maximum improvement observed by 24 months [29, 31], even though normalization of BMD may not be achieved in this timeframe [31]. Nonetheless, BMD in some hypogonadal men continues to increase even after long-term testosterone treatment [45], supporting a sustained beneficial role of TRT on male skeleton.

The age-related decline in sex hormones has been associated with reduction in BMD and increased risk of osteoporotic fractures [42, 48]. However, earlier clinical trials in this patient population reported inconsistent effects of TRT on BMD and bone quality. A meta-analysis of randomized trials found a significantly greater increase in lumbar spine but not femoral BMD in older men receiving intramuscular testosterone compared to placebo (Figure 10.4.4.5a); interestingly use of transdermal testosterone did not show benefits [49]. More recently, in the Bone Trial of the TTrials, TRT in men with age-related low testosterone showed an increase in volumetric BMD and estimated bone strength on quantitative computerized tomography scan compared to men receiving placebo [50], however, these effects appear modest when assessed with dual energy X-ray absorptiometry (DEXA) scan (Figure 10.4.4.5b), a tool more likely to be utilized by clinicians.

To date, no randomized trial has evaluated the effects of TRT on fracture rate. Future studies should be powered to determine whether improvements in BMD from TRT translate into reduced fracture risk. In the interim, bone-specific osteoporosis therapy with agents that have proven antifracture efficacy should remain the main therapeutic approach for men who are at a high risk for fracture [51].

Mood

Epidemiological studies have demonstrated an association between lower testosterone levels and chronic low-grade depression in men [52, 53]. However, in young and middle-age men with refractory depression, placebo-controlled trials of testosterone have not consistently shown a beneficial effect of testosterone, either in men with total testosterone concentrations below 12.1 nmol/L (350 ng/dl) [54, 55] or in men with normal testosterone levels [56, 57]. In a previous meta-analysis, TRT in hypogonadal men resulted in greater improvements in depression scores than did placebo, an effect that was not seen in eugonadal men [58]. However, in a recent meta-analysis including 27 randomized trials of testosterone administration in hypogonadal or eugonadal men reporting depressive symptoms (determined with psychometrically validated depression scales), testosterone treatment was associated with a significant reduction in depressive symptoms compared to placebo [59]. It is not clear, however, if these improvements are clinically relevant. Importantly, one should not conclude that testosterone treatment induces remission of major depression or that it might improve the response to antidepressants in these patients.

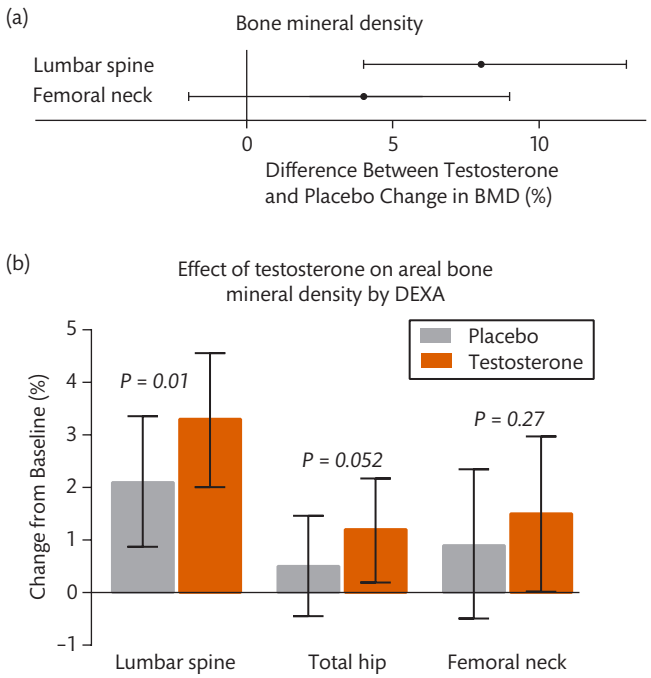

Figure 10.4.4.5 The effects of testosterone therapy on bone health in intervention trials. Panel A shows the effects of testosterone therapy on lumbar and femoral bone mineral density in a meta-analysis of randomized trials. Panel B shows the effects of testosterone replacement for 12 months on bone mineral density of the spine, hip, and femur, as assessed by DEXA scan.

Data in Panel A derived from a meta-analysis by Tracz *et al., J Clin Endocrinol Metab.* 2006;91(6):2011–16. Panel B reproduced with permission from Snyder *et al. JAMA Intern Med.* 2017;177(4):471–9. Copyright © 2017, American Medical Association.

Vitality

In older hypogonadal men with sexual dysfunction, decreased vitality, and/or mobility limitation, higher endogenous testosterone levels have not been associated with improved vitality or depression scores. In the *Vitality Trial* of the TTrials [18], TRT for 12 months did not improve vitality in older men who were carefully selected for low vitality. However, men receiving testosterone had small but significant improvements in mood and lower severity of depression. Other randomized controlled trials in older men have failed to show a clear benefit on vitality and health-related quality of life with testosterone therapy [60, 61]. However, in a randomized trial of adult hypogonadal men (mean age 55 years) with decreased energy or decreased sex drive, TRT for 9 months significantly improved energy assessed by a new questionnaire known as hypogonadism energy diary (HED) [62]. The reasons for these conflicting findings are not clear, but it is conceivable that the currently available tools (questionnaires) are not able to capture changes in energy in a meaningful way.

Cognition

Cohort studies have reported weak associations of testosterone levels with measures of visuospatial cognition and verbal fluency [63], but the findings have not been consistent [64]. Other studies have reported a complex relationship between serum androgen levels and spatial ability [65, 66]. A recent study found an association between the age-related decline in serum testosterone levels with impairment in cognitive function [67]. Additionally, in a meta-analysis of prospective cohort studies of older men, low serum testosterone was associated with increased risk of being diagnosed with Alzheimer's disease [68].

Earlier clinical trials evaluating the impact of testosterone therapy on cognitive function have been small and not well-designed, and reported mixed findings, either in cognitively healthy older men [69, 70] or in older men with impaired cognition or Alzheimer's disease [71, 72]. More recently, a secondary analysis of the TEAAM trial evaluated the effects of testosterone administration for 3 years on multiple domains of cognitive function in a large cohort of cognitively healthy older men; testosterone therapy was **not** associated with improved cognitive function [73]. These findings are similar to those reported by the *Cognitive Function Trial* of the TTrials, in which TRT for 12 months in hypogonadal older men was *not* associated with improvements in any domain of cognitive function [74] (Figure 10.4.4.6).

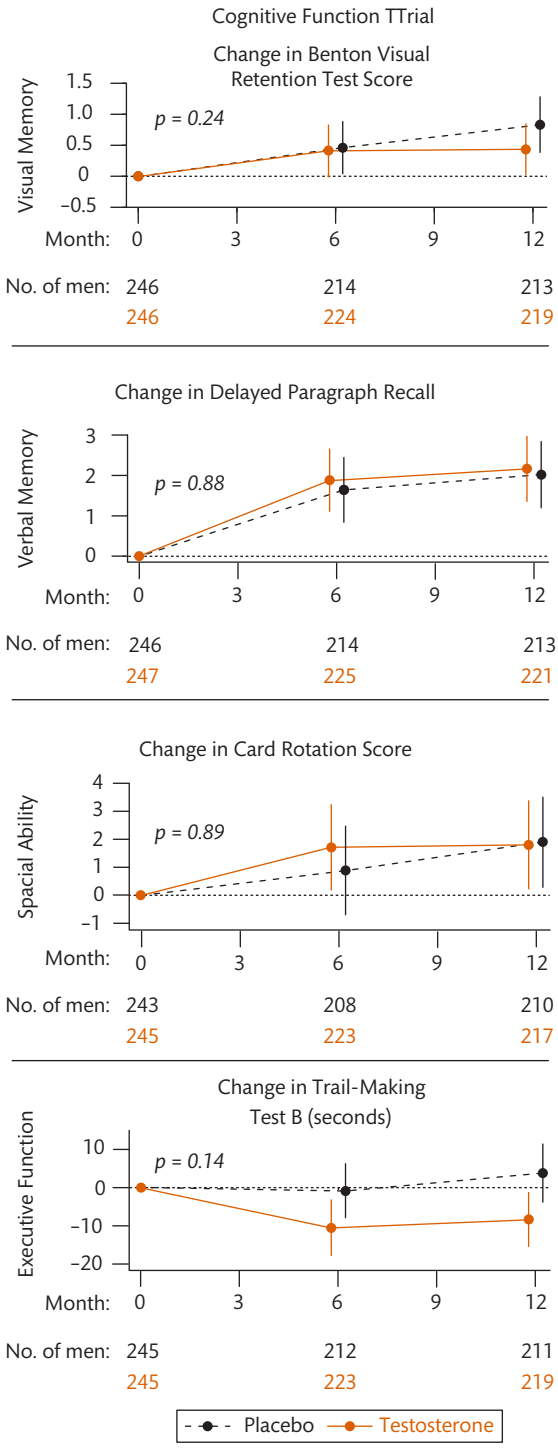

Figure 10.4.4.6 Effects of testosterone therapy on cognitive function in older men. Panels show adjusted mean change from baseline at 6 and 12 months for men with age-associated memory impairment by treatment group in cognition domains in the Cognitive Function Trial of the TTrials.

Source data from Resnick SM et al. Testosterone Treatment and Cognitive Function in Older Men With Low Testosterone and Age-Associated Memory Impairment. JAMA. 2017;317(7):717–727. Copyright © 2017, American Medical Association.

Based on the cumulative data, the current evidence suggests that testosterone therapy does not benefit cognitive function. In fact, TRT with supraphysiological doses may even have a negative impact on cognitive function [75]. These data suggest that testosterone therapy should not be initiated in men solely for the purposes of improving cognition.

Anaemia

Testosterone plays an important role in erythropoiesis. It stimulates erythropoiesis via multiple mechanisms which include (i) increasing iron availability [76–78] via suppression of hepatic secretion of hepcidin [79, 80], the liver-derived master iron regulatory peptide hormone that controls systemic iron homeostasis [81]; (ii) stimulation of erythroid progenitor cells and; (iii) stimulation of erythropoietin (EPO) secretion [77, 82]. Indeed, before the discovery of EPO, androgens were widely used in the treatment of anaemias of various aetiologies [77]. Additionally, erythrocytosis is the most common adverse event observed in men receiving TRT [1] and anaemia is a common adverse effect of androgen deprivation therapy in men with prostate cancer [83]. Moreover, lower testosterone levels are associated with lower haematocrit in men [84] and an increased risk of anaemia [85].

In the TTrials, TRT significantly increased haematocrit and haemoglobin levels in men with anaemia from known causes as well as in men with unexplained anaemia [86]. Furthermore, changes in haemoglobin concentrations in the testosterone group were associated with changes in walking speed [35]. In the TEAAM trial, testosterone-induced attenuation of the age-related decline in aerobic capacity (VO_2peak) was also associated with changes in haemoglobin [36]. These observations highlight the importance of haemoglobin concentrations to cardiovascular capacity and physical function and suggest that testosterone-induced increments in haemoglobin contribute to improvement in some aspects of quality of life in hypogonadal men. However, it should be noted that anaemia alone is not an approved indication to initiate TRT.

Metabolic Health

A large body of evidence suggests that testosterone plays an important role in the maintenance of metabolic health in men. Population studies have shown that higher endogenous serum testosterone concentrations are associated with a lower risk of metabolic syndrome and diabetes [87–90]. Indeed, initiation of androgen deprivation therapy for prostate cancer is associated with worsening of metabolic parameters and increased risk of developing metabolic syndrome and diabetes [91–96]. Similarly, acute interruption of TRT in hypogonadal men worsens insulin sensitivity [97]. Additionally, endogenous testosterone levels were positively associated with insulin sensitivity assessed with hyperinsulinaemic-euglycemic clamp [98]. Data suggests that adiposity modulates the beneficial role of TRT on insulin sensitivity. In a prospective cohort study, men with total testosterone concentration in the lower quartiles had an increased risk of developing diabetes [90]; however, this higher risk was dependent on waist circumference. This finding was later corroborated by a cross-sectional study [99]. Conversely, the association of endogenous testosterone concentrations and risk of incident diabetes was independent of adiposity in other cross-sectional studies [89], suggesting that low testosterone is itself a risk factor for metabolic dysfunction.

Notwithstanding the protective effect of **endogenous** testosterone on male metabolic health reported in population studies, large randomized trials of TRT have reached conflicting conclusions. In the TTrials, TRT for 12 months in older men resulted in modest

improvements in fasting insulin and homeostasis model assessment of insulin resistance (HOMA-IR) compared to placebo [100]. To the contrary, in a trial in older non-diabetic men with low to low-normal serum testosterone with an intervention duration of 3 years, testosterone treatment did not improve insulin sensitivity (assessed by the octreotide insulin suppression test) compared to placebo [101].

Findings from randomized trials evaluating the effects of TRT on glucose metabolism in men **with type 2 diabetes** and low serum testosterone are also conflicting. In a study of diabetic men aged 35 to 70 years with HbA1c ≤8.5% and baseline testosterone ≤346 ng/dl, testosterone treatment for 40 weeks did not improve insulin sensitivity (assessed by HOMA-IR) nor HbA1c compared to placebo [102]. Conversely, in a small trial of diabetic men aged 30 to 65 years with HbA1c ≤8% and hypogonadotropic hypogonadism, TRT for 24 weeks significantly improved insulin sensitivity as assessed by hyperinsulinaemic-euglycemic clamp [103].

In summary, despite the robust epidemiological data supporting a positive impact of **endogenous** testosterone level on metabolic parameters, trials of TRT have yielded conflicting results both in diabetic and in community-dwelling older non-diabetic men. Therefore, the current evidence does not support initiating TRT solely with the intent of improving glycaemic control.

Conclusion

Testosterone therapy in young hypogonadal men with known disease of hypothalamic-pituitary-testicular axis is generally beneficial and safe, and improves several health outcomes. However, the benefits of testosterone therapy in older men with age-related low testosterone levels are modest and mainly limited to sexual function. Despite testosterone-induced increases in lean mass in older men, improvements in physical function have been small and inconsistent. Additionally, even though testosterone treatment has been demonstrated to consistently increase bone density, no trials have evaluated the effects of TRT on fracture rate; TRT is therefore not recommended solely for the purposes of improving physical function or bone health in this population. Similarly, randomized trials in older men evaluating mood and cognition have yielded mixed results. Moreover, the long-term safety of TRT in men with age-related low testosterone has not been determined. Therefore, testosterone therapy is mainly indicated in men with **organic hypogonadism** (most of these men are young but may include men of all ages); as for men with age-related low testosterone levels, TRT might be indicated for **select** men who have sexual dysfunction.

10.4.5 Risks of Testosterone Treatment

Adrian Dobs and Swaytha Yalamanchi

Introduction

Testosterone has increasingly been prescribed for middle-aged and older men with relatively non-specific symptoms that mimic androgen deficiency, many without a formal diagnosis of hypogonadism. It has been speculated that this trend is at least in part due to direct-to-consumer advertising in the United States and the availability of more convenient forms of testosterone replacement such as gels and patches [1–5]. However, there is evidence that since 2013, testosterone prescribing may have declined, possibly due to concerns regarding adverse effects [6].

There is also concern that a substantial proportion of this increase in testosterone therapy is being prescribed for age-related decline in testosterone levels, which is not an approved indication for use [7]. While benefits in young men with organic (classic) hypogonadism are well-established with low frequency of adverse events, limited data on efficacy and safety are available in older men. As will be discussed, adequately powered randomized controlled trials to examine serious adverse effects and key patient-important outcomes are generally lacking. In this chapter we will outline the available data on the effects of exogenous testosterone on erythrocytosis, lower urinary tract symptoms, prostate cancer, and cardiovascular disease risks in older men. The potential beneficial effects of testosterone therapy on sexual function, body composition, physical function, and bone health are discussed elsewhere (see Chapter 10.4.4, 'Benefits of Testosterone Treatment').

Erythrocytosis

The stimulatory effects of androgens on erythropoiesis have been recognized since the early twentieth century [8]. In clinical studies, men were noted to have higher red cell mass than women and animal studies consistently showed that androgens promote haemoglobin synthesis.

With respect to mechanisms, it has been hypothesized that testosterone stimulates erythropoietin (EPO) secretion and recalibrates the set point of EPO relative to haemoglobin by increasing iron utilization for erythropoiesis [9]. It has also been hypothesized that upregulation of the GATA-1 transcription factor (also termed erythroid transcription factor) and GATA-dependent genes could increase EPO sensitivity and stimulate stress erythropoiesis [10]. The association of circulating EPO concentrations with

testosterone in human studies however has been conflicting [9, 11–14]. Hepcidin, which plays a major role in the negative regulation of iron intestinal absorption and release of iron from macrophages, is another mechanism whereby testosterone can promote erythropoiesis via suppression of hepcidin transcription [15]. Aromatization of testosterone to oestradiol may be required in the regulation of hepcidin transcription [9, 16–18].

An increase in haematocrit may be of benefit to men with anaemia and androgens were previously used to treat various forms of refractory anaemia [8]. Data from the Testosterone Trials (TTrials) demonstrated that among men aged 65 years or older with low testosterone levels (defined as <9.54 nmol/L), exogenous testosterone increases haemoglobin levels in those with unexplained anaemia [19]. However, the pro-erythropoietic actions of testosterone increase the potential for an excessive rise in haematocrit with treatment.

Observational data from the Framingham study demonstrated a 35% increase in cardiovascular mortality in individuals with the highest quintile of haematocrit (46–65% in men) compared to the third quintile of haematocrit (42–43%) (odds ratio 1.35, $P = 0.05$) [20]. Elevated haematocrit has also been associated with increased prevalence of atherosclerosis, coronary artery disease, unstable angina, and myocardial infarction, as well as increased risk of venous thrombosis [21].

In a meta-analysis of 19 randomized control trials of testosterone (n = 651 men treated with testosterone and 433 men with placebo), erythrocytosis defined as haematocrit >50% was the most commonly reported adverse effect (OR 3.69, 95% CI 1.82, 7.51) [22]. Coviello *et al.* performed a secondary analysis of data in a testosterone dose-response study in younger (19–35 years, n = 61) and older men (60–75 years, n = 60) who received long-acting gonadotropin-releasing hormone (GnRH) agonist therapy to suppress endogenous testosterone production and then were given one of five weekly intramuscular doses of testosterone enanthate (20, 50, 125, 300, or 600 mg) [11]. Haemoglobin and haematocrit increased in a dose-dependent linear fashion in both groups of men, though increases in these levels were greater in older compared to younger men. The study suggested that testosterone causes a dose-dependent effect of erythropoiesis that may be more pronounced in older men. The type of testosterone formulation may also impact on the risk of erythrocytosis (haematocrit >52%) with the highest incidence reported with injections such as testosterone cypionate and enanthate (wide range of risk reported, 3–18% with transdermal administration and up to 44% with injections) [23–25]. In the TTrials, a rise in haemoglobin concentration to >17.5 g/dl was seen in only 2% of men who were not anaemic at baseline and were treated with testosterone gel, mostly when serum testosterone was elevated [19].

Another systematic review and meta-analysis (2010) including 51 studies (randomized and non-randomized) with transdermal, oral, and intramuscular formulations with a follow up duration ranging from three months to three years reported that the relative risk of erythrocytosis was three fold higher in testosterone treated men compared to non-treated men [26]. In subgroup analyses, intramuscular route and high testosterone treatment doses were associated with greater increases in haemoglobin and haematocrit. However, a recent meta-analysis [27] including three randomized placebo-controlled trials using exclusively transdermal testosterone for 12–52 weeks in symptomatic hypogonadal (testosterone ≤10.41 nmol/L) men, an eight fold higher risk (relative risk: 8.14; 95% CI, 1.87, 35.40; n = 1579) of erythrocytosis (haematocrit >54%) was reported. Patients predisposed to erythrocytosis due to smoking, hypoventilation syndrome, sleep apnoea, living at high altitude, end stage renal disease, and lung disease may be at higher risk of polycythemia [28].

Evidence-based guidelines suggest baseline haematocrit >48% (>50% for men living at high altitudes) should be a relative contraindication to commencing testosterone treatment, as such men may be at higher risk of experiencing a haematocrit rise to a potentially harmful level [29]. Should men with elevated haematocrit be considered for testosterone treatment, further evaluation of possible causes of erythrocytosis and thorough discussion about risk of polycythemia on treatment is recommended before starting. Currently, it is recommended that both testosterone and haematocrit be monitored at 3–6-month intervals for the first year after initiation, and annually thereafter.

If haematocrit exceeds 54% during treatment, testosterone should be withheld until haematocrit normalizes—this may take several weeks or months. Therapeutic phlebotomy is effective in rapidly lowering the haematocrit in the immediate management of erythrocytosis in the context of testosterone pharmacotherapy. Thereafter periodic phlebotomy may allow continuation of testosterone therapy, when clinically indicated.

Venous Thromboembolism (VTE)

VTE is associated with morbidity and mortality [30, 31]. The association of testosterone with VTE risk is unclear. It has been hypothesized that testosterone may increase the risk of VTE via erythrocytosis-induced viscosity; other postulated mechanisms include platelet aggregation, increased thromboxane A_2 concentration in platelets, and an increase in circulating oestrogens [32]. A population-based case control study demonstrated that the risk of thromboembolism was elevated in the first six months of therapy, translating to ten additional VTE events/year above the base rate of 15.8 per 10 000 person-years [33]. In 2014, the FDA required manufacturers to include information on VTE risk on testosterone products based on post-marketing data, noting that VTE may occur even in the absence of an excessive rise in haematocrit. It is possible that men who developed VTE while on testosterone may have an undiagnosed susceptibility for thromboembolism, which becomes unmasked by the testosterone treatment. Glueck *et al.* (2014) reported that among 42 individuals (38 men and 4 women) who developed thrombotic events after starting testosterone treatment (median 5 months), 40 had evidence of thrombophilia-hypofibrinolysis [32]. Men with VTE were more likely to have Factor V Leiden heterozygosity and high levels of both Factor VIII and factor XI compared to controls [32]. Similar results were seen among individuals hospitalized for pulmonary embolism [34]. Currently available data are limited to uncontrolled anecdotal case reports and short-term studies. A meta-analysis of randomized controlled data (mean duration 42 weeks, mean age 47 years) including different cohorts and different formulations/doses of testosterone did not demonstrate an increased risk of VTE with testosterone (Mantel–Haenszel-odds ratio 1.96 [0.75, 5.17], $P = 0.17$) [35]. Screening all patients before starting testosterone for thrombophilia (including but not limited

to Factor V Leiden and prothrombin mutations) is not currently recommended, but a thorough personal and family history of thromboembolic events is important. While known thrombophilia is a contraindication to testosterone therapy in current guidelines, a history of VTE is not because there are too few testosterone-associated VTE events in RCTs to make meaningful inferences [29]; clearly more data are needed.

Prostate

Lower Urinary Tract Symptoms (LUTS)

Androgens play an important role in prostate development and growth; this had led to concerns that exogenous testosterone may increase prostate volume and exacerbate LUTS. LUTS is a term used to describe a range of symptoms due to storage (irritative) and/or voiding (obstructive) disturbances related to problems of the lower urinary tract (including bladder irritation and prostate enlargement due to benign prostatic hypertrophy) common in ageing men. The International Prostate Symptoms Score (IPSS) is a validated measure consisting of seven questions designed to evaluate symptom severity (0–7 mild symptoms; 8–19 moderate symptoms; 20–35 severe symptoms) and response to therapy.

In the TTrials (n = 778 participants), exogenous testosterone for 12 months was not associated with a difference in men with moderately severe LUTS (defined as IPSS >19) [36]. Exogenous testosterone has not been demonstrated to cause *de novo* or worsen mild to moderate LUTS—a consistent finding in systematic reviews and meta-analyses [27, 37, 38]. However, it is important to bear in mind that men with severe LUTS (IPSS score >19) have invariably been excluded from entering testosterone trials; therefore it is unknown whether exogenous testosterone will exacerbate LUTS in this population

Consequently, all guidelines recommend against starting testosterone in men with severe LUTS (AUA/IPSS>19) [29].

Prostate Cancer

The relationships between testosterone and prostate cancer is poorly understood. Currently there is not clear evidence that endogenous testosterone levels are associated with increased risk of prostate cancer [39], nor is there any evidence that exogenous testosterone causes the development of prostate cancer de novo [26].

Traditionally, prostate cancer has been considered to be a contraindication to testosterone treatment, partly on the basis of studies in the 1940s that demonstrated clinical/biochemical improvements with castration therapy and acceleration of prostate cancer progression during testosterone treatment [40]. In the 1980s, the saturation model for androgen action in the prostate was proposed on the basis of androgen receptor binding studies of benign prostate tissue. The model suggests that, at an intraprostatic androgen concentration threshold corresponding to a relatively low concentration of circulating testosterone, prostate androgen receptors may become saturated and are relatively insensitive to further increases in serum testosterone. Thus androgens may have limited ability to stimulate prostate cancer growth [40–42]. However, the saturation model has been criticized as being overly simplistic—it does not account for complexities in the interchange between serum/intraprostatic androgens, nor for the functional heterogeneity and transformation of androgen receptor signalling (modified by transcriptional activators/repressors) in prostate cancer cells. Additionally, as evidenced by the established role of androgen deprivation therapy (medically or surgically) in advanced prostate cancer [43], androgen receptor signalling clearly plays an important role in the growth of metastatic prostate cancer.

The majority of available data on exogenous testosterone and incident prostate cancer are limited to small and prospective studies insufficiently powered to assess prostate cancer risk. It has been estimated that to detect a 30% increase in the incidence of prostate cancer, a trial would require 6000 men in each arm of a randomized placebo controlled trial receiving testosterone treatment for 5 years [44]. A meta-analysis in 2010 of a variety of safety endpoints in 51 randomized controlled trials did not detect an increase in prostate cancer [26]. More recently, Corona *et al.* (2018) identified a total of seven published systematic reviews and meta-analyses on the relationship between testosterone and prostate safety since 2005 [35]. Both parenteral and transdermal preparations were reported to be associated with short-term PSA elevation within the normal range, but no increased risk of histologically positive prostate biopsy or prostate cancer.

Reports of increased prostate cancer in men on testosterone may be related to detection bias. Men on testosterone undergo increased surveillance, thus increasing the risk of detecting subclinical prostate cancer; additionally, testosterone-induced rises in PSA levels may increase the rate of prostate biopsy. Testosterone treatment increase the likelihood of detecting PSA levels above the threshold of 4 ng/ml, raising the risk of prostate biopsy by up to 1.8-fold, and consequently the detection of prostate cancer [22].

Recognizing the importance of minimizing the risks and expense of unnecessary testing, especially the potential harms of prostate biopsy, current guidelines recommend discussing the benefits and risks of prostate cancer screening and monitoring with hypogonadal men aged 55–69 years being considered for testosterone therapy, who have a life expectancy greater than 10 years, in order to reach a joint decision with the clinician on prostate evaluation. In hypogonadal men 40–69 years old who are at increased risk of prostate cancer (such as African Americans or those with a first-degree relative with prostate cancer), prostate cancer screening and monitoring should be offered after discussing the risks. It is not recommended to screen men <40 years (due to low risk for prostate cancer in this age group), nor screening men >70 years (as the risk of dying from prostate cancer if diagnosed is not high). Among men who choose prostate screening/monitoring, PSA and digital rectal exam should be performed before initiating and 3–12 months after starting treatment and thereafter in accordance with local guidelines for prostate cancer screening depending on the age and race of the patient. A urological consultation is recommended if there is a confirmed PSA >4.0 ng/ml or an abnormal prostate on digital rectal examination at any time, and a confirmed increase in PSA to >1.4 ng/ml above baseline during the first year of treatment.

The Endocrine Society classifies men with metastatic prostate cancer and/or breast cancer (considered to be hormone-dependent cancers) at very high risk of serious adverse outcomes and recommends against testosterone in this group. Men with unevaluated prostate nodules or induration, or unevaluated PSA >4 ng/ml (>3 ng/ml in men at high risk for prostate cancer) are classified as

moderate to high risk of adverse outcomes and testosterone is not recommended in these individuals without prior urological evaluation. The Endocrine Society refrained from offering a general recommendation on testosterone treatment in patients with adequately treated organ-confined prostate cancer. However, the American Urological Society states that hypogonadal patients with a history of prostate cancer should be informed that there is inadequate evidence to quantify the risk-benefit ratio of testosterone therapy; in the setting of treated prostate cancer, testosterone therapy should be a negotiated decision based on perceived potential benefit of treatment vs. limited knowledge of potential risks [45].

Cardiovascular System

Multiple studies have described an inverse relationship between endogenous testosterone and adverse cardiovascular outcomes independent of traditional risk factors. The evidence overall suggests that physiologic testosterone levels may be beneficial, while lower testosterone concentrations have been associated with increased cardiovascular risks [46, 47]. However, data are largely observational, and may therefore be influenced by unadjusted variables and/or unknown confounders, making it difficult to designate testosterone as a mediator (as opposed to a risk marker) in the pathway leading to cardiovascular disease. Indeed, obesity and a high comorbid burden may be associated with central suppression of the hypothalamic–pituitary–testicular axis, suggesting that in some men, low testosterone could therefore simply be a biomarker of poor health including cardiovascular disease (see Chapter 10.6, 'HPT Axis Function in Systemic Diseases and Effects of Medications').

Definitive data on cardiovascular risk associated with testosterone use do not exist.

No placebo-controlled randomized control trials in men on testosterone have been designed with primary cardiovascular endpoints and much of our knowledge is derived from trials aimed to explore other outcomes.

One of the first trials to raise concern about adverse cardiovascular events was the Testosterone in Older Men with Mobility Limitations (TOM) trial [48]. This randomized placebo-controlled trial included community-dwelling older men (mean age 74 years) with limitations in mobility, and serum total testosterone levels 3.47–12.15 nmol/L. Although cardiovascular outcomes were not a pre-specified endpoint, the study was terminated early because of a higher frequency of self-reported 'cardiovascular-related' events in the treatment arm. Because of early termination, small sample size, lack of predominance of a single event (events ranged from oedema to myocardial infarction (MI) and death), and small number of cardiovascular events, it is difficult to interpret this data. Two retrospective cohort studies reported an association of exogenous testosterone with an increased risk of cardiovascular disease. The first demonstrated that veterans started on testosterone therapy after coronary angiography had a higher percentage of cardiovascular events at three years compared to men who were not treated (19.9% vs. 25.7%) [49]. The second study compared the incidence rate of acute non-fatal myocardial infarctions in the 90 days post-testosterone prescription with the rate in the one year prior to the prescription [50]. The authors reported 2.9-fold of excess risk of cardiovascular evens in men ≥65 years of age and in younger men with a prior history of heart disease post-prescription as compared to pre-prescription. However, several other studies have not shown an increased cardiovascular risk associated with testosterone treatment [26, 51, 52]. In particular, most meta-analyses have not demonstrated a significant association with adverse cardiovascular events/mortality and major adverse cardiovascular effects [53, 54]. The FDA (31 January 2014) issued a statement, despite the conflicting and inconclusive evidence, to warn against the possibility of increased cardiovascular risk with exogenous testosterone and mandated that manufacturers of testosterone products change their labelling to clarify approved uses and to include information about the possibility of increased risk of myocardial infarction and strokes. In contrast, the European Medicines Agency issued a report stating that the signal for an increased risk of cardiovascular associated with use of testosterone remains weak and inconclusive [55].

An overview of systematic reviews of randomized controlled trials published up to 2016 identified six systematic reviews, each including a meta-analysis, that showed no overall significant association between testosterone and cardiovascular events [54]. Among these six meta-analyses [22, 26, 56–59], two showed an increased risk only in subgroup analyses (one with oral testosterone [58] and the other in men ≥65 years of age in the first year [59]). A subsequent systematic review and meta-analysis included 39 randomized controlled trials and 10 observational studies similarly demonstrated no increase in the risk of myocardial infarction, stroke, or mortality in randomized controlled trials [60]. It has been suggested [54] that in order to detect a true difference in cardiovascular risk in a randomized controlled trial among men receiving testosterone and controls (assuming P value of 0.05 and power of 80%) the study would require at least 17 664 participants in each arm. Despite the obvious difficulties, such a study, mandated by the FDA and led by industry, is planned [54]. In summary, the very low quality of available evidence precludes definitive conclusions on the association between testosterone and cardiovascular adverse outcomes.

In accordance with the aforementioned data, current guidelines acknowledge that there is no conclusive evidence that exogenous testosterone is associated with increased cardiovascular risk in hypogonadal men [29]. However, as a precautionary good clinical practice statement (or opinion), exogenous testosterone is not recommended in those with uncontrolled heart failure, myocardial infarction, or stroke with the past 6 months. Although testosterone has been explored as a potential treatment for heart failure [61], testosterone may cause fluid retention and oedema and use is not currently recommended in men with uncontrolled heart failure [48].

Conclusion

Age-related decline in testosterone levels may be physiologic, due to disorders at one or more levels of the hypothalamic–pituitary–gonadal system or due to gonadal axis suppression by accumulation of age-related comorbidities, including obesity. Testosterone treatment is generally recommended only in those considered to have organic (classical hypogonadism). However, the vast majority of symptomatic older men with low testosterone do not have any identifiable aetiology usually associated with organic hypogonadism. Further compounding the diagnostic difficulties, management decisions in older patients often have to be made on the

basis of limited data on the risks/benefits of testosterone. Due to a possible association with erythrocytosis, testosterone is not recommended in men with an elevated haematocrit at baseline or at increased risk for thrombophilia. VTE risk, if it does exist, may be highest in the first 6 months of treatment. Available data do not suggest worsening of low to moderate LUTS with testosterone, though data are lacking in men with severe LUTS. Testosterone is not recommended in men who have untreated prostate cancer. Among hypogonadal men with cured prostate cancer, the risk of testosterone treatment is unclear. Data with regards to cardiovascular risk are inconclusive, but presently testosterone initiation is not recommended in men with uncontrolled heart failure, myocardial infarction, or stroke within the last 6 months or thrombophilia.

There are no adequately powered randomized controlled trial data on all the aforementioned safety endpoints, limiting our ability to ascertain the true level of risk associated with testosterone. Further research is urgently needed to understand the benefits as well as risks of testosterone in men with age-related hypogonadism.

10.5

Management of Idiopathic Male Infertility

Herman Tournaye and Biljana Popovic-Todorovic

Introduction

According to the World Health Organization (WHO), the definition of infertility is 'the inability of a sexually active, non-contracepting couple to achieve spontaneous pregnancy in 1 year [1]. About 15% of all couples are infertile and seek medical treatment for fertility [2]. Male infertility is wholly or partly the cause in 20–70% of infertile couples [3]. Excellent fertility status in a female partner might compensate for reduced fertility of a male partner. Alternatively, poor fertility in a male partner could hamper or eliminate conception altogether, irrespective of the female partner's fecundity [3].

Epidemiology

In 2010, around 48.5 million couples worldwide were considered to have primary infertility [4]. The WHO surmises that the real prevalence of infertility is probably 2.5 times higher [5, 6]. It is estimated that more than 30 million men worldwide may be infertile [7].

Causes of Male Infertility

Male infertility has traditionally been divided into three major aetiological categories: pretesticular, testicular, and post-testicular. A new clinically based aetiological construct which describes the underlying causes of male fertility in terms of hypothalamic–pituitary axis function, quantitative and qualitative spermatogenesis impairments, and ductal obstruction or dysfunction (**Table 10.5.1**) has been proposed recently [3]. Since increasing numbers of underlying genetic bases for defects in male reproduction are being discovered, this classification can be further subdivided into genetic, non-genetic, and environmental categories (for detailed description of the classification, please consult [3]).

Genetics of Male Infertility

Spermatogenesis can be impaired by gross chromosomal anomalies identifiable by karyotype analysis or by submicroscopic deletions and gene mutations [3]. The gross chromosomal anomalies most commonly include Klinefelter's syndrome (47XXY) which is a direct cause of male reproductive failure in 15% of azoospermic men and frequency is one per 600 men [8] and 46XX male syndrome (de la Chapelle syndrome) is seen in one per 20,000 male neonates and causes azoospermia (see Chapter 10.3, 'Klinefelter Syndrome'). Structural changes that might alter the natural composition and integrity of the Y chromosome are isodicentricism, truncation, or ring formation [9] where the degree of spermatogenesis defect depends on the proportion of cells with the aberrant Y chromosome. Structural chromosomal anomalies such as Robertsonian translocations, inversions, and reciprocal translocations are more commonly seen in oligozoospermic men than in normospermic men, with a frequency of 4–8%, which is ten times more frequent than in the general population [3]. Y-chromosomal microdeletions are the most frequent known molecular genetic causes of severe impairment of spermatogenesis, accounting for around 10% of cases of non-obstructive azoospermia and 3–5% of severe oligozoospermia [3].

Spermatogenesis is one of the most complex cellular differentiation processes in which germ cells transform from spermatogonia to spermatozoa while undergo meiosis [10] (Chapter 10.1.1, 'Male Reproductive Physiology and Spermatogenesis'). Spermatogenesis is thought to be orchestrated by a up to 2000 genes, of which 600 to 900 seem to be exclusively expressed in the male germ cells [11–13]. Accordingly, genetic defects underlying abnormal spermatogenesis have been actively sought, initially through a candidate gene single nucleotide polymorphisms (SNP) [14] and latterly by high-throughput genome-wide association studies (GWAS), comparative genomic hybridization-arrays (array-CGH), and next generation sequencing (NGS).

Table 10.5.1 New classification for male reproductive impairment

Hypothalamic pituitary axis	
Genetic	Congenital hypogonadotropic hypogonadism with anosmia (e.g. Kallmann's syndrome) or normosmia
Non-genetic	CNS malignancy or transphenoidal resection or radiation (ablative);haemochromatosis, sarcoidosis, tuberculosis or fungal (infiltrative); secreting and non-secreting pituitary adenoma (compressive); and exogenous androgen or testosterone use (suppressive)
Spermatogenic, quantitative	
Genetic	Y-chromosomal microdeletions in the AZFa, AZFb, AZFc subregions of the long armAZF region, 47,XXY Klinefelter's syndrome, 46,XX male syndrome, or isodicentric Y chromosomes, partial androgen insensitivity syndrome (mild form), chromosomal structural anomalies (translocation, inversions), X chromosomal TEX11 mutation
Non-genetic	Varicocele (grade 3), previous cytotoxic chemotherapy or radiotherapy, previous testicular torsion leading to loss of testis, bilateral mumps orchitis, bilateral testis malignancy and orchiectomy, and systemic illness (liver or renal insufficiency)
Presumed non-genetic	Idiopathic oligozoospermia or azoospermia and cryptorchidism or testicular dysgenesis syndrome
Spermatogenic, qualitative	
Genetic	Globozoospermia, immotile cilia syndrome, stump-tail syndrome, macrocephalic sperm head, and advanced paternal age
Non-genetic	Oxidative stress or DNA damage
Presumed non-genetic	Phospholipase C ζ deficiency, idiopathic asthenozoospermia, idiopathic teratozoospermia, autoimmune
Ductal obstruction or dysfunction	
Genetic	Congenital absence of the vas deferens with normal renal anatomy
Non-genetic	Previous vasectomy, idiopathic epididymal occlusion, bilateral inguinal hernia repair, ejaculatory duct obstruction, diabetes mellitus with vasal peristaltic deficiency, spinal cord injury, multiple sclerosis, neural tube defects, retroperitoneal lymph node dissection, pelvic surgery, and ejaculatory or erectile dysfunction
Presumed non-genetic	Congenital bilateral absence of the vas with unilateral renal agenesis, Young's syndrome

The results of these research effort to date however have been largely unsuccessful in identifying common genetic factors in male infertility [15]. A few rare single gene defects have been described in association with azoospermia and oligozoospermia [16] and teratozoospermia and asthenozoospermia [17]. One recently identified mutation associated with non-obstructive azoospermia is the X-chromosome meiotic gene *TEX11* [16]. Approximately 80% of the patients with macrozoospermia and globozoospermia are associated with mutations in one single gene, AURKC for macrozoospermia and DPY19L2 for globozoospermia [17]. In addition, four genes have been linked to asthenozoospermia: *CATSPER1, CATSPER2, SEPT12*, and *SLC26A8* but all of the four mutations are rare [14].

Idiopathic Male Infertility

A recent prospective clinical-epidemiological study, conducted in 8518 couples trying to achieve pregnancy for more than 1 year [18], revealed that 20.4% (n = 1737) of men had total sperm numbers below 39 million per ejaculate, the lower limit of normal proposed by the WHO. In 60% of these men, the primary causal factor could not be assigned [18].

In general, 30–40% of male infertility cases have no clear identified cause, a heterogeneous group referred to as idiopathic male infertility [2]. Despite the fact that these men have no history of diseases affecting fertility while physical examinations and endocrine, genetic, and biochemical tests are normal, their semen analysis often reveals non-specific abnormal semen parameters such as 'oligozoospermia' (reduced sperm count), 'asthenozoospermia' (reduced sperm motility), 'teratozoospermia' (reduced percentage of sperm with normal morphology). Combinations are common; most frequently 'oligoasthenoteratozoospermia' or 'OAT syndrome'. It can be seen from Table 10.5.1 that idiopathic male infertility patients are mostly classified in the presumed non-genetic causes. However, it is likely that in the years to come, novel genetic mutations associated with male infertility will be identified as more powerful molecular genetic diagnostic methods such as whole genome sequencing are applied to studies of large cohorts of patients. This could enable rapid identification of many more genetic alterations (including copy number variations) associated with male infertility [14, 16].

Diagnosis

Standardized investigation of the male partner of an infertile couple should start with an accurate medical history focusing on past medical (e.g. cryptorchidism, mumps orchitis, TB, STI, respiratory disease) and surgical history (e.g. orchidopexy, herniorrhaphy), sexual history (including libido, erection, and ejaculation) histories medication usage, dietary supplements, and anabolic steroids exposure, family history of infertility.

Physical examination should include assessment of secondary sex characteristics (distribution of pubic hair, body proportions, voice changes, and the presence of gynaecomastia) and genitalia

examination including penis, testes (position, size, consistency), other scrotal contents (including vas, epididymis, varicoceles, cysts). Enhanced, out-of-proportion upper body muscular development can indicate anabolic steroid misuse. Body weight, body-mass index, and waist circumference should be recorded. Routine semen analysis is the best method to assess male fertility and should be performed according to WHO guidelines [1] (see Chapter 10.2.3, 'Diagnostic Semen Analysis').

Management of Idiopathic Male Infertility

Presently, there is no specific treatment for idiopathic male infertility. Thus, the management of idiopathic male infertility is based on maximizing the chance of spontaneous conception in the couple and/or artificially by assisted reproductive technology (ART).

Various lifestyle factors may contribute to a decrease in sperm quality and male fecundity [19, 20]. Although smoking, marijuana use, high alcohol consumption, obesity have been reported to be associated with reduced sperm quality, a direct negative causal impact remains unproven [19]. In addition, there are no good intervention studies on the possible benefits of lifestyle change on semen quality [20, 21]. Nevertheless, it is generally sound to recommend a healthy lifestyle including diet, exercise, avoidance of smoking and illicit drugs, for infertile men seeking conception [19].

Empirical Medical Therapy for Idiopathic Male Infertility

In the absence of any targeted therapy, a number of empirical drugs, including hormonal preparations and antioxidants have been used off-label to treat infertile men without clear benefits [22]. Hormonal treatments include the use of gonadotropins, aromatase inhibitors and selective oestrogen receptor modulators (SERMs).

Gonadotropins

Gonadotropins are the only class of medications approved for the medical management of male factor infertility in case of hypogonadotropic hypogonadism [22] (see Chapter 10.4.3, 'Gonadotrophin Induction of Spermatogenesis') while their use in the idiopathic male infertility is controversial.

A Cochrane review including six randomized controlled trials involving 456 patients with idiopathic male subfertility treated with FSH [23], and a more recent meta-analysis [26] including 15 controlled clinical studies (614 men treated with FSH and 661 treated with placebo or untreated), suggested a possible beneficial effect on pregnancy rate in the treatment group compared to placebo or no treatment. The limited data of the Cochrane review [23] showed that the live birth rate per couple randomly assigned (27% vs. 0%; Peto odds ratio (OR) 9.31, 95% confidence interval (CI) 1.17 to 73.75, one study, 30 participants, very low-quality evidence) and the spontaneous pregnancy rate per couple randomly assigned (16% vs. 7%; Peto OR 4.94, 95% CI 2.13 to 11.44, five studies, 412 participants, I(2) = 0%, moderate-quality evidence) were significantly higher in men receiving gonadotrophin treatment than in men receiving placebo or no treatment. In the more recent meta-analysis by Santi *et al.*, (2015), there was a significantly higher treatment-related spontaneous pregnancy rate, with an OR of 4.5 (CI: 2.17–9.33) and OR of 1.60 (CI: 1.08–2.37) for pregnancy after ART [24]. However, it must be recognized that both meta-analyses included studies of low to moderate quality, flawed by methodological issues: significant heterogeneity due to differing types of gonadotropins used (hCG, hMG, purified FSH, and recombinant FSH), different treatment duration, and no reporting on live birth rates. The latest systematic review and meta-analysis by Omar *et al.*, (2019) in idiopathic male infertility reiterated that the quality of included studies is low, found some improvements in semen parameters in the FSH-treated patients, but due to methodological flaws it was difficult to draw conclusions on pregnancy and live births [25]. Therefore, based on current evidence, the use of gonadotrophins in the management of idiopathic male infertility cannot be recommended.

SERMs

An empirical therapy for idiopathic male infertility is the use of SERM (which may have mixed/partial agonistic and antagonistic properties in different tissues). The basic rationale is to inhibit the negative feedback of oestrogen on the hypothalamus and pituitary, thereby increasing endogenous gonadotropin secretion in men where these levels are low. In turn, FSH and LH stimulate Leydig cells with the possible increase in testosterone production and spermatogenesis [26]. Clomiphene citrate (CC) and tamoxifen are the most commonly used, CC in doses of 25–50 mg daily and tamoxifen in 10–30 mg doses. Based on low-quality meta-analysis involving 11 trials (where 10 out of 11 were published before 1997) including only few randomized controlled trials (RCTs), small studies, majority not accounting for the female fertility status, the evidence of a beneficial effect of SERMs in idiopathic male infertility is questionable [26]. The use of SERMs for idiopathic male infertility is not recommended.

Androgens

The use of androgens is sadly still being misused for treatment of idiopathic male infertility [27]. Exogenous testosterone has a suppressive effect on spermatogenesis, being a highly effective male contraceptive [27] (see Chapter 10.8, 'Hormonal Male Contraception'). Androgens are contraindicated in men seeking conception [19].

Antioxidants

Contemporary studies have found elevated reactive oxygen species reactive oxygen species (ROS) levels in ejaculated spermatozoa in 30% to 80% of infertile men [28]. It has been postulated, based on *in vitro* studies, that ROS damage the sperm membrane, decreasing sperm motility and its ability to fertilize the oocyte. In addition, ROS can alter the sperm DNA, resulting in the passage of defective paternal DNA on to the conceptus [28].

The use of antioxidants, assessed in 48 RCTs which investigated: magnesium, zinc, folic acid, N-acetylcysteine, coenzyme Q10, vitamins E and C, selenium, docosahexaenoic acid (DHA), various carnitines, and pentoxifylline, was summarized in a Cochrane review on in 4170 subfertile men [29]. Again, the methodological quality of most of these trials is poor and often focused only on

sperm parameters or DNA damage as the main outcome measure, rather than pregnancy rates. Despite suggestions that oral antioxidant therapy might improve seminal oxidative status and possibly sperm motility in infertile men, [30] there is no evidence to support any benefits on pregnancy outcomes.

Assisted Reproduction for Idiopathic Male Infertility

Since there is no evidence that empirical medical treatment of idiopathic male infertility is effective, most infertile couples with significant male factors should be advised to consider evidence-based methods of assisted reproduction techniques [19]. The flow of ART is usually from less invasive, low-cost, low-technology such as intrauterine insemination (IUI) to high-cost, more invasive assisted reproductive technologies of *in vitro* fertilization (IVF) and intracytoplasmic sperm injection (ICSI) [31, 32].

Intrauterine Insemination

IUI is one of the most frequently used fertility treatments for couples with male subfertility. Intrauterine insemination is a technique which is used to increase the number of motile sperm that are morphologically normal at the site of fertilization by injecting a small volume of prepared semen transcervically into the uterine cavity at the expected time of ovulation. The rationale behind this procedure is to bypass the cervix and to bring the semen closer to the oocyte released into the Fallopian tube.

The increasing use of IUI in idiopathic male infertility is mainly the result of the refinement of techniques for the preparation of washed motile spermatozoa, as used in IVF procedures [31]. Retrospective data from the European Society of Human Reproduction report a live birth of 8.9% following IUI for couples with subfertility including unexplained infertility and mild male factor subfertility [33].

The most recent Cochrane review on assisted reproductive techniques for male subfertility [34] compared IUI versus timed intercourse in natural (unstimulated) cycles and found no significant difference between pregnancy rates per woman. Neither were there significant differences between pregnancy rates per couple for IUI with ovarian stimulation versus IUI in natural cycles. However, the quality of studies included in this Cochrane review was low and no firm conclusions could be drawn [34].

In 2013 the United Kingdom's National Institute for Clinical Excellence (NICE) guidelines on fertility treatment advised against routinely offering IUI to subfertile couples but to proceed immediately to treatment with *IVF* after a period of expectant management of two years in women under 36 years of age [35]. It is interesting that the majority of the fertility clinics in the United Kingdom did not adhere to these guidelines [36]. Indeed, the most recent recommendation from a systematic review [35] regarding the treatment of couples with idiopathic male factor infertility with a total motile count (TMC = volume × density × percentage progressive motile spermatozoa/100) of >10 million is to offer at least three cycles of IUI [37]. It is however accepted that IUI is not a treatment option for couples with exceeding poor sperm quality and IVF or ICSI is the most appropriate treatment [19].

IVF/ICSI

Assisted reproductive techniques (IVF and ICSI) aim to increase the probability of fertilization by bringing the spermatozoa closer to or even within the oocyte(s), thereby bypassing some functional deficits of the male gametes. In IVF/ICSI gamete interaction and fertilization take place outside the woman's body.

Conventional IVF involves insemination of the oocyte with a number of processed motile spermatozoa.

In ICSI the rate of fertilization is enhanced by microinjecting one single spermatozoon directly into the oocyte's cytoplasm. The introduction of ICSI in 1992 has been an unparalleled revolutionary treatment of male infertility [38]. Almost three decades later, ICSI is now by far the most used infertility treatment for both male and non-male infertility [39].

When the TMC is too low to perform IUI (post processing TMC below 1 million) or when pregnancy is not achieved after 3–4 IUIs in couples with moderate male factor subfertility with at least 1 million motile sperm after semen preparation, the next treatment option is IVF [19].

The success rates of IVF/ICSI are increasing in comparison with IUI where pregnancy rates have remained unchanged over the years. After three IVF/ICSI cycles, the cumulative live birth rate in the population of patients with male infertility was 74% when the age of the female partner is below 37 years and 57% between 37 and 40 years [19].

An important debated issue is whether ICSI should be preferred to conventional IVF for circumventing male factor infertility. Even if the sperm quality is normal or near normal, ICSI has overtaken conventional IVF in routine clinical practice in an effort to maximize fertilization rates [40]. A meta-analysis including 11 studies with a total of 901 couples (female age range 30–35 years) with 11,767 sibling oocytes showed that the pooled relative risk (RR) of a mature oocyte fertilizing was higher with ICSI than with conventional IVF (RR 1.49, 95% confidence interval [CI] 1.35–1.65.) The pooled RR of total fertilization failure was significantly higher with conventional IVF than with ICSI (RR 8.22, 95% CI 4.44–15.23) [41].

Although there are currently no studies directly comparing either ICSI vs. IUI or IVF vs. ICSI for idiopathic male factor infertility, as shown by the most recent Cochrane review [34], the therapeutic mindset of preferred use of ICSI can be explained by the fact that about five out of ten patients will have their own child within three treatment cycles [42–44].

Conclusions

The diagnosis of idiopathic male infertility, made by exclusion after the standard work-up in the male partner, is more than an assessment of the semen. Its management is closely linked to the fertility status (and age) of the female partner and would often benefit from a multidisciplinary approach, consisting of a urologist or clinical andrologist, gynaecologist, and endocrinologist. Given the assumption that idiopathic male infertility may have a genetic background, the future role of a geneticist will probably become more important as genome-wide carriership screening enter the diagnostic scene. The treatment of men with idiopathic infertility should commence with advocating a healthy lifestyle in an attempt to increase natural fecundity. There is however no

proven benefit of food supplements and oral antioxidant preparations. Based on current evidence, empiric hormonal treatment has no role in unexplained male infertility. ART have gained considerable momentum in the management of idiopathic male infertility: IUI and/or ICSI are increasingly used to shorten time to pregnancy in couples with idiopathic/unexplained male infertility. However, more prospective trials focusing on cumulative live birth rates of these procedures are needed.

Hypothalamo–Pituitary–Testicular Axis Function in Systemic Diseases and Effects of Medications

Gary Wittert, Bu B. Yeap, and Mathis Grossmann

Introduction

Organic pathology of the hypothalamic-pituitary-testicular (HPT) axis resulting in low serum testosterone concentrations (i.e. 'pathological hypogonadism') occurs in under 2.5% of the male population. However, epidemiological studies have shown that with increasing age up to 40% of men have serum testosterone concentrations that are low compared to those found in young healthy males [1]. In many older men low testosterone may be attributable to acute and chronic health conditions external to the HPT axis, medication use and lifestyle behaviours (i.e. 'functional hypogonadism'). This chapter describes the effects of acute and chronic disorders and medications on the HPT axis. The important message to take away is that a low serum testosterone concentration may be a 'barometer' of overall poor physical and psychological health and well-being and when found should prompt assessment for and optimization of ill health rather than the knee-jerk prescription of testosterone.

Undernutrition

Both under- and overnutrition can disrupt the function of the HPT axis. For example, a study undertaken in non-obese men showed that a 7-day period of overfeeding decreased serum testosterone by 6%. Following a subsequent 3-week period of calorie restriction (50% of energy requirements) sufficient to reduce body weight by 7.5% and fat mass by 17.8%, serum testosterone concentrations decreased by a further 11%. After 14 days of refeeding, testosterone increased by 6% on average. Over these three varying food intake periods, there was a 14% decrease, followed by a 41% increase and then a 40% decrease respectively, in serum sex-hormone-binding-globulin (SHBG) [2].

In states of chronic energy deficit, either because food intake is insufficient or physical activity is excessive relative to nutrient intake, there is a positive association between fat mass and serum testosterone that appears to be mediated by leptin. The starvation-associated leptin decline signals energy deficits to the hypothalamus, with subsequent HPT axis suppression intended to limit procreation and promote survival. Restoration of fat mass leads to an increase in both leptin and serum testosterone concentrations [3].

Obesity

Obesity is the clinical condition most strongly associated with lowered testosterone concentrations in men [4].

In men aged 18–55 years with class 1–2 obesity (BMI 30–40 kg/m^2), but who are otherwise healthy, reductions in total testosterone primarily reflect obesity-associated reductions in its circulating

carrier protein SHBG [5]. These men have no clinical evidence of clinical androgen deficiency or of defective spermatogenesis. Men with class 3 obesity (BMI >40 kg/m^2) have reductions in total and free testosterone concentrations with decreased luteinizing hormone (LH) diurnal concentrations and pulse amplitudes compared to lean controls [6]. Despite these changes, studies have not found evidence of clinical androgen deficiency, in these men [5, 6].

The obesity-hypogonadism relationship has subsequently been examined in large population-based studies of middle-aged and older men with varying degrees of comorbid burden that by and large excluded men with classical hypogonadism. These studies have confirmed that obesity is the single most important factor associated with low testosterone, overriding the effects of age and comorbidities [4].

In many of these epidemiological studies, low testosterone was associated with androgen deficiency-like symptoms and clinical markers of androgen deficiency such as sexual dysfunction, reduced lean mass, reduced physical performance, reduced bone density, and anaemia. However, observational studies cannot clarify whether low testosterone is causing these clinical features, or whether instead obesity and associated comorbidities lead to HPT axis suppression and non-specific symptoms and signs that mimic androgen deficiency.

Although variations in circulating testosterone can influence fat mass, current evidence suggests that the effects of obesity on testosterone concentrations are more substantial than the effects of testosterone on adiposity. Weight loss is associated with increases in serum testosterone in proportion to the amount of weight lost. Following bariatric surgery (Roux-en Y Gastric Bypass and Sleeve Gastrectomy) total testosterone, gonadotropins and free testosterone all increase, suggesting a genuine reactivation of the HPT axis [7].

In contrast, changes in circulating testosterone concentrations induced either by testosterone treatment [8] or testosterone deprivation [9] have limited effects on overall body weight, although significant changes in body composition occur. Reductions in body weight with testosterone treatment have been reported in registry studies, this has to date not been demonstrated in randomized controlled trials (RCTs) [8].

Therefore, in obese men presenting with lowered testosterone, after classical hypogonadism has been excluded by an individualized approach, the first line therapeutic approach should be to treat the obesity and its related comorbidities (particularly depression and sleep apnoea), optimize health-related behaviours to induce weight loss and, bariatric surgery (preferably a Roux-en-Y gastric bypass) when indicated for those with intractable and severe obesity [10]. Given the lack of long-term, large RCTs powered for patient-important outcomes and long-term safety, testosterone treatment cannot be routinely recommended for men with obesity-associated non-classical hypogonadism [11].

Type 2 Diabetes and the Metabolic Syndrome

Observational studies consistently show that men with type 2 diabetes (T2D) and/or the metabolic syndrome have modestly reduced (−1.6 mmol/L) circulating testosterone concentrations, with 30–50% of them having low concentrations relative to reference ranges based on healthy young men, after adjustment for age and obesity [12]. However, some studies suggest it is the low SHBG that underlies this relationship [13]. There is a feedforward effect of low testosterone concentrations associated with obesity and the metabolic syndrome so as to increase the likelihood of developing T2D [1]. Androgen deficiency-like symptoms in diabetic men with lowered testosterone are non-specific and their presence is more closely correlated with increasing age rather than diabetes status in itself [14].

Low testosterone concentrations in men with T2D are independently associated with insulin resistance [15]. Experimental evidence suggests that testosterone promotes the commitment of pluripotent stem cells into the myogenic lineage, inhibits their differentiation into adipocytes [16] and regulates the metabolic functions of mature adipocytes and myocytes in ways that reduce insulin resistance. For example, testosterone has been reported to promote lipolysis in male rat adipocytes [17], and to prevent abdominal fat accumulation in men by regulating adipocyte triglyceride uptake and lipoprotein lipase activity [18]. Moreover, testosterone promotes skeletal muscle glucose uptake by activating the glucose metabolism-related glucose transporter type 4 (GLUT4) signalling pathway in skeletal muscle cells [19]. Reducing testosterone concentrations to near zero by androgen deprivation therapy in men with prostate cancer leads to insulin resistance [9], and testosterone therapy reduces fat mass and increases lean body mass [8].

The evidence from randomized controlled clinical trials of testosterone treatment on glycaemic outcomes are inconclusive. A meta-analysis of seven RCTs including 833 men with type 2 diabetes and/or the metabolic syndrome concluded that testosterone treatment may modestly improve surrogate measures of insulin resistance but had no effect on glycaemic control (assessed by HbA1c) or on androgen deficiency-like symptoms [20]. While larger, longer-term studies are needed, current guidelines recommend against testosterone treatment in men with type 2 diabetes and low testosterone as means of improving glycaemic control [11].

Cardiovascular Disease

The presence of cardiovascular disease (CVD) is associated with lower endogenous testosterone concentrations. In the acute setting of hospitalization for unstable angina or myocardial infarction, this reflects a variable but generally moderate suppression of the HPT axis which may be secondary to the acute event, physiological stress and accompanying use of medications such as opioids for analgesia [21]. Testosterone concentration at the time of acute admission appears to have limited utility as a predictor for outcomes and routine measurement of serum testosterone is not recommended in this context. Assessment for underlying hypogonadism in men with symptoms and signs suggestive of androgen deficiency should only be conducted after recovery from the acute cardiovascular event. In one study, endogenous testosterone concentrations had largely recovered when re-assessed 6 months after the acute admission [21].

Testosterone concentrations are reduced in community-dwelling men with prevalent CVD [22–24] by a central mechanism of action reflecting reduction of HPT axis function. Of note, relative reductions in HPT axis function resulting in lower endogenous testosterone concentrations are associated with incidence of cardiovascular events such as stroke, independently of conventional cardiovascular risk factors [25]. However, studies might not have accounted for sleep apnoea, depression, and other confounders.

Testosterone treatment was associated with adverse cardiovascular events in one clinical trial, but other trials found no excess of such adverse events [26–28]. Thus, ongoing uncertainty exists over the effects of testosterone treatment on the cardiovascular system. Whether testosterone treatment has beneficial, neutral, or harmful effects on the cardiovascular system remains to be clarified by the conduct of adequately powered clinical trials (refer to Chapter 10.4.5, 'Risks of Testosterone Treatment').

Chronic Obstructive Airways Disease

In community-dwelling men higher testosterone concentrations are associated with better indices of pulmonary function, independently of age, smoking status, and other covariates [29]. Conversely, men with chronic obstructive airways disease commonly exhibit lower testosterone concentrations compared to men without apparent pulmonary disease [30], which may be the result of chronic hypoxia, inflammation, and to some extent the use of glucocorticoid medication. Of note, men with chronic obstructive airways disease exhibit clinical features that overlap androgen deficiency, particularly loss of lean muscle mass [31]. Further research is required to establish whether testosterone therapy will safely and efficaciously improve clinically relevant health outcomes in men with chronic obstructive airways disease in the absence of pathological hypogonadism.

Chronic Kidney Disease

Serum testosterone is low in men in men with chronic kidney disease associated with the decreasing estimated glomerular filtration rates (eGFR) and lower haemoglobin concentrations. There is an independent relationship between the degree of visceral adiposity and lower testosterone concentrations among men with chronic kidney disease stages 3 to 5 not undergoing dialysis [32]. With end-stage renal disease testosterone concentrations are in the hypogonadal range in 40–60% of men [33]. The most common mechanism is decreased testosterone synthesis in Leydig cells resulting in hypergonadotropic hypogonadism [34] although in some men with significant hyperprolactinaemia (common in renal failure), gonadotrophins may not be elevated. Testosterone concentrations increase rapidly following recovery from renal transplantation [35] particularly in patients under the age of 50 [33]. Haemodialysis is thought not to improve testosterone concentrations, but this may depend on the technique used [36] and in some centres, well-dialysed patients have normal serum testosterone.

Chronic Liver Disease

In men with chronic liver disease, serum testosterone is reduced in proportion to the severity of the disease. Serum testosterone is reduced in up to 90% of men with cirrhosis, and an independent predictor of mortality [37]. SHBG concentrations are increased in moderate to severe disease but are low normal in end-stage disease. Serum oestradiol is increased. Multiple mechanisms contribute to HPT axis dysregulation, including non-specific illness effects, porta-systemic shunting and altered sex steroid clearance [38]. Aetiology-dependent toxins such as alcohol and iron deposition (in haemochromatosis) contribute. Increased oestradiol is thought to mediate gynaecomastia and spider naevi, whereas low testosterone contributes to sarcopaenia and testicular atrophy. In clinical trials, testosterone treatment robustly increases lean mass, but effects on patient-important outcomes are unknown [39]. Successful liver transplantation markedly improves HPT axis dysregulation, suggesting the effects are functional [40].

Cancer

Primary hypogonadism because of toxicity of prior cancer therapy (particularly in childhood) may merit testosterone supplementation to treat symptoms and signs of androgen deficiency. Cancer can also negatively impact on central HPT axis function, particularly in the presence of metastatic or advanced disease and when anorexia and cachexia are present [41]. Lower testosterone concentrations can also reflect use of opioid analgesia and are frequently associated with symptoms such as weight loss, depression, and poor sense of well-being [42]. In an RCT of late stage cancer patients, seven weeks of testosterone therapy at standard replacement dose increased lean body mass (compared with placebo recipients who lost lean mass) and improved quality of life [43].

Androgen deprivation therapy (ADT) for prostate cancer has deleterious effects on metabolic parameters, and body composition [11, 18].

Inflammatory Disorders

Men with hypogonadism are at increased risk of developing autoimmune disorders particularly those affecting the musculoskeletal system [44]. Testosterone concentrations are lower in men with rheumatoid arthritis than in healthy men, but in those who respond to disease-modifying treatment, serum testosterone increase over a 2-year period [45]. Inflammatory bowel disease is associated with low testosterone concentrations in men; the extent to which this is the disease itself or the treatment is unclear [46]. The testosterone-suppressive effects of acute and chronic inflammation have been reported to be mediated by inflammatory cytokines on steroidogenesis in Leydig cells [47, 48].

Thyroid Disease

Thyroid hormones regulate several aspects of testicular function, including steroidogenesis and spermatogenesis [49]. Small studies in adult men with hyperthyroidism have reported that circulating SHBG, gonadotrophins, total testosterone and oestradiol are increased compared to euthyroid controls, whereas the opposite changes occur in hypothyroid men [50]. Both hyper- and hypothyroidism are associated with erectile dysfunction and reduced libido, while premature ejaculation is increased in hyperthyroid men. Delayed ejaculation more frequent in hypothyroid men. These alterations generally normalize once euthyroidism is restored [49]. Reversible abnormalities in spermatogenesis have been described in both hyper- and hypothyroid men. Gynaecomastia is considered to be the consequence of increases in the oestradiol to testosterone ratio as a result of the increased SHBG [50].

Infections

In men with severe septic shock HPT axis function is suppressed with resultant low LH and testosterone concentrations [51]. Older men hospitalized for respiratory tract infections have also been found to have lower testosterone concentrations with either normal or elevated LH [52]. Thus, where pre-existing androgen deficiency is suspected on clinical grounds assessment for pathological hypogonadism should be deferred until after recovery from an acute infection. Of note, impaired HPT axis function with secondary hypogonadism has also been reported as chronic sequelae of central nervous system infections [53].

There has been considerable interest in the effect of human immunodeficiency virus (HIV) infection on the function of the HPT axis [54]. Early studies commented on the ability of HIV manifesting as the acquired immunodeficiency syndrome (AIDS) to involve multiple endocrine systems including the HPT axis with biochemical features of secondary hypogonadism in affected men [55]. Low testosterone concentrations in men with AIDS appeared to correlate with weight loss and with depressive symptom scores [55]. Furthermore, in RCTs involving men with AIDS wasting syndrome, testosterone improved depressive symptoms scores and increased lean and muscle mass with a corresponding improvement in well-being [56]. Other testosterone RCTs in men with HIV and low testosterone concentrations have reported increases in lean and muscle mass and reductions in fat mass [57, 58]. In the current era of highly active antiretroviral therapy, only a minority of HIV-infected men are found to have low testosterone concentrations in the presence of low or normal LH and increased adiposity, with an even smaller proportion having elevated LH [54]. A current guideline suggests consideration of short-term testosterone therapy in HIV-infected men with low testosterone concentrations and weight loss (when other causes have been excluded) to benefit body composition noting that the evidence to support this recommendation was of low quality [59].

Disorders of Sleep

The production of testosterone is dependent on sleep rather than an endogenous rhythm entrained to the light dark cycle. Circulating testosterone begins to increase with the onset of sleep, peaks at the first rapid eye movement (REM) sleep episode and remains stable thereafter until waking. If REM latency is increased, then the rise in testosterone will be slower [60]. Therefore, the effect of sleep restriction on serum testosterone will depend on the timing of occurrence and duration. For shift workers serum testosterone will peak at the time of waking and provided the minimum sleep requirements are met, concentrations will be normal.

Testosterone deficiency is associated with reduced slow-wave sleep and overall sleep efficiency that is improved by treatment with testosterone [60].

Obstructive sleep apnoea (OSA) is not an independent cause of low testosterone after adjustment for the degree of obesity [60, 61] and treatment of OSA with continuous positive airways pressure does not in and of itself increase serum testosterone [62]. There is a widespread belief, reflected in the recent US Endocrine Society guideline for treatment of hypogonadism [59], that untreated sleep apnoea is a contraindication to testosterone treatment. However, recent data have shown that, testosterone replacement therapy in obese men with severe OSA leads to a slight transient worsening of some indices of sleep-disordered breathing that recover after 3–4 months of continued treatment [63]. That said, the prevalence of OSA has increased dramatically in association with the obesity epidemic, and OSA, even if severe may not be associated with subjective sleepiness [64]. When clinically suspected it should be actively excluded even if not considered a contraindication to initiation of testosterone treatment.

From a practical standpoint lower serum testosterone concentrations, poor energy, sexual dysfunction, obesity, and OSA often coexist and are difficult to disentangle. Treatment of OSA by weight reduction and/or continuous positive airway pressure (CPAP) may lead to significant symptomatic improvement without resorting to testosterone replacement.

Psychiatric Disorders

Eating Disorders

Anorexia nervosa is associated with hypogonadism. Although adolescent and young men considered to comprise 10–15% of patients diagnosed with anorexia nervosa [65] the proportion with the disorder is likely to be closer to 30% and many cases are overlooked [66]. Men with anorexia more frequently use exercise as a compensating mechanism as compared to women and may look muscular rather than particularly thin. Presentation may be with a dominant concern about muscle size. Hypogonadism resolves with weight gain, implying it is functional.

Approximately 36% of the patients suffering from bulimia nervosa are male. This is not a condition in and of itself known to be specifically associated with low testosterone.

Major Depressive Disorder and Anxiety Disorder

Compared with healthy men, serum testosterone concentrations are lower in older men with major depressive disorder (MDD) but not in those with MDD and comorbid anxiety [67]. In a longitudinal cohort study of community-dwelling middle-aged and older men, severe depression was associated with lowered serum testosterone [23], and a very large population-based cohort study showed an inverse association of serum testosterone with depressive symptom burden [68]. There is recent evidence that the reduced testosterone in MDD may be limited to a subgroup of atypical depressives [69].

Although symptoms such as dysphoria, lack of motivation, fatigue, and lethargy, and decreased libido that present in organic hypogonadism may improve with testosterone treatment, these symptoms, in the context of hypogonadism constitute a different construct to MDD-associated low testosterone and evidence to implicate testosterone in the pathogenesis of MDD is lacking.

Post-traumatic stress disorder is associated with sexual dysfunction but there are no associations with testosterone although, dehydroepiandrosterone (DHEA) has been reported to be higher in men with post-traumatic stress disorder (PTSD) as compared to healthy men in one small study [70].

Psychoses

Disorders such as schizophrenia are not associated with low testosterone in and of themselves. Antipsychotic medications induce

increases in prolactin and obesity, both of which reduce testosterone concentrations by a central mechanism of action.

Medications

Medications may lower serum testosterone concentrations by mechanisms that impair: hypothalamic gonadotrophic-releasing hormone (GnRH) and/or pituitary gonadotroph LH production, either directly or consequent to increased prolactin; Leydig cell function and pathways of steroidogenesis in the testis; binding of testosterone to the androgen receptor or induce enzymes that metabolize testosterone. Some drugs affect the function of either 5-α reductase or aromatase altering biotransformation of testosterone to dihydrotestosterone and oestradiol, respectively.

Medications (Long acting GnRH agonists, 5-α reductase and aromatase inhibitors and androgen receptor antagonists) specifically designed to inhibit one or more components of the HPT axis for therapeutic purposes are discussed elsewhere in this volume. Table 10.6.1 lists medications that may affect the HPT axis, and the mechanism/s whereby this effect occurs.

Table 10.6.1 Medications and mechanisms of effect on the hypothalamo–pituitary–testicular axis

	Hypothalamic/ pituitary	Steroidogenesis	Degradation CYP3A4	Biotransformation	Androgen receptor	SHBG
Analgesics						
Opioids	Direct ↑ Prolactin			↓ aromatase		
Psychotropics						
^Antipsychotics	↑ Prolactin					
SSRI antidepressants	The effects are unresolved. Some studies suggest a decrease while others no effect.					
Clomipramine	↑ Prolactin					
Lithium	↑ Prolactin					
Antiepileptics						
Phenytoin			↑↑			↑↑
Carbamazepine			↑↑			↑↑
Topiramate			↑↑			
Anti-inflammatory						
Glucocorticoids	Direct	↓↓↓	↑↑			
Antimicrobial						
Azole antifungals		↓↓↓	↓↓

Statins (Simvastatin)		↓				
Diabetes						
Glitazones		↓	↑↑			
Gastrointestinal						
Cimetidine					+	
Other						
Modafinil			↑↑			
Capsaicin			↑↑			

The medications listed are those associated with reductions in serum testosterone concentrations and the mechanism/s by which this occurs. CP3A4 it is an enzyme of the cytochrome P-450 complex involved in the degradation of testosterone.

In practice opioid prescribed for analgesia is the medication most frequently implicated in in low testosterone concentrations with low or normal LH in men [71]. There is a worldwide scourge of overprescribing opioids for chronic musculoskeletal pain [72] and the appropriate management is to withdraw the opioids. Treatment with testosterone has not been shown to affect self-reported pain or opioid dosage [73].

Although associated with major adverse consequences for spermatogenesis (see Chapter 10.4.3), there are limited data relating to the effects of chemotherapeutic agents on serum testosterone concentration in men. In one study [74], 8.8% of adult survivors of cancer treatment during childhood or adolescence had low serum testosterone concentrations; none had been commenced on replacement therapy. Based on the Children's Oncology Group Long-Term Follow-Up Guidelines for Survivors of Childhood, Adolescent, and Young Adult Cancer (COG-LTFU) Guidelines, the risk is greatest with high dose alkylating agents or testicular radiation above 20 Gy. The testis has greater resistance to radiotherapy post puberty. Pubertal status does not affect the risk of hypogonadism associated with chemotherapy. Follow-up should be lifelong. Mild, subclinical Leydig cell dysfunction can become overt due to interaction with any of the disorders described earlier. Treatment with testosterone is beneficial for overt hypogonadism but there is no evidence of benefit from mild or subclinical Leydig cell dysfunction [75].

Glucocorticoids remain widely prescribed and the magnitude of effect to reduce serum testosterone concentration depends dose, duration, and individual patient sensitivity. Long-term treatment with even modest doses of glucocorticoid leads to reduced bone density and muscle mass and increased risk of fracture. Treatment with testosterone has been shown, independent of the starting plasma concentration, to increase muscle mass and strength, reduce fat mass, and improve bone density at the lumbar spine in chronic steroid treated men [76]. To date, however, studies have been small, short-term, and there are no data on fracture outcomes. There has been no trial since 2003 and clearly further study of this neglected area is warranted. Until then, in the absence of contraindications, it is reasonable to consider treatment with testosterone on an individual patient basis.

Antipsychotic medications lower serum testosterone by increasing prolactin. This is best managed wherever possible using antipsychotics with either no or minimal effect on serum prolactin. These include aripiprazole, clozapine, olanzapine, and quetiapine. OSA occurs with substantially increased frequency and severity in people affected by schizophrenia treated with antipsychotics and should be diagnosed and treated. Testosterone treatment is beneficial for men with schizophrenia and hypogonadism and may ameliorate negative symptoms.

Selective serotonin reuptake inhibitors (SSRI) are the medications most commonly prescribed to treat depression. It is unlikely that they have clinically significant effects on serum testosterone concentrations, however they are associated with sexual dysfunction. Those antidepressants that primarily modulate adrenergic (e.g. desvenlafaxine, vortioxetine), dopaminergic (e.g. bupropion) or melatonin (agomelatine) receptor systems attenuate the risk of emergent sexual dysfunction during treatment of depression.

Medications used for the treatment of epilepsy may disrupt the HPT axis either by increasing the degradation of sex steroids by induction of CYP3A4 (e.g. phenytoin, carbamazepine, topiramate) or by increasing SHBG (e.g. phenytoin, carbamazepine). This appears not to occur with newer drugs used for seizure control (e.g. lamotrigine and levetiracetam).

10.7

Management of Sexual Dysfunction

Vincenzo Rochira, Cesare Carani, and Antonio R.M. Granata

Introduction

Sexuality is a complex construct encompassing not only the act of sexual intercourse. but also includes the physiological, behavioural, and relational aspects of human sexual life, which are variously influenced by psychological (e.g. sexual fantasies, desire, arousal, psychosexual orientation, and the choice of the sexual object), as well as social and organic (vascular, nervous, and endocrine) factors [1, 2].

From a male sexual functional point of view, a normal penile erection may be defined as an erection that permits the penetration of a lubricated vagina without additional assistance. Concerning the erectile mechanism, the haemodynamic changes in the penis require a high degree of central and peripheral neurovascular coordinated control and an intact endocrine system [1, 3, 4].

Penile Anatomy

The penis consists of two paired and elongated sponge-like bodies, the *corpora cavernosa*. These are ventrally joined to the *corpus spongiosum*, all of which are covered by a tough fibroelastic sheath, the *tunica albuginea*. The *corpus spongiosum* surrounds the urethra and distally forms the glans [3] (**Figure 10.7.1a**).

The erectile tissue of the *corpora cavernosa* is composed of sinusoidal spaces, also known as lacunae, lined by endothelial cells. The lacunae are surrounded by trabecular tissue, consisting of an intricate network of both smooth muscle cells and fibroblasts joined by collagen and elastin. The trabeculae have both structural and contractile functions [3]. The structural function is provided by the extracellular, fibroelastic component of collagen and elastin; contraction of the smooth muscle component is associated with the flaccid state of the penis while relaxation leads to lacunae engorgement and penile erection (**Figure 10.7.1b**).

Arterial inflow to the penis is supplied by the helicine arteries which branch out from the two deep cavernosal arteries. When the penis is flaccid, the helicine arteries are contracted. During erection arterial relaxation causes an increase in blood flow and a consequent enlargement of the lacunar spaces. The structural elasticity of the trabeculae allows the increase in penile size from the flaccid to the erected state [3] (**Figure 10.7.1b**). Blood drainage from the *corpora cavernosa* is provided by the circumflex and emissary veins which end in the deep dorsal penile vein.

Innervation of the penis comes from the thoracolumbar spinal centre of erection (T12–L2), the sacral spinal centre of erection (S2–S4), the hypogastric plexus, and the pelvic, cavernous, and pudendal nerves [3, 4].

Erectile Physiology

An erection occurs as a consequence of haemodynamic changes in the penile structures induced by integration of one or more central and peripheral neurological signalling events. Erections are mediated by the spinal centres, which can be activated by genital sensory stimulation and by neural pathways from the brain. Normal erection depends on multiple regulatory inputs including psychological, neurological, and hormonal components that are closely integrated and reinforce each other [1, 2, 4] (**Figure 10.7.2**). For example, psychological stimuli (i.e. visual, auditory, olfactory, and internal imagery—imagination/fantasy) increase the sensitivity to reflexive (i.e. tactile) stimuli (**Figure 10.7.2**). *Vice versa*—undesired tactile stimuli (i.e. painful stimulation) might inhibit central psychogenic activity (**Figure 10.7.2**).

Central erotogenic stimulation promotes sexual arousal, a subjective state which stimulates the man to search for sexual stimulation and sexual intercourse [2].

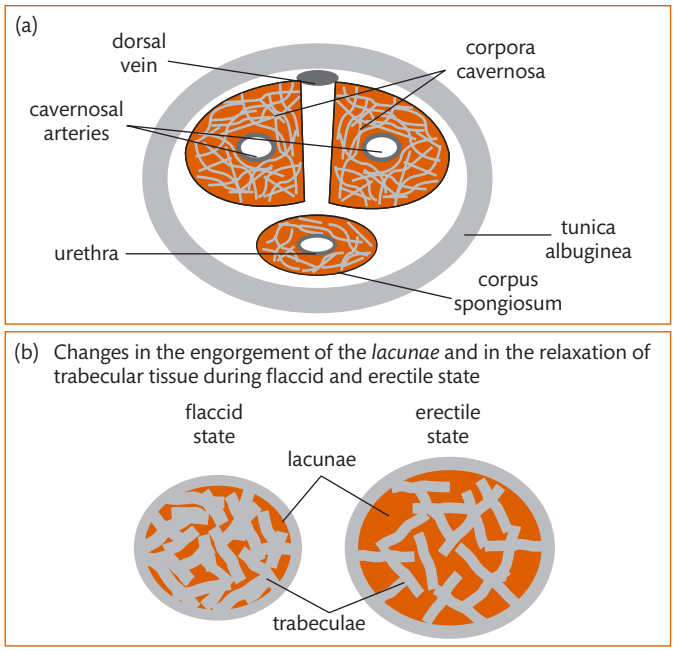

Figure 10.7.1 Schematic representation of the gross penile anatomy (a) and of the different engorgement of the tissue of *corpora cavernosa* and *corpus spongiosum* during the flaccid and the erectile state (b).

The main areas of the central nervous system involved in the promotion of the male sexual response are the limbic system, the preoptic region, and the hypothalamus, while the sympathetic pathway that exerts an inhibitory control on erection corresponds to the sympathetic thoracolumbar spinal erection centre (T12–L2) [1, 2, 4].

In addition to psychogenic erections, direct physical stimulation of the penis and perineal skin induces a reflexogenic erection by activation of the sacral spinal reflex pathway. This results from the inhibition of the thoracolumbar sympathetic centre of erection (T12–L2), a stimulation of the parasympathetic centre of erection (S2–S4), and the activation of both parasympathetic and non-adrenergic non-cholinergic (NANC) pathways [4] (Figure 10.7.3).

Furthermore, sleep-related erections occur during rapid eye movement (REM) sleep; however, the precise physiological mechanism involved in sleep-related erections is not thoroughly understood.

The endocrine system also contributes to penile erection. Androgens are the hormones involved in erectile physiology. Most of the actions of testosterone on the brain seem to be mediated by oestrogens after aromatization [5–7]. Dihydrotestosterone also plays a role on penile erection as suggested by erectile dysfunction as a side effect of 5-α-reductase-inhibitors treatment for benign prostatic hyperplasia and hair loss [8].

Prenatal and perinatal brain androgenization is a prerequisite for normal male sexual function in some species, and androgens are necessary for secondary sexual maturation in mammals [1].

In adult men, androgens are required to maintain sexual behaviour; lack of testosterone frequently produces loss of libido and sexual dysfunction [1, 9]. In hypogonadal men testosterone replacement therapy consistently increases spontaneous sexual interest and sexual arousal thereby facilitating erectile function and increasing sexual activities [9]. Note however that most cases of erectile dysfunction (without a major loss of sexual interest) are predominantly associated with vascular diseases and not testosterone deficiency (see next). Similarly, erections in response to visual erotic stimuli are not affected by the lack of testosterone [10]. In contrast, nocturnal (sleep-related) or early morning erections are androgen-dependent, being impaired in hypogonadal men and restored by testosterone replacement therapy [11].

Local Mechanisms of Erection

Neurological activation or inhibition of penile erection is mediated by modulation of neurotransmitter release in the penile vasculature [3, 12] (Figure 10.7.2). Knowledge of neurotransmitters responsible for the local regulation of erection has recently been extended by

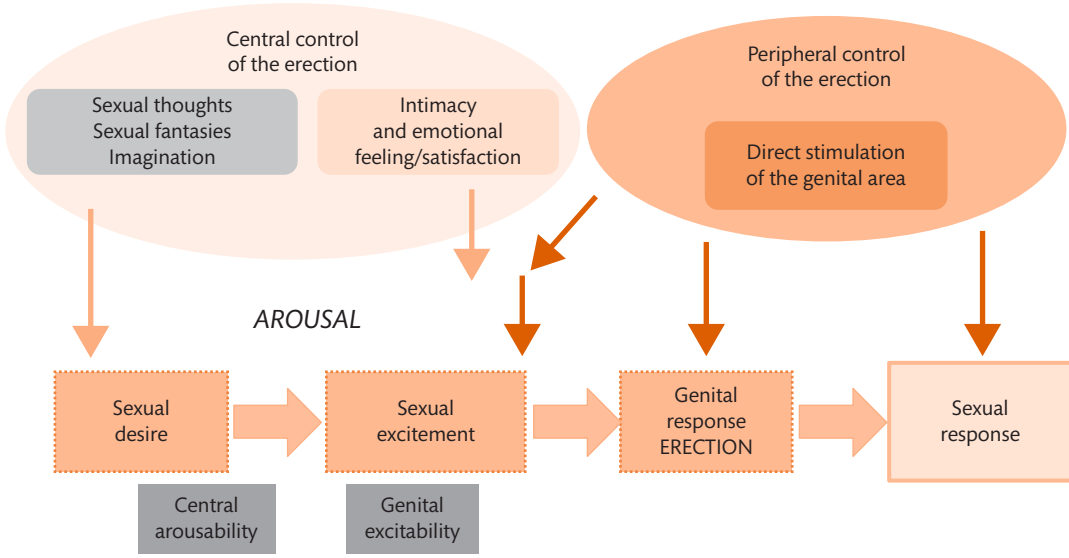

Figure 10.7.2 Mechanisms involved in the central and peripheral control of penile erection during the various phases of male sexual response from initiation to the achievement of a full erection.

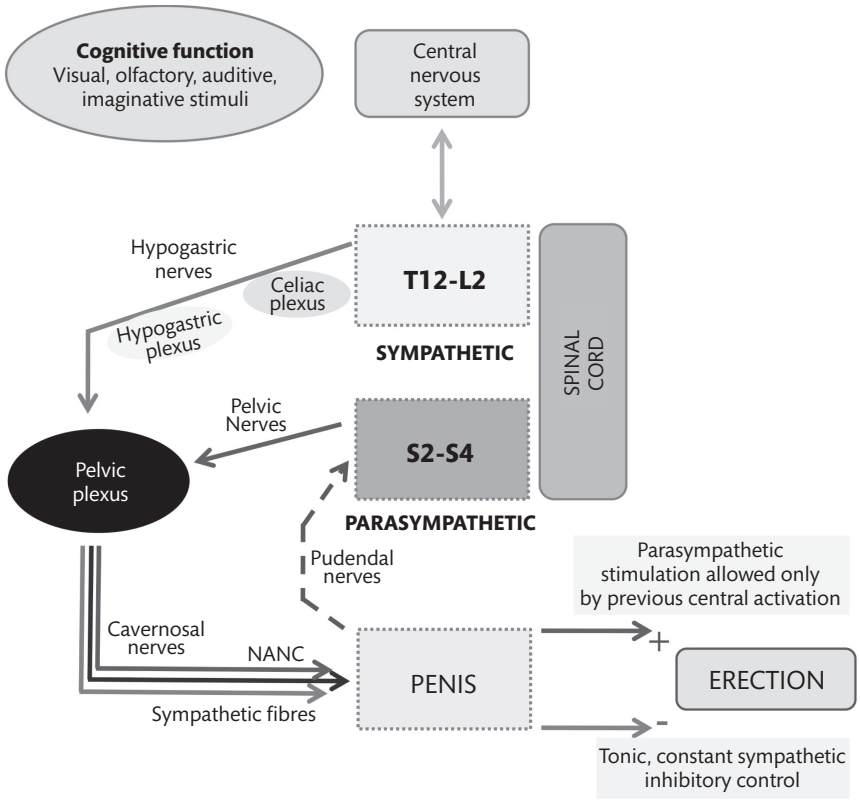

Figure 10.7.3 Central and peripheral nervous pathways involved in the control of erection.
T10–L2: toracholumbar spinal centre; S2–S4: sacral spinal centre; NANC: non-adrenergic-noncholinergic neurons/fibres.

the identification of NANC fibres, which are the terminal effectors of the nervous system in controlling erection [3, 12]. The activation of cholinergic fibres stimulates postganglionic NANC nerve neurons to synthesize and release nitric oxide, which is the principal neurotransmitter involved in the haemodynamic promotion of penile erection [3, 12]. The sympathetic system exerts a constant negative control on erection by inhibiting postganglionic NANC neurons [3, 12]. Nitric oxide is released by both neuronal fibre endings and endothelial cells, but under physiological conditions neuronal nitric oxide plays the dominant role [13].

Nitric oxide is a cleavage product whose synthesis from amino acid L-arginine is catalysed by nitric oxide synthase (NOS). Nitric oxide relaxes the trabecular smooth muscle cells of corpora cavernosa by increasing the synthesis of cyclic guanosine monophosphate (cGMP) via a direct stimulation of guanylate cyclase [3, 12, 13] (Figure 10.7.4). The cGMP activates protein kinase G, which then causes a reduction of transmembrane Ca^{2+}influx, and membrane hyperpolarization. This sequence of events induces smooth muscle relaxation of trabeculae (Figure 10.7.4). Residual cGMP is catabolized by phosphodiesterase 5 (PDE5) [3, 12, 13] (Figure 10.7.4).

Based on animal studies, it has been suggested that testosterone may directly promote erections through the penile nitric oxide pathway by stimulating both neuronal NOS synthesis/release and by modulating PDE5 activity [14–16]. However, the relevance of this work to human erectile physiology is uncertain.

Other substances, including neurotransmitters, hormones, prostaglandins, and other peptides also play a role in the local control of erection. In particular, prostaglandin E_1 and vasoactive intestinal peptide (VIP) relax the smooth muscle, while substance P and prostaglandin F_2-α cause contraction [3, 12]. Prostaglandin E_1 induces smooth muscle relaxation by reducing intracellular Ca^2+ uptake, as a result of the activation of adenylate cyclase and a consequent increase of intracellular cyclic adenylate monophosphate (cAMP), which activates protein kinase A (Figure 10.7.4) [3, 12].

Vascular Response

Erection and detumescence are linked haemodynamic events regulated by smooth muscle relaxation and contraction, respectively. Therefore, the tone of the *corpora cavernosa* smooth muscle is the major determinant in controlling the flaccid or erect state of the penis. The haemodynamic events involved in penile erection are as follows [3, 12, 13]: (1) the resistance of intracavernosal arterioles decreases by relaxation of the trabecular smooth muscle cells; (2) the dilatation of the arterial bed (particularly helicine arteries) increases the arterial flow causing [17] the engorgement of sinusoids and the engorgement of lacunae; (4) these events cause an increase in penile tumescence/rigidity and penile length; (5) the stretching of the poorly distensible tunica albuginea and the expansion of the lacunae activate a veno-occlusive mechanism with reduced venous outflow due to compression of the subtunical and emissary veins [3, 12, 13].

Erectile Dysfunction

Erectile dysfunction had its first official definition in 1993: the inability to attain and/or maintain a penile erection sufficient to

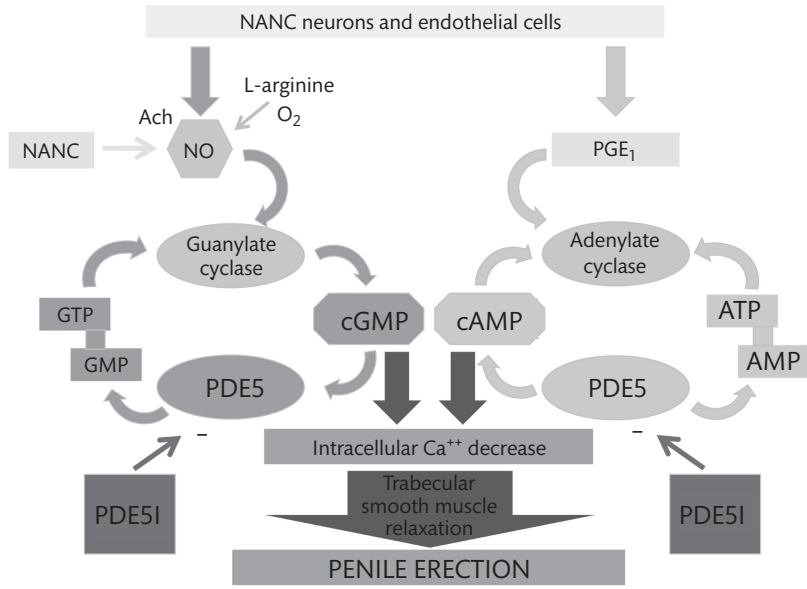

Figure 10.7.4 Signalling pathways mediating the erectile response.

Ach, acetylcholine; O_2, oxygen; NO, nitric oxide; NANC, non-adrenergic-noncholinergic neurons; PGE_1, prostaglandin E_1; GTP, guanosine triphosphate; GMP, guanosine monophosphate; cGMP, cyclic guanosine monophosphate; cAMP, cyclic adenosine monophosphate; ATP, adenosine triphosphate; AMP, adenosine monophosphate; PDE5, phosphodiesterase type 5; PDE5I, phosphodiesterase type 5 Inhibitors; Ca^{++}, calcium.

permit satisfactory sexual performance (Box 10.7.1) [18]. A more recent definition in 2000 [19] stated that erectile dysfunction is the persistent or recurrent inability to attain, or to maintain until completion of sexual activity, an adequate erection.

Erectile dysfunction *per se*, should be differentiated from other aspects of sexual dysfunctions such as loss of libido, decreased spontaneous erections, or disorders of ejaculation, and disorders of orgasm. Loss of libido can be the consequence of both hypogonadism [1, 2, 20, 21] and psychogenic erectile dysfunction [22]; on the other hand, quality of spontaneous (especially nocturnal) erections is related to organic rather than psychogenic erectile dysfunction [23, 24]. It is important to be reminded that erection constitutes only part of the overall multifaceted process of normal sexual function, which also includes psychological, behavioural, and relational components that can contribute to the overall picture of sexual dysfunctions.

Aetiologies and Epidemiology of Erectile Dysfunction

Erectile dysfunction (ED) may be caused by psychological, organic (vascular, metabolic, neurological, hormonal), and iatrogenic disorders [13, 25, 26]. Up until the 1960s, psychological disorders were considered the most frequent cause of erectile dysfunction [26]; at present this is true only in young men; about 70% of men less than 35 years old presenting with erectile dysfunction, the main cause is psychogenic [13, 25, 26]. In middle-aged and older men, organic disorders now account for two-thirds of the causes of erectile dysfunction [13, 26]. In the Massachusetts Male Aging Study, the combined prevalence of minimal, moderate, and complete impotence was 52% in the general population. The prevalence of complete impotence tripled from 5 to 15% between subject ages 40 and 70 years. Erectile dysfunction correlated positively with age, cigarette smoking, depression, diabetes mellitus, and cardiovascular diseases [26, 27].

Among organic causes, vascular disorders are the most frequent [26]; neurological causes occur in 3–10% of the cases [26]. Although hormone abnormalities (e.g. hypogonadism, hyperprolactinaemia, hyperthyroidism, acromegaly) can be detected in 3–5% of patients with ED [9, 13, 26], low T frequently **coexists** with ED in men with chronic diseases (such as obesity, diabetes mellitus, HIV infection, cardiovascular/peripheral vascular disease, and chronic kidney disease) [28–31], rather than being the overriding *cause* of the erectile failure [32].

Although erectile dysfunction may be exclusively of psychological origin, a psychological disorder often arises secondarily to organic erectile dysfunction [33]; therefore, organic and psychogenic erectile dysfunction often coexist in many patients.

Box 10.7.1 Definitions of erectile dysfunction

1993: The inability to attain and/or maintain a penile erection sufficient to permit satisfactory sexual performance [12]

2000: The persistent or recurrent inability to attain, or to maintain until completion of the sexual activity, an adequate erection [13]

Psychogenic Erectile Dysfunction

Psychogenic erectile dysfunction is frequently associated with generalized trait anxiety, situational anxiety (e.g. performance anxiety), relationship conflicts, disorders involving sexuality (psychosocial sexual inhibition, sex-preference conflicts, history of childhood sexual abuse, disorders of sexual orientation), fear of pregnancy, fear of sexually transmitted infections, sexual performance anxiety, fear of erectile failure, and decreased libido [23, 26, 29, 34]. The suggested mechanism in primary psychogenic erectile dysfunction is an activation of the sympathetic nervous

system with increased adrenergic and noradrenergic vasoconstrictive tone [3, 13, 26, 33].

Psychogenic erectile dysfunction can also occur in primary psychiatric diseases, such as depression [24, 34]. Loss of libido is an important symptom of depression, which may lead secondarily to erectile dysfunction and is possibly worsened by antidepressant drug administration [23, 34]. Accordingly, serotoninergic antidepressants may lead to mild to severe sexual dysfunction (i.e. decreased libido and delayed orgasm frequently) in >60% of patients, while other sexual dysfunctions such as anorgasmia and arousal difficulties occur less frequently (30%) [35] (**Box 10.7.2**). In contrast, noradrenergic, dopaminergic, or melatonergic antidepressants do not cause sexual dysfunction but the clinical profile of patients receiving these compounds could be different [35].

Vasculogenic Erectile Dysfunction

Vasculogenic erectile dysfunction is caused by reduced arterial inflow into the penis or an impaired veno-occlusive mechanism, or both, and its frequency increases with ageing. Arterial insufficiency is a common cause of erectile dysfunction and results from many disorders, including thrombotic and thromboembolic occlusion of the terminal aorta and the iliac, hypogastric, pudendal, and penile arteries. Atherosclerosis is the most common cause of arterial occlusion; therefore, arterial penile insufficiency shares the same risk factors for atherosclerosis, including age, cigarette smoking, hypertension, dyslipidaemia, diabetes mellitus, and the metabolic syndrome [28, 36]. Arterial penile insufficiency may also be due to congenital anomalies, surgery, and perineal or pelvic trauma [13, 37].

Impairment of the veno-occlusive mechanism of erection may cause erectile dysfunction because of venous leakage with increased venous blood outflow. Failure of the veno-occlusive mechanism may occur at many levels: tunica albuginea, trabecular tissue, endothelial cells, nerve fibres, and veins [37].

Diseases of the tunica albuginea include fibrosis, Peyronie's disease, penile fracture, diabetes, trauma, and congenital tunical abnormalities (e.g. reduced tunica thickness) [3, 13, 26].

Trabecular compliance is impaired when changes in the smooth muscle/collagen ratio occurs. Morphological and functional changes in cavernous smooth muscle may be due to smooth muscle

Box 10.7.2 Principal drugs affecting erection according to the strength of the body of evidence

(In parenthesis): 1: good evidence; 2: moderate evidence; 3: poor evidence

Antihypertensive drugs
- *Diuretics*
  - Thiazide diuretics (1)
  - Spironolactone (1)
- *Sympatholytics*
  - β-blockers (1)
- *Central agents*
  - Methyldopa (1)
  - Clonidine (1)
- *Calcium-antagonists (2)*
- *ACE inhibitors (2)*

Psychotropic drugs
- *Antidepressant drugs*
  - Monoamine oxidase inhibitors (2)
  - Tricyclics (1)
  - Selective serotonin reuptake inhibitors (1)
  - Serotonin noradrenaline reuptake inhibitors (2)
  - Lithium (3)
- *Antipsychotics*
  - Chlorpromazine (3)
  - Fluphenazine (2)
  - Loxapine (3)
  - Mesoridazine (3)
  - Molindone (3)
  - Thioridazine (3)
  - Thiothixene (3)
  - Trifluoperazine (3)
  - Haloperidol (2)
  - Clozapine (2)
  - Olanzapine (2)
  - Quetiapine (2)
  - Risperidone (2)
  - Aripiprazole (3)
  - Ziprasidone (3)
- *Others*
  - Sulpiride (3)
  - Barbiturates (3)
  - Benzodiazepines (2)
  - Anticonvulsant (2)
  - Diphenylhydantoin (1)
  - Ketoconazole (3)
  - Disopyramide (2)

Gastrointestinal drugs
- *H^2 blockers*
  - Cimetidine (3)
  - Ranitidine (1)
- Metoclopramide (1)

Cytotoxic agents
- Methotrexate (2)
- Mitotane (1)

Hormonal drugs
- LHRH-agonists or antagonists (1)
- Antiandrogens
  - Flutamide (2)
  - Cyproterone acetate (1)
  - 5-α-reductase inhibitors [Finasteride] (2)*
- Oestrogens (at high doses) (2)
- Progestins (3)

  - Cannabinoids (Cannabis/Marijuana/Hashish) (2)
- *Alcohol [high consumption] (1)*

* see the specific paragraph at the end of this chapter for further details

atrophy with replacement by fibrotic tissue (as in atherosclerosis and diabetes), and to local functional disorders with impaired neurotransmitter release or receptor function [3]. *In vitro* studies suggest that testosterone exerts a trophic effect on the penile nerves, vasculature and cavernosal tissue and regulates nitric oxide release by enhancing both the expression and activity of NOS [16], but the significance of these animal data to human physiology and clinical erectile dysfunction remains unclear.

Venous drainage may be impaired by congenital abnormal or ectopic veins and by pathological shunts (traumatic, post-priapism, surgical, or congenital) between the *corpus cavernosum* and the *corpus spongiosum* of the glans penis [13, 25, 26].

Endocrine Erectile Dysfunction

Among the endocrine disorders, men with organic hypogonadism due to established hypothalamic–pituitary commonly present with low libido and may have erectile dysfunction [9]. However, in older men with age-related low testosterone in the absence of recognizable hypothalamus–pituitary–testicular HPT axis pathology, sexual dysfunction is commonly caused by coexisting neurovascular disease, rather than due to androgen deficiency. Organic hypogonadism is not a common finding in patients with ED, occurring in about 2–32% of cases depending on how hypogonadism is defined, age of patients and different clinical settings [38]. In general, there is a lack of association between serum testosterone levels and erectile function [38]. In men over 50, ED and hypogonadism are common but independently distributed rather than causally linked disorders [32]. Among men presenting with erectile dysfunction, low serum T below 300 ng/dl (10.4 nmol/L) may be detected in 12% of 1022 consecutive ED patients, including 4% under and 15% over the age of 50 [39]. The prevalence of low serum T <200 ng/dl, 7 nmol/L was even lower: 1.8%, 0.8% before 50 years, and 2.6% after this age [39]. Even then, this association does not prove causality, given the evidence is observational [38] (see Chapter 10.4.2, 'Types of Treatment').

Hyperprolactinaemia with or without hypotestosteronaemia may also be associated with loss of libido and erectile dysfunction [9], but does not appear to modify sleep-related erections and response to visual erotic stimulation, suggesting that hyperprolactinaemia negatively affects libido and sexual behaviour directly [40]. Hyperprolactinaemia is common (30–65%) in patients with chronic kidney disease (CKD); however the specific contribution of hyperprolactinaemia to the very high frequency (60–80%) of erectile dysfunction in men with CKD remains unclear due to concomitant prevalent vascular abnormalities [30, 31]. Among the other endocrinopathies associated with erectile dysfunction are adrenal insufficiency, acromegaly, Cushing's syndrome, hyperthyroidism, and hypothyroidism [9, 41–43]. Again, the exact role and the mechanisms by which these conditions contribute to erectile malfunction are unclear.

Neurological Erectile Dysfunction

Brain, spinal cord, and neuropathic diseases can cause neurogenic erectile dysfunction. Lesions in various brain areas may induce erectile and sexual dysfunction (e.g. Parkinson's disease, cerebrovascular or expansive lesions of either temporal lobes or limbic system) [13, 44]. Congenital (e.g. spina bifida, syringomelia) or acquired (traumas, neoplasia, and inflammatory disorders as multiple sclerosis) spinal cord diseases are the most frequent causes of neurogenic erectile dysfunction [13, 44]. Injuries to lower spinal cord segments (lumbar and sacral) often result in complete erectile dysfunction, while lesions of the upper spinal cord segments (cervical and thoracic) do not affect reflexogenic erections [4, 44]. In the peripheral nervous system, erectile dysfunction can result from traumatic (pelvic fracture) or surgical (radical prostatectomy, cystoprostatectomy, proctocolectomy) injuries to the pudendal and cavernous nerves [44]. Peripheral neuropathy in diabetes mellitus (the most common cause), uraemia, amyloidosis, vitamin deficiency (folic acid, B_6, and B_{12}), and alcoholism can cause erectile dysfunction [44].

Iatrogenic Erectile Dysfunction

Drugs

Erectile function can be affected by many drugs acting through different mechanisms (i.e. penile arterial flaw, central action on libido, changes in hormonal secretion/action) (**Box 10.7.2**) [3, 25, 26]. Data on drugs and erectile dysfunction are often collected by uncontrolled studies and/or case reports; therefore, a cause–effect relationship is not always proven.

Erectile dysfunction is commonly associated with the use of antihypertensive drugs (thiazide diuretics, β-blockers). Some drugs affecting the hypothalamus–pituitary–testicular axis (oestrogens, progestins, antiandrogens, both luteinizing hormone-releasing-hormone agonists, and antagonists) can impair erectile function by decreasing gonadotropin and testosterone release. The peripheral bioavailability of androgens is decreased by digitalis, cimetidine, and spironolactone. Hyperprolactinaemia, and the often-related low libido and erectile dysfunction, can result from antipsychotic drugs (phenothiazines, sulpiride, and related drugs) and H_2-receptor antagonists. Alcohol abuse can cause low testosterone serum levels, peripheral neuropathy, and chronic liver damage [3, 25, 26].

Surgery

Pelvic surgery, such as radical prostatectomy, cystoprostatectomy, proctocolectomy, is a frequent cause of erectile dysfunction due to pelvic vessel and/or pelvic nerve lesions [13, 25, 26, 37, 44], occurring in 20–80% of patients undergoing the above-mentioned surgical procedures, the prevalence depending on several factors such as the extent of surgery, the surgical technique used, the skills of the surgeon [13, 25, 26, 37, 44]. Also external pelvic radiotherapy can cause erectile dysfunction, with delayed onset 2–5 years after treatment. Comparison between patients with prostate cancer who underwent radical prostatectomy or radiotherapy shows higher prevalence after the former treatment (79% versus 63%) [45], with apparently lower frequency when a robot-assisted radical prostatectomy is performed [46]. Renal transplantation and vascular surgery on the aortoiliac arteries may also cause erectile dysfunction [31].

Trauma

Pelvic fractures can cause erectile dysfunction if injury to a vessel or to nerves involved in the erectile mechanism occurs [37, 44].

Diagnosis

More than one cause can be simultaneously responsible for erectile dysfunction at the time of the diagnosis, even if they may have occurred at different times.

The diagnostic approach to erectile dysfunction should include several sequential steps which may be influenced by the expertise (psychologist/sexual medicine, endocrinologist, urologist) of the clinician (Figure 10.7.5).

General Clinical Interview

A general medical interview and examination can identify systemic diseases, medications/drugs or previous surgery/trauma which can cause erectile dysfunction [13, 23, 25, 26, 34].

Sexological Interview

The sexological interview constitutes a main step, because it may indicate either psychogenic or organic erectile dysfunction [13, 23, 25, 26, 34].

Some information concerning sexual orientation, the presence of one, more, or no constant partner, sexual habits, and frequency of sexual intercourse is required [23, 34]. Other information (e.g. cultural level, religious beliefs, or profession) is also helpful [34].

A sexological interview can reveal psychogenic erectile dysfunction suggested by: abrupt onset, full morning erections, full erections following visual erotic stimulation, full erections with masturbation, inconstant occurrence, occurrence only with some form of sexual intercourse, and occurrence with one partner, but not with another [23, 26, 34].

Conversely, organic erectile dysfunction is often characterized by a progressive loss of erectile function and by an almost constant presence of the problem [13, 23, 25, 26, 34].

Libido needs to be enquired carefully. When a patient complains of low libido, the physician should try to determine if what is occurring is loss of libido, or unwillingness to face erectile dysfunction [13, 23, 25, 26, 34]. Low libido justifies an evaluation of testosterone and prolactin levels, and consideration of depression, or the use of neuroleptics or antiandrogens [13, 21, 23, 25, 26]. Some structured interview instruments for use with patients complaining of erectile dysfunction or other sexual problems are currently available [26, 47, 48]. The International Index of Erectile Function (IIEF) is a validated and extensively used instrument in research and in the clinical work-up of individual patients with erectile dysfunction [34], while others are more suitable for research [48]. The short version of the IIEF (IIEF-5; 5 items) is a self-administered questionnaire that may be used as a diagnostic tool in evaluating erectile function (EF domain), ascertaining if erectile dysfunction is present (EF score ≤25) or not (EF score >25), as well as assessing the degree of erectile function impairment (mild, moderate or severe for EF scores of 17–25, 11–16, 6–10, respectively) [17, 48, 49]. The long version of the IIEF (IIEF-15; 15 items) provides further information also on the domains concerning sexual desire, orgasmic function, intercourse satisfaction, and overall satisfaction [17, 48]. Other questionnaires (e.g. the Aging Male Symptom Scale for male hypogonadism) [50] are not recommended due to poor clinical discriminating power [34, 48].

The interview should also be directed to check other symptoms of hypogonadism such as the decrease of the volume of the ejaculate, the presence of hot flushes and the changes in body hair and beard growth and distribution. See Chapter 10.4.4, 'Benefits of Testosterone Treatment'.

Psychological Evaluation

A psychological evaluation of the patients affected by erectile dysfunction is almost always helpful because of the very frequent involvement of psychological factors, even when the causes are organic [23, 26]. Psychological evaluation should ideally be performed formally by a psychologist with experience/training in psychosexual problems. However, when this is not readily available, self-completed, brief questionnaires are available in order to provide a picture of the patient's personality and anxiety levels, and to detect clinical depression [33, 47].

Physical Examination

The physical examination should focus on the presence of signs of hypogonadism (i.e. reduced facial and body hair, reduced volume of the testes, reduced muscle mass, and increased body fat), the presence of penile fibrosis, the peripheral pulses and the presence of signs of peripheral and autonomic nervous system abnormalities.

Blood Chemistry

Erectile dysfunction is associated with almost all severe endocrinological diseases, particularly hypogonadism. For this reason, measuring serum morning fasting total testosterone is mandatory in all patients with erectile dysfunction, especially in those with low sexual desire or symptoms and signs of hypogonadism [23, 51] (Figure 10.7.5). Further diagnostic procedures are needed in case of low serum total testosterone [51] (see Chapter 10.4.4, 'Benefits of Testosterone Treatment'). Prolactin should be measured in all subjects who complain of low libido and have documented low serum testosterone and low or inappropriately normal gonadotropins [9] (Figure 10.7.5) (see Chapter 2.3.9, 'Prolactinomas and Hyperprolactinaemia').

Fasting blood glucose should be checked because of the high prevalence of erectile dysfunction in diabetics. Cholesterol and triglycerides should also be measured in order to detect risk factors for arteriosclerosis (Figure 10.7.5).

Further Investigations

Further investigations aiming to better define the cause and mechanism of erectile dysfunction may be pursued in selected patients managed under specialized clinical settings. Documenting the presence of full erections under defined circumstances may be useful to rule out an organic cause of impotence. Visual erotic stimulation by movies, slides, or magazines provides an inexpensive test, where the erectile response is self-scored by the patient. A full erection in response to visual erotic stimuli indicates that both vascular and nerve supplies involved in erection are intact. However, erection in response to visual erotic stimuli may not occur (despite intact neurovascular system) because of embarrassment or because the patient is accustomed/desensitized to visual erotic stimulation. Furthermore, a full erection can occur during visual erotic

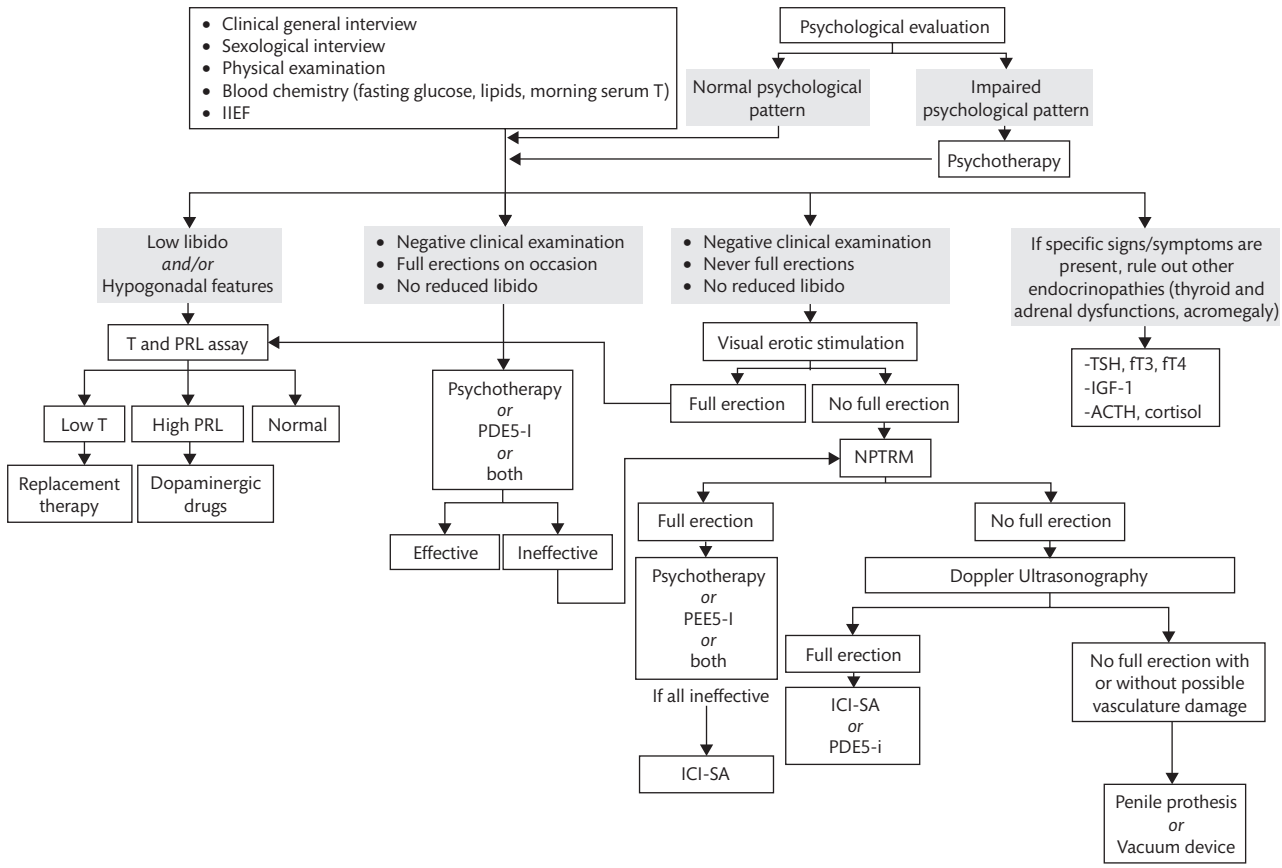

Figure 10.7.5 Diagnostic and therapeutic algorithm of erectile dysfunction.

T, testosterone; PRL, prolactin; NPTRM, nocturnal penile tumescence and rigidity monitoring; ICI, intracavernosal injection; ICSI, intracavernosal self-injection; PSV, peak systolic velocity; RI, resistance index; PDV, peak diastolic velocity.

stimulation in hypogonadal men, which renders the test uninformative in excluding erectile dysfunction due to low testosterone and/or high prolactin levels [10, 40].

Nocturnal penile tumescence and rigidity monitoring (NPTRM) may help to differentiate between psychogenic (normal NPTRM) and organic (impaired NPTRM) erectile dysfunction [24]. Furthermore, devices (e.g. RigiScan®) recording and measuring nocturnal penile tumescence and rigidity reduce the possibility of false positive diagnosis of psychogenic erectile dysfunction due to normal increase of tumescence but impaired rigidity [24].

Impaired NPTRM can occur because of hormonal (namely, low testosterone) vascular and neurological pathologies [10, 11, 14, 24, 40]. Thus, an impaired response cannot identify the specific cause underlying organic erectile dysfunction. The usefulness of NPTRM is also limited by the possibility of impaired sleep-related erections in men without organic pathologies but suffering from depression or sleep disturbances. Despite these drawbacks, there is general agreement that NPTRM is a valuable method to study the integrity of the erectile mechanism without psychological interferences [52].

To investigate the integrity of the vasculature within the penis, the simplest test is the direct intracavernosal injection of vasoactive drugs, useful both for obtaining information about the possible vasculature damage and the effectiveness of these drugs as potential treatment for erectile dysfunction [23, 33, 34, 53]. Intracavernosal injection of vasoactive drugs directly promotes penile erection by increasing arterial blood inflow and the subsequent achievement of a full erection indicates a normal veno-occlusive mechanism [23, 33, 34, 53]. Although many substances have been used for this test, to date prostaglandin E_1 and papaverine hydrochloride are the drugs most frequently used, both alone or added to phentolamine. This is not an appropriate test to evaluate the arterial penile vessels [53] because a full erection in response to this test is reached by as many as 20% of patients with borderline low arterial inflow, according to penile Doppler parameters (see next) [54].

Penile Doppler ultrasonography is the most accurate tool to investigate arterial haemodynamics in the penile arteries after an intracavernosal injection of a vasoactive drug [23, 26, 34]. The cavernosal artery peak blood flow velocity (normal: above 25–30 cm/sec) is a measure of vascular integrity of penile blood vessels which can reveal local atherosclerotic disease within the penis, that may reflect the general status of other small-to-medium-sized arteries in the patient [55]. Thus, investigation and detection of vasculogenic erectile dysfunction may prompt further investigation of unsuspected generalized cardiovascular diseases in the patient [56].

Management of Erectile Dysfunction

In the management of erectile dysfunction, the physician should consider the goal(s) that the patient (and his partner) is seeking and determine which therapy is best suited to the patient's psychological pattern and sexual habits (Figure 10.7.5).

General and Psychosexual Counselling

General counselling should provide the patient with information on lifestyle risk factors (e.g. obesity, smoking, alcohol, and recreational drug abuse) of erectile dysfunction and on how to modify them if present. As adjunctive intervention, lifestyle modification may lead to small improvement of both the erectile function and/or the hormonal secretion, especially testosterone [26, 34, 36].

Ideally, every patient suffering from erectile dysfunction, not only with psychogenic aetiologies, can potentially benefit from some behavioural and couple-oriented psychosexual counselling to tackle common contributory psychological factors in organic erectile dysfunction as well as any relationship issues of the couple. In general, the physician managing patients with erectile dysfunction should be skilled in providing simple, elementary psychosexual support (behavioural advice, sex education information) but should be able to recognize who and when to refer to sexologist, psychiatrist or psychologist/counsellor for specialized care [34, 36]. Pharmacological treatments for erectile dysfunction may be administered even in patients undergoing psychotherapy (cognitive-behavioural interventions) and/or drugs prescribed by the psychiatrist [34, 36].

Oral Non-Hormonal Drugs

Several oral agents (e.g. yohimbine, phentolamine, and apomorphine) were used in the past for the treatment of erectile dysfunction, but most of them are now of historical interest only [12, 26].

Type 5 Phosphodiesterase Inhibitors (PDE5Is)

Sildenafil, vardenafil, tadalafil, and avanafil are the drugs currently used as first-line treatment of erectile dysfunction; they belong to the class of orally-active inhibitors of PDE5, the enzyme that metabolizes and inactivates cGMP and cAMP in the penile blood vessels (Figure 10.7.2). PDE5Is decrease PDE5 enzyme activity and the consequent increase of cGMP and cAMP that causes the efflux of intracellular $Ca^{2}+$ to induce penile vascular smooth muscle relaxation (Figure 10.7.2) [3, 12, 13, 26, 57].

PDE5Is are effective for both psychogenic and organic erectile dysfunction but their action is contingent upon sexual arousal and central erectile neurological stimulation [13, 25, 26, 34, 36, 57]. The dose should be titrated to the maximum tolerated dose (Table 10.7.1). The starting dose is chosen by the clinician and it is not mandatory to start with the lowest dose, except in older people (>65 years) [57]. PDE5Is do not differ from each other in terms of efficacy, the only differences being the time of onset and duration of action, and the dose range (Table 10.7.1) [57]. PDE5Is are preferably used on-demand, except for tadalafil, which is effective at the same dose also when administered once daily due to its longer duration of action (Table 10.7.1) [26, 34, 36, 57]. Daily therapy may be advisable in case of psychogenic erection, post-radical prostatectomy, couples discomforted by the need for programming sexual activities [36, 57]. PDE5Is therapy should be stopped when there is no response (defined as lack of efficacy after at least 8 maximum doses of the drug with sexual stimulation) as well as in patients with psychogenic erectile dysfunction after having restored normal erections or when other drugs contraindicated in PDE5Is therapy are indispensable [20, 26, 34, 58]. Non-responders to PDE5Is are common among patients with type 2 diabetes mellitus and those who underwent radical prostatectomy [34, 36].

The safety profile of PDE5Is is excellent when the drugs are used at the right dosage and within the appropriate clinical context [12, 26, 34, 36, 58]. Their adverse effects are usually transient and have minor importance; these include headache, flushing, rhinitis, dyspepsia, dizziness, blue vision, and abnormal vision (change in brightness perception) (Table 10.7.1) [26, 34, 36, 58]. Other minor side effects, such as back pain, myalgia have been described occasionally [12, 58]. Absolute contraindications to the use of PDE5Is are the concomitant administration of nitrate medications for ischaemic heart disease or as recreational drug (i.e. poppers) as well as other potent vasodilators such as nicorandil [34, 36, 58]. Retinitis pigmentosa, an inherited disorder of retinal PDE6, is also an absolute contraindication [26, 34, 36]. The dosage of PDE5Is should be reduced in case of older patients (>65 years), impaired hepatic and/or renal function and use of potent cytochrome P450 3A4 (CYP3A4) inhibitors (e.g. ritonavir, squinavir, cimetidine, erythromycin) [34, 36, 58]. PDE5Is might further reduce blood pressure in men taking antihypertensive drugs, but the decrease is usually too small to lead to symptomatic hypotensive episodes [34, 36, 58]. PDE5Is are safe in patients with cardiovascular diseases with the caveats on vasodilator medications; in particular they do not increase the overall incidence and the occurrence of further cardiovascular events (i.e. myocardial infarction); *vice versa* they seem to exert beneficial effect on the cardiac arterial bed [34, 36, 58].

Sildenafil and vardenafil have a reduced maximal plasma concentration when taken after a high fat meal and should ideally be administered on an empty stomach in which an acidic environment increases the bioavailability [59]. Alcohol consumption should be avoided or moderated when taking any PDE5Is in order to minimize the hypotensive effects of these drugs [59].

Misuse of PDE5Is drugs for recreational purposes is increasing in young men [60, 61] especially among men who have sex with men, HIV infected patients and sex workers [29, 62, 63].

Hormonal Therapy

Testosterone should be reserved only for patients with an established diagnosis of hypogonadism [34, 36, 51], where improvement in libido and, concomitantly, erectile function can be expected [20] (see Chapters 10.4.2, 10.4.4, and 10.4.5). As mentioned earlier, this represent a minority of patients presenting with erectile dysfunction as the predominant complaint. Before testosterone treatment is considered, plans for paternity should be ascertained. Patients should be informed that testosterone treatment, while not being a fully reliable contraceptive, suppresses spermatogenesis, and reduces fertility.

Phosphodiesterase 5 inhibitors can improve erectile function in eugonadal and hypogonadal men [14, 57, 59, 64]. However, the efficacy and the place of combination therapy with testosterone and PDE5Is in the management of ED and/or hypogonadism is debated.

Table 10.7.1 Pharmacokinetic of PDE5 inhibitors

	Tmax (h) range (median)	T1/2 (h) range (median)	Dose (mg)	Way/Onset of action (h)	Duration of action (h)	Food effect on drug availability	Headache	Flushing	Dyspepsia	Altered colour perception	Dizziness
Sildenafil	1–2 (1)	3–5 (3.82)	25–100	On-demand/1 h	4	++	++	++	+	+++	+
Vardenafil	1–2 (1)	4–5 (3.94)	5–20	On-demand/1 h	4	+	+++	++	+	+++	+
Tadalafil	0.5–6 (2)	17–50 (10–24)	5–20	On-demand; daily/1 h	36	–	++	+	++	+/–	+
Avanafil	0.5–0.75 (1/2)	6–17 (5.0)	50–200	On-demand/1/2 h	6	–	++	+	+/–	+/–	+/–

PDE5, phosphodiesterase 5; Tmax: time required for maximum serum drug concentration to be reached; T1/2: time required for drug serum concentration to be reduced by one-half of its maximum concentration.

Several uncontrolled clinical studies have shown an apparent synergic effect between testosterone and PDE5Is in patients with ED, not all of whom had low T in the hypogondal range [14, 65–67]. However, a randomized controlled trial in men with ED and T levels <330 ng/dl failed to demonstrate further improvements in erectile function with the addition of T to an optimized regimen of PDE5I (Sildenafil) [64]. Similarly, addition of T to impotent men treated with PDE5 (tadalafil 10 mg daily for 4 weeks) did not produce any further improvements in erectile function unless the baseline T levels were ≤ 300 ng/dl [68]. Based on current evidence, a reasonable approach in the older ED patients with low T (but without a diagnosis of organic hypogonadism) is to optimize sexual function using (unless contraindicated) a PDE5I in the first instance, and consider add-on T treatment on a case by case basis, educating the man about the lack of definitive evidence.

Low libido and/or erectile dysfunction in hyperprolactinaemic men with or without hypogonadism can be successfully treated with dopaminergic drugs; testosterone alone may be ineffective in these patients if the hyperprolactinaemia remains uncorrected [9, 40]. In case of hypogonadism and hyperprolactinaemia due to CKD, the recovery of normal renal function following renal transplantation is able to improve or even restore normal function of the testis with beneficial effects also on erectile function (in the absence of pelvic complication due to surgery on nerves and vessels), especially in younger patients [30, 31]. See Chapter 10.6, 'Hypothalamo–Pituitary–Testicular Axis Function in Systemic Diseases and Effects of Medications'.

Intracavernosal Self-Injection Therapy

This therapy is effective in more than 70% of men with psychogenic and neurogenic erectile dysfunction, and is also effective in men with mild to moderate vasculogenic erectile dysfunction [57, 69, 70]. The injection is given, usually by the patient prior to sexual activity, at the penile base on a lateral side.

The main side effect linked with regular therapeutic use of intracavernosal injections is the development of fibrous plaques as in Peyronie's disease, which are reported to occur in up to 2–4% of self-injecting men after one year of injections at a rate of once per week [57]. An ischaemic, veno-occlusive priapism, that is a rigid and painful erection lasting more than 4 hours and characterized by absent cavernous blood flow [71] can occur when an excessive dose of prostaglandin E1 is used, but this can be easily avoided by patient education and careful dose titration starting with lower doses (5–10 mcg) initially [57, 69]. Priapism is a medical emergency, requiring urgent treatment to relieve pain and avoid penile fibrosis, persistent erectile dysfunction, and possible major penile deformity [72]. Treatment of priapism consists of blood aspiration from corpora cavernosa or intra corpora cavernosa administration of sympathomimetic drugs (most frequently phenylephrine or etilefrine) or both measures to restore penile flaccidity. If treatment is delayed by 48–72 hours after priapism onset, there may be worsening of the erectile response when intracavernosal self-injection is restarted [72].

Transurethral Therapy

Transurethral administration of prostaglandin E1 (250–1000 mcg) [57, 73] is less effective than intracavernosal injections; the occurrence of full erection ranges from 10% to 65% of patients. Furthermore, the transurethral absorption of prostaglandin E_1 can lead to more acute systemic side effects (dizziness, sweating, and hypotension), than intracavernosal injections, but the absence of the risk of penile fibrosis is noteworthy [57].

External Devices

Among external devices available for purchase on the market, vacuum pumps are the most commonly. They consist of a suction pump connected to a cylinder, which is placed over the penis. The negative pressure causes increased blood flow into the penis. A tension ring is placed at the base of the penis when the erection is reached; the pump is then removed. Adverse effects of the vacuum device include pain, blocked and painful ejaculation, haematoma, ecchymosis, petechiae, and ischaemic penile injury [26, 74]. Depending on individual patient's and partner's preferences, external penile devices may be an effective alternative to medications or intracavernosal injections for some couples to achieve intercourse [74].

Extracorporeal Shockwave Therapy

There is recent literature describing the use of low intensity extracorporeal shockwave therapy applied to the penis in men with erectile dysfunction. Shockwave therapy should improve penile haemodynamics, but a widespread acceptance of this treatment has not yet been reached [75].

Penile Prosthesis

Thanks to the increased availability and effectiveness of intracavernosal self-injection, oral drugs, and the pump devices, penile prosthesis are less commonly employed as a surgical treatment for erectile dysfunction. It remains the last resort treatment for erectile dysfunction that is refractory to all the above-mentioned therapies. There are semi-rigid and inflatable penile prostheses, which provide penile rigidity continuously or on-demand, respectively. The invasiveness of this treatment continues to be a deterrent for the patient, even though the surgical complications have decreased in recent years [26, 76]. Perioperative infection, poor erection, penile deformity, device failure, and penile glans trauma during sex are amongst the complications of penile prostheses [26, 76].

Vascular Surgery

Vascular surgery is reserved for venous leakage and focal arterial block. The treatment of venous leakage by ligation of the superficial and deep dorsal veins is disappointing with respect to long-term effectiveness [26, 77]. In contrast, arterial surgery—anastomosis of the inferior epigastric artery to the penile dorsal artery or to the deep dorsal vein—seems more promising [26, 77].

Post-Finasteride Syndrome

Post-finasteride syndrome is a controversial entity that has been recently described in men (usually young adults) taking finasteride for counteracting hair loss [78]. It is characterized by a multitude of sexual (low libido, erectile dysfunction, sexual anhedonia (i.e. reduced motivation or ability to experience pleasure), loss of pleasure during orgasm) physical (gynaecomastia, fatigue, weakness, skin lesions), and psychological (memory and cognitive impairment, depressed mood, anxiety, suicidal ideation, no emotional changes, insomnia), symptoms which may be present in different

combinations [78, 79]. Much of the information comes from patients' self-reports [79]. The most rigorous study to date has failed to identify consistent objective parameters validating the existence of this 'syndrome' [78]. From a pathophysiological perspective, the side effects of finasteride may be due, at least in part, to its antiandrogen action (sexual symptoms) but this mechanism does not explain psychoneurological symptoms, and/or their persistence after cessation of finasteride. Recently, changes in some neurosteroids have been found in cerebrospinal fluid of patients with the post-finasteride 'syndrome' compared to controls but whether they are cause or consequence is not known [80].

The management of this 'syndrome' is complex since symptoms seem not to reverse in most of the patients after finasteride discontinuation and/or testosterone therapy [78, 79]. No data on the possible beneficial effects of exogenous androgens administration are available. Furthermore, there are no predictive factors that can identify patients at risk of developing this 'syndrome', except that a pre-existing mood disturbance seems to be frequent [79]. At present there is no known effective treatment for this poorly understood condition.

Conclusions

Due to advances in the understanding of the physiological mechanisms of penile erection and the availability of PDE5Is, the awareness, diagnosis and management of erectile dysfunction has improved greatly in the last two decades for an increasing number of patients. Significant benefits on sexual activities and satisfaction can now be extended also to some patients with chronic diseases (e.g. chronic kidney disease, HIV infection, diabetes, cardiovascular disease). However, despite these welcomed improvements, treatment for sexual/erectile dysfunction remain unsatisfactory for a significant proportion of men (and their partners). Consultations for erectile dysfunction may alert clinicians and patients to the presence of undiagnosed cardiovascular diseases. Finally, the recovery of a satisfying sexual relationship often results in improved self-esteem and overall quality of life in a previously under-served group of patients.

Hormonal Male Contraception

Stephanie T. Page and Maritza T. Farrant

Introduction

Effective male contraception requires the reduction of motile sperm in the ejaculate to levels that reliably prevent fertilization. To date, all approved forms of male contraception aim to reduce female exposure to spermatozoa via mechanical blockade (condoms and vasectomy). The last half of the twentieth century saw the introduction of reliable, reversible hormonal contraceptive options for women, yet men continue to rely on less effective and irreversible family planning methods, with condoms, withdrawal, rhythm, and male sterilization, accounting for one-quarter of all contraceptive use worldwide [1]. Despite advances in female contraceptive methods and availability, in 2012 nearly 40% of all pregnancies worldwide were unintended and 50% of these ended in termination [2]. Men's role in furthering effective family planning has been underexplored and the development of more efficacious, reliable, safe, and reversible male contraceptive methods could have an enormous public health impact [3].

Reversible suppression of the hypothalamic–pituitary–testicular axis, resulting in abrogation of spermatogenesis, provides the foundation for reversible male hormonal contraception (MHC) regimens. High levels of intratesticular testosterone (and adequate intratesticular oestradiol) are required for normal human spermatogenesis. Administration of appropriately dosed exogenous androgens +/– progestins to men serves two purposes simultaneously. First, due to negative hypothalamic–pituitary feedback leading to suppression of GnRH and gonadotropin secretion, testicular steroidogenesis is inhibited. At the same time, peripheral androgen action is maintained to support non-gonadal tissues and prevent the sequalae of male hypogonadism (such as hot flashes, impairment of sexual function, bone density loss, and reduction in lean body mass). Progestins are used to augment androgen-induced hypothalamic–pituitary suppression, as androgens by themselves may not be sufficiently potent and at high doses exogenous androgens may also have direct, stimulatory intratesticular effects.

Here we provide an overview of various regimens and formulations that have been evaluated as potential MHC, including novel modified steroids that show promise as reversible contraceptive methods for men.

Physiology of Male Hormonal Contraception

Testosterone (T) is essential for maintenance of male secondary sexual characteristics including hair pattern, sexual function, muscle, and bone mass, as well as spermatogenesis. In eugonadal men, starting at puberty, pulsatile release of gonadotropin-releasing hormone (GnRH) from the hypothalamus stimulates the release of gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), from the pituitary gland. LH binds to Leydig cells in the interstitium of the testes, stimulating T synthesis within the testes and generating high local concentrations of intratesticular T (between 50 and 100 times serum T concentrations) that are essential for spermatogenesis. Within the testes 1–2% of T is metabolized to produce both oestradiol (E2), and dihydrotestosterone (DHT). All three sex steroids are secreted into the circulation and inhibit FSH and LH secretion from the pituitary. Nurtured by Sertoli cells and stimulated by FSH, spermatogenesis occurs in the seminiferous tubules in this high T environment. FSH also stimulates inhibin B production from Sertoli cells that supresses FSH secretion by negative feedback.

Reversible MHC interrupts this naturally occurring negative feedback loop. The administration of an exogenous androgen (+/– a progestin), often at a supraphysiogical dose, results in suppression of GnRH and gonadotropin production through

interactions with the androgen, oestrogen, and progesterone receptors in the hypothalamus and pituitary gland. Importantly, intratesticular testosterone concentrations plummet without LH stimulation of Leydig cells, depriving developing spermatogonia of local testicular endocrine and paracrine signals required for completion of spermatogenesis. In the acute phase following administration of the MHC, there is blockade in the differentiation of Type A to Type B spermatogonia. Because the existing type B spermatogonia complete their maturation process despite the altered intratestiscular hormonal milieu, MHC requires 8–16 weeks for maximal suppression of mature sperm in the ejaculate. Therefore, markedly decreased sperm concentrations are only achieved after 3–4 months of MHC administration. Following cessation of exogenous steroid administration, the hormonal axis recovers in a matter of days, while sperm concentrations require 3–6 months to return to pretreatment levels [4]. Adjuncts to exogenous androgens, including progestins, are used to augment the androgen-mediated hypothalamic–pituitary suppression, providing further reduction of gonadotropin production, and, consequently, spermatogenesis.

Testosterone Formulations for MHC

Steady-state serum concentrations of serum testosterone at least within normal range are required for maintaining systemic eugonadism. In addition, exogenous androgens inhibit gonadotropin production, contributing to at least partial suppression of spermatogenesis. Injectable androgens have been the mainstay of MHC (see following sections), but alternative oral, transdermal, and implantable androgen delivery systems hold promise for novel MHC regimens in the future.

Oral androgens undergo significant first-pass metabolism, alter hepatic protein secretion, and have limited bioavailability. Early studies of oral testosterone undecanoate (TU), which is safe, as part of MHC were encouraging but limited by a requirement for twice daily dosing [5]. Transdermal T patches are approved in many countries to treat male hypogonadism, but, even when combined with a progestin, are not effective for male contraception [6, 7], likely due to the due to failure to consistently maintain high normal T concentrations. In addition, skin irritation occurs frequently at the patch application sites often leading to discontinuation [8]).

Several proof-of-concept studies have demonstrated that transdermal T-gels may be effective as MHC when combined with a progestin. The combination of T-gel (10 g daily) with nestosterone (NES), a non-androgenic progestin, led to severe oligospermia (<1 million sperm/ml, see sperm targets next) in 89% of men with minimal adverse effects, compared to 23% in the group receiving T-gel alone [9]. The median serum total and free T concentrations were maintained within the adult male range throughout the 24-week treatment period with combination therapy. Based upon these promising results, a combined Nes-Tes gel is slated for Phase 2 testing in a multinational MHC efficacy trial in 2018. Similarly, T-gel combined with depomedroxyprogesterone acetate (DMPA) injections resulted in severe oligospermia in 90% of men treated for 24 weeks [10]. Sexual function was preserved during treatment, and the majority of men reported satisfaction with the regimen [11]. Skin irritation associated with T-gels is uncommon, while potential downsides for some users include the need for daily application and care to avoid transferring the gel to female partners and children.

The subdermal T-implant, originally developed in 1937, lasts 3–6 months and achieves steady testosterone concentrations. Clinical use of T-implants and pellets as androgen replacement therapy increased in the 1990s [12]. T-pellets were used successfully in combination with long-acting progestin injections (DMPA) in a proof-of-concept MHC efficacy study [13]. T-pellets are generally well-tolerated, but their insertion requires a minor surgical procedure and there is a small risk of painful self-extrusion and infection [14], making T-pellets less attractive for some settings and users.

Androgen-Alone MHC Studies

Systematic dose-finding and feasibility studies using testosterone for MHC began in the 1970s [15]. The largest experience with androgen-alone regimens arose from landmark WHO-sponsored studies in the 1990s. The first [16] enrolled 271 fertile men in seven countries given 200 mg testosterone enanthate (TE) intramuscularly (IM) weekly, twofold the physiologic dose. Sixty-five per cent (65%) of these men became azoospermic, and an additional 30% became severely oligospermic. The 119 men who became azoospermic then discontinued other birth control methods and continued the injections as their only method of contraception with their female partner for 1 year. There was one pregnancy during the efficacy phase (0.8 conceptions [95% CI 0.02–4.5] per 100 person-years), a rate comparable with female contraceptive methods [17] demonstrating supraphysiologic testosterone-induced azoospermia to be a highly effective contraceptive.

The second international WHO study [18] was designed to evaluate the contraceptive effects of suppression to near azoospermia. In this nine-country study, 399 healthy men (123 from Asian and 276 from non-Asian countries) in stable heterosexual relationships were recruited and again received 200 mg/week IM TE. Of the men who completed the 6-month sperm suppression phase, 98% suppressed to the target threshold (<3 million (M) sperm/ml). The combined pregnancy rate for the men whose sperm concentration suppressed from 0 to 3 M/ml was 1.4 per 100 person-years. The combined pregnancy rate for men whose sperm concentration suppressed to 0–1 M/ml was 0.7 per 100 person-years, providing the benchmark for subsequent MHC studies stipulating a sperm concentration of ≤1 M/ml for entrance into an efficacy phase (wherein the experimental method is relied upon for contraception [19]).

Testosterone undecanoate (TU) in castor oil is a promising longer-acting injectable T formulation approved for use in many countries to treat male hypogonadism. Two studies in China demonstrated that IM TU is an effective hormonal contraceptive. In the first study [20], 308 men were enrolled in a 6-month suppression phase with a loading dose of 1000 mg IM TU followed by 500 mg monthly. 97% of men had sperm concentrations suppress to <3 M/ml during the suppression phase, and 296 couples were enrolled in a 6-month efficacy phase. There was only one pregnancy in the 280

couples who completed the efficacy phase. Based on these promising results, a longer follow-up study [21] recruited 1045 healthy Chinese men using the same regimen and suppression criteria in a 24-month efficacy phase study. 893 couples completed the suppression phase and 95% of these enrolled in the efficacy phase. Nine pregnancies occurred, with a resulting cumulative pregnancy rate of 0.55 per 100 person/years. Thus, using a long-acting injectable T formulation, these studies confirmed the efficacy findings of the shorter-acting WHO testosterone-alone trials. The most common side effects associated with these supraphysiologic doses of IM TU included injection site discomfort, acne, and acute, post-injection coughing.

Testosterone Plus Progestin Combinations

Progestins suppress gonadotropin secretion and may have additional direct, intratesticular effects, resulting in more rapid and complete suppression of spermatogenesis when a progestin is added to T for MHC [22]. The addition of a progestin also allows for lower, more physiological T dosing, reducing androgenic side effects and minimizing any long-term risks associated with supraphysiologic androgen exposure. The combination of T plus a progestin achieves severe oligospermia in 85–90% of men [10, 23–27]. Turner *et al.* demonstrated contraceptive efficacy using combination MHC in a proof-of-concept Australian study enrolling 55 couples, using T-pellets plus IM DMPA [13]. No pregnancies occurred in 426 person-months (95% CI contraceptive failure rate, 0–8%/year).

Based on results of preliminary work administering IM TU plus IM norethisterone enanthate [26] demonstrating an 8-week dosing interval induced severe oligozoospermia in 100% of men, a multicentre efficacy study [28] of this regimen was undertaken. Of the 320 participating couples, 96% of men (95% CI 92.8–97.9) suppressed to a sperm concentration ≤1 M/ml within 24 weeks. During the 1-year efficacy phase, four pregnancies occurred among 266 participants, giving a pregnancy rate of 1.57/100 continuing users (95% CI, 0.59–4.14). This study was discontinued early due to sponsor safety concerns (not those of the Data Safety Monitoring Board). There was one suicide during the efficacy phase judged by the investigators to be unrelated to the study medications, one case of depression (judged probably related to the study), and one attempted paracetamol overdose (judged possibly related). Additional adverse effects of concern included site injection pain, mood changes, increased libido, and acne. Adverse events surrounding mood, libido, and injection site pain were much more frequent in one of the ten study centres.

Testosterone Plus GnRH Antagonists

Systemically dosed gonadotropin-releasing hormone (GnRH) antagonists, acting on the pituitary, suppress circulating gonadotropin concentrations within hours of administration. It has been hypothesized that the addition of a GnRH antagonist to androgen-based MHC could potentiate suppression of gonadotropins and, consequently, spermatogenesis. However, GnRH antagonists are expensive to synthesize and difficult to deliver. There have been no efficacy trials of MHC regimens that include a GnRH antagonist, but studies of an androgen plus short acting GnRH antagonists (given daily) have not generally demonstrated superiority over androgens alone [29, 30] although one small study suggested that suppression induced by a GnRH antagonist plus testosterone might be sufficiently maintained with a physiologic dose of testosterone-alone. A similar study using 19-nortestosterone did not replicate these results [31]. A longer-acting GnRH antagonist, acyline, administered by subcutaneous injection, suppresses LH within hours, and lowers serum T concentrations to castrate levels within 24 hours, with effects lasting 14–15 days after a single injection [32]. However, a study of daily transdermal T-gel plus IM DMPA with or without acyline showed a similar degree and rapidity of suppression to severe oligozoospermia between groups [10].

Novel Synthetic Androgens

With the goals of minimizing androgen-related side effects, maximizing efficacy, and optimizing delivery systems for users with varied preferences, novel synthetic androgens are currently in development for MHC. Derivatives of 19-nortestosterone that retain the androgen effects of T but may have a longer half-life, negligible hepatotoxicity with oral administration, and progestogenic activity [33] have shown promise in recent clinical trials. In addition, ideal androgens for MHC are: (1) resistant to 5α-reductases, enzymes highly expressed in the prostate gland which convert T to the more potent androgen dihydrotestosterone (DHT) and are implicated in prostate cancer; and (2) aromatizable to metabolites which bind and activate the human oestrogen receptor. The role of oestrogen in male physiology has been increasingly recognized; oestrogen deficiency in men may result in bone loss, accumulation of body fat, decreased sexual function, and vasomotor symptoms (VMS) [34].

7α-methyl-19-nortesterone (MeNT) an attractive 'prostate-sparing' androgen, is aromatizable yet resistant to 5α-reductase [35, 36]. In a small 6-month study [37] MeNT implants administered to hypogonadal men maintained most androgen-dependent functions without prostate effects, although there was some bone loss suggesting oestrogenic activity may not have been adequate. As a contraceptive, an initial 1-year pilot study of MeNT implants was encouraging, with 8/11 of men developing severe oligozoospermia [38]. However, subsequent studies of MeNT plus a progestin were stymied by an implant design flaw, preventing sustained and adequate release of MeNT, which will need to be overcome before further human testing [39].

Dimethandrolone undecanoate (DMAU) and 11β-methyl-19-nortestosterone-17β-dodecylcarbonate (11β-MNTDC) are orally bioavailable 19-nortestosterone derivatives that bind and potently activate both androgen and progesterone receptors. Both DMAU and 11β-MNTDC are de-esterified to their active metabolites, dimethandrolone (DMA) and 11β-methyl-19-nortestosterone (11β-MNT), respectively, *in vivo*, and neither are reduced by 5α-reductase [40] nor likely aromatized to oestrogenically active metabolites. In castrated rodents, administration of DMAU demonstrated favourable changes in androgenic endpoints and maintenance of bone mineral density [41] with doses comparable to exogenous testosterone, while in rabbits oral DMAU given daily was an effective, reversible contraceptive [42]. These encouraging preclinical data supported the first-in-human trials of oral

DMAU and 11β-MNTDC. Placebo-controlled Phase I studies of escalating single doses of oral DMAU have assessed pharmacokinetics, safety and food effects in men [43, 44] and have demonstrated that oral DMAU is well-tolerated and significantly suppresses gonadotropin and T production in men, properties required for effective MHC. Of note, concomitant administration with a high-fat meal markedly improves oral DMAU/DMA pharmacokinetics and similar results were reported for single doses of 11β-MNTDC [45]. Recently, a one month, double-blind Phase I trial of daily oral DMAU administered to healthy men demonstrated doses of 200–400 mg are well-tolerated, markedly suppress gonadotropins, and suppress serum T to near castrate levels without significant, acute hypogonadal side effects [46]. These exciting results support the further development of DMAU as a single-agent oral male contraceptive pill and investigations are ongoing.

Contraceptive Efficacy, Sperm Targets, and Variable Responsiveness to MHC

In healthy men, sperm concentrations in the ejaculate are 15–150 million per millilitre (M/ml). Sperm concentrations of greater than 15 M/ml are associated with normal fertility [47]. The absence of spermatozoa in the ejaculate, azoospermia, is the ideal target of MHC, analogous to anovulation. However, the early WHO clinical efficacy studies demonstrated that oligospermia (<3 M/ml) and severe oligospermia (≤1 M/ml) are efficacious in the prevention of pregnancy [16, 18, 28].

An integrated analysis [22] reviewed MHC studies of at least 3 months' treatment duration, including a total of 1756 healthy men. Restricting the analysis to contraceptive efficacy studies employing optimized regimens (testosterone plus progestin) the authors concluded 96% of men suppress sperm output to <1 M/ml by 6 months using MHC. Current expert opinion based on phase II dose-finding trials [19] recommends a sperm concentration threshold of ≤1 M/ml as suitable for reliable contraception.

One question that has plagued the field is why some men, 5–10%, do not suppress their sperm production completely. Initial MHC studies with supraphysiologic T-alone found that 60% of non-Chinese and more than 90% of Chinese men became azoospermic [16, 18]. High rates of azoospermia among Chinese men have been replicated using monthly TU injections [3, 20, 21]. The explanation for differences in susceptibility to hormonally induced azoospermia between individual men and across ethnicities remains largely unknown, but may include both genetic and environmental factors [48]. In some men gonadotropin production may be incompletely suppressed thus allowing for persistent spermatogenesis but analyses of gonadotropin concentrations in multiple MHC studies have not supported this explanation [22, 49]. However, it remains possible that there are very small differences in serum gonadotropin concentrations or responsiveness in men who fail to reach severe oligospermia [50]. Rodent studies have demonstrated that spermatogenesis can be maintained by persistent, gonadotropin-independent testicular steroidogenesis [51, 52] although this has yet to be demonstrated in men.

Reversibility of MHC

Following cessation of short-term MHC in studies of reproductively normal men, hormone and sperm count recovery is nearly universal. In a multivariate, integrated analysis of individual data gathered from approximately 90% of all published androgen or androgen-progestin MHC trials, the median times for sperm to recover to thresholds of 20 or 10 M/ml were 3.4 months (95% CI 3.2–3.5) and 3.0 months (95% CI 2.9–3.1), respectively [4]. The typical probability of recovery to 20 M/ml was 90% within 12 months and 100% within 24 months. Various covariables were associated with time to recovery, but not the extent of recovery, including shorter duration of treatment, shorter-acting T preparations, higher sperm concentrations at baseline, and lower blood concentrations of LH at baseline [4]. Treatment duration appears to be a clinically important covariable [21, 53] but understanding its importance is limited by lack of 'long-term' MHC studies (>30 months treatment duration) highlighting a need for post-marketing surveillance [54]. There are no systematic studies of eugonadal men treated with androgens beyond 30 months, although users of androgenic-anabolic steroids generally have spontaneous sperm recovery within 12 months [55]. MHC efficacy data are limited for men of African or Hispanic origin; longer treatment studies in more diverse populations of men are required [54], although one study in African men demonstrated full reversibility [24].

Acceptability

Survey data suggest that men, women, and heterosexual couples across a wide range of countries find hypothetical MHC acceptable and appealing. In an extensive cross-cultural, multicentre population survey of more than 9000 men, the willingness to use a hypothetical MHC averaged 55% (range 29–71%) [56, 57]. A smaller four-country study yielded similar results [58]. A small Australian study [59], reported 75% of men willing to try an MHC. In this study, the three most popular choices for method of administration of MHC were (in descending order) an oral pill, a 3-monthly injection, or a 2-yearly injection. Female partners from a variety of cultures also indicate high level of interest in MHC. In a survey of 1894 women attending family planning clinics in Scotland, China and South Africa, 65% felt the responsibility for contraception falls too much on women and more than 90% in South Africa and Scotland thought that a 'male pill' was a good idea, with Chinese women only slightly less positive. Overall, 40–78% indicated they would support and trust their male partners in stable relationships to use MHC [60].

Most study participants in MHC trials would be willing to use the method under evaluation were it available, although such data have inherent responder bias given the self-selection of participants volunteering in clinical trials. A Chinese acceptability study [61] of monthly IM testosterone undecanoate (TU) carried out concurrently with, but independently from, a clinical efficacy trial, indicated the majority of participants were satisfied with monthly injections. More recently, as part of a six-month, double-blind, randomized controlled trial of T and NES transdermal gels, 56% of men were satisfied with the method, and 51% reported that they would recommend a transdermal gel-based MHC [11]. More than 75% of

men, and their female partners, who participated in the most recent MHC efficacy study of long-acting T and progestin injections would use the method were it available [28].

Together, these studies support the development of effective MHC but further work is needed to more clearly define the potential market. Such work is challenging without an available product, as the introduction of new contraceptive methods may influence behaviours and acceptability in unforeseen ways. Models of limited uptake suggest that MHC could influence unplanned pregnancy rates [62].

Adverse Effects

Potential adverse effects from MHC include alterations in sexual function, mood, body composition, and other changes in androgen-sensitive tissues. Side effects of exogenous androgen administration include reversible testicular atrophy and acne, and these can occur with T containing MHC. Androgen administration can also modestly lower high-density lipoprotein-cholesterol (HDL-C), as has been observed in some MHC studies [54], although the clinical significance of alterations in HDL-C are unclear [63].

Potential adverse effects of MHC related to mood and sexual function are difficult to quantify as very few studies of prototype MHC have included a placebo group. A recent placebo-controlled androgen-progestin trial [53] to assess sperm suppression and safety, demonstrated changes in mood, libido, acne, weight gain, and night sweats that were statistically more prevalent than in the active compared to placebo groups. Adverse effects were self-reported by 93% of men receiving active treatment versus 81% of placebo-treated men. Although mood changes have been reported as mild in T-only studies, the most recent MHC efficacy study combing TU and a long-acting progestin [28] raised concerns regarding the potential for adverse mood effects of progestin-containing regimens, a finding that requires further study in future MHC trials.

The influence of MHC on long-term disease risk in men is unknown. There has been no evidence to suggest that MHC increases the risk of prostate disease or cardiovascular events, but studies to date have been done in healthy men who are young or middle-aged (18–50 years), have been short in duration (1–2.5 years), and underpowered to identify cardiovascular, thrombotic, or prostatic events. Longer-term studies will be required, at a minimum, as well as post-marketing evaluation if and when MHC is approved.

Conclusion

MHC has the potential to offer a new effective and reversible family planning option for men and couples. Androgens provide the basis of MHC via suppression of the hypothalamic–pituitary–testicular axis and, as a result, spermatogenesis; adding a progestin improves sperm suppression and can reduce androgen dosing and androgen-related side effects. Short-term side effects of T-progestin regimens are mild, but there are concerns regarding potential effects on mood and long-term disease risks. Novel, orally bioavailable, synthetic androgens with both androgen and progestin activity, are in clinical trials and are promising candidates as single-agent MHC, including as a once daily 'male pill'.

Management of Gynaecomastia

Glenn D. Braunstein

Introduction

The term gynaecomastia is used to describe the unilateral or bilateral benign enlargement of the glandular tissue in the male breast. Various studies have defined gynaecomastia as glandular tissue exceeding 0.5–2.0 cm [1, 2]. The condition may present as an acute growth with pain and tenderness, or may be an incidental, painless finding detected during a physical examination. It is relatively common and needs to be distinguished from other causes of breast enlargement in males including fat deposition (lipomastia or pseudogynaecomastia) and breast carcinoma. Although gynaecomastia itself is benign, and often occurs as part of normal puberty or senescence, or as an adverse reaction to some drugs, its presence may indicate an underlying pathological abnormality. Therefore, it is important to have an understanding of its pathophysiology, causes, and diagnostic approach to arrive at a rational plan for managing gynaecomastia and any associated conditions.

Prevalence of Gynaecomastia

Transient gynaecomastia has been noted in 60–90% of newborns, presumably due to the transplacental transfer of maternal oestrogens during pregnancy. Physiological gynaecomastia also occurs during puberty, ranging from 4% to 69% in different epidemiological studies, with a median prevalence of about one-third of adolescent boys exhibiting some degree of breast glandular tissue enlargement. Clinical and autopsy studies have shown that about one-third to two-thirds of adult men may exhibit gynaecomastia [1–3].

Pathophysiology

Breast tissue at birth is identical in both males and females, and their responses to hormonal stimulation is the same. Oestrogens stimulate growth and branching of the ducts, hyperplasia of the ductal epithelium, fibroblast proliferation in the periductal areas, and increase in the vascularity of the breasts. Insulin-like growth factor may help sensitize the glandular tissue to the effects of oestrogens. Acinar development, a requirement for lactation to occur under the influence of prolactin, is generally not seen in males because luteal phase progesterone levels are required. Androgens antagonize the effects of oestrogen on breast glandular tissue. Thus, gynaecomastia occurs when there is an imbalance between the stimulatory effects of oestrogens and the inhibitory effects of androgens [1].

An alteration of this balance can occur when oestrogen secretion is increased, androgen secretion decreased, exogenous oestrogen or oestrogen-like substances are present, exogenous antiandrogens are present, or there are abnormalities in androgen receptor function.

About 95% of testosterone, 15% of oestradiol, and less than 5% of estrone are secreted by the testes in adult males. The majority of the circulating oestradiol and estrone is produced in peripheral tissues from androgen precursors, testosterone, and androstenedione, the latter being secreted by the adrenal glands. This conversion is mediated by the aromatase enzyme complex that is widely distributed throughout the body, being present in the testes, adrenals, fat, skin, liver, muscles, bone, and kidneys. Aromatase activity increases with age, reflecting the age-related increase in fat mass, and also the increased aromatase activity per fat cell. Testosterone and androstenedione are interconverted in extragonadal tissues by 17-ketosteroid reductase, as is oestradiol and estrone. Approximately one-half to two-thirds of the sex steroid hormones are transported in the blood bound to sex hormone-binding globulin (SHBG), a low capacity, high affinity transport protein; about one-third bound to albumin, a high capacity, low affinity binding protein; with 1–2% being unbound or free to enter target tissues. Since the steroids bound to albumin may disassociate and also enter target tissues, the combination of free and albumin-bound steroids is termed 'bioavailable'. When testosterone enters target tissues, it may bind directly to the androgen receptor or be converted to dihydrotestosterone (DHT) by 5α-reductase, which also binds to the androgen receptor. Following receptor binding, the androgen-androgen receptor complex is translocated into the

nucleus, binds to DNA, and transcribes androgen action in the target tissues. Similarly, oestrogens bind to oestrogen receptors to bring about oestrogenic effects. Alterations in any of these activities may result in a change in the oestrogen/androgen relationship to a sufficient degree to stimulate breast glandular tissue growth [1, 2].

Conditions Associated with Gynaecomastia

Box 10.9.1 lists the conditions that have been associated with gynaecomastia and the primary pathophysiologic mechanisms identified for pathologic gynaecomastia. Combined results from several series of adult patients seeking consultation at plastic surgical or endocrine clinics have shown that 25% of patients have acute or persistent pubertal gynaecomastia, 25% were classified as having idiopathic gynaecomastia, 10–20% related to medications or drugs, 8% from cirrhosis or malnutrition, 8% from primary hypogonadism, 3% from testicular tumours, 2% secondary hypogonadism, 1.5% from hyperthyroidism, and 1% from kidney disease (2). A more recent survey at a single medical centre of 786 men with gynaecomastia over the age of 18 years reported that 25% had persistent pubertal gynaecomastia, 37% with idiopathic, 10.8% associated with medicine intake, 10% had used anabolic steroids or suffered from substance abuse, 10% had hypogonadism, 2.9% hepatic insufficiency, 2.3% other endocrine disorders, 0.8% had a testicular tumour, and 0.1% renal insufficiency (3).

Pubertal Gynaecomastia

Pubertal gynaecomastia has an onset usually between the ages of 10 and 12 years, with a peak occurrence between the ages of 13 and 14, when Tanner genital or pubic hair stages 3 to 5 are reached. Gynaecomastia usually occurs within one year of the boy's peak height velocity. The development of gynaecomastia may be asynchronous, with one breast enlarging weeks to months before the other enlarges. Although most boys who develop gynaecomastia will have it resolved in 6–18 months, it may persist beyond puberty in up to 20% or higher of late adolescents to young men, accounting for the high proportion of patients with gynaecomastia presenting to endocrine or plastic surgical clinics for evaluation and treatment [4].

The cause of pubertal gynaecomastia has not been fully elucidated. Some studies have shown an imbalance in oestrogens/androgens at the start of or during pubertal gynaecomastia while others have not, possibly due to the investigator missing the peaks of increased oestrogen production, which may have antedated the appearance of the breast growth. The rate of change of oestrogen and androgen production during puberty may also be a factor, since oestrogen levels rise 3-fold across puberty and androgens increase 30-fold, with the oestrogen levels reaching adult concentrations before the testosterone concentration peaks. The activity of aromatase may be increased in pubertal males who develop gynaecomastia in comparison to those who do not, as aromatase activity was shown to be increased in pubic skin fibroblasts in some boys with pubertal gynaecomastia. However, a randomized, placebo-controlled trial of the aromatase inhibitor anastrozole in pubertal gynaecomastia did not show any improvement over placebo, suggesting that aromatization of androgens in fat or other tissues is not of major importance in the genesis of pubertal gynaecomastia [5]. Similarly, studies have shown that serum oestradiol levels largely determine the oestrogen

Box 10.9.1 Conditions associated with gynaecomastia and their pathophysiologic mechanisms

Physiologic
Neonatal
Pubertal
Ageing

Pathologic
Decreased testosterone action
- Primary hypogonadism
- Secondary hypogonadism
- Defects in testosterone synthesis
  - Congenital
  - Drug-induced (e.g. ketoconazole)
- Decreased androgen receptor function
  - Congenital androgen receptor defects
  - Drug-induced (e.g. spironolactone, cimetidine)

Increased oestrogen
- Increased aromatization of androgens
  - Germ cell tumours (testicular and extragonadal)
  - Sertoli cell (sex cord) tumours
  - Leydig cell tumours
  - Feminizing adrenocortical tumours
  - Disorders of sexual development
  - Obesity
  - Hyperthyroidism
  - Liver disease
  - Androgen insensitivity syndrome
  - Refeeding after starvation
  - Primary aromatase-excess
- Displacement of oestrogen from SHBG
  - Spironolactone
  - Ketoconazole
- Decreased oestrogen metabolism
  - Cirrhosis
- Exogenous sources
  - Topical oestrogen creams, lotions, or patches
  - Ingestion of oestrogen
  - Environmental exposure
- Human chorionic gonadotrophin-producing tumours
  - Eutopic (germ cell tumours)
  - Ectopic (e.g. lung, liver, gastric, renal)

Drug-induced
- Good evidence

levels in normal breast tissue. Blood levels of two other hormones, leptin, and insulin-like growth factor-1 (IGF-1), have been found to be elevated in boys with pubertal gynaecomastia in comparison to those without. The finding that pubertal gynaecomastia occurs in a temporal association with peak height velocity, the time when IGF-1 levels also peak, lends credence to the suggestion that oestrogens and IGF-1 both play a role in the genesis of pubertal gynaecomastia [6]. Also, the observation that gynaecomastia may occur during growth hormone therapy, which elevates the levels of IGF-1, supports a role of IGF-1 in the development of pubertal gynaecomastia. In addition, polymorphisms of the leptin and oestrogen receptor-β genes and the G protein-coupled receptor (GPR30), a membrane bound receptor mediating non-classical oestradiol signalling, have been implicated in an increased susceptibility for pubertal gynaecomastia [7].

Ageing

The frequent finding of asymptomatic gynaecomastia in older men is probably multifactorial. Body composition changes during ageing, with fat mass increasing while lean body mass decreases. Since fat contains aromatase and aromatase levels per fat cell increases with age, there is enhanced conversion of androgens to oestrogens as part of the ageing process. Additionally, in many men, testosterone levels decrease over time and SHBG concentrations increase, resulting in a lowering of the free and bioavailable fractions of testosterone, and, thus, less antagonism of oestrogen at the breast glandular tissue level. A rise in luteinizing hormone (LH) levels that accompanies the drop in testosterone in some older men also may stimulate enhanced aromatization of testosterone to oestradiol in the testes. Also, older men are more likely to take medications (**Box 10.9.1**) that may be associated with gynaecomastia [1, 2, 8].

Drug-Induced

Many different drugs, including some illicit substances, have been associated with gynaecomastia in adults, but most of the reports, often anecdotal or small clinical series, relied on just a temporal relationship between taking the drug and the subsequent occurrence of gynaecomastia. An evidence-based review placed drugs into three categories based upon the level of evidence. Good evidence required a systematic review of randomized controlled trials, or randomized placebo-controlled trial, or prospective cohort studies with or without concurrent controls plus a good pathophysiological explanation. Fair evidence required retrospective studies or case-control studies or case series with a good pathophysiological explanation. Isolated case reports alone were classified as poor level of evidence. Drugs with good evidence of association with gynaecomastia include oestrogens, spironolactone, cimetidine, ketoconazole, growth hormone, gonadotropins, antiandrogen therapies (flutamide, bicalutamide, nilutamide, enzalutamide, cyproterone acetate, goserelin, leuprorelin) and 5α-reductase inhibitors (finasteride, dutasteride). Drugs with fair evidence of an association with gynaecomastia include some antipsychotics (haloperidol, risperidone), calcium channel blockers (verapamil, nifedipine), omeprazole, HIV antiretroviral drugs (especially protease inhibitors), alkylating agents, anabolic steroids, lavender, and tea tree oil, alcohol, and opioids. All of the other drugs reported to be associated with gynaecomastia currently fall in the poor level of evidence category [9].

Drugs such as cimetidine, spironolactone, flutamide, bicalutamide, nilutamide, enzalutamide, and cyproterone acetate are known to bind to the androgen receptor and inhibit androgen action.

Drug-induced gynaecomastia generally has its onset as early as a week after starting the offending medication, with the majority of patients experiencing gynaecomastia within 9 months of continuous drug usage, although onset between 2 and 3 years of continuous drug usage have been reported.

Hypogonadism

Primary hypogonadism due to intrinsic testicular failure results in a low testosterone and elevation of LH and often follicle-stimulating hormone (FSH). Oestrogen antagonism at the breast glandular tissue level is reduced. The most common genetic cause is Klinefelter syndrome (XXY genotype) characterized by small firm testicles, gynaecomastia, and varying degrees of hypogonadism. The degree of hypogonadism and gynaecomastia is related in part to the number of CAG repeats in the androgen receptor gene—those with longer repeats are less virilized [10]. Patients with Klinefelter syndrome are at increased risk for the development of breast cancer as well as germ cell tumours, which may cause gynaecomastia through the secretion of human chorionic gonadotropin (hCG) [11]. Other causes of primary hypogonadism include anorchia, cryptorchidism, Leydig cell aplasia, Noonan syndrome, myotonic dystrophy, viral orchitis, granulomatous diseases, and defects in testosterone biosynthesis.

Secondary hypogonadism results from hypothalamic or pituitary dysfunction, and ranges from panhypopituitarism to specific defects in gonadotropin production or secretion. Genetic causes include defects in the *KAL1* gene that leads to anosmia and hypogonadotropic hypogonadism and mutations in the *FGFR1, KISS1, KISS1R, GnRH1, PROK2*, and *PROKR2* genes that are associated with secondary hypogonadism without defects in the sense of smell. Hypogonadotropic hypogonadism also is found with defects in the genes encoding leptin, leptin receptor, and the β-subunit of LH. Several complex congenital syndromes have secondary hypogonadism as part of the clinical picture [1]. These include Prader–Willi, Laurence–Moon Bardet–Biedl, Mobius, and Lowe syndromes, as well as cerebellar ataxia. Acquired causes may result from tumours, infection, vascular issues, and infiltrative diseases involving the pituitary or hypothalamus. The loss of hypothalamic gonadotropin-releasing hormone (GnRH) production or destruction of or defects in the gonadotrophs in the anterior pituitary results in inadequate LH secretion that in turn leads to lowered testosterone secretion.

Prolactin-secreting pituitary tumours in men causes hypogonadism through several mechanisms. Macroadenomas may destroy enough gonadotrophs to result in inadequate LH secretion. Additionally, the elevated prolactin may inhibit hypothalamic GnRH secretion and, thus, inadequate gonadotroph stimulation, reducing LH stimulation of testicular testosterone production. Finally, the high prolactin may directly suppress testosterone release from the testes. Lowering the prolactin through the use of a dopamine agonist often results in a rise in testosterone as long as sufficient gonadotrophs are functional. Of note, prolactin, which stimulates milk production in breasts that have been primed by oestrogens and progesterone, does not stimulate breast glandular growth and has not been directly associated with the development of gynaecomastia.

Testicular Tumours

Approximately 95% of testicular tumours are germ cell neoplasms and close to 10% of patients have gynaecomastia at presentation due to the secretion of hCG which inhibits testicular 17,20-lyase and 17-hydroxylase activity and stimulates Leydig cell aromatase activity, leading to a relative increase of oestradiol to testosterone [12]. Following treatment, close to 15% of patients will develop at least transient gynaecomastia due to therapy-related hypogonadism Ectopic production of hCG by non-trophoblastic neoplasms, such as lung, gastric, renal, or hepatocellular carcinomas, may rarely be associated with gynaecomastia if the tumour secretes intact hCG rather than the biologically inactive hCGβ-subunit, through the same mechanism as with the germ cell trophoblastic tumours (eutopic production).

Leydig cell tumours secrete increased quantities of oestradiol resulting in gynaecomastia in 20–30% of males harbouring this tumour, 90% of which are benign. The elevated oestradiol inhibits LH secretion leading to a decrease in testosterone production, contributing to the oestrogen/androgen imbalance.

The rare large-cell-calcifying Sertoli cell (sex cord) testicular tumours exhibit excessive aromatase activity and are associated with gynaecomastia. These tumours occur sporadically and in patients with two autosomal dominant disorders, Peutz–Jeghers syndrome, and Carney complex. Peutz–Jeghers is due to a mutation in the *STK11 or LKB1* genes and results in prepubertal gynaecomastia, gastrointestinal hamartomatous polyps, and mucocutaneous macules. Carney complex also is associated with prepubertal gynaecomastia, pigmented lentigines, blue nevi, myxomas, Cushing syndrome, and thyroid nodules including thyroid cancer [13].

Feminizing Adrenocortical Tumours

Gynaecomastia is found in virtually all males with feminizing adrenocortical tumours, three-quarters of which are malignant. Over half of these patients have a palpable tumour and about half of the patients have testicular atrophy. These tumours have high levels of aromatase activity and secrete increased amounts of oestrogens. The high oestrogen levels also lead to secondary hypogonadism with a reduction in testosterone [14].

Disorders of Sexual Development

Disorders of sexual development in which both testicular and ovarian tissue is present may also be associated with gynaecomastia due to the secretion of oestradiol from the ovarian tissue, which suppresses LH and testicular production of testosterone. These disorders are usually diagnosed in childhood because of the presence of ambiguous genitalia.

Hyperthyroidism

Estimates of the prevalence of gynaecomastia in males with hyperthyroidism vary from less than 10% to as high as 40%. Hyperthyroidism is associated with an increase in LH levels, excessive aromatization of androgens to oestrogens, and elevated SHBG levels [15]. Given SHBG binds testosterone with higher affinity than oestradiol, increased SHBG concentrations lead to a raised free E2/free T ratio, further aggravating the gynaecomastia.

Liver Disease

The gynaecomastia associated with severe liver disease or cirrhosis is multifactorial. About two-thirds of patients with cirrhosis exhibit breast glandular enlargement due to increased adrenal production of androstenedione, increased aromatization of the androstenedione to estrone, increased conversion of estrone to oestradiol, raised SHBG levels and the use of spironolactone to treat the fluid retention of cirrhosis [16, 17].

Obesity

Breast enlargement is common in obese males and may be due to fat deposition (pseudogynaecomastia or lipomastia), gynaecomastia, or a combination of the two. In adults, a close correlation has been found between the prevalence of gynaecomastia and the body mass index and the amount of adipose tissue [16]. As previously noted, fat tissue contains the aromatase enzyme complex and it has been found that oestrogen production rates increase in proportion to the percentage increase in body weight above normal [18]. Thus, it has been hypothesized that the gynaecomastia found in some obese patients is due to the local production of oestrogens from androgen precursors such as androstenedione by the periglandular fat tissue in the breast, a process termed intracrinology [19]. However, it has been shown that breast tissue oestradiol levels are primarily derived from the blood and not locally produced [20]. In addition, aromatase inhibitors have not been found to be effective in treating gynaecomastia not associated with the aromatase-excess syndrome (see next). Finally, there is conflicting data in adolescents, with some studies showing a correlation between body mass index and the prevalence of gynaecomastia, while others show no correlation or even a negative correlation. It is possible that much of the gynaecomastia reported in obese males essentially reflects lipomastia/pseudogynaecomastia and not true gynaecomastia.

Refeeding After Starvation

Testicular atrophy, decreased libido, and erectile dysfunction were noted to be a common occurrence in American prisoners of war following the Second World War, and about 10% exhibited gynaecomastia. Studies on patients with chronic disease and weight loss have shown that the gonadotropins are low as is testosterone. During refeeding, the gonadotropins rise as does the testosterone, and many men developed transient breast tenderness, pain, and gynaecomastia about 2–3 months following initiation of refeeding, a process that some have termed a 'second puberty'. Refeeding gynaecomastia resolves within one to two years. This mechanism probably accounts in part for the gynaecomastia that can occur in men with chronic renal failure after they start dialysis, and some patients with treated congestive heart failure [1, 2].

Chronic Renal Insufficiency

Men with chronic kidney disease often have gynaecomastia that may be multifactorial. Leydig cell dysfunction with low testosterone production and elevated LH levels may be present. Renal failure reduces the clearance of LH and prolactin and the elevated prolactin may contribute to the reduction in testosterone production [21, 22]. As already noted, improvement in nutrition and health status with dialysis or transplantation may lead to a transient 'refeeding' gynaecomastia.

Androgen Receptor Defects

Congenital inactivating mutations in the androgen receptor gene results in a spectrum of clinical findings ranging from the complete androgen insensitivity ('testicular feminization') syndrome to partial androgen insensitivity syndrome (PAIS). In the absence of androgen receptor function, affected individuals whose genotype is XY will appear to be phenotypic females at birth with open labioscrotal folds, a short vagina, absent uterus, and fallopian tubes, abdominal or inguinal testes. During puberty, there will be absence of pubic or axillary hair and, because of unopposed oestrogen action, gynaecomastia will develop. Patients with PAIS show a spectrum of clinical findings from some degree of ambiguous genitalia (e.g. hypospadias), to normal phenotypic males with gynaecomastia being the only clinical manifestation. In all of these syndromes, testosterone is elevated as is oestradiol (from aromatization of the elevated testosterone). LH is also elevated since suppression of GnRH from the androgen component is absent. The gynaecomastia is the result of unopposed oestrogen effect on the breast glandular tissue [23].

Patients with Kennedy syndrome (spinobulbar muscular atrophy), an X-linked disorder that leads to proximal muscle weakness with fasciculations and tremor and gynaecomastia is the result of an increased number of CAG repeats in the androgen receptor gene that leads to PAIS.

Congenital Aromatase-Excess Syndrome

The rare familial prepubertal gynaecomastia or aromatase-excess syndrome is an autosomal dominant constitutive activation of the aromatase gene (*CYP19A1*) due to heterozygous inversions, duplications, and polymorphisms. Boys with these mutations exhibit prepubertal or peripubertal gynaecomastia, accelerated growth and bone maturation in childhood, with diminished height in adulthood due to premature fusion of the epiphyseal plates in the long bones, elevated oestradiol and estrone from the excessive aromatization and low testosterone [4, 24].

Diagnostic Evaluation

Breast Examination

It is important to establish whether the patient has true gynaecomastia versus pseudogynaecomastia (lipomastia), breast carcinoma, or other conditions that can lead to unilateral or bilateral breast enlargement. Gynaecomastia cannot be diagnosed from a photograph. It requires careful palpation. One method is to have the patient lie flat on his back with his hands locked behind his head. The examiner separates his or her thumb and forefinger, places them on either side of the breast, and slowly and gently brings them together. True gynaecomastia will be felt as a firm or rubbery disc of tissue that is concentric to the nipple-areolar complex, while in patients with pseudogynaecomastia the thumb and forefinger will not meet resistance until they come to the nipple. If gynaecomastia is of recent onset, tenderness to palpation may be present [8].

In contrast, breast cancer, which is rare in men, generally presents as a unilateral, hard, or firm non-tender mass that is eccentric and may be fixed to the underlying tissues. Dimpling of the skin, nipple retraction, nipple discharge, and axillary lymphadenopathy may also be found.

Other lesions affecting the breast include hematomas, lipomas, dermoid cysts, neurofibromas, and lymphangiomas. These are usually unilateral and generally do not present as a mass that is concentric to the nipple-areolar complex.

History

It is important to document when the patient became aware of the gynaecomastia, whether it was unilateral or bilateral, was or is associated with pain and tenderness, and whether the breast tissue has continued to grow. A family history of gynaecomastia suggests a genetic aetiology. A medication and drug history is essential. Has the patient taken any of the drugs known to be associated with gynaecomastia, and is there environmental exposure to oestrogens or oestrogen-like agents? Over-the-counter preparations should be considered as some herbal remedies have been adulterated with hormones. Is there a temporal relationship between starting a medication and the occurrence of breast enlargement? A full pubertal history should be obtained including age of onset of axillary and pubic hair, growth spurt, acne, sexual function, and whether the patient recalls pubertal gynaecomastia. Symptoms of hyperthyroidism, liver, or renal disease should be sought. Recent weight loss or weight gain should be recorded and the reasons for the weight change evaluated.

Physical Examination

In addition to the breast examination, a full physical examination should be performed looking for signs of pituitary tumours, hyperthyroidism, liver or renal insufficiency, abdominal masses, testicular size and tumours, incomplete sexual development, and neurological abnormalities.

Laboratory Studies

Most breast masses in males represent gynaecomastia, especially if it is bilateral and extends concentrically beneath the nipple-areolar complex, and do not require imaging for diagnosis. However, if it is unclear whether the breast mass is gynaecomastia or breast carcinoma, an ultrasound, mammogram, breast MRI, or needle aspiration of the mass could be performed to make the distinction.

If a specific condition associated with gynaecomastia is suspected, appropriate laboratory and imaging studies should be performed. Chronic, asymptomatic gynaecomastia discovered incidentally on a physical examination is rarely associated with laboratory abnormalities. However, the prevalence of compensated or uncompensated primary hypogonadism increases with ageing, and, therefore, it is reasonable to measure a serum testosterone level. If it is low or low normal, remeasurement of total or free testosterone with a serum LH may provide the diagnosis [8].

Gynaecomastia occurring in the pubertal age range generally does not require any evaluation other than a careful physical examination and ascertaining whether the adolescent is using anabolic steroids. Most often reassurance and a follow-up examination at 3 monthly intervals until it resolves or is determined to be persistent is all that is necessary.

In an adult, the onset of acute, symptomatic gynaecomastia should warrant an evaluation of hepatic and renal function tests, thyroid-stimulating hormone (TSH), total testosterone, LH, hCG, and oestradiol. Figure 10.9.1 provides a means to arrive at the probable diagnosis based upon the results.

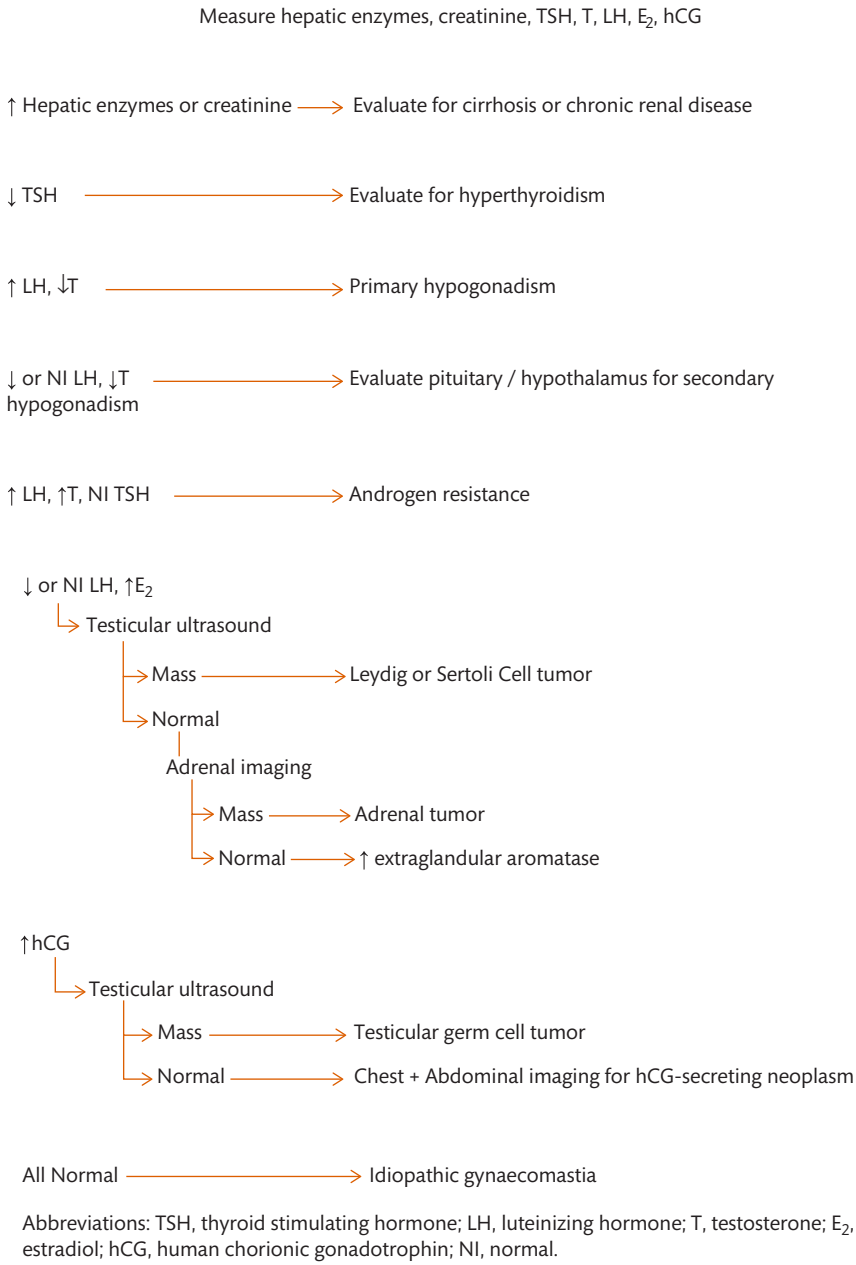

Figure 10.9.1 Laboratory evaluation for gynaecomastia.
Measure hepatic enzymes, creatinine, TSH, T, LH, E_2, hCG.
Abbreviations: TSH, thyroid stimulating hormone; LH, luteinizing hormone; T, testosterone; E_2, oestradiol; hCG, human chorionic gonadotrophin; NI, normal.

Treatment

Treatment depends upon the duration of the gynaecomastia, the underlying aetiology, if known, and whether the patient is bothered by its presence due to pain, tenderness, or embarrassment.

The longer the gynaecomastia is present, the less reversible it becomes. Histological studies have shown that there are three phases that the breast tissue exhibits. During the acute phase, which lasts up to about 6 months, there is proliferation of the ducts and hyperplasia of the ductal epithelium, along with an increase in the stromal and periductal connective tissue, and a marked increase in vascularity accompanied by periductal oedema. It is during this phase that pain and tenderness is present. If the inciting cause is treated (e.g. the medication stopped or a testicular tumour removed), regression of the gynaecomastia takes place. Also, it is during this stage that spontaneous resolution also is most likely. Gynaecomastia that has been present for over a year generally shows some hyalinization of the stroma, reduction of the ductal epithelial hyperplasia and dilation of the ducts. This fibrotic stage of gynaecomastia is less likely to respond to medical therapy or resolve on its own, although spontaneous resolution of gynaecomastia present for over 2 years has been noted in epidemiological studies. Between the acute florid stage and chronic fibrotic stages is an intermediate stage with mixtures of both components.

Since the majority of adolescents who develop pubertal gynaecomastia have spontaneous resolution of the condition, counselling, and observation generally is all that is needed. It is important to rule out confounding factors such as the use of anabolic steroids, and to perform a careful physical examination including the genitalia to determine that the gynaecomastia has occurred at the anticipated time during the pubertal process.

Several medical therapies have been examined to treat gynaecomastia. However, few of the trials have been double-blind and placebo-controlled, which is important when studying a condition that has a high spontaneous resolution rate. Additionally, the numbers of subjects in the individual trials generally have been low, the causes of the gynaecomastia have been mixed, and some have included patients with long-standing gynaecomastia which, because of the fibrosis in the breast, are unlikely to show improvement.

Medical therapies have included androgens, selective oestrogen receptors modulators (SERMS), and aromatase inhibitors.

In hypogonadal men with painful gynaecomastia, testosterone replacement may resolve the breast enlargement. However, long-standing gynaecomastia is unlikely to respond. Testosterone therapy for eugonadal men with gynaecomastia is not useful. Testosterone has also had some success in treating gynaecomastia associated with cirrhosis. The testosterone metabolite, dihydrotestosterone, which is not aromatizable has been used as a gel in uncontrolled studies to treat gynaecomastia. However, there is insufficient published data to recommend its use. The impeded androgen, danazol, has shown some efficacy in limited trials.

Several selective oestrogen receptor modulators, including clomiphene citrate, tamoxifen, and raloxifene, have been tried with some success. The best studied has been tamoxifen in doses of 10 mg twice daily for three months, used in a non-regulatory agency approved ('off label') manner. Analysis of six studies including 109 patients indicated that this treatment is effective in reducing the size of gynaecomastia in up to 80% of individuals and is safe, although it may not lead to complete resolution of the gynaecomastia [25].

Although theoretically ideal for treating a condition where there is an imbalance in oestrogen to androgens in breast tissue, the results from aromatase inhibitor trials have been disappointing. A double-blind, placebo-controlled trial in adolescents with pubertal gynaecomastia did not show superior results compared to the placebo arm [5]. However, aromatase inhibitors have been effective in patients with the aromatase-excess syndrome; further studies with some of the newer, more potent aromatase inhibitors in patients with recent-onset gynaecomastia should be performed.

For long-standing gynaecomastia, or gynaecomastia that does not respond to medical therapy, surgical removal of the breast tissue should be considered in patients with persistent pain and tenderness or who are psychologically distraught over the condition. There are several plastic surgical techniques that have been developed, but most include blunt dissection and removal of the glandular tissue along with liposuction to contour the breasts. Exuberant gynaecomastia often requires skin excision in addition. Complications of surgery include dehiscence of the wound, sloughing of tissue, contour irregularity, infection, seroma, or haematoma formation. Surgery should not be performed in adolescents until the patient is at the end of puberty because of the risk of regrowth of breast tissue if performed during the time that the oestrogen/androgen balance is fluctuating [26]. It is important to have the procedure performed by a breast plastic surgeon with extensive experience in performing gynaecomastia surgery in order to minimize the complication rate and maximize patient satisfaction.

Prevention

Men receiving antiandrogen treatment for prostate cancer have a high risk of developing gynaecomastia. Indeed, those receiving bicalutamide monotherapy, have about a 70% chance of developing the condition. Concurrent treatment of these individuals with tamoxifen reduces this rate to about 10%. Similarly, prophylactic radiotherapy also prevents antiandrogen-induced gynaecomastia in the majority of the patients [8].

Exogenous Factors and Male Reproductive Health

10.10.1 Environmental Influences on Male Reproductive Health

Jorma Toppari

Introduction

Adverse trends in male reproductive health have raised concerns about environmental effects. Reproductive toxicology has long been one of the main requirements of chemical testing that aims to demonstrate product safety. The crucial role of hormonal regulation of the development and functions of reproductive organs brought endocrine-disrupting chemicals, also referred to as endocrine disruptors, into the limelight of reproductive toxicology. Endocrine disruptors have been on the top of agenda in chemical regulation in the European Union, the United States, and elsewhere with reproductive health being a major focus. What is the role of endocrine disruptors in male reproductive health problems? Male reproductive health and endocrine disruption was first considered with oestrogenic chemicals [1], but antiandrogens have attracted more attention recently. Comprehensive reports have been produced by World Health Organization [2], and Endocrine Society [3].

Environmental effects are not limited to chemical exposures. Irradiation, heat, and other physical effects can contribute to reproductive problems. Lifestyle and general health also affect reproductive function. Consideration of all these factors together is necessary for full assessment of possible environmental effects on reproduction.

As for many other health outcomes, foundations of reproductive health are largely laid early in development. In normal male development, structural integrity of reproductive organs is established already during gestational weeks 8–15, and the perinatal period is important for testicular and penile growth. Late prepuberty and puberty finalize sexual and reproductive development. Adverse effects during these developmental windows can produce irreversible damage. In adult age, reproductive health can also be impaired, but the effects are often temporary and therefore reversible. For example, cancer therapy can induce sterility for several years, after which spermatogenesis recovers if spermatogonial stem cells have not been destroyed. Environmental influences can be analysed in these two contexts: developmental effects and adult effects. As said, the former can cause structural anomalies and permanent functional deficiencies, whereas the latter cause functional defects that can be reversible. There is robust evidence of adverse effects of endocrine disruptors on the male reproductive system in experimental animals (**Table 10.10.1.1**). In contrast, human evidence is based on epidemiological observational studies where single exposures have been correlated with various outcomes and the results are less clear. Occupational and accidental exposures are informative exceptions as described next.

Contemporary Effects

Cancer chemotherapy and irradiation have direct toxic effects on spermatogenic cells. Spermatogonia are actively proliferating and therefore particularly susceptible. Critical doses of X-irradiation have been quantified decades ago [4]. Gonadal exposure to higher than 4–6 Gy can produce permanent azoospermia, whereas recovery can occur within 5 years after lower doses, and the recovery time is inversely correlated to the dose. Even exposure to 0.15 Gy produces a significant but transient decline in sperm production, and there is no safe radiation dose. Fractionation of irradiation leads to even worse disruption than a single dose. Alkylating cancer drugs, such as cyclophosphamide, can cause permanent azoospermia, while non-alkylating agents (e.g. vincristine and methotrexate) are less toxic for spermatogenic cells.

Table 10.10.1.1 Effects of endocrine disruptors on male reproductive system in experimental animals

EDC	Observations
Synthetic oestrogen Diethylstilboestrol (DES)	Reduction in testis weight; testicular lesions; reduction in the number of spermatogonia with multinucleate cells in lumina of testis; distension and overgrowth of the rete testis; underdevelopment of the epididymal duct epithelium; epididymal cysts; reduction in epithelial height in the vas deferens; convolution of the extra-epididymal vas; distension and reduction in epithelial height of the efferent ducts; decreased androgen receptor expression in testis, epithelium of the rete testis, caput and cauda epididymis and vas deferens; inflammatory disease of the accessory sex glands; nodular enlargements of the seminal vesicles and/or prostate; decreased testosterone levels; increased gonadotrophin levels; decreased pituitary response to GnRH; cryptorchidism; sterility
Antifouling agent (Tributyltin)	Increased anogenital distance; reduced number of Sertoli cells and gonocytes in fetal testis
Phytoestrogens (genistein, daidzein)	Impaired erectile function; decreased testosterone levels; increased testis weight; reduction in epithelial height of the efferent ducts
Surfactants Alkyl phenol ethoxylates (*p*-tert-octylphenol, *p*-nonylphenol)	Changes in testis weight; decreased seminiferous tubule diameter; decreased epididymal weight; decreased total cauda epididymal sperm count; reduction in epithelial height of the efferent ducts
Plasticizers Phthalate esters (DEHP, BBP, DINP, DBP)	Histopathological changes of testis; decreased testis weight; multinucleated gonocytes; haemorrhagic testis; lesion of the rete testis; reduced anogenital distance; nipple retention; cryptorchidism; reduced accessory sex organ weights; agenesis of epididymis and vas deferens; agenesis of the seminal vesicles and coagulating glands; agenesis of bulbourethral glands; agenesis of gubernacular cords; cleft phallus and hypospadias; delayed preputial separation; reduced testicular testosterone levels; increased serum testosterone levels; reduced serum inhibin B levels; increased plasma LH levels; reduced daily sperm production; reduced fecundity; reduced fertility
Chlorinated pesticides (DDE)	Reduced anogenital distance; hypospadias; reduced accessory sex organ weights; poorly organized testis; nipple retention; decreased plasma testosterone levels; delayed preputial separation; abnormally small penis
Pollutants (Dioxins)	Decreased testis weight; delayed testis descent; decreased daily sperm production; decreased sperm numbers; epididymal malformations; reduced accessory sex organ weights; reduced anogenital distance; dose-related tendencies to decrease plasma testosterone and dihydrotestosterone (DHT); altered sex behaviour
Dicarboximide Fungicides (Vinclozolin, Procymidone, Prochloraz)	Decreased testis weight; abnormal morphology of seminiferous tubules; increased number of apoptotic germ cells in testis; decreased sperm number and daily sperm production; reduced elongated spermatid content per testis; increased sperm head abnormalities; low ejaculated sperm count; spermatogenic granuloma; epididymal granulomas; chronic inflammation of epididymis; cryptorchidism; hypospadias; cleft phallus; reduced anogenital distance; nipple retention; reduced accessory sex organ weights; glandular atrophy and chronic inflammation of prostate; agenesis of prostate; reduced secretion and chronic inflammation of seminal vesicles; reduction of erections during the ex-copula penile reflex test; increase in seminal emissions during the ex-copula penile reflex tests; decreased testosterone levels; decreased fertility
Herbicides (Linuron)	Decreased testis weight; testicular and epididymal malformations; reduced spermatid number; decreased anogenital distance; nipple retention; epispadias; reduced accessory sex organ weights; delayed preputial separation
UV screens (4-MBC, OMC)	Reduced sperm count; decreased testosterone level; decreased weight of ventral prostate; delayed preputial separation

Based on Toppari J, Adamsson A, Boas M, Juul A, Main KM, Skakkebaek NE, Virtanen HE: Endocrine disrupters and child health. Heat is another well-known disruptor of spermatogenesis. In undescended testes, spermatogonia undergo apoptosis over time, although body temperature is only few degrees higher than in the scrotum [5]. Extended bathing in a hot tub (>15 min at temperature >36°C) or working in very hot environment can affect spermatogenesis [6, 7], whereas results on sauna effects at temperatures as high as 80°C are equivocal [7, 8]. Variable results on the effects of tight underwear or sportswear have also been published [7, 9, 10]. Obesity and sitting work, such as truck driving have also been linked to increased scrotal temperature and impaired sperm production, however, many other factors may have contributed to these results [7].

Occupational exposures to specific toxicants can be much larger than those in the general population. The classic example of male infertility associated with exposure to 1,2.dibromo-3-chloropropane (DBCP) received much attention in the 1970s. Toxicity of DBCP was found only after an alert by the wives of men working in the chemical factory producing this nematocide. The young couples noticed their common fertility problem and started to suspect that it might be related to occupational exposures. Indeed, subsequent investigations demonstrated a positive association between the extent of exposure and the degree of suppression of sperm production. While in many of the men, sperm production recovered after removal from exposure, some remained permanently infertile [11, 12]. Interestingly, animal experiments using dibromochloropropane (DBPC) clearly showed reproductive toxicity much earlier, but this was ignored [13]. This is an example where ordinary citizens spotted the problem, while regulatory authorities and occupational health professionals initially failed to notify and prevent it.

In addition to DBCP, other chlorinated pesticides such as chlordecone, carbaryl, and ethylene dibromide have similarly been associated with reproductive toxicity [14].

Developmental Effects

Genetic disorders of male reproductive health have taught us much about the mechanisms of development and function of reproductive organs, thereby guiding the search for environmental

influences [15]. Hormones regulate reproductive development and male-specific differentiation depends on normal androgen action. Androgen insensitivity due to inactivating androgen receptor mutations and defects in androgen biosynthesis lead to complete sex reversal or varying degrees of undermasculinization. The lack of normal androgen action causes maldescent of the testes, hypospadias, poor sperm production, and a marked increase in the risk of testicular germ cell cancer [16]. Fetal exposure to antiandrogenic chemicals can cause similar effects. There is substantial epidemiological evidence suggesting that all the above-mentioned male reproductive disorders may share similar developmental risk factors leading Skakkebaek and coworkers to coin the term testicular dysgenesis syndrome (TDS) to emphasize the possibility of a common aetiological or pathogenic pathway (see **Figure 10.10.1.1**) [16–19]. In the case of reproductive disorders that manifest during or beyond young adulthood (e.g. testicular cancer or defects in sperm production) potential developmental origins of these conditions are difficult to ascertain given that fetal development occurred more than 20 years earlier. Undescended testes (cryptorchidism) and hypospadias can be observed immediately after birth, which allows an earlier opportunity to study the preceding fetal exposures without a 20- or 30-year time gap. Cryptorchidism is a very frequent birth defect (1–8% of full-term newborns), whereas hypospadias occurs in less than one percent of boys, and therefore most of the studies on environmental exposures and reproductive birth defects have focused on cryptorchidism.

Cryptorchidism

Occupational and epidemiological studies have shown an association between pesticide exposure *in utero* and risk of cryptorchidism [20–22], but other studies did not confirm these associations (reviewed in Virtanen *et al.* [23]). Exposure measurements are expensive and few large-scale studies can meaningfully analyse direct exposure-outcome relationships. However, there are studies showing an association between the levels of organochlorine pesticides, polybrominated diphenyl ethers (PBDEs; used as flame retardants), polychlorinated biphenyls (PCBs; used as flame retardants and insulators), and dioxins (pollutant from e.g. incineration and traffic) in either breast milk or child's adipose tissue and the risk of cryptorchidism [24–28]. In studies where pesticide levels were measured in maternal serum or in cord serum, no significant association with cryptorchidism was found [25, 29, 30, 31]. Levels of PCBs in maternal or cord serum, placenta, umbilical cord, or boy's adipose tissue were not associated with the risk of cryptorchidism in most studies [33]. When breast milk levels of 106 environmental chemicals were combined in an analysis, PBDEs and dioxins were identified as risk factors for cryptorchidism [33]. Levels of perfluorinated compounds (used in surface materials, such as water-proof shoes and clothes) in amniotic fluid or cord blood were not associated with the risk of cryptorchidism [34, 35]. All the above-mentioned chemicals are persistent and measurable even long after exposure. Fetal exposure to some of these chemicals, such as dioxins can be extrapolated also from samples taken years after birth when the duration of breast feeding is taken into account, whereas exposures that took place largely after birth and non-persistent chemicals need to be measured at the right time [26]. Exposure to persistent chemicals has been declining after most of them have been banned and governments have committed to phase out these harmful chemicals according to the Stockholm convention (https://www.pops.int).

There are fewer studies on the association of exposure to non-persistent chemicals and the risk of cryptorchidism than those of persistent compounds. Antiandrogenic phthalates (used as plasticizers) have been high on the list of suspected contributors to cryptorchidism. Risk of cryptorchidism was positively associated with phthalate levels in maternal urine during pregnancy [36], but no positive association was found when phthalates were measured in amniotic fluid, cord serum, or breast milk [25, 37, 38]. Serum levels of bisphenol A (used widely in plastics and tin coatings) were associated with the risk of cryptorchidism in one study [39], while no

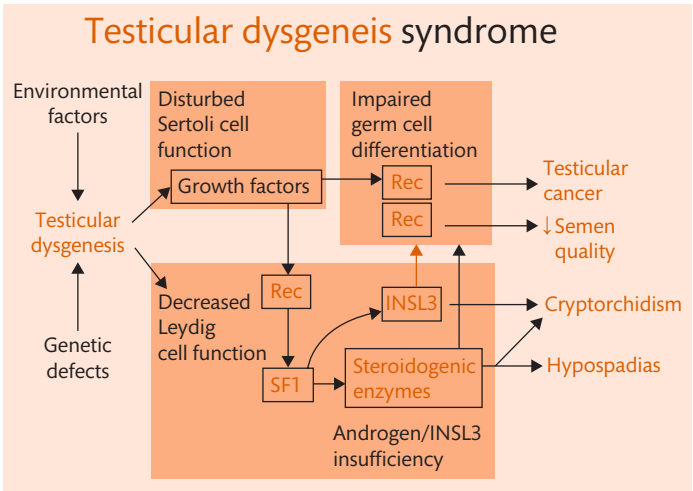

Figure 10.10.1.1 Genetic and environmental factors can disrupt the function of fetal Sertoli cells and Leydig cells that communicate with each other by growth factors. Steroidogenic factor-1 is an important transcription factor in the Leydig cells controlling steroidogenesis and production of insulin-like peptide-3 (INSL3). Insufficient production of androgens and INSL3 affect developing germ cells and external genitalia causing testicular germ cell cancer, poor semen quality, cryptorchidism, or hypospadias.

association was found when bisphenol A (BPA) levels were measured in cord blood [40, 41].

A problem in many of the studies is their small sample size that limits their statistical power, which may give false negative results. Furthermore, there can be a publication bias that reduces the number of publications that show only negative results. Meta-analyses are difficult in this area, because the matrices in which the exposures have been measured are variable (breast milk, maternal serum and urine, amniotic fluid, placenta, adipose tissue, serum or urine of the child, etc.), number of chemicals is large, and outcome measures are poorly standardized.

Hypospadias

Hypospadias can be associated with cryptorchidism and a shortened anogenital distance, but usually present as an isolated birth defect [42, 43]. Anogenital distance has been used as a post-natal read-out of androgen effects *in utero* [44]. Epidemiological studies on hypospadias have been more challenging because the prevalence of hypospadias is low. Most studies have assessed persistent chemicals. In ecological and occupational studies, exposure to pesticides has been associated with the risk of hypospadias. According to a meta-analysis, the risk ratio was 1.36 (95%CI 1.04–1.77) after maternal exposure to pesticides and 1.19 (95%CI 1.00–1.41) after paternal exposure [45]. A positive association between fetal exposure to pesticides and hypospadias was also reported in two recent studies [20, 46], whereas no association was observed in others [47–49].

Case–control studies have reported either positive or no association between hypospadias and pesticides or the sum of PCBs in maternal serum or in the boy's serum (reviewed in Virtanen *et al.* [32] and Vand Der Zanden *et al.* [50]). A positive association of placental concentrations of pesticides, BPA, and benzophenone (UV screen) with cryptorchidism and hypospadias together was reported [51, 52]. Meta-analyses combining data from different exposures measured in different matrices did not reveal any positive associations with either hypospadias or cryptorchidism [53].

Testicular Cancer

Testicular cancer usually refers to testicular germ cell tumours (TGCTs) since more than 90% of these cancers have a germ cell origin [54]. They appear after puberty and the incidence peaks within the reproductive age. Thus, TGCTs are the most common cancers of young men in Western countries, and the incidence has increased rapidly in all parts of world [55, 56]. Testicular cancer is preceded by germ cell neoplasia in situ (GCNIS) that develops either into seminoma or non-seminoma. GCNIS cells are very similar to fetal gonocytes, and it is likely that the TGCTs have a fetal origin [54]. Genetic studies have identified several genes, such as *KIT* and *CDC27*, whose polymorphisms are associated with an increased risk of testicular cancer [57]. Cryptorchidism, hypospadias, and other genital malformations are risk factors for testicular cancer [58].

Many studies on environmental effects on testicular cancer have focused on contemporary exposures, which have not produced much evidence on increased risks, perhaps because the relevant exposure time during fetal and early childhood development have not been documented. However, some case–control studies have reported an association between testicular cancer and exposure to organochlorine pesticides, while there are conflicting results regarding the association with exposure to PCBs [59–63].

Maternal samples may reflect exposures during pregnancy better than samples from adult offsprings. Measurement of DDT enantiomers ratios gives information on the timing of exposure because DDT conformation changes over time, thereby revealing when DDT has entered body [64, 65]. This approach helped to identify higher DDT exposures in mothers of cryptorchid boys than in controls in a U.S. pregnancy cohort when chemical analysis were made in postpartum serum samples [66].

Measurements have been made in mothers' serum also in samples collected years after pregnancy, and extrapolations of fetal exposures to persistent chemicals in such samples are possible, although exposures after pregnancy confound the findings. Swedish studies of men with testicular cancer compared men's serum chemical levels and then maternal serum chemicals in a case–control setting [67–69]. Mothers of men with testicular cancer had significantly higher serum levels of PCBs, hexachloro benzene, PBDEs, and cis- and transnonachlordanes than controls, whereas only cis-nonachlordane concentration was higher in serum of cases themselves as compared to controls.

Semen Quality

Semen quality encompasses many aspects of sperm counts and seminal plasma constituents. Sperm concentration and total sperm counts can be measured very accurately (see Chapter 10.2.3, 'Semen analysis'). Assessment of sperm morphology and motility is less accurate and not well standardized, thus hampering comparisons between studies. Several meta-analyses have indicated decline of sperm concentrations in developed countries since 1940s [70–73]. Although, there are regional differences both in timing and degree of this decline, the current level of sperm concentration of young men in different areas of the world is surprisingly similar [74]. However, both the existence of a secular decline in sperm counts and its possible association with environmental effects have been disputed and the debate continues [73, 75–77].

Sperm production depends on the number of Sertoli cells in the testis, because each Sertoli cell can host and support only a finite number of germ cells. Sertoli cells cease proliferating in puberty, and therefore the sperm production capacity is determined before puberty. Sertoli cells actively multiply first in fetal development, then after birth during the so-called minipuberty and finally during late prepuberty [78]. Toxicants, heat and irradiation (and illnesses, etc.) can reduce sperm production (see earlier), but otherwise, sperm production rate in an individual remains remarkably stable during adult life. Since fetal and childhood testicular developments are decisive windows for determining lifelong sperm production capacity, it is possible that mechanisms operating during these early critical periods could account for the putative decline in adult sperm counts at the population level.

Accidental exposure to high levels of persistent pollutants such as PCBs and 2,3,7,8,-tetrachlorodibenzo-p-dioxin (TCDD) as fetus or infant has been associated with reduced semen quality in adulthood [79–81]. Serum concentrations of TCDD and polychlorinated dibenzo-p-dioxins (PCDDs) toxic equivalents (TEQs) at the age of 8 to 9 years were inversely associated with sperm concentration, total sperm count and total motile sperm count at the age of 18 to 19 years in a prospective Russian study, although the TCDD exposure was much lower than in the Seveso study by Mocarelli [82]. These studies suggest that dioxins have adverse developmental effects on the testis.

Perfluororinated compounds, prefluorooctanoic acid (PFOA), and perfluorooctanesulfonate (PFOS) have been of concern because of their toxicity and endocrine-disrupting properties [2]. Prenatal exposure to background levels of PFOA was inversely associated with semen quality (sperm concentration, total sperm count), whereas no association with PFOS, PCBs, or p,p'-DDE was observed [83, 84]. There is also some evidence that contemporary (i.e. adult), exposure to phthalates is associated adversely with semen quality [85–87]. Results on bisphenol A remain inconclusive [88].

Hormone Levels

Reproductive hormone levels can reflect toxic effects on the testis, pituitary, or hypothalamus. The levels need to be considered in relation with each other and with other findings. Increased follicle-stimulating hormone (FSH) levels and decreased inhibin B levels in adult men who had been exposed to high levels of TCDD perinatally in the Seveso accident pointed to adverse testicular effects of dioxins [89]. Prenatal exposure to background levels of PFOA was associated positively with adult FSH and luteinizing hormone (LH) levels, whereas no significant associations with hormone levels were found for PFOS, PCBs, and p,p'-DDE [83, 90]. Prenatal exposure to phthalates has also been associated with increased serum concentration of FSH and LH in adult men [91–93]. Phthalate and PBDE concentrations in breast milk were positively associated with LH and LH-free testosterone ratio in the male offspring at minipuberty (3 months of age) [27, 38].

Mixture Effects

Exposures to environmental chemicals (unless accidental) seldom occur alone. We are constantly exposed to a complex mixture of chemicals that can act additively, synergistically, and sometimes in opposite directions. Male reproductive disorders can be seen when several antiandrogenic compounds act together at concentrations below their individual no-adverse-effect levels [94, 95]. Dioxins add to the overall exposure load, although their mechanism of action is clearly different from that of antiandrogens [96]. Clear evidence on adverse effects of endocrine disruptors on human male reproductive health is still limited. However, the ample data from the animal experiments (Table 10.10.1.1), well-known mechanisms of action (aryl hydrocarbon receptor agonism, androgen receptor antagonism, and inhibition of androgen synthesis), and emerging evidence on mixture effects give us a reasonable basis for risk assessment in chemical regulation. However, current safety margins may not guarantee health and safety, because the net effects of combined exposures of multiple chemicals can be harmful, even though individual chemicals in the mixture are present at lower concentrations than their no-observed-effect-levels that are used for determination of accepted daily doses of exposure [97]. Insightful regulation of chemicals is believed to be able to produce considerable healthcare savings in future reproductive healthcare [98].

Conclusions

Experimental evidence from animal studies has clearly shown reproductive toxicity of many endocrine disruptors (Table 10.10.1.1), but the risk for human reproduction is still controversial unproven out. Many endocrine disruptors have been banned, and therefore our exposure to several harmful compounds is decreasing. It takes, however, several generations before we can be rid of the most persistent organic pollutants, such as DDE, because they are transferred from mother to offspring via breast-feeding [99]. Multiple new chemicals are being introduced all the time, and it is important that appropriate resources and strategies are mandated to their safety testing in order to avoid adverse reproductive outcomes in humans.

SECTION 11

Management of the Transgender Patient

11.1

Introduction to Transgender and Gender Diverse People

Jon Arcelus and Walter Pierre Bouman

Introduction

Gender identity is an essential part of any person, and expressing it is a basic human need and the right of each individual, regardless of age, gender, ethnicity, religion, disability and sexual orientation [1]. The liberalization of society, particularly in the Western developed world, has led to more positive and less restrictive attitudes and views in the population regarding the expression of one's gender identity [2–4]. The latter is reflected in a significant growth in literature concerning transgender health, especially in the last few decades, as well as in the growing interest shown in this topic by the media [5–9]. Clinicians, researchers, educators, journalists, programme makers as well as global organizations, such as the World Professional Association of Transgender Health (WPATH; wpath.org), the European Professional Association of Transgender Health (EPATH; epath.eu), Global Action for Trans* Equality (GATE; transactivists.org), and Transgender Europe (TGEU; tgeu.org) continue to highlight the plight of transgender people and the need for a world wherein people of all gender identities and gender expressions have access to evidence-based healthcare, social services, justice, and equality. In many parts of the world, transgender people remain effectively marginalized and clearly discriminated against, with limited or no access to adequate (transgender) health services [10–12].

This chapter provides an introduction to transgender health. It starts with a brief historical and cultural overview concerning being transgender, followed by a description of current language and terminology in transgender health, the classification, and prevalence of identifying as transgender. It further describes transgender health services, including assessment and gender-affirming medical treatments. The chapter concludes with a synopsis of mental health problems in the transgender population. Other routes into the literature are provided by textbooks [13, 14] and many of the books, chapters, and articles cited elsewhere in this chapter.

Historical Background

Descriptions of the adoption of varying gender roles have been reported throughout history and across cultures. As early as the fifth century BC, Herodotus described the disease of the Scythians (morbus feminarium), which was thought to be divine retribution for their pillaging of the temple, in line with his view of diseases as being from divine causes [15]. Hippocrates described transgender women using the term 'Anandrii', and believed the disease was due to excessive riding on horseback. At the end of the nineteenth century, Edvard Westermarck, a Finnish philosopher and sociologist, reported that in nearly every part of North America there have been, throughout history, men dressing themselves in female clothes and performing female societal roles [16]. The history of transgender men has perhaps been generally less visible, although there are many accounts of assigned females at birth living as men, working and marrying without attention, sometimes only found to be assigned females at birth at death and, at other times, suffering great adversity and even death upon discovery. During the American Civil War (1861–1865) people assigned female at birth are known to have worn what was traditionally men's clothing and fought as soldiers. Many may have worn men's clothes as this was their only means of fighting and participating in the war effort. Some of them may have been transgender men and continued to live as men throughout their lives. There are many other people, male and female, some famous and others less so, who are thought

to have identified as transgender throughout history (for further reading see [17–19]).

Equally, there are many more examples across the world and among different cultures of gender role change [20, 21]. Different terms are used when talking about people expressing themselves as 'other' from male assigned at birth and female assigned at birth. The people from the Pueblo Indians of New Mexico use the term 'Mujerados', the term 'Hijras' is used in India [22], 'rhawaja sira' in Pakistan [23], 'Fa'afafine' in Samoa [24], 'Kathooey' in Thailand [25], 'Travestis' in Brazil [22], 'Mahu' in Hawaii [25], and 'Mahoos' in Tahiti [26]. Most of these terms have been used for people who were assigned male at birth, based on their sexual characteristics, but who live their lives as women. Terms and descriptions for transgender men (people assigned female at birth), compared with their female transgender counterparts throughout cultures and in history, are comparatively rare. Individuals assigned female at birth are often underrepresented in medical and legal discourse [27–29].

In addition to the aforementioned terms for what we often may understand to be transgender women, Non-Western societies have also generally been more tolerant and inclusive of people identifying outside the binary concept of being male or female. There are many cultures where gender was not commonly binarized. Such cultures include the indigenous Chukchi people in Siberia [30], the Waria in Indonesia [31], First Nation tribes of the United States and Canada [32], and the Machi of Latin America [33], among others. They show the heterogeneity of gender identity and expression and demonstrate especially that the Western notion of a gender binary, which is deeply rooted in Christianity, is only one of many possible perspectives [34]. Most societies, however, have only two distinct classes of gender according to a binary system, male or female, that correspond with the biological sexes of male and female. When a baby is born, society allocates the child to one of two possible genders, on the basis of their external genitalia. The assigned gender is subsequently specified on one's birth certificate and passport and most countries require that a passport gender marker is either female or male. A few countries, such as Australia, Bangladesh, Denmark, Germany, India, Nepal, and New Zealand allow passports to have a non-binary gender marker, called X (unspecified), T (transgender or third gender), E (eunuch), or O (other), depending on the country [35]. Having a non-binary marker on one's passport may make it difficult to travel to a country whose passports do not give that option [36]. Only relatively recently there is a growing awareness and understanding that a sizeable group of people in terms of raw numbers in Western and North American societies identify as non-binary [37–41].

As our understanding of gender identity and gender expression evolves, it is important to have a clear understanding of the meaning of the terminology and use of appropriate language in the field of transgender health. Language and terminology are addressed in the next paragraph.

Language and Terminology

In order to be able to describe who transgender and cisgender people are, we need first to define the terms 'transgender' and 'cisgender'. The word 'transgender' is an adjective often used as an umbrella term to describe anyone whose gender identity, expression, or behaviour is different from the assigned gender at birth based on the sexual characteristics. The term 'trans' is often used as an abbreviation for transgender. An asterisk used in the term 'trans*' indicates the inclusion of all gender diverse groups and includes non-binary people who self-describe or self-identify in a number of ways (e.g. as pangender, agender, polygender, bigender, neutrois, and so on. For further information, see [40]). The term 'cisgender' refers to a person whose assigned gender at birth is in line with their gender identity, or, in other words, someone who is happy to remain the gender assigned at birth. The term 'cis' is also used as an abbreviation for cisgender. So, a transgender woman is a person who was assigned male at birth, based on their sexual characteristics, but who identifies as female. Equally, a transgender man is a person assigned female at birth, based on their sexual characteristics, but who identifies as male. A cisgender woman is a person who was assigned female at birth, based on their sexual characteristics, and who identifies as female. Cisgender men are people who were assigned male at birth, based on their sexual characteristics, and who identify as male. Also, many trans people consider themselves men or women and no longer identify as a trans person following gender-affirming medical interventions, which may include cross-sex hormone treatment and surgery, and which change the body irreversibly. This process is known as transition [42–45].

Terminology has changed significantly over the past decade in particular, and many new terms have been introduced, while older ones have been discarded and are no longer deemed politically correct [36, 46]. It is important, both for respect and for clarity, to use the correct language. The community often referred to as the transgender or trans* community is an extraordinarily diverse group of people. Defining and quantifying the transgender population is problematic as there are currently few measurable and/or standardized criteria (e.g. physical, social, political) regarding what might or should constitute a transgender person. Furthermore, there is a relative invisibility in which many transgender people exist in their daily lives [47]. Moreover, language and terminology are important when attempting to address and target a community for access to healthcare and education, health promotion, disease prevention and service development [48–50].

People, including our patients, expect gender pronouns to be used according to the gender that they identify with. This applies to anyone, whether they identify as cisgender, transgender, non-binary, or otherwise. People who identify as female generally prefer that the pronouns 'she' and 'her' and the adjective 'her' are used, while people who identify as male prefer the pronouns 'he' and 'him' and the adjective 'his'. So, for a trans man, this would equally be 'he' or 'him'; and for a trans woman, 'she' or 'her'. Preferred pronouns can change over time, as a person comes out as transgender and transitions or discovers more about what feels right. If you are unsure as to how to address someone, it is generally a good idea to ask which pronouns (he or she or they; him or her or them) someone prefers and to use these pronouns accordingly [51]. There are trans people who do not identify within the binary spectrum of male and female, and they tend to prefer the pronouns 'they' and 'them' and the adjective 'their'. It is always better to ask rather than getting it wrong and potentially jeopardizing the quality of the patient–doctor relationship [36, 52]. Definitions and descriptions of frequently used and relevant terms in transgender healthcare are provided in alphabetical order in the following glossary in **Box 11.1.1**.

Box 11.1.1 Glossary of transgender-related nomenclature

Affirmed gender: This term is used to describe transgender people post-transition. This term indicates that the gender identity is now in line with the social gender role and the physical characteristics of the person.

Differences of sex development (DSD): Refers to people born with a sexual anatomy and/or chromosome pattern that does not fit the typical sexual anatomy and/or chromosome pattern of male and female. In some cases, the appearance of the genitalia at birth may not be clear and the assigned gender and gender role (boy or girl) given may not be consistent with the gender identity of the person. The inconsistencies in the development of the sexual organs may be associated with atypical sex chromosomes, such as Klinefelter syndrome (XXY), or Jacob's syndrome (XYY). The term Intersex has also been used instead of DSD. There remains controversy as to which term is more appropriate, DSD or intersex. We would suggest asking what a person prefers rather than assuming which term is best.

Gender and sex: These terms are often used interchangeably, but the meaning of both terms is different. The term 'sex' refers to the biological differences between male and female. This includes biological indicators such as sex chromosomes, anatomy of the reproductive system and secondary sexual characteristics, such as body hair. The term 'Gender' is more complex to define. It is related to the internal awareness or personal identification of being male, female, or other gender. It is also closely related to the cultural, social, and psychological differences between being male or female, which are part of gender role.

Gender-affirming treatment: Transgender people who wish to transition permanently to their experienced gender in order to affirm their gender may undergo treatment. This treatment includes hormone treatment and gender-affirming surgery.

Gender-affirming surgery: This term is used to describe the surgical procedures required in order for a transgender person to change their body to reflect their gender identity. This may include chest reconstructive surgery, breast augmentation surgery, gender-affirming genital surgery, and other surgeries such as vocal cord surgery, facial surgery, and so on.

Gender-affirming genital surgery: This refers to the surgical procedures required in order for a transgender person to change their genitals to reflect their gender identity. In the past, the terms sex reassignment surgery (SRS) and genital reconstructive surgery have been used. The term gender surgery is also used. Colloquially, 'bottom' surgery can be used.

Gender dysphoria: This term is generally used *as a symptom* which denotes the personal experience of dissonance between one's gender and phenotype [148]. The distress, which often accompanies gender dysphoria, is frequently manifested as depression, anxiety, or self-harm, and may also be related to feelings of non-acceptance, discrimination, and victimization by people and society. As a consequence of gender dysphoria many people access transgender health services in order to be considered for gender-affirming treatment. The term gender dysphoria (GD) is also used **as a diagnosis** in the Diagnostic and Statistical Manual (DSM-5) of the American Psychiatric Association [55].

Gender expression and gender role: Refers to all of the external characteristics and behaviours that are socially defined as either masculine or feminine. A person can express their gender through their behaviour, mannerism, clothing, hairstyle, voice, or body characteristics. Some of those expressions are culturally bound, for example, outside of Western cultures, it is not uncommon for men to wear skirts and skirt-like garments; however, in Europe and North America, the wearing of a skirt is usually associated with being a woman. Other stereotypical gender expectations are that men should not cry and that women are gentle.

Gender identity: Refers to the sense of oneself as male or female [150]. Whether a person looks like a man or a woman may be easy to identify. However, only the individual knows the gender they identify with. Some people identify themselves with the sex they were assigned at birth, however, not everyone does. In those cases, the term transgender (as an adjective) or trans is used [90].

Gender identity disorder: An obsolete term, which is considered a poignant remnant of the historic pathologization of transgender people. Gender identity disorder has been removed from the DSM-IV-TR [54] and ICD-10 [53], and no longer features in current nosological classification systems of transgender people [55–59].

Gender recognition certificate: In the United Kingdom, transgender people who have undergone a permanent change of social gender status can obtain legal recognition in the form of a Gender Recognition Certificate (GRC), which allows them to change their birth certificate. Obtaining a GRC does not necessarily require hormone treatment or gender confirmation surgery [151].

Misgender/Misgendering: When somebody makes incorrect assumptions about your gender or refuses to accept your gender and uses language that makes this apparent, such as using pronouns or gendered language like 'sir' or 'madam'.

Passing: Being seen or read as a certain gender. The opposite meaning is conveyed by the terms 'to be read' or 'to be clocked', which means not passing.

Non-binary gender: This term is used to describe people who do not identify as being part of the binary gender (male or female). Non-binary identifying can also be defined as identifying as either having a gender which is in-between or beyond the two categories 'man' and 'woman', as fluctuating between 'man' and 'woman', or as having no gender, either permanently or some of the time. As part of the non-binary spectrum people can identify themselves as genderqueer, neutrois, pangender, polygender, third gender, agender, gender fluid, etcetera. The pronoun that non-binary people often prefer is 'they' and the title 'Mx'.

Transition: The process of changing one's gender presentation permanently to correspond with one's felt gender. It is usually the time when a person begins to live as their felt gender. This can take the form of a social gender role transition (by coming out to people, asking people to use the right pronoun and name, changing name legally, changing the way one presents and looks, etcetera). Transitioning may or may not include gender-affirming medical interventions, such as cross-sex hormone treatment and surgery.

Trans*: This term has been used as the most inclusive umbrella term to include anyone who does not identify as cisgender. In other words, the asterisk used at the end of trans* indicates inclusion of all gender diverse groups and includes genderqueer and non-binary people who self-describe or self-identify in a number of ways (e.g. as pangender, agender, polygender, bigender, gender fluid, neutrois, and so on).

Transsexual: The term transsexual (as an adjective) has been used since 1949 to refer to people who had a clear sense of being '[born] in the wrong body' [149]. The terms 'transsexual' and 'transsexualism' have been used as a diagnosis in the International Classification of Diseases and Health Related Problems (ICD-10; [53]), but are being replaced by a different nomenclature, namely 'gender incongruence'. The terms 'transsexual' and 'transsexualism' are often considered old-fashioned and stigmatizing, and this terminology is increasingly being replaced with terms, such as 'transgender' and 'trans', which most clinicians and members of the trans* community deem more acceptable. Older trans people seem more inclined to use 'transsexual', and to distinguish between this binary identity and other non-binary or intermittent gender expressions. Also, after physically transitioning, many transsexual people consider themselves men or women and no longer identify as a transsexual person.

Finally, we will use the term 'transgender' to refer to individuals who wish to be socially recognized as a gender distinct from their assigned sex at birth, with or without the desire for body modification. For reasons of order and containment, we will limit the content of this chapter to populations—however inconsistently defined—that have either transitioned from one gender to another or who present with a desire to do so. Although we have striven to be as consistent and comprehensive as possible regarding the use of terminology, the listings are by no means exhaustive and continue to develop. For further reading we refer to more extensive glossaries of relevant textbooks [36, 43, 51].

Classification

Over the years, different terms have been used to indicate gender identity-related phenomena. People who experience distress because they do not identify with their gender assigned at birth were formerly known as transsexual people [53], or people with a gender identity disorder [54]. Recently, the name of the diagnosis changed to gender dysphoria (GD) [55], and in the forthcoming 11th version of the International Classification of Diseases of the World Health Organization (WHO), the proposed term for the diagnosis is **gender incongruence** [56–59]. People with GD (as a symptom) have a marked incongruence between the gender they have been assigned at birth and their experienced/expressed gender. This discrepancy is the core component of the diagnosis. There must also be evidence of distress regarding this incongruence for a diagnosis of GD [55]. Experienced gender may include alternative gender identities beyond binary stereotypes. Consequently, the distress is not limited to a desire to simply be of the other gender, but may include a desire to be of an alternative gender, provided that it differs from the individual's assigned gender at birth [40, 55]. The diagnostic criteria for a diagnosis of GD are:

(A) A marked incongruence between one's experienced/expressed gender and assigned gender, of at least 6 months' duration, as manifested by at least two of the following: (1) A marked incongruence between one's experienced/expressed gender and primary and/or secondary sex characteristics (or in young adolescents, the anticipated secondary sex characteristics); (2) A strong desire to be rid of one's primary and/or secondary sex characteristics because of a marked incongruence with one's experienced/expressed gender (or in young adolescents, a desire to prevent the development of the anticipated secondary sex characteristics); (3) A strong desire for the primary and/or secondary sex characteristics of the other gender; (4) A strong desire to be of the other gender (or some alternative gender different from one's assigned gender); (5) A strong desire to be treated as the other gender (or some alternative gender different from one's assigned gender); (6) A strong conviction that one has the typical feelings and reactions of the other gender (or some alternative gender different from one's assigned gender).

(B) The condition is associated with clinically significant distress or impairment in social, occupational, or other important areas of functioning [55].

The American Psychiatric Association (APA) has been criticised for retaining identifying as transgender as a diagnosis in the current mental disorders classification (e.g. [60, 61]). Both the DSM-5 work group of the APA and the ICD-11 working group of the WHO wrestled with the challenges of reducing stigma (which underlies the call for removal of the gender diagnoses) and maintaining access to care (which requires the existence of a diagnosis in order to obtain gender-affirming medical treatment) [62]. The APA chose to retain a diagnosis of GD in the psychiatric classification to ensure access to care and treatment due to existing health insurance infrastructures, mainly in North America, while the WHO took a clear position that issues related to transgender identity should not be classified as mental disorders in the ICD-11. Consequently, the WHO opted for a non-pathologizing reclassification of the newly coined term gender incongruence outside their Mental and Behavioural Disorders chapter; and effectively 'declassified' being transgender as a mental disorder. Individuals with gender incongruence may, or may not, experience distress and they may, or may not, want to live as 'the other gender' (see [59, 63] for an overview). Treatment preferences may also differ from the standard cross-sex hormone treatment and gender-affirming surgeries [41, 64].

Prevalence

Estimating prevalence rates of identifying as transgender is complicated. Most studies investigating prevalence rates in the transgender population have been based on clinical populations [36]. There is growing evidence that an increasing number of people come out as transgender identifying [5, 65, 66], but not every transgender individual chooses to, or is in a position to seek gender-affirming medical interventions [66]. There also remain significant barriers to accessing transgender healthcare [67–69]. The time of the study also affects the prevalence rates, as older studies collected information in an era where society was less tolerant towards transgender people and transgender health services were lacking. An example is the low prevalence rates found in some studies from the 1960s onwards, for example 0.40 per 100 000 [70]; 1.42 per 100 000 [71]. Studies from non-Western countries, such as Thailand and Singapore, where transgender people have a higher visibility and genital affirming medical interventions are more generally available, produce higher prevalence rates. For example, Tsoi found a prevalence of 23.60 transsexual people (as defined at that time) per 100 000 people [72], while Totman reports a prevalence of 333.33 transgender females per 100 000 people [73]. Some prevalence studies have focused on those undergoing gender-affirming genital surgery only, which some transgender people choose not to for a variety of reasons [64]. For example, prevalence rates of 10 per 100 000 were found in Spain [74], 4.28 per 100 000 in Belgium [75], and 16.67 per 100 000 in Sweden [76]. Other prevalence studies are based on transgender people accessing transgender health services or taking cross-sex hormone treatment. These studies have provided prevalence rates of 8.05 per 100 000 people [77], 6.77 [78], 4.42 [79], or 3.88 per 100 000 [80]. Arcelus *et al.* investigated the meta-analytical prevalence of transsexual people and found rates of 4.6 per 100 000 [81]. There was a difference regarding the rates of transsexual women (6.8 per 100 000) and men (2.6 per 100 000). This study found a clear increase in prevalence rates over time. However, the reviewed studies are mainly based on clinical populations. Recently, population studies have investigated prevalence rate of trans* people in a more inclusive way. Unsurprisingly, these studies have found higher rates of people who feel incongruent with their gender assigned at birth.

Population studies from the Netherlands and Flanders in Belgium found rates varying from 0.7 to 1.1% in people assigned male at birth and 0.6 to 0.8% in those assigned female at birth [38, 39]. A meta-regression study of population-based probability samples from the United States found prevalence rates of transgender people of 0.39%, which accounts for approximately 1 million people in North America [82]. The high rates of gender incongruity in people does not necessarily means a high rate of referrals to transgender health services, but may explain the recent increase in demand for these services [65, 67, 83].

Transgender Health Services

In the past two decades, there has been a move away from national, centralized, specialized transgender health service in Western Europe to the gradual introduction and development of regional transgender health services. This has occurred in the Netherlands, Sweden, Finland, Italy, Spain, and the United Kingdom, among others [84–86]. In small countries such as Belgium, Denmark, and Serbia centralized specialist centres remain. Some Northern European countries, most notably the Netherlands, Belgium, and Sweden, which historically have been academic and clinical leaders in the field of transgender healthcare, have moved transgender health services away from psychiatry and based these clinical services within the department of medicine (endocrinology). These developments will not only reduce stigma associated with being trans*, but also serve as exemplary clinical service development models for education and training. Moreover, they will stimulate research in a multidisciplinary setting firmly grounded in physical healthcare [87–89]. The majority of adult transgender health services in Europe consist of a multidisciplinary team or clinical network of clinical professionals, including mental health practitioners (psychologists, psychiatrists, and psychotherapists/counsellors), endocrinologists, speech and language therapists, and surgeons. The assessment team usually makes recommendations to the endocrinologist and surgeon regarding the commencement of gender-affirming medical interventions [45, 90].

In the United States, on the other hand, a loose network of medical and mental health providers exists, often affiliated with the WPATH. The first transgender health clinic in China (Hong Kong) opened as recent as 2016 (personal communication Dr Irene Lam). However, there remain many countries with no transgender health services, while other countries only provide these privately.

WPATH developed the Standards of Care (SoC) for gender transition, which are used globally and currently revised and expected to be published as the WPATH SoC 8th edition in 2020. In the current WPATH SoC7, mental health professionals are tasked with determining whether transgender people who want to undergo gender-affirming treatments meet eligibility criteria, have the capacity to provide informed consent, and have adequately anticipated the psychosocial impact of their transition [90, 91]. Furthermore, the WPATH SoC provides evidence-based recommendations regarding assessment and gender-affirming medical treatment that clinical services for transgender people should follow. WPATH SoC7 has also attempted to improve access to care by including the informed consent model for cross-sex hormone prescription. In multidisciplinary clinics providing transgender care, clinicians specialized in transgender healthcare can diagnose and assess patients with GD [55], who may benefit from treatment with cross-sex hormones, without referral from a mental health practitioner. Patients with coexisting mental health conditions should be referred to mental health services when appropriate. The SoC is closely aligned with the Endocrine Treatment of Gender-Dysphoric/Gender-Incongruent Persons: An Endocrine Society Clinical Practice Guideline of the Endocrine Society [92]. The latter established an evidence-based framework for endocrine treatment for transgender people, and reaffirms the core role of the endocrinologists in transgender healthcare.

Finally, WPATH advocates for the depathologization of transgender identity, the medical necessity of transgender care, and improvement of access to legal gender change [1, 90].

Assessment of Gender Concerns

A careful and comprehensive assessment procedure, generally comprising one or two appointments [45, 83] is necessary, particularly as most gender-affirming medical interventions are not easily reversible [13]. The assessment should include the age and circumstances when the patient became first aware of a sense of difference from peers regarding the sex assigned at birth, as well as experiences of low self-esteem or negative effect related to that sense of difference. Self-harm and suicidality should always be assessed, as should protective factors such as social and family support [93, 94]. Self-harm, suicidality and suicide are significantly increased in the transgender population [95–99]. Any history of peripubertal and/or pubertal distress due to the anticipation and/or emergence of unwanted secondary sex characteristics, as well as body image, should be explored [100–103]. Past experiences of gender-related stigmatization, discrimination, harassment, and violence should also be addressed [91, 104, 105]. Fertility preservation and child wish must be discussed, particularly with young people, prior to starting cross-sex hormone treatment [106, 107]. Autistic spectrum presentations have been found to be overrepresented among people with GD, although the relationship is far from clear [108, 109]. It is important to clarify of what each patient hopes to achieve and what difficulties may need to be overcome. Some individuals may have considerable anxiety regarding the social transition to another gender role, and may need some support and information, as well as counselling/psychotherapy, regarding the potential gains and losses they may experience by making such a change [110]. Exploring the options for gender expression, as well as the potential risks and benefits of transition, can be some of the tasks of such psychotherapy, although one must note that mandatory psychotherapy (rather than supportive assessment) for transgender people has been shown to be harmful [111, 112]. Psychotherapists may discuss some of the challenges and negotiations that occur in relationships and may explore the impact of stigma and both external and internalized transphobia. The mental health practitioner may provide information, preparation, and support regarding cross-sex hormone and surgical treatments if these are requested [110]. Eligibility for both gender-affirming cross-sex hormone treatment and surgery requires persistent GD, a documented diagnosis of GD or gender incongruence according to established classification criteria [55, 59], and the capacity to give informed consent. In addition, any significant medical or

psychiatric coexisting condition must be sufficiently controlled, so that the risks associated with gender-affirming medical interventions are minimized and there is no interference with the patient's ability to safely adhere to the treatment regimen [90, 91].

Gender-Affirming Medical Interventions

Transgender people may seek any one of a number of gender-affirming interventions, including cross-sex hormone treatment, surgery, facial hair removal, interventions for the modification of speech and communication, and behavioural adaptations, such as genital tucking or packing, or chest binding [42, 90]. There is flexibility in this process, given that some people do not pursue all of these interventions or choose to do so in a different sequence [64]. Generally, the endocrinologist initiates, administers, and monitors hormone treatment, although in some countries, like the United Kingdom, the general practitioner does so guided by the advice of the transgender specialist [42, 45]. A significant proportion (around 20%) of transgender people obtain cross-sex hormones via the internet [113] prior to their first appointment at a transgender health service, partly due to difficulties in accessing services, including long waiting lists. Further detailed information regarding hormone treatment will be provided in the subsequent sections. Gender-affirming surgery is the surgical procedure (or procedures) by which a transgender person's physical appearance and the function of their existing sexual characteristics are altered to resemble that socially associated with their identified gender. For transgender women, genital reconstruction usually involves the surgical construction of a vagina, clitoris, labia, and urinary tract, with removal of the penis and testicles [114]. Breast augmentation, chondrolaryngoplasty (reduction of the Adam's apple), voice surgery, hair implants, and facial feminization surgery are also part of gender-affirming surgeries for transgender women [115]. For transgender men, genital reconstruction may involve construction of a penis, through either phalloplasty or metoidioplasty [116]. Gender-affirming genital surgery may also involve other medically necessary ancillary procedures, such as vaginectomy, hysterectomy, and bilateral salpingo-oophorectomy [117]. Most transgender men choose to undergo a bilateral mastectomy and chest reconstruction (the shaping of a male-contoured chest).

Before genital reconstructive surgery, the WPATH SoC7 also recommend 12 months of continuous hormone treatment (unless hormones are clinically contra-indicated) and 12 continuous months of living in a social gender role that is congruent with the patient's gender identity [90]. Postoperative regret following gonadectomy is low and reported as 0.6% for transgender women and 0.3% for transgender men [66]. For further information regarding gender-affirming surgeries see [13] and [15].

Mental Health and Transgender People

Research investigating mental health problems in transgender people has primarily focused on those attending transgender health services [74, 88, 104, 118–123]. These studies found that the main mental health problems in transgender people accessing transgender health services relate to depression [123], anxiety [13], and self-harm [96, 97]. The high level of mental health problems in the transgender population compared with their cisgender counterparts has been linked to gender minority stress [124–126]. The prevalence of severe psychiatric disorders does not appear to be more common than in the cisgender population [127].

Research investigating the role of cross-sex hormone treatment found that people on cross-sex hormone treatment experience better self-esteem [104, 128], lower symptoms of depression [74, 120, 121, 123, 129–131], lower symptoms of anxiety [46, 74, 104, 119–121, 129, 130], less self-harm behaviour [96, 97], and improved quality of life [122, 128, 132, 133, 134]. Improved body image and a reduction in eating disorders psychopathology have also been found in transgender people taking cross-sex hormone treatment [100, 103, 135–137]. Research investigating the role of gender-affirming surgeries shows improved quality of life, body image, and mental health indicators following surgery [130, 138, 139]. Some studies are controlled for age and gender, but lack a longitudinal design. Few longitudinal studies have taken place to evaluate the effect of gender-affirming medical treatment on mental health and quality of life [140–144]. These studies show a clear improvement of mental health indicators and quality of life, reaching similar levels to those in the cisgender population, but they lack a control group. Other factors (than cross-sex hormone treatment) linked to improved mental health and quality of life consist of social support [93, 104, 118, 145], interpersonal function [146], and lack of transphobia experiences [118, 147]. There is a growing body of scientific evidence that gender-affirming medical interventions are beneficial to binary transgender people, but longitudinal and robustly designed outcome studies are lacking. There is a growing number of non-binary-identifying people attending transgender health services too, with initial evidence indicating that mental health and physical problems are significantly more prevalent in this group than in their binary transgender counterparts. Evidence-based medical treatment options in non-binary people remain unexplored [41].

Conclusions

The last decade has seen a significant worldwide increase in the visibility of transgender and gender-diverse identifying people with a concomitant rise in those seeking gender-affirming medical interventions. Transgender healthcare is a relatively new and multidisciplinary specialty providing assessment, treatment, and support for transgender and gender-diverse identifying patients. There is a growing body of evidence that cross-sex hormone treatment and gender-affirming surgery have a positive beneficial effect of the mental health, body image, and quality of life of the vast majority of transgender and gender-diverse identifying people. The role of the endocrinologist is crucial in the provision of an adequate standard of care in transgender healthcare. It is vital that transgender healthcare constitutes an intrinsic part of education and training within the medical and specialist curriculum.

11.2

Endocrine Treatment of Transgender Youth

Daniel Klink

Introduction

The endocrine treatment of transgender adolescents consists of two phases: pubertal suspension or gonadal suppression followed by the addition of the desired hormones. During the first phase (further) pubertal development is halted and adolescents can further explore their gender identity and prepare for the next phase. To start treatment The Standards of Care of WPATH [1] mentions the following minimum criteria for puberty suppressing hormones:

1. The adolescent has demonstrated a long-lasting and intense pattern of gender non-conformity or gender dysphoria (GD).
2. GD emerged or worsened with the onset of puberty.
3. Any coexisting psychological, medical, or social problems that could interfere with treatment (e.g. that may compromise treatment adherence) have been addressed, such that the adolescent's situation and functioning are stable enough to start treatment.
4. The adolescent has given informed consent and, particularly when the adolescent has not reached the age of medical consent, the parents or other caretakers or guardians have consented to the treatment and are involved in supporting the adolescent throughout the treatment process.

The minimum ages when puberty suppression should start and when the treatment with gender-affirming hormones (GAH) should commence, remains an issue of debate. At first, an age of 12 and 16 years, respectively, was recommended [2]. These criteria have more juridical roots rather than they are based on endocrine factors. The treatment protocol was developed in the Netherlands, where children may take medical decisions together with their caretakers from the age of 12 years. Subsequently, patients are considered to be legally adult to make medical decisions at age 16. However, boys and girls enter puberty at different ages. Also, psychological maturity differs between adolescents [3]. Therefore, not age but onset of puberty is now mentioned in the Standards of Care. Of course, it is up to the clinicians to assess readiness for treatment, even in older adolescents who have already reached Tanner stage 5. As for starting sex hormones in transgender adolescents the present recommended age by the Endocrine Society still remains 16 years. However, the need for re-evaluating is recognized by the medical profession [4] and the recommended age of starting GAH may shift in the future.

Gonadotropin-Releasing Hormone Analogue (GnRHa) Treatment

Background

Gonadotropin-releasing hormone (GnRH) was isolated and analysed in 1971 [5, 6]. GnRH is an oligopeptide that consists of 10 amino acids: Glu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly [7, 8]. In 1973 the first GnRHa, were introduced. These analogues reduce the levels of gonadotropins leading to a decrease of gonadal stimulation and subsequent fall of sex hormone levels in the blood to prepubertal levels. They have been used in the treatment of central precocious puberty since 1981 [9, 10]. The benefits of GnRHa have been well-established and their use in central precocious puberty is regarded both safe and effective, with no long-term adverse effects [11]. However, although there is now a broad experience in the transgender population, somatic data is scarce and limited to reported studies of a few centres worldwide [12].

GnRHa treatment will lead to regression of the first stages of the already developed sex characteristics. In adolescents with GD assigned female at birth (transgender boys), the present breast tissue will become weak and may disappear completely. In adolescents

with GD assigned boy at birth (transgender girls), testicular volume will regress to a lower volume. When treatment is started in adolescents in later phases of pubertal development, the various physical changes of pubertal development, such as a late stage of breast development in transgender boys and lowering of the voice and facial hair in transgender girls, will not regress completely, although any further progression will be stopped [3].

Treatment Protocol

In clinical practice, transgender boys usually can start when in Tanner stage Breast 2 and transgender girls when they have a testicular volume of 6–8 ml (see Table 11.2.1). Also, adolescents who have already physically matured but are not yet ready to decide on hormones can use GnRHa to inhibit unwanted pubertal functions, such as breast formation and menses in transgender boys or further male phenotype development and erections in transgender girls to bridge the period until the adolescent's gender identity is more stable [4].

The use of GnRHa in transgender adolescents is off-label but the general safety and efficacy of triptorelin 3.75 mg every 4 weeks subcutaneously have been studied [3, 13]. Anthropometry and body development, hormonal status and metabolic parameters were followed prospectively in late pubertal transgender girls (n = 49)) and transgender boys (n = 67) during 12 months of triptorelin monotherapy [13].

Table 11.2.1 Baseline and follow-up protocol during GnRHa treatment

Start GnRHa at Tanner stage 2–3	Follow-up frequency
Clinical assessment	Every 3–6 months
Height, weight, sitting height	
BMI-SDS	
Tanner stage	
Blood pressure	
Laboratory	
LH, FSH, E2/T	Every 6–12 months
25OH vitamin D	Upon indication
Metabolic profile (upon indication)#	Every 24 months
Liver function	
Fasting glucose and insulin	
Lipids	
Karyotype (upon indication*)	Once
Imaging	
Bone density using DXA	Every 12–24 months
Bone age (upon indication)	Every 12–24 months

Abbreviations: BMI-SDS Body Mass Index Standard Deviation Score; E2, oestradiol; FSH, follicle-stimulating hormone; LH, luteinizing hormone; T, testosterone; DXA, dual-energy X-ray absorptiometry

* in premenarchial transgender boys when physical examination of external genitals is atypical

clinical indication of compromised metabolic health such as obesity and/or prolonged GnRHa monotherapy is expected.

What the Primary Care Pediatrician Needs to Know About Gender Incongruence and Gender Dysphoria in Children and Adolescents. *Pediatr Clin North Am.* 2016 Dec;63(6):1121–35.

Effects on the Hypothalamic–Pituitary–Gonadal (HPG) Axis

Puberty was adequately suppressed with a decrease of testicular volume from 14 ml to 9 ml in 33 transgender girls. In transgender boys, when early in puberty, Tanner Breast 2, breast tissue fully regressed to stage 1 (n = 4) and when menarche had already started menses ceased and breast tissue became unstimulated. Luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels decreased in 3 months to prepubertal levels in both transgender girls as transgender boys. As for sex hormones, testosterone decreased to below detection level in transgender girls within 3 months of therapy. In transgender boys, oestradiol decreased to early pubertal levels [13].

Effects on Anthropometry and Metabolic Profile

In both transgender girls and transgender boys during the first year of GnRHa treatment height standard deviation score (SDS) calculated for sex assigned at birth significantly decreased, reflecting in transgender girls arrested linear growth and in transgender boys the attainment of final height. Changes in body mass index (BMI) SDS were not clinically relevant. With respect to body composition, the lean body mass percentage decreased and fat percentage significantly increased. Glutamyl transferase, aspartate aminotransferase (AST), alanine aminotransferase (ALT), and creatinine levels did not significantly change from baseline to 12 months of treatment but alkaline phosphatase decreased, most likely reflecting the decrease in growth velocity [13].

Effects on Bone Mass

Although bone mass accrual during puberty is regulated by genetic factors and environmental factors such as physical activity and adequate supply of nutrients (calcium, vitamin D), gonadal hormones are key [14–16]. Thus, the hypogonadal state induced by GnRHa monotherapy affects bone mineral density (BMD) [3, 17, 18]. In 30 transgender girls who started GnRHa at a median age of 14.7 years and were on GnRHa monotherapy for 1.7 years the bone mass defined as bone mineral apparent density (BMAD) of the lumbar spine remained stable whereas the BMAD of the hip significantly decreased. Since during puberty normally bone mass accrual occurs *Z*-scores inherently decreased from −0.37 to −1.15 and from −0.5 to −0.95, respectively. Likewise, in transgender boys (n = 41, median age start GnRHa 15.1 years, median duration GnRHa monotherapy 1.3 years) BMAD of the lumbar spine and the hip region decreased. Corresponding Z-scores decreased from 0.14 to −0.62 and from −0.07 to −0.39, respectively [17].

Adverse Events

GnRHa is generally well tolerated with the exception of hot flushes early in treatment [3]. However, hypertension in transgender adolescents under triptorelin treatment was reported in three cases in a cohort of 138 subjects. They were all transgender boys. Hypertension was reversible upon cessation of triptorelin but in one case increased intracranial pressure developed which required the temporary use of acetazolamide [19]. GnRHa induced hypertension

is an uncommon side effect and has only been reported incidentally in girls [20, 21]. Indeed, the association that females seem to be more susceptible than males also is described in adult patients [22, 23].

Monitoring GnRHa Treatment

Based on the evidence published, the guidelines for follow-up have been revised recently [4] and are summarized in Table 11.2.1. However, the cohorts studied were relatively older and more matured populations, mid-teens, and Tanner stage G/M4 and up, which coincides with a relatively shorter duration of an induced hypogonadal state. There are currently no publications available focusing on treatment of the young and less matured (Tanner 2 or 3) adolescent with GD and therefore the effects of prolonged gonadal suppression (i.e. 3 to 4 years; short- or long-term are unknown). Thus, vigilance remains warranted.

Gender-Affirming Hormone Treatment

Hormone therapy in adolescents with GD generally has two treatment regimes. When GnRHa treatment had started in the early stages of pubertal development, the 'new' puberty is induced with a dosage scheme that is also common in hypogonadal patients. Alternatively, when GnRHa treatment had started in physically matured transgender persons and thus the duration of the hypogonadal state was limited, hormones can be given at a higher start dose and more rapidly increased until maintenance dosage (Table 11.2.2). An additional advantage of GnRHa treatment is that hormones do not have to be administered in supraphysiological dosages, which would otherwise be needed to suppress endogenous sex steroid production [4].

Oestrogen Treatment in Transgender Girls

The natural 17β-oestradiol has a less thrombogenic profile compared to synthetic oestrogens, such as ethinyl oestradiol and is therefore preferred. 17β-oestradiol is available in both oral and dermal preparations. Both formulae are off-label for a pubertal induction in transgender girls. Dosage schemes are summarized in Table 11.2.2. For oral 17β-oestradiol it is recommended to start at a dosage of 5 μg/kg/day, followed by 6-monthly increments of 5 μg/kg until a maintenance dosage of 2 mg or higher is reached. A second treatment regime suitable for transgender girls who commenced GnRHa treatment in late puberty (Tanner 4 and up) is recommended. After a preferably short period of gonadal suppression varying from 3 to 6 months, oestrogens can be given at a daily start dosage of 1 mg and increased to 2 mg after 6 months [24, 25]. Transdermal 17b-estradiol may be an alternative for oral 17b-estradiol. Although it is increasingly used for pubertal induction in hypogonadal adolescent females (mostly Turner syndrome), the lack of low-dose oestrogen patches may be a problem. To achieve the appropriate start dosage of 6.25–12 μg/24 hour individuals may need to cut patches. The patch is applied twice a week with increments 12.5 μg/24 hour every 6 months. Adult

Table 11.2.2 Hormone therapy

Dosing scheme for pubertal induction		Dosing scheme when GnRHa started at T_{4-5}	
Transgender girls			
p.o.17β-oestradiol therapy	Increase every 6 months	p.o. 17β-oestradiol therapy	
5 μg/kg/day		1 mg/day	First 6 months

maintenance varies from 50 to 200 μg/24 hour [26]. Currently data on dermal oestrogen therapy in adolescent transgender girls is not available and only the effects of the addition of oral 17β-oestradiol were studied prospectively in transgender girls (n=28; minimum duration of oestrogen therapy 1 year) [25].

Breast Development and Effects on the HPG Axis

When oestrogen treatment had started at a median age of 16.0 years after median duration of 24.8 months of triptorelin monotherapy, breast development had started within 3 months and after 1-year median Tanner stage was Breast 3. In the next 3 years there was progression to Breast 5 (n = 16) with a variability of all breast stages. The gonadotropins remained low and when the adult dose of 2 mg oestradiol daily was used during a median duration of 2 years the median serum oestradiol was 100 pmol/L (range 24–380 pmol/L). A change in prolactin levels was not seen [25].

Effects on Anthropometry and Metabolic Profile

In the first 12–24 months, waist circumference SDS (female reference) decreased and while hip circumference increased, the hip circumference SDS did not change. The changes in body shape resulted in a decrease of waist/hip ratio (WHR) SDS from 0.48 to 0.04 SDS reflecting a change towards the affirmed phenotype. BMI increased but BMI-SDS did not. When bone age was less than 15 years at the start of oestradiol median height gain was 6.8 cm after 3 years of oestrogen therapy. Overall final height was 182.7 cm corresponding to +1.9 SD for Dutch adult women. Regarding metabolic parameters, haemoglobin, haematocrit, HbA1c, liver enzymes and creatine did not change [25].

Effects on Bone Mass

After start of oestrogen therapy bone mass accrual reassumed [17] and was described during the first two years of oestrogen treatment in 28 transgender girls after a median duration of GnRHa treatment of 2.5 years. The bone mass defined as BMAD in the lumbar spine increased with 8–12% with a coinciding significant *Z*-score increase. The BMAD of the hip and *Z*-score did not increase [18].

Androgen Treatment in Transgender Boys

For pubertal induction the use of testosterone-esters injections is recommended. The start dosage is 25 mg/m² every two weeks IM; and is increased with 25 mg/m² every 6 months. The maintenance dosages vary from 200 mg every 2 weeks for testosterone monoesters, such as testosterone enanthate, to 250 mg per 3–4 weeks for testosterone-esters mixture. For transgender boys who started treatment in late pubertal stage testosterone can be started at 75 mg IM every 2 weeks, followed by the maintenance dosage after 6 months (Table 11.2.2) [4]. It is advised to continue GnRHa at least until maintenance dosage of testosterone is reached and is preferred to continue until gonadectomy. The effects of androgens and triptorelin have been studied prospectively in ten transgender boys [3].

Effects on the HPG Axis

Virilization of the body occurred with lowering of the voice, increased muscular development, particularly in the upper body, facial and body hair growth, and clitoral growth [3, 4].

Effects on Anthropometry and Metabolic Profile

With respect to metabolic profile, both carbohydrate metabolism and lipids did not change during 2 years of testosterone therapy (n = 10) [3].

Effects on Bone Mass

After start of GAH the BMD increases both at the lumbar spine as in the hip [17]. During the first 2 years of GAH therapy BMAD of the lumbar spine increased with 4–9% coinciding with an increase of *Z*-score. The degree of bone mass accrual depended on the bone age. A bone age younger than 14 years (female reference) favoured a higher increase. The BMAD of the hip increased with 5–8% resulting in an increase of *Z*-score [18].

Monitoring Gender-Affirming Hormone Therapy

Guidelines for follow-up during pubertal induction are summarized in Table 11.2.3. Once pubertal induction is completed, guidelines for transgender adults can be followed. However, BMD should be monitored closely until the age of 25–30 or until peak bone mass has been reached [4].

Long-Term Outcome of Gender-Affirming Therapy in Adolescence Using GnRHa

The psychological benefits of gender-affirming treatment for young adolescents with GD using GnRHa have been established [27, 28]. One year after surgery the GD was alleviated, psychological functioning had steadily improved and well-being was similar to or better than same-age young adults from the general population [28]. In addition, some somatic outcome in young adulthood has also become available [17, 29].

Effects on Bone Mass

The effect of gender-affirming treatment in adolescence on bone mass in young adulthood has been studied. In transgender girls (n = 15; median age at start of GnRHa 14.9 years; duration of gonadal suppression 1.5 years) the areal BMD *Z*-score of the lumbar spine was −0.77 at start GnRHa. During GnRHa monotherapy areal BMD remained stable. However, since the physiological development would be bone mass accrual, *Z*-score—as expected—decreased to −0.1. After commencing treatment, oestrogens areal BMD increased but *Z*-score decreased further to −1.36 at the age of 22. Three transgender women had a T-score <−2.5.

In transgender boys (n = 19; median age start GnRHa 15.0 years; median duration GnRHa monotherapy) during GnRHa monotherapy both areal BMD of the lumbar spine and of the hip decreased. Corresponding Z-scores decreased from 0.17 to −0.72 and from 0.36 to −0.35, respectively. Subsequently, between start testosterone therapy and age 22, areal BMD of the lumbar spine and hip increased significantly. Z-score of the lumbar spine showed a trend of increase to −0.33 whereas Z-score of the hip remained the same at −0.35. At age 22 years, a BMD Z-score of the lumbar spine was lower when compared to start GnRHa but this was not significant. No subject had a T-score <−2.5.

Concluding, at age 22 the *Z*-score of the lumbar spine was under pretreatment level, implying a possible delay in or loss of peak

Table 11.2.3 Baseline and follow-up protocol during pubertal induction

What the Primary Care Pediatrician Needs to Know About Gender Incongruence and Gender Dysphoria in Children and Adolescents. *Pediatr Clin North Am*. 2016 Dec;63(6):1121–35.

bone mass. This was more pronounced in transgender women than in transgender men. Taken into consideration that even before the start of GnRHa transgender girls had a Z-score below reference population, transwomen who have started gender-affirming therapy in adolescence may be more at risk for lesser bone health than transgender men [17]. One case report has been published on long-term BMD development and it was shown that absolute BMD and Z-scores of a transgender man, treated with GnRHa in his adolescence was in the normal range at age 35. However, pretreatment data was not provided [30].

Anthropometry and Metabolic Profile

The change in body shape and body composition from the start of treatment with GnRHa until 22 years was studied in 192 transgender individuals. At a mean age of 14.5 years 71 transgender girls started GnRHa, to be followed by the addition of 17β-oestradiol (mean age 16.4 years). During treatment till the age of 22 waist and hip circumference increased with 8 cm and 17 cm, respectively. WHR decreased from 0.81 to 0.77. Regarding metabolic profile only body composition was studied and it was found that the percentage of total body fat increased with 9% and thus the percentage of lean body mass decreased with 9%. Percentage of body fat increased in the android region with 9% and the gynoid region with 11%.

Transgender men (n = 121) who started GnRHa at a mean age of 15.3 years, followed by the addition of testosterone (mean age 16.9 years) were studied. From start treatment to the age of 22, transgender men showed increases in waist and hip circumference of 6 cm and 5 cm, respectively. WHR increased from 0.77 to 0.80. Percentage of total body fat decreased with 3% to 27% and percentage of lean body mass inversely increased to 73%. Percentage of body fat decreased in the gynoid region with 5% with no change in the android region.

When compared at 22 years to age-matched peers, it was found that in young adult transgender women, SDS for WHR, body fat, and lean body mass showed greater similarity to ciswomen than to cismen. In transgender men SDS for WHR, body fat, and lean body mass were within reference values for ciswomen and cismen. in transgender men, an earlier Tanner stage at start of treatment appeared to be associated with a closer resemblance of body shape to their affirmed sex at 22 years, and this tended to be the same in transgender women [29].

Alternatives to GnRHa Treatment

GnRHa treatment can be costly and when resources are limited, alternative treatment regimens should be considered. Antiandrogens such as cyproterone acetate (CPA) or spironolactone can be used in transgender girls. Transgender boys can be treated with progestogens [4].

Induction of Hypogonadal State with Antiandrogens in Transgender Girls

Similar to transgender women, in late pubertal transgender girls endogenous androgen production can be suppressed using antiandrogens. CPA is dosed 25–50 mg daily and spironolactone dosages varies from 100 to 300 mg per day [4]. The effects of prolonged CPA monotherapy were studied retrospectively [31, 32].

Effects on HPG Axis

After 6 months of CPA 50 mg once daily testosterone decreased and remained stable at 7.8 nmol/L. LH and FSH however were not suppressed. Prolactin increased almost twofold but none developed galactorrhoea. Clinically more than half of the subjects reported reduced shaving frequency and in 29.6% breast development (Tanner stage Breast 2–3) was reported [31].

Effects on Anthropometry and Metabolic Profile

Weight development did not demonstrate an increase of BMI-SDS. Metabolic parameters such as lipid profile and glucose homeostasis were not negatively affected [31]. However, there was a significant increase in fat mass and decrease in lean mass. The fat tissue accumulation in transgender girls was more than in their age-matched male peers [32].

Effects on Bone Mass

Twenty-one transgender girls were started on 50 mg CPA once daily at a chronological age of 16.3 years (bone age 17.1 years) and changes in bone were studied over a period of 10.6 months.

Already at start of CPA, areal BMD was lower in transgender girls as compared to their peers of the same natal sex. During the study period, areal BMD of total hip decreased, coinciding with a *Z*-score decrease. At the lumbar spine, areal BMD remained stable, but *Z*-scores decreased [32].

Adverse Events

Only a transient increase of liver enzymes was seen in 15% of the study subjects. The levels remained under the threshold of three times the upper limit and therefore treatment was not stopped. The use of CPA is associated in adults with depression [33] but the only reported side effect in adolescents was fatigue [31].

Pubertal Induction in Antiandrogen-Treated Transgender Girls

For the start of oestrogens, the same dosage schemes (Table 11.2.2) as in GnRHa-treated transgender girls can be used. When choosing a dosage scheme, factors such as pretreatment sexual maturation level and duration of hypogonadal state should be taking into consideration. Data on the addition of oestrogens to antiandrogenic therapies in transgender adolescents is limited to two published studies. In one study the subjects received CPA [31] and in the other study spironolactone [34] was used.

Breast Development and Effects on HPG Axis

When 17β-oestradiol was started at 0.5 mg orally once daily and subsequently increased to 0.75 mg after 6 months, initiation or further progression of breast development occurred. After 12 months of oestrogen therapy 66.7% of the participants reached Tanner Breast 3 and 9.5% reached Tanner Breast 4. During this period testosterone decreased significantly to 0.06 nmol/L. LH and FSH became more suppressed. Prolactin levels decreased and the mean 17β-oestradiol level was 121 pmol/L [31].

Effects on Anthropometry and Metabolic Profile

The addition of oestrogens to CPA monotherapy did not result in a change of BMI-SDS. With regards to metabolic parameters, lipid profile and glucose homeostasis did not change [31]. Oestrogens were added in transgender girls (n = 44; age range 14–25 years) who received spironolactone (dosage 50–200 mg daily) in different methods, namely, oral (dosage 1–8 mg daily), intramuscular (dosage 20–80 mg monthly) or transdermal (dosage 0.025–0.200 mg weekly). For all methods there were no changes reported in BMI, metabolic parameters, lipid profile. The use of spironolactone did not change potassium levels [34].

Adverse Events

Serious adverse events were not reported [31, 34]. The adverse event 'fatigue' as reported during CPA monotherapy resolved in almost all transgender girls. Although transient ALT and AST increases were observed sporadically, interruption of treatment was never needed. Also there was a decline in prolactin levels [31]. Prolactin levels in spironolactone treated transgender girls were not affected [34].

The Use of Progestational Agents in Transgender Boys

In postmenarche adolescent transgender boys as alternative for GnRHa to stop or decrease menses frequency, progestogens such as lynestrenol [35] or medroxyprogesterone acetate [36] can be used. Effects of lynestrenol monotherapy were reported [32, 35].

Effects on HPG Axis

LH decreased but levels of FSH did not change. Testosterone levels decreased by almost 30% whereas oestradiol decreased by almost 60% and remained stable afterwards. In the first 6 months metrorrhagia occurred in 50% but reduced to 18% in the following 6 months. Percentage of amenorrhoea was not reported [35].

Effects on Anthropometry and Metabolic Profile

Weight increased during the first 6 months of lynestrenol monotherapy but returned to baseline value after 12 months. Haemoglobin and haematocrit increased but remained in the normal male range. Serum creatinine significantly increased during the first 6 months but remained stable afterwards. Total cholesterol and triglyceride levels did not change; however, mean high density-lipoprotein (HDL) decreased significantly and mean low-density lipoprotein (LDL) levels increased significantly in the first 6 months of lynestrenol monotherapy. No significant changes in haemoglobin A1c (HbA1c), glucose levels, insulin levels, or homeostasis model assessment (HOMA) index were reported (n = 42) [35]. When body composition was studied, it was found that during the first year of treatment lean mass, but not fat mass, significantly increased coinciding with a decreased body fat percentage. Compared to their age-matched female peers transgender boys became more lean. Also, pQCT measurements demonstrated that the muscle area increased at the non-dominant forearm and left lower leg (n = 44) [32].

Effects on Bone Mass

Changes in bone mass were studied during lynestrenol monotherapy (dose 5–10 mg daily, duration 11.6 months) in transgender boys (n = 44; age at start 16.2 years). Bone mass—as defined areal BMD—of the hip increased with an increase of *Z*-score. In the lumbar spine, areal BMD increased while *Z*-scores remained stable, suggesting an acquisition similar to age-matched female peers. Based on pQCT scans, both trabecular and cortical bone parameters at the radius and the tibia increased during the study period, to the same extent as in age-matched control girls [32].

Adverse Events

Fatigue (7%), headache (12%), and hot flushes (10%) were reported. In addition, in one patient, ALT levels transiently increased moderately after 12 months of lynestrenol but normalized after adding testosterone [35].

Pubertal Induction in Transgender Boys Treated Previously with Progestational Agents

Testosterone can be added to progestogens following the dosage schemes summarized in Table 11.2.2. In choosing which dosage scheme is appropriate, one should consider duration of endogenous sex steroid exposure prior to start progestogens. The clinical effects and effects on metabolic parameters in adolescent transgender boys have been investigated retrospectively [34, 35].

Effects on HPG Axis

Testosterone therapy increased mean testosterone levels significantly in the first months, already at the lowest dose (50 mg/2 weeks) and further increased in the next months to reach testosterone values well within the male reference range. Some patients exceeded the male upper reference due to blood sampling close to the last testosterone

injection. There was a non-significant rise in oestradiol levels most likely representing the effect of aromatization of the injected testosterone esters. Complete suppression of both gonadotropins was now achieved after the addition of testosterone to lynestrenol [35].

Anthropometry and Metabolic Profile

Clinically, there was weight gain as both BMI [34] and BMI-SDS increased [35]. Haemoglobin and haematocrit increased but mostly remained within the normal male range [35]. Rarely, haematocrit increased to supraphysiological levels [34]. ALT, AST, creatinine increased but remained in the normal range. Lipid profile was more unfavourable with an increase of cholesterol and LDL and a decrease of HDL. Glucose homeostasis parameters HbA1c [34, 35] and insulin, glucose, or HOMA index [35] were not affected.

Adverse Events

The prevalence of acne significantly increased in the first 6 months of testosterone therapy requiring treatment with oral retinoic acid in some individuals. In addition, fatigue was reported [35]. Despite sporadic incidence of polycythemia, no serious cardiovascular adverse events were reported [34].

Therapy Monitoring

In contrast to GnRHa treatment there are no international guidelines for alternative treatment regimes in transgender adolescents and clinicians are for therapy monitoring referred to protocols for adults [4]. Although data in adults are more abundant, protocols cannot be readily translated to adolescents. Firstly, adolescents may not respond the same to therapeutic interventions. Indeed, where in adult transgender women CPA and oestradiol resulted in increased body weight and body fat [37, 38], in adolescent transgender girls these changes were not observed [31]. Secondly, although adolescents reach sexual maturation in their teens, other tissues such as bone and brain are not fully developed until young adulthood [39, 40]. Therefore, it is recommended to follow the guidelines for monitoring gender-affirming hormone therapy in adolescents as summarized in Table 11.2.3 for, at a minimum, during the endocrine transition process.

Conclusion

Early medical intervention in transgender youth has been performed for about 20 years. After at first considered very controversial, nowadays treatment is generally accepted and endorsed by international endocrine communities. The limited availability of somatic outcome and the specific therapeutic needs of the transgender adolescent warrants a multidisciplinary approach provided in specialized centres.

11.3

Hormone Therapy in Transgender Women

Vin Tangpricha and Craig Sineath

Introduction

Recent studies estimate that 0.6% of the adult population and 0.7% of the adolescent population currently identify as transgender, equalling about 1.4 million transgender people in the United States [1]. As this number continues to rise and treatment options become more readily available, more transgender patients will be presenting to their physicians for medical and surgical treatment for gender affirmation [2, 3].

When a transgender woman is ready to pursue medical transition, she must meet with a physician to be prescribed gender-affirming hormone therapy. Traditionally, this physician was an endocrinologist; however, to improve access to hormone therapy, there has been a shift towards other medical providers prescribing hormone therapy. With the ease of prescribing hormone therapy and monitoring its potential side effects and complications as outlined in this chapter, more primary care physicians should become comfortable prescribing hormone replacement therapy (HRT). The most recent Endocrine Society guidelines for hormone therapy for gender dysphoric/gender incongruent persons allow for hormone therapy to be initiated by non-endocrinologists who are able to make and confirm the diagnosis of gender dysphoria. Several other barriers exist to transgender people receiving hormone therapy. One study demonstrated that barriers to transgender people receiving care included bias within the medical field and lack of provider awareness and education about interacting with and treating transgender people [4].

Medical transition via hormone therapy in transgender women has the goal of reversing some of the effects of androgens and providing feminizing effects on the body of the person and allowing the person's physical body to be more congruent with their gender identity. Effects of these therapies include softening of the skin, redistribution of body fat, breast development, and decreased hair growth. Atrophy of androgen dependent tissue (i.e. seminal vesicles and prostate) also occur.

These effects are achieved medically via supplementation with oestrogens and antiandrogens, or surgically by removal of the androgen-producing testes from the body via bilateral orchiectomy. This chapter outlines the use of hormone therapy in transgender women, their wanted and adverse effects on the body, how they should be monitored in the clinical setting, and future directions in the medical hormonal treatment of transgender women.

Initial Evaluation

Before being prescribed gender-affirming hormone therapy, an initial evaluation should be conducted by a physician. According the recent guidelines released by the Endocrine Society, this evaluation should include well-documented gender dysphoria/incongruence, capacity for informed consent, age of majority, and well-controlled mental health concerns if present [5].

This visit should also be a place for the patient to discuss goals of therapy with the physician. Many people presenting with gender dysphoria desire total feminization from hormone therapy, but this is not always the case. It is important to understand where the person is in their transition and what they hope to gain from taking hormone therapies. Some transgender people may not be ready for full medical transition due to not being 'out' to family members or fear of discrimination at work. It is also important to note that many transgender people describe psychological improvement when starting even low doses of hormone therapies before any physical effects take place [6]. Furthermore, some transgender people may identify as gender nonbinary which means that they wish to acquire some but not all of the features of a different gender to better align with their gender identity.

This initial visit should also include a discussion on risks and benefits of hormone therapy with the person. Also, a complete history and physical should be taken with an emphasis of modifying adverse events such as thromboembolic disease (i.e. smoking, sedentary lifestyle, obesity, and underlying personal or family history of blood-clotting disorders). While hormone therapy for transgender people is considered relatively safe under medical supervision, there are some adverse effects that may occur that should be discussed with each individual person [7–9].

These are discussed later in this chapter. For monitoring purposes throughout the transgender person's transition, baseline labs should be drawn at this visit for comparison after the person starts therapy. These should include serum oestradiol and serum testosterone. Once a person has begun therapy, the goal is to keep these values within the normal female reference range. Having levels above this range increases the risk of adverse outcomes such as venous thromboembolism (VTE), ischaemic stroke, and lipid abnormalities [5].

Gender-Affirming Hormone Therapy

Gender-affirming hormone therapy for transgender women requires a dual approach: antiandrogens are needed to reduce the effects of testosterone on the body and oestrogens to increase the supply of feminizing hormone. Progestins have often been added to regimens in the past. These were thought to augment breast development when prescribed with oestrogens; however, there have been no data to show any benefit or additional feminization [3]. In fact, progestins, when prescribed with oestrogens, have been shown to increase the risk of cardiovascular and cerebrovascular disease [6]. Therefore, physicians should counsel all individuals that the risks of progestins out-weigh any potential perceived benefits of such therapy.

The effects of hormones on the physical changes will vary from person to person. There are a variety of formulations currently available on the market and the exact regimen for each person should be tailored based on their physiologic response to the medications and the available local pharmacy formulary. Care should be taken to ensure the levels of these hormones do not exceed normal physiologic levels that occur in reference cisgender females, since many of the adverse events related to HRT may be worsened at higher hormonal levels. Table 11.3.1 outlines the various medications currently available and recommended for hormone therapy in transgender feminine individuals.

Oestrogen Agents

Many forms of oestrogen are available on the market including oral, intramuscular, and transdermal formulations. Ethinyl oestradiol is the form of oral oestrogen commonly used in birth control and was formerly the mainstay in oestrogen replacement for gender-affirming hormone therapy. Guidelines currently recommend against the use of this agent for hormone therapy in transgender people due to a strong associated increase in the risk of cardiovascular disease and venous thrombosis [3, 10]. Oral 17 β-oestradiol, which must be taken daily, has been shown to have less of these complications and is commonly used for gender transition. Conjugated oestrogens such as Premarin are also not recommended because levels are oestradiol are not able to be monitored in blood which may result in inadvertent supraphysiologic levels of oestrogens in the circulation.

Injectable and transdermal (patch) formulations of oestradiol avoid first-pass metabolism from the liver. This property theoretically allows the medication to have a more favourable profile in terms of adverse effects. However, no head to head studies have been conducted to demonstrate the superiority of these compounds to oral preparations of oestrogen.

Testosterone-Lowering Agents

Many drugs exist for testosterone-lowering agents in gender-affirming hormone therapy. There is currently no standard for prescribing these medications.

Spironolactone, a mineralocorticoid receptor antagonist with an added property of inhibiting androgen receptors, is commonly prescribed by physicians as part of gender-affirming hormone therapy [3]. This is the primary antiandrogen prescribed by physicians in the United States. Cyproterone acetate (CPA) is a progestin and androgen receptor antagonist and is widely used in Europe due to historical reasons.

Gonadotropin-releasing hormone (GnRH) is a hormone that is cyclically released in the hypothalamus and causes the pituitary gland to release follicle-stimulating hormone and luteinizing hormone. When a GnRH agonist medication is given, this disrupts the cyclic nature of the hormone and causes the pituitary to halt release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH), resulting in a decline in testosterone production. These medications, such as leuprolide, are relatively expensive, but are used as first-line treatment in the United Kingdom [3].

5-alpha reductase inhibitors block the conversion of testosterone to its more active form. These medications are not recommended by the Endocrine Society since they do not lower testosterone concentrations and have been associated with sexual dysfunction and depression [5].

Table 11.3.1 Preferred options for gender-affirming hormone therapy in transgender women

	Mode of administration	Type	Total dose	Frequency
Oestrogen	Oral	Oestradiol (17β-oestradiol valerate)	2–6 mg	Once or twice daily
	Parenteral (IM)	Oestradiol valerate	5–30 mg	Every 1–2 weeks
		Oestradiol cypionate	2–10 mg	Every week
	Transdermal	Oestradiol patch	0.1–0.4 mg	New patch every 3–5 days
Antiandrogens	Oral	Spironolactone	100–400 mg	Once or twice daily
GnRH agonists	Intramuscular	Leuprolide	3.75–7.5 mg	Monthly
	Implant	Histrelin	50 mg	Implanted every 12 months
	Implant (subcutaneous)	Goserelin	3.6 mg	Implanted monthly

* The medications listed in this table are not FDA approved for gender transition due to no studies being available.

It is important to note that after surgical removal of the testes, the main androgen-producing organ, patients no longer need to take antiandrogen medications and may require a reduction in their oestrogen dosage [3].

Feminizing Effects of HRT

The goals of gender-affirming hormone therapy for transgender women, outlined next, are to reduce the virilizing effects of testosterone (i.e. decrease terminal hair growth, oiliness of the skin, muscle mass, and voice changes) and to enhance the feminizing effects of oestrogen (i.e. redistribution of body fat, breast growth, softening of the skin). Many of the physical results of taking hormone therapy are irreversible (Table 11.3.2).

Breast Development

A recent study suggests that most breast development in patients taking feminizing hormones occurs within the first 6 months of therapy, and only modest growth occurs after 12 months [11]. Furthermore, there has been no correlation seen with breast development based on dose or even type of hormone regimen given, and most transgender patients report insufficient breast growth from HRT [12]. However, the transgender women studied here were also taking cyproterone which may have interfered with the breast development. The histologic changes that occur in breast tissue of a transgender women taking feminizing hormones appear to be identical to cisgender women with formation of ducts, lobules, and acini [13]. More research is still needed to understand breast development in transgender women taking hormones. Patients who are not fully satisfied with the breast development that occurs from hormone therapy may choose to have breast augmentation surgery.

Table 11.3.2 Feminizing effects of HRT

Effect	Expected onset	Expected maximum onset
Redistribution of body fat	3–6 months	2–3 years
Decrease in muscle mass and strength	3–6 months	1–2 years
Softening of skin/decreased oiliness	3–6 months	Unknown
Decreased sexual desire	1–3 months	3–6 months
Decreased spontaneous erections	1–3 months	3–6 months
Male sexual dysfunction	Variable	Variable
Breast growth	3–5 months	2–3 years
Decreased testicular volume	3–6 months	2–3 years
Decreased sperm production	Unknown	>3 years
Decreased terminal hair growth	6–12 months	>3 years
Scalp hair	Variable	–
Voice changes	None	–

Body Fat Distribution

After starting feminizing hormone therapy transgender women experience an increase in body fat and changes in body fat distribution. One study showed that transgender women experience a body fat increase of 18% the android region (abdomen, chest, and shoulders), 42% in the leg region, and 35% in the gynoid region (hips, thighs, and buttocks). Transgender women also had a decrease in the waist-to-hip ratio, mainly due to an increase in hip circumference [14].

Dermatological Effects

Transgender women on hormone therapy see several changes in their skin including hair growth and sebum production. While hormone therapy does not completely reverse the androgen effects of hair growth that have already taken place if a person has already undergone puberty, there is a decrease in facial and body hair growth and density [15]. Hair-shaft diameter also decreases and has been shown to reach its maximum reduction in size after four months of oestrogen plus antiandrogen therapy [16]. These changes are often more evident on the abdominal hair compared to facial hair due to having lower hair density and hair-shaft diameter. Many transgender women opt to undergo laser hair removal to correct the masculinizing effects of testosterone. Transgender women on oestrogen and antiandrogen agents also have a decrease in skin sebum production to levels that are almost undetectable. One study showed transgender women had significantly less oily skin after four months of therapy [16]. Patients with acne often will notice less lesions due to the decrease in sebum production.

Voice

Feminizing hormone therapy has no effect on the voice. Therefore, if a patient has undergone virilizing puberty where their voice has deepened, starting hormone therapy will not provide any feminizing effects on the voice (i.e. increasing the tone). Many transgender women choose to see a voice therapist to learn techniques for making their voice sound more feminine. Some patient may also choose to undergo vocal cord surgery to tighten their vocal cords and make their voice higher pitched.

Genitalia and Sexual Desire

Patients on feminizing hormone therapy see a reduction in testicular and prostate size and decreased erectile function [6]. Also, testosterone levels are attributed to maintaining a person's sexual desire. In feminizing hormone therapy, testosterone levels are generally kept at low levels, resulting in a reduction in sexual drive [17].

Monitoring

According to the Endocrine Society's 2017 guidelines, a person on gender-affirming hormone therapy should be monitored every 3 months in the first year and every 6–12 months thereafter with a physical exam and labs. Serum testosterone levels should be kept below 50 ng/dl and oestradiol levels should be kept in the physiologic range of about 200 pg/ml. Keeping the hormone levels within these parameters has been shown to be relatively safe and have less adverse effects than if the patient were to achieve supraphysiologic levels of oestrogen.

Cardiovascular Safety

The greatest health concern with feminizing hormone therapy is thromboembolic disease, which is increased in patients on oestrogen [7]. The risk of this adverse event is even more pronounced in patients with compounding risk factors including age greater than 40, tobacco use, sedentary lifestyle, obesity, and pre-existing underlying thrombotic disease [6]. Physicians should counsel their transgender women on these risks and encourage lifestyle changes such as smoking cessation to reduce these adverse events. Furthermore, the risk of thromboembolic disease may be decreased in individuals who are taking oestrogens transdermally or intramuscularly compared to those on oral pills [3].

There is also some evidence that the lipid profile of a person changes when they are taking feminizing hormone therapy. Improved measures include a decrease in low-density lipoprotein (LDL) and an increase in HDL [18]. Hypertriglyceridemia has also been shown to be associated with feminizing hormone therapy [19]. Oral oestrogen therapy seems to have a larger impact on this when compared to transdermal therapies here as well; however, the clinical implications of this increase in triglycerides has yet to be studied.

Studies have also demonstrated a relationship with feminizing hormone therapy increased blood pressure [18]. However, it is thought that this change may be more so related to changes in bodyweight and fat distribution when a person is taking gender-affirming hormone therapy than actual direct effects of the medications.

Hepatic Safety

Use of oestrogens has been linked to transient elevation in liver enzymes with the rare complication of hepatotoxicity [6]. As mentioned previously, use of injectable and transdermal formulations of oestrogen avoid first-pass metabolism through the liver and may have lower risk of this complication. Neither the Endocrine Society nor the World Professional Association for Transgender Health (WPATH) recommend routine evaluation of liver enzymes in patients on feminizing hormone therapy.

Endocrine Safety

Prolactin levels should also be monitored in transgender women on HRT at baseline, one year after starting hormone therapy, and then every two years indefinitely [5]. Oestrogen is a strong stimulator of prolactin formation and release from the pituitary gland, and there have been case reports of patients on gender-affirming feminizing hormone therapy who have developed prolactinomas [20]. However, the risks of hyperprolactinemia have been debated and may be increased in transgender women taking cyproterone as compared to those taking spironolactone [21].

Electrolyte Changes

Patients on spironolactone, traditionally used as a potassium-sparing diuretic, have the added risk of hyperkalaemia. Serum electrolytes should be monitored every three months when beginning this therapy, and then every 12 months thereafter [5].

Bone Health

Sex hormones are integral to the preservation of bone density. Use of oestrogens in HRT has shown to increase bone density and reduce the formation of osteoporosis [3]. There have been no evidence-based guidelines released on monitoring the bone density of transgender women. The Endocrine Society recommends that clinicians consider doing a bone-mineral density test at baseline before starting therapy and then screen for osteoporosis in low-risk patients at 60 years of age or in patients who are not adherent to hormone therapy [5].

Oncology

Very little research has been published on cancer in transgender individuals and there are currently no guidelines for cancer screening specifically in transgender patients. While it is rare, there have been several cases reported of prostate cancer in patients on feminizing hormone therapy, and effects of receiving a bilateral orchiectomy on development of prostate cancer in this patient population has yet to be established [22]. There have also been cases of breast cancer development in transgender women reported in the literature [13]. While no evidence-based guidelines have been released, the Endocrine Society recommends that physicians continue with current guidelines for cancer screening recommended for cisgender populations for all anatomy that is present in the person. This would include prostate and breast cancer screening in this population.

Mental Health

Transgender patients have unique mental health needs. Diagnoses of depression and anxiety occur at disproportionately high prevalences in patients with gender dysphoria, and transgender people are at increased risk of suicide compared to their cisgender peers [23, 24]. A mental health professional is often very helpful in addressing any coexisting mood or social situations before and during the hormone transition process. While many psychological symptoms may be directly linked to a person's gender dysphoria and improve after starting gender-affirming treatment, the transgender population remains a vulnerable population for chronic psychiatric conditions due to the unique daily stress and trauma they experience as a result of stigma and discrimination [25]. It is important for transgender people to have access to culturally competent mental health services throughout their lives to meet their unique healthcare needs.

Other Considerations

Fertility Preservation

Taking oestrogens has been shown to reduce spermatogenesis in transgender women. However, research on the exact effects of dosing, length of treatment, and reversibility of hormone therapy on fertility have yet to be established [26]. Since it is known that taking gender-affirming feminizing hormone therapy has currently unpredictable and potentially irreversible dramatic effects on a person's fertility, it is important to counsel all transgender women starting this therapy on options for fertility preservation. These options include sperm banking for patients who are able to provide sperm of sufficient quality and quantity. However, some transgender women experience such severe dysphoria concerning their genitals, and this is not an option. There are several procedures that can be done by specialists (i.e. urologists) that include surgical sperm extraction and testicular tissue cryopreservation [27]. It is important to note

that while these technologies are available, most are expensive and are not feasible for a large proportion of transgender people (more details can be found in Chapter 11.5).

Lactation

There are case reports of functional lactation achieved in transgender patients. One such case report describes a transwoman on domperidone, oestradiol, progesterone, with breast pump stimulation who was able to achieve lactation with the ability to feed her child solely on her own milk for 6 weeks [28]. Breastfeeding as a transgender woman has not been described well in the literature, but is a promising and expanding field of research.

11.4

Hormone Therapy in Transgender Men

Guy T'Sjoen and Justine Defreyne

Introduction

As the number of trans persons actively seeking psychological, endocrinological, and/or surgical treatment is increasing [1, 2] it is important to get healthcare professionals acquainted with transgender care. Currently, transgender care is often not a (strong) part of the medical curriculum [3–5], which may lead to miscommunication, misinformation, and not referring trans persons to the appropriate care providers. This may lead to people taking hormones without the follow-up of a physician or undergoing clandestine gender-affirming surgery. Due to real or perceived stigma and fear of medicalization when reaching out to healthcare providers, trans persons may encounter barriers when accessing healthcare [6]. As gender-affirming hormonal and surgical treatment has been shown to reduce or even resolve feelings of gender dysphoria in trans persons [7–17], gender-affirming care should be accessible to all trans persons.

In most countries, hormonal treatment is ideally prescribed under the supervision of endocrinologists. However, many endocrinologists may feel uneasy and unskilled when working with the transgender population. This chapter aims to summarize the endocrine treatment for transgender men wishing physical transition.

Initial Evaluation

The Endocrine Society guideline 'Endocrine treatment of gender-dysphoric/gender-incongruent persons: an Endocrine Society clinical practice guideline' recommends that a medical professional confirms the diagnosis of gender dysphoria in transgender persons prior to the initiation of gender-affirming hormone therapy. Medical professionals should document that the gender dysphoria has been persistent and that the individual is of legal age and able to make an informed decision and consent for treatment. If significant medical or mental health concerns are present, they must be reasonably well-controlled, but the presence of mental health concerns does not necessarily exclude patients from gender-affirming hormones [18]. If hormone therapy is contraindicated due to serious health conditions, the practitioner should ensure access to non-hormonal interventions for gender dysphoria, which can be discussed with a qualified mental health professional (see Chapter 11.1).

Transgender people seeking gender-affirming hormone therapy expect to change their physical appearance to better match their gender identity and expression, which can range from an androgynous presentation to maximum virilization [18]. Therefore, hormone prescribing physicians should always individualize the hormone therapy based on the patient's goals, the risk/benefit ratio of the treatment, the presence of other medical conditions, taking into account possible social and economic issues [19]. The physician who prescribes the hormones is responsible for discussing the expected effects of testosterone therapy and the possible adverse health effects, including the possible reduction in fertility (which should ideally be discussed before the patient is referred to the endocrinology department). He/she should also provide ongoing medical monitoring with regular physical and laboratory examination and communicate as needed with the patient's primary care provider, mental health professional, surgeon, and/or other healthcare professionals involved [18, 19]. Gender-affirming hormonal treatment (and surgery) has been shown to reduce and in some cases even resolve gender dysphoria and mental health problems. In addition, gender-affirming treatment increases self-reported quality of life (QOL). Satisfaction rates among transgender persons are high and gender-affirming treatment is rarely regretted [20–23]. Ideally, gender-affirming hormonal therapy is only available by prescription. However, one must realize that there is a black market for steroids, including testosterone analogues. In addition, in non-Western countries or areas where gender-affirming care is less easily available, gender-affirming hormone therapy is often self-prescribed without supervision by a medical professional. Available evidence from the United States and Europe suggest that hormone therapy initiated and monitored under the supervision of a medical professional is associated with very low rates of adverse events [24–27].

Guidelines, including the World Professional Association for Transgender Health (WPATH) Standards of Care edition 7 (SOC

7) and the Endocrine Society guideline advises to screen transgender people for conditions that can be aggravated by hormone therapy, before initiating gender-affirming care. Medical history should be assessed thoroughly, including history of thromboembolic diseases (e.g. deep vein thrombosis, pulmonary embolism), arterial hypertension, polycythemia and sleep apnoea [18]. Testosterone therapy is usually continued lifelong after oophorectomy, unless medical contraindications arise [19].

Gender-Affirming Hormone Therapy

Testosterone Agents

Hormonal therapy in transgender men is aimed at inducing virilization and consists of testosterone agents, which is preferably administered intramuscularly or transdermally. If patients are screened adequately and follow-up visits are provided regularly, testosterone therapy is safe on the longer term [28–30]. Testosterone therapy is contraindicated in case of (desired) pregnancy or lactation. In order to maintain virilization and avoid hypogonadism symptoms (e.g. osteoporosis or vasomotor symptoms), testosterone therapy must be continued lifelong. Testosterone regimens in transgender men follow the general principle of hormone replacement therapy of male hypogonadism, aiming at cisgender male reference ranges for serum testosterone levels [18]. Most commonly prescribed are injectable testosterone esters, used in dosages of 200–250 mg IM every 2–3 weeks [18, 31]. Long-acting testosterone undecanoate 1000 mg IM every 10–12 weeks is also being used for treatment of transgender men [32]. In the United States, both the patient and provider must undergo risk evaluation and mitigation strategy (REMS) training in order to be able to initiate testosterone undecanoate therapy, due to the potential risk of oil pulmonary embolism. The use of oral testosterone (testosterone undecanoate 160–240 mg/day), axillary solutions, patches, nasal sprays, buccal tablets, or pellets is rarely reported for treatment in transgender men. If transgender men wish to self-inject testosterone, subcutaneous administration is also an option at a at a median dosage of 75 mg weekly [31, 33]. Other options include topical androgen gel 1% (25–100 mg per day) or transdermal patches (2.5–10 mg/day) [18]. As long as patients adhere to the prescribed dose controlled by their physician, there is no difference between the different testosterone formulations regarding short-term safety, compliance, metabolic parameters, body composition and general life satisfaction [34]. The dose of testosterone may be increased (e.g. from 200 mg of testosterone esters to 250 mg, biweekly or from testosterone undecanoate once every 12 weeks to once every 10 weeks) if trough serum total testosterone levels do not reach cisgender male levels after six months of testosterone therapy, with subsequent monitoring of serum haematocrit levels. The dose of testosterone may be decreased if serum haematocrit levels rise above male reference ranges or if desired by the patient (see monitoring—cardiovascular safety) (Table 11.4.1).

As transgender men often describe menstrual bleeding as a discomfort [35, 36] medication to induce amenorrhea should be discussed with every transgender man early in the transition process. If suppression of the menses is desired or menstrual bleeding does not cease, a progestational agent or a gonadotropin-releasing hormone (GnRH) analogue can be added to the treatment regimen. Suppression of menstrual bleedings is less likely in people treated with transdermal or oral testosterone [24] and enquiring about the persistence of menstrual bleeding and the degree of inconvenience due to this should be part of the assessment. The most commonly used agents include oral lynestrenol 5–10 mg daily or medroxyprogesterone 5–10 mg daily. The use of progestational agents is contraindicated in case of pregnancy (history of) breast cancer or any other gynaecological cancer, unexplained vaginal bleeding, severe arterial disease, liver insufficiency, and severe liver or bile diseases. Possible side effects include gastrointestinal discomfort, water- and salt retention, weight gain, decreased sexual desire and spotting. GnRH analogues are rarely used in adults because of the costs of the therapy. Another rarely used option is endometrial ablation [26]. After hystero-oophorectomy, progestational therapy can be stopped.

Virilizing Effects of Testosterone Therapy

Hormone therapy with testosterone induces virilization; it causes the voice to break, sometimes menses stop, facial and body hair

Table 11.4.1 Preferred options for gender-affirming hormone therapy in transgender men

	Mode of administration		Type	Dosage	Frequency
Testosterone	Parenteral	Intramuscular	Testosterone esters	200–250 mg	Every 2–3 weeks
			Testosterone undecanoate[a]	1000 mg	Every 10–12 weeks
		Subcutaneous	Testosterone esters	75–125 mg	Every week
	Transdermal		Androgen gel 1%[b]	25–100 mg	Once daily
			Transdermal patches	2.5–10 mg	Once daily
Progestational agents	Oral		Lynestrenol	5–10 mg	Once daily
			Medroxyprogesterone	5–10 mg	Once daily
			Nomegestrol	5–10 mg	Once daily
	Parenteral		Medroxyprogesterone	150 mg	Once every three months

[a] One thousand milligrams initially followed by an injection at 6 weeks, then at 12-week intervals.
[b] Avoid cutaneous transfer to other individuals.

appears in a male pattern, the clitoris enlarges (mean 3.83 +/– 0.42 cm after 2 years of testosterone therapy) and the musculature becomes bulkier and more pronounced, leading to an overall good passability (being perceived by others as a cisgender man) in daily life [7, 9]. It is important to discuss the possibilities and limitations of testosterone therapy before and during gender-affirming hormone therapy; height and bone structure will not change if testosterone therapy is initiated after puberty. In addition, testosterone therapy will not affect the degree of subcutaneous fat, unless physical activity is initiated or increased (Table 11.4.2) [37].

Dermatological Effects

In the pilosebaceous unit of the skin, both androgen and oestrogen receptors are expressed, enabling testosterone to have effects on both the skin and hair of transgender men. Testosterone therapy leads to an increase in acne both at the face and back after four months, with peak severity after 6 months [30]. Long-term data (10-year follow-up) shows no to mild acne in 93.9% of transgender men [38]. Testosterone therapy also leads to a desirable increase in body and facial hair. The increase is already apparent during the first year of treatment, although after 12 months of testosterone therapy, the facial and abdominal hair profile is still less compared to cisgender men [39]. Long-term data (10-year follow-up) shows further increasing body and facial hair growth after the first year, with an increase of the Ferriman–Gallwey score from median 0.5 (before hormone therapy) to 12 after 1 year, while long-term testosterone treatment (10 years) resulted in a median score of 24 [38]. While body and facial hair increases, male pattern baldness (MPB) may occur with thinning of hair related to the duration of testosterone therapy. One retrospective study found that 38.3% of transgender men had MPB type II-V [39] and another study by Wierckx *et al.* reported a 17% incidence of developed androgenetic alopecia based on the Norwood-Hamilton classification after 1 year of treatment [40]. Studies with longer follow-up data report an incidence of 32.7% of mild frontotemporal hair loss and 31% of moderate to severe androgenetic alopecia after 10 years of testosterone therapy [41]. If desired, oral finasteride 1 mg daily can be added to the treatment regimen [41].

Voice

Testosterone causes hypertrophy of muscle cells with a reduction of surrounding fat cells. These effects are also exerted at the level of the larynx, which results in acoustic changes [42]. In high dose, testosterone is responsible for the development of the male voice characteristics. Androgens act virilizing to the voice in birth-assigned females from a concentration of 150 μg/dl. Repeated exposure to concentrations higher than 200 μg/dl results in irreversible changes, which occur predominantly during the first three months of testosterone therapy [43]. Often, the voice of transgender men cannot be distinguished from cisgender men, although transgender men are more likely to experience problems with pitch quality (incidence 10%) [44, 45]. In transgender men in whom the voice was perceived as male, overall well-being was higher compared to those in whom the voices were less gender congruent [46].

Genitalia

Testosterone therapy causes the clitoris to grow. Clitoral length already increases by 60% after only 3 months of testosterone therapy (mean clitoral length after three months: 3.19 ± 0.54 cm) and continues to enlarge during the testosterone therapy (mean clitoral length after 2 years: 3.83 ± 0.42 cm). As long-term follow-up data are not available, it is uncertain if further growth past the second year of testosterone therapy is to be expected [7]. Long-term testosterone use causes vaginal and cervical atrophy, with decreased vaginal secretions which can result in vaginal dryness or itching, and painful penetration reported by some patients [47]. If necessary, vaginal dryness can be helped by simple over-the-counter lubricants [48].

Sexual Desire

In cisgender men, numerous studies have shown a relationship between sexual desire and circulating levels of testosterone [49–51], which has also been described in cisgender women [52, 53]. Testosterone therapy in transgender men may facilitate sexual desire and arousal. However, to date, studies focusing on sexual functioning in trans men treated with testosterone who did not (yet) undergo genital gender-affirming surgery are scarce. Wierckx *et al.* [54] reported higher sexual desire in transgender men who recently initiated testosterone therapy. Costantino *et al.* [51] reported an increase in frequency of desire, masturbation, sexual fantasies, and arousal after 1 year of testosterone administration. Studies on trans persons (without substratification of trans men and trans women) show an increased sexual QOL in persons on gender-affirming hormones [55].

Monitoring

See Box 11.4.1.

Cardiovascular Safety

Testosterone is one of the most anabolic hormones in the human body; it has a positive effect on protein synthesis, stimulates fat oxidation and reduces lipid storage [56]. Despite this, cardiovascular mortality is higher in adult men, compared to women [57]. This difference may be caused by sex hormone differences, although at physiological levels, both testosterone and oestradiol are thought to be involved in maintaining insulin sensitivity [58].

Box 11.4.1 Suggested guideline for the monitoring of testosterone therapy in transgender men

- Provide adequate follow-up every 3 to 4 months during the first year of testosterone therapy and one to two times per year thereafter.
- Monitor for appropriate signs of virilization, serum sex steroid levels, and development of adverse reactions.
- For testosterone esters, the testosterone level should be measured midway between injections with a target level of 400–700 ng/dl (13.9–24.3 nmol/L) of total serum testosterone.
- For testosterone undecanoate, testosterone should be measured just before the following injection. If the level is <400 ng/dl (13.9 nmol/L), increase the dosing interval.
- For transdermal testosterone, the testosterone level can be measured at least 2 hours after application. It is not advised to measure serum testosterone levels within the first week of testosterone therapy.
- Measure serum haematocrit or haemoglobin at baseline and every three to four months during the first year and one to two times per year thereafter.
- Monitor weight, blood pressure, and serum lipid levels at regular intervals.
- Screening for osteoporosis should be conducted in transgender men who stop testosterone therapy, are not compliant with hormone therapy or who develop risks for bone loss.
- If cervical tissue is present, monitoring is recommended as in cisgender females.
- Conduct annual breast examinations if mastectomy was performed. If mastectomy has not been performed, monitoring is recommended as in cisgender females (by mammography).

Studies examining the effects of the administration of androgens on insulin resistance and glucose intolerance in cisgender men showed conflicting results [59–62]. Despite this, there is currently no evidence for an increase in adverse cardiovascular outcomes in transgender men taking testosterone therapy on short and medium (10 years) follow-up time, although data on older transgender men are lacking [63–65]. However, a systematic review of the literature concluded that the level of evidence was too low to allow an interpretation of the risk of testosterone therapy on morbidity (stroke, myocardial infarction, venous thrombo-embolism) and mortality in transgender men [66]. Testosterone therapy does alter independent cardiac risk factors, including the lipid profile (decrease in high-density lipoprotein cholesterol and increase in triglycerides and low-density lipoprotein cholesterol), increasing inflammation parameters and (minimally) increasing systolic blood pressure and increasing serum haematocrit levels (to cisgender male reference values). To date, there is scarce evidence that these changes in risk factors result in altered morbidity [67–69]. The majority of the studies on transgender men report no changes in insulin resistance or diastolic blood pressure [30, 34, 64, 70], although one prospective study on 43 transgender men reported an increased incidence of metabolic syndrome after 1 (16.3%) and 2 years (18.6%) of testosterone ester therapy every 3 weeks [71]. One prospective study on 13 transgender men on testosterone esters every 2 weeks, reported diminished peripheral glucose uptake after 4 months [72]. The Endocrine Society guideline [18] suggests monitoring weight, blood pressure, and lipids at regular intervals. If cardiovascular risk factors emerge, they should be managed according to established population-based guidelines.

Testosterone therapy is associated with an increase in serum haemoglobin (+ 4.9–12.5% range) and haematocrit (+ 4.4–17.6% range) levels during the first year of treatment, with the most pronounced increase during the first three months (+2.7% Hct, 95% CI 1.94–3.29). Serum haematocrit levels remain stable after the first year of testosterone therapy [32, 38, 67]. As serum haematocrit levels can be found in the reference range of the perceived gender as from three months after the initiation of gender-affirming hormonal treatment, it is advised to consult the reference range for men in transgender men after the initiation of testosterone treatment [68]. Although theoretically, testosterone therapy increases the risk for erythrocytosis, clinically significant erythrocytosis is very rare [30, 67, 68]. In a large prospective study by the European Network for the Investigation of Gender Incongruence (ENIGI), which included 192 transgender men, the maximum measured haematocrit level was 54.0% and none of the transgender men experienced a thromboembolic event during follow-up. There are no reasons to assume that the observed mild increase in serum haematocrit levels is associated with an increased thrombotic risk in the short term [68]. Transgender men on testosterone undecanoate exhibit lower erythrocytosis rates compared to transgender men on testosterone esters or gel. Changing the treatment to testosterone undecanoate seems a valid option if the hormone prescribing physician and/or the patient are concerned about elevated serum haematocrit levels. This may prevent unnecessary interruptions in hormonal treatment [68]. The Endocrine Society guideline [18] suggests measuring haematocrit or haemoglobin at baseline and every 3 months for the first year and then one to two times a year.

Hepatologic Safety

An increase in liver enzymes can be observed during testosterone therapy [18], but this is mainly observed in transgender men taking oral 17-alkylated testosterone, which is no longer recommended [73, 74]. Two prospective studies reported no significant increase in liver enzymes in transgender men during gender-affirming hormone therapy [32, 75]. In addition, in the prospective study by Wierckx *et al.*, none of the 53 transgender men had liver enzyme values exceeding twice the upper limit according to male reference ranges and only 1.9% of the transgender men had liver enzyme values exceeding twice the upper limit according to female reference ranges, during one year of follow-up [30]. The Endocrine Society guideline [18] states that hepatotoxicity is not anticipated in transgender men taking parenteral or transdermal testosterone.

Bone Health

Many studies have assessed bone mineral density (BMD) in transgender men and results have recently been meta-analysed by Singh-Ospina *et al.* [76]. This meta-analysis revealed a similar BMD compared to cisgender females prior to testosterone therapy [76–79] and no decrease in BMD after the initiation of testosterone therapy [76, 77, 80]. There are two possible explanations for this: the aromatization of testosterone to oestradiol and the androgen-mediated increase in muscle mass, which stimulates bone formation according

to the Mechanostat theory [81]. In the study by Van Caenegem *et al.* [82], both muscle mass and strength were positively associated with trabecular and cortical parameters and bone size.

There are very limited data on the risk of osteoporotic fractures in transgender men [76]; only one cohort study of 53 transgender women and 53 transgender men reported hard outcomes such as fracture results. There were no fractures after 12 months of follow-up [30].

After ovariectomy, testosterone therapy becomes crucial to preserve BMD, as it prevents oestrogen-deprivation related bone loss in the short (<2 years) [34, 38, 77, 78, 80, 83–85] and long term (>10 years) [82, 86–88] and can even result in a prospective increase in BMD at cortical sites [84]. In addition, testosterone therapy also results in an increased cortical thickness [89] compared to postmenopausal cisgender women. However, bone loss has been described in transgender men who are not compliant with their testosterone therapy, who did not receive an adequate dose of testosterone or who stopped testosterone therapy completely [83, 86]. The Endocrine Society guideline [18] suggests screening for osteoporosis in those who stop testosterone treatment, are not compliant with hormone therapy, or who develop risks for bone loss.

Oncology

With more countries abandoning laws requiring gonadectomy for legal gender affirmation in transgender people, the number of transgender men who do not wish for hystero-oophorectomy is increasing. Both healthcare practitioners and transgender men have expressed concern about the impact of long-term testosterone therapy on its oncological risk. However, high-quality empirical data assessing cancer incidence and mortality among transgender people are lacking primarily because of an absence of large-scale prospective studies.

Breast Cancer

It is estimated that, in cisgender women, the incidence of breast carcinoma after prophylactic mastectomy is probably less than 2% [90]. In the current literature, seven cases of breast cancer in transgender men taking testosterone therapy have been reported [91–94]. In addition, Van Renterghem *et al.* [95] examined mastectomy specimens of 148 transgender men. They did not report invasive cancer, but apocrine metaplasia was seen in 23.6%, lactational changes in 2%, columnar cell changes in 37.2%, sclerosing adenosis in 4.7%, fibroadenoma in 4.1%, usual ductal hyperplasia in 27%, flat epithelial atypia in 0.7% and atypical ductal hyperplasia in 3.4%. In cisgender women, an increased risk of breast carcinoma has been reported in both pre- and postmenopausal women with higher serum testosterone levels. However, no causal relationship or association between testosterone therapy and the incidence of breast carcinoma in transgender men has been found and routine histopathological examination of mastectomy specimens may assess whether there is an increased risk of breast carcinoma in transgender men, compared to cisgender women [95]. Gooren *et al.* even found a lower incidence rate of breast cancer in transgender men, compared to cisgender females (5.9 versus 155 per 100 000 person-years) [91]. It should also be noted that breast cancer can still occur after mastectomy has been performed, thus adequate screening is still necessary postmastectomy [92, 94]. To date, no large studies on breast cancer risk have been performed in this population. The Endocrine Society [18] recommends conducting sub- and periareolar annual breast examinations if mastectomy has been performed. If mastectomy is not performed, then mammography should be considered, as recommended by the American Cancer Society.

Cervical Cancer

In cisgender women, the presence of human papilloma virus (HPV) increases the risk for cervical cancer [96]. However, it is unsure whether serum testosterone is related to cervical cancer in cisgender women; in premenopausal women, a positive correlation was found between free testosterone and higher risk of invasive cervical carcinoma, whereas in postmenopausal women, there was a positive correlation with total testosterone [97]. Whether testosterone therapy is associated with an increased risk for cervical cancer in transgender men remains unknown to date. In the literature, only two case reports of transgender men diagnosed with cervical cancer have been published [98, 99]. Both cases were diagnosed upon gender-affirming surgery. If cervical tissue is present, the Endocrine Society guideline [18] suggests monitoring as recommended by the American College of Obstetricians and Gynecologists [100].

Endometrial and Ovarian Cancer

Observational studies have reported an association between endometrial or ovarian cancer and higher total serum testosterone levels in postmenopausal women. The proposed explanation is twofold: testosterone can be aromatized into oestradiol, which results in lower testosterone levels and an increased in oestrogen levels, which may stimulate endometrial and ovarian epithelium proliferation, and testosterone can also be converted into dihydrotestosterone (DHT) by 5α-reductase. DHT and testosterone can both increase endometrial and ovarian epidermal growth. However, as DHT also has antiproliferative effects on the endometrial and ovarian cancer cells, higher testosterone levels may also lead to a decreased cancer risk [97]. In addition, cisgender women with polycystic ovary syndrome (PCOS) are at higher risk for endometrial cancer due to androgen-mediated endometrial epithelium proliferation [97]. Whether testosterone therapy induces PCOS morphology of the ovarian cortex in transgender men remains unsure, as results are contradictory [101, 102]. In the current literature, only one case of endometrial cancer in a transgender man after 7 years of testosterone therapy [98] and three cases of ovarian cancer in transgender men receiving testosterone therapy have been reported, of which two cases were tested for the endometrial epidermal growth factor receptor; both were positive [103, 104].

However, in Europe, in the past, many transgender men included in published studies underwent hystero-oophorectomy after 12–18 months of gender-affirming hormone therapy, which reduces the cohort of transgender men at risk for endometrial and ovarian cancers and increases the need for large long-term cohort studies on cancer risk in transgender men who do not undergo this surgery.

Other Cancers

To date, only eight published papers assessed cancer incidence or mortality in transgender men, these articles examined different populations (the Netherlands, Belgium, Sweden, and the United States) in different time periods (1989–2016) [24, 28, 65, 91, 105–107].

Although large representative prospective studies of transgender populations across multiple clinical sites are not available to date,

there is evidence that transgender people are more frequently exposed to cancer risk factors such as smoking, obesity and lack of/inadequate cancer screening due to perceived barriers for accessing healthcare [97, 108]. These factors result in transgender people less frequently accessing healthcare for preventive care, such as cervical smears in transgender men [109]. However, to date, the number of cancers reported in transgender men is relatively low compared to transgender women [105, 106] which may be due to the younger age of transgender men in the majority of the published articles. However, as long as large-scale epidemiological data on long-term cancer risk in transgender people has not been published, it is advised to adhere to the general screening protocols.

Psychological Monitoring

Depression, suicide attempts and anxiety rates in the transgender sample are high (36–63%, 32%, and 33–47%, respectively) [110–113]. Avoidant coping is more frequent in the beginning of the gender-affirming process [112], which in turn can increase symptoms of depression and anxiety. In addition, social support is directly and indirectly related to depression and anxiety [112]. Therefore, it is important to enquire about psychosocial well-being during each contact and to refer to a psychologist/psychiatrist if necessary. If additional risk factors are present, the WPATH Standards of Care [19] warn for a possible increased risk of destabilization of certain psychiatric disorders (including bipolar, schizoaffective, and other disorders that may include manic or psychotic symptoms) in transgender men on too high dosage of testosterone. In addition, the WPATH Standards of Care also warn for aggression or expansive mood at the beginning of an injection cycle with testosterone esters [19]. However, in transgender men who adhere to the prescribed dose of testosterone, a decrease of coexistent psychopathology has been observed upon the initiation of gender-affirming hormone therapy [114] and the absence of increase in aggression has been observed [115].

Other Considerations

Fertility Preservation

Hysterectomy and bilateral oophorectomy in transgender men lead to an irreversible loss of natural reproductive capacity; therefore, it is important for healthcare professionals to discuss reproductive options beforehand [116]. As many transgender men desire children [117], it is important for healthcare providers to get acquainted with the fertility needs of transgender men and to be able to discuss reproductive options at each stage of the gender-affirming process and the impact of hormonal therapy on fertility. There have been case reports of transgender men who became pregnant after stopping testosterone therapy [118] and it is possible to stop testosterone therapy in order to preserve germ cells, but most transgender men experienced this as emotionally difficult [36]. Therefore, we advise freezing of germ cells prior to the initiation of gender-affirming therapy if there is a genetically related parental desire. If germ cells have been frozen, it may remain possible for transgender men to have genetically related children, even after gonadectomy. However, the preservation of oocytes, ovarian tissue, or embryos implicates extra costs for the retrieval procedure and an annual cost for the preservation, financed by the patient. Further details regarding fertility options in trans men are discussed in De Roo *et al.* [119] and Chapter 11.5.

11.5

Fertility Options for Transgender Persons

Chloë De Roo and Guy T'Sjoen

Introduction

Persons with gender dysphoria inherently possess normal reproductive capacity [1]. Treatment options to facilitate the transition and to live in accordance with the identified gender often comprises both hormone therapy and/or surgical interventions [2]. Unfortunately, both these options have a negative effect on fertility [2, 3]. Healthcare professionals should address the consequences for future fertility with their patients before treatments have started.

Although there are only few studies that investigated the desire of transgender people to have children, they all conclude that approximately half of transgender women and half of transgender men wish to have children [4–6].

The relevance of this topic is also reflected in the fact that transgender people with children score significantly better on mental health and vitality scores than transgender people without children [4]. In transgender women, parenting was even identified as a suicide protective factor [7]. Apart from an apparent child wish, a small majority of transgender men and transgender women would actually have cryopreserved their gametes, or would have seriously considered doing it, if the technique would have been available [4]. Especially lesbian and bisexual transgender women were interested in using their own cryopreserved sperm to fulfil a future child wish [4]. Regardless of their personal desire, the majority of transgender people clearly expressed the opinion that fertility preservation techniques should be discussed and offered [6].

On the contrary and quite striking is the fact that some of the transgender patients are willing to completely sacrifice their fertility, since fertility preservation was considered not important enough to postpone their transition process [6] as most of transgender people are in favour of a fast transition [5]. Also cost, physical discomfort and the invasiveness of the procedures were identified as burdens for fertility preservations [8, 9]. However, decisional regret and quality of life following declining fertility preservation needs to be further explored [8].

The World Professional Association for Transgender Health (WPATH) Standards of Care recommend in their seventh version to discuss fertility options with patients prior to any treatment or medical intervention, especially before gender-affirming surgery [2]. The impact of each treatment on fertility as well as a possible fertility preservation option to maintain the possibility of having future genetically related children, should be addressed.

The Effect of Gender-Affirming Therapy on Fertility

Gender-Affirming Surgery

Gender-affirming surgery with penectomy and orchidectomy or hysterectomy with bilateral oophorectomy leads to irreversible sterility [4, 10].

Pubertal Suppression

Gonadotropin releasing agonists (GnRH-a) preventing development of secondary sexual characteristics, inhibit germ cell maturation [11]. However, discontinuation results in normal pubertal progression [1, 12]. Hagen *et al.* (2012) showed that GnRH-a administration in girls with precocious puberty resulted in a significant decline of anti-Müllerian hormone (AMH—a marker for ovarian follicle reserve) after 3 months with recovery to pretreatment AMH serum levels 6 months after interruption of the treatment [11].

Hormone Treatment Therapy in Transgender Women

Clinically, prolonged oestrogen treatment results in reduction of the testicular volume [13]. Additionally, oestrogens have a suppressive effect on sperm motility and density in a (cumulative)

dose-dependent manner [13]. Hamada *et al.* (2014) clearly demonstrated a poor semen quality in transgender women following feminizing therapy. Their results show a high incidence of oligozoosperma, asthenozoospermia, and teratozoospermia [7, 14]. If semen samples of such poor quality are used, assisted reproduction techniques, such as *in vitro* fertilization (IVF) or intracytoplasmic sperm injection (ICSI) are needed [15].

Payer *et al.* (1979) described the histological effects on Leydig cells of treatment with oestrogens alone or with medroxyprogesterone acetate [13]. Three morphologies were distinguished: Leydig cells very similar to untreated Leydig cells (type 1); the absence of Leydig cells in presence of cells with increased microfilaments and abundant smooth endoplasmic reticulum and lipid drops (type 2); and complete absence of any cell type but with varying amounts of microfilaments and pigmentation (type 3) [13]. The persisting spermatogonia showed the typical features of the so-called pale type-A spermatogonia [16]. Because of the low mitotic rate of these cells, the pale type-A spermatogonia survive disturbances of the endocrine balance, as well as other noxious stimuli such as radio- and chemotherapy [16]. Therefore, these cells are regarded as the stem cells of the human testis [16].

These histological findings explain why feminizing hormonal therapy induces hypospermatogenesis, ultimately leading to azoospermia [10]. This impact is—to a certain extent—heterogenous possibly due to different types of cross-sex hormone therapy [17] and reversible upon cessation of oestrogen therapy based on the presence of the spermatogonial stem cells [16]. Thresholds for hormone treatment in transgender women to avoid permanent reproductive impairment have not been established [1].

Androgen Therapy in Transgender Men

Masculinizing hormonal therapy will in most cases lead to a reversible amenorrhea but ovarian follicles are not depleted from the tissue [18, 19]. Increased androgen levels may however adversely affect follicle growth, mostly affecting the more matured follicle stages as these follicles are surrounded by an androgen-sensitive theca cell layer [19–21]. Apparently, primordial follicles in cryopreserved and xenotransplanted ovarian cortical tissue do not lose their potential to resume growth and maturation [22].

An ongoing debate is still ongoing whether or not masculinizing therapy induces polycystic ovarian syndrome (PCOS) [20, 21, 23]. Descriptive histology by Pache *et al.* (1991) showed some evidence for altered morphology induced by testosterone treatment comprising of enlarged ovaries, collagenized ovarian cortex, theca interna hyperplasia, and stromal hyperplasia [20, 24]. The idea that androgens induce high AMH levels, which is a particular feature of PCOS, is however questionable [25]. Moreover, a (3D) transvaginal ultrasound study in trans men treated with long-term testosterone therapy showed no increased polycystic ovarian morphology [26].

One must realize that hormonal interventions do not exclude possible pregnancy in transgender men [27, 28]. This implies that exogenous testosterone is not an adequate mean of birth control. Testosterone has teratogenic effects on the fetus, therefore transgender men must avoid pregnancy while on testosterone therapy. In the absence of surgery, contraception should be discussed. Data on the choice of the correct contraceptive are currently lacking. Progesterone-only pills, a (progesterone-releasing) intrauterine device or barrier methods of birth control in order to avoid the use of oestrogen treatment are suggested [29].

The Current Fertility Preservation Options for Transgender Men

Current fertility preservation options include cryopreservation of embryos, oocytes, or ovarian tissue. The theoretical options are presented in Table 11.5.1, including a short description of every technique, considerations in favour of and against the technique and the potential use in case of a (future) male or a female partner. These options are based on the known fertility preservation options for patients undergoing gonadotoxic treatment [30] transposed to the specific needs of transgender patients. It is preferable to bank gametes before using hormones. For transgender men and transgender women already using hormones, an interruption of hormone treatment is recommended at least 3 months to restore possible therapy-induced effects.

Embryo Cryopreservation

The embryo cryopreservation technique consists of a hormonal stimulation and oocyte aspiration for IVF/ICSI techniques to create embryos that are subsequently cryopreserved for future embryo transfer [15, 31]. This is an appropriate option for post-pubertal transgender men with a male partner and offers the possibility of a genetically related child. However, if desired, a sperm donor can also be used to create embryos [31]. This fertility preservation method requires a controlled ovarian stimulation and thus female hormone exposure [31]. Additionally, frequent vaginal ultrasound monitoring is needed during the ovarian stimulation phase and a transvaginal surgical procedure is performed for oocyte aspiration [10, 31]. This can be a physical and psychological burden for many transgender men, hereby limiting their future reproductive options [4]. Although technically possible, genital exams in transgender men may need to be postponed until a well trusted doctor-patient relationship is established [32].

Nowadays embryo freezing is a routine procedure in the field of assisted reproduction. In case of an embryo transfer, a recipient uterus (surrogacy mother) is required, especially when the uterus has been removed in the transgender man [10, 15]. In case of a female partner, partner donation—where an oocyte of the transgender man is inseminated with donor sperm and subsequently transferred to the female partner—is a possibility.

Oocyte Cryopreservation

Oocyte cryopreservation includes hormonal stimulation and oocyte retrieval for oocyte vitrification [31]. Therefore, the same considerations as for controlled ovarian stimulation for embryo cryopreservation have to be taken into account. Cryopreservation of oocytes does not require fertilization before cryopreservation. Therefore, there is no need for a partner or for the use of donor sperm at the moment of the fertility preservation procedure. Again it is an established technique and future use of the cryopreserved oocytes requires the use of partner sperm or donor sperm and a recipient uterus which can be the female partner or a surrogate if a male partner is present [10].

Table 11.5.1 Fertility preservation options in transgender men

Technique	Description	Considerations	Future use
Embryo cryopreservation	Controlled ovarian stimulation for oocyte retrieval and fertilization to obtain embryo's for cryopreservation	• Established method • Controlled ovarian stimulation • Vaginal procedure • Postpubertal • Partner or donor sperm	*Male partner* Use of partner's sperm prior to cryopreservation, need of a surrogate mother *Female partner* Fertilization by donor sperm prior to cryopreservation, implantation into the partner's uterus
Oocyte cryopreservation	Controlled ovarian stimulation to obtain oocytes for cryopreservation	• Established method • Controlled ovarian stimulation • Vaginal ultrasounds • Postpubertal • No partner required	*Male partner* Use of partner's sperm, need of a recipient uterus (7) *Female partner* Fertilization by donor sperm, implantation into the partner's uterus
Ovarian tissue cryopreservation	Surgical excision of ovarian tissue for cryopreservation	• Experimental • Prepubertal or postpubertal • No controlled ovarian stimulation • Possible at moment of transitioning surgery • No partner required	*Male partner* *In vitro* maturation and use of partner's sperm, need of a recipient uterus (7) *Female partner* *In vitro* maturation, fertilization by donor sperm, implantation into the partner's uterus

Ovarian Tissue Cryopreservation

Ovarian tissue cryopreservation is the resection and cryopreservation of the ovary [31]. The technique requires a surgical procedure but does not include an ovarian stimulation. Since hormonal therapy does not deplete the ovary, resection of the tissue can be performed at the time of gender-affirming surgery [18]. At the moment, it is a promising but experimental procedure [31].

Future use of the frozen tissue can be either transplantation of thawed tissue or *in vitro* maturation of primordial follicles. Transplantation of ovarian cortical strips can however include unwanted side effects by restoring female hormone activity. It makes natural conception theoretically possible in case the uterus was not removed or if this transplanted ovarian tissue is stimulated in order to obtain mature oocytes for IVF/ICSI techniques. *In vitro* maturation of primordial follicles (the abundant follicle stage in ovarian cortex) would prevent the recovery of female hormone activity after transplantation, but *in vitro* maturation starting from these immature follicles is not yet possible [4, 15, 33]. Like oocyte cryopreservation, once a mature oocyte is obtained, the use of partner sperm or donor sperm and a recipient uterus upon thawing of the oocytes for future use (female partner or surrogate mother) enables fertility treatment.

The Current Fertility Preservation Options for Transgender Women

The fertility preservation options for transgender women include cryopreservation of sperm collected through ejaculation or direct testicular extraction and cryopreservation of immature testicular tissue. An overview is provided in Table 11.5.2.

Sperm Cryopreservation

The cryopreservation of ejaculated sperm (through masturbation or vibratory stimulation) is the simplest and most reliable method of male fertility preservation [31]. Transgender women may find it difficult to masturbate in order to produce a semen sample for preservation. Even the fact that they have semen samples stored would remind them of their male past and would therefore not make them feel as a complete woman [5, 6]. Depending on the sperm quality, the cryopreserved spermatozoa can be used for future intrauterine insemination or to perform IVF/ICSI in case of a female partner [10]. The need for IVF/ICSI however creates the necessity to start controlled ovarian stimulation in the female partner, followed by oocyte aspiration. The obtained embryo can subsequently be transferred in the partner's uterus. In case of a male partner, a donor oocyte and a surrogate mother are both necessary.

Surgical Sperm Extraction

In case of surgical sperm extraction, a percutaneous aspiration of sperm from the testis of epididymis is performed [31]. Again, this is an established method in daily IVF practice. Although a solution for the transgender women for whom masturbation is a burden, one must not forget that this is a surgical procedure [31]. The obtained spermatozoa can be used for future IVF or ICSI procedures in case of a female partner. In case of a male partner, an oocyte donor and surrogate mother again are both necessary in order to fulfil their child wish [15].

Testicular Tissue Cryopreservation

For cryopreservation of immature testicular sperm, a surgical biopsy of testicular tissue from prepubertal or postpubertal transgender women is performed [31]. This option overcomes the need of masturbation and is possible in prepubertal boys [31]. It is a surgical procedure that can be combined with the sex reassignment surgery. In contrast with the other two options, this is an experimental method. For future use, an *in vitro* maturation procedure or retransplantation is necessary, followed by assisted reproduction techniques. Retransplantation can however restore the male endocrine environment, which clearly is an undesired effect for transgender women.

Table 11.5.2 Fertility preservation options in transgender women

Technique	Description	Considerations	Future use
Sperm cryopreservation	Cryopreservation of ejaculated sperm through masturbation or vibratory stimulation	• Established technique • Masturbation • Postpubertal	*Male partner* Need of a donor oocyte and surrogate mother *Female partner* Intrauterine insemination or IVF/ICSI depending on sperm quality followed by embryo transfer in partner
Surgical sperm extraction	Percutaneous aspiration of sperm from testis or epididymis	• Established technique • No masturbation • Surgical procedure • Postpubertal	*Male partner* Need of a donor oocyte and surrogate mother *Female partner* IVF/ICSI treatment followed by embryo transfer in partner
Immature testicular tissue cryopreservation	Surgical biopsy to of testicular tissue	• Experimental • Prepubertal or postpubertal • Possible at moment of sex reassignment surgery	*Male partner* *In vitro* maturation and need of a donor oocyte and surrogate mother *Female partner* *In vitro* maturation and IVF/ICSI followed by embryo transfer in partner

Future Fertility Preservation Options for Transgender Patients

Current research focuses on optimizing the *in vitro* maturation of immature oocytes and spermatogonial stem cells. An optimized culture model would allow to use the currently banked ovarian or testicular tissue without the need of transplantation. This would solve the unwanted side effect of endocrine restoration by the transplanted tissue.

For trans men, the *in vitro* maturation of obtained cumulus-enclosed oocytes collected during ovarian tissue processing is very promising. These oocytes originate most probably from antral follicles punctured through manipulation of the tissue during the cryopreservation procedure. In combination with freezing of the ovarian cortex, cryopreservation of *in vitro* matured oocytes might further broaden the reproductive perspectives for trans men.

Apart from a testicular biopsy in trans women, to obtain spermatogonial stem cells, research to obtain artificial gametes through stem cells is ongoing [15, 34]. This possibility would be a true revolution for those patients who have not stored their own gametes and currently need oocyte or sperm donation to fulfil their future child wish [3].

Transgender Gestation

In cases where transgender men retain their ovaries and uterus, they may regain fertility after discontinuing androgen therapy. It is a fact that transgender men are becoming pregnant and are having babies, regardless of prior testosterone use [28]. This also emphasizes the need for specialized obstetric care, addressing the specific needs of pregnant transgender men. This care includes a gender-neutral environment and specific attention for increasing gender dysphoria during and after pregnancy. Clinical concerns should also be addressed, such as interruption of testosterone therapy when trying to conceive and postpartum considerations including options for chest (breast) feeding or how and when to reinitiate testosterone [35].

In transgender women, being pregnant and giving birth is still impossible. The Swedish research unit of Brännström and his colleagues conducted a series of uterus transplants and reported a first live birth in 2014 [36]. This opens the possibility for assisted gestation for transgender women [37]. However, there are important medical concerns regarding uterus transplantations if introduced to transgender people [3, 7]. A difficult surgical procedure would be needed in order to change the anatomy of the male pelvis with the intention to perform a successful uterus transplantation. Moreover, immunosuppressive therapy would be necessary and is possibly contraindicated during a pregnancy [3], but that *in se* would not be any different from a uterus transplantation in a cisgender female patient.

Trans Parenting and Children

The above-mentioned options clearly show the opportunities (and limits) for transgender patients with a present or future child wish. All these possibilities, however, are strictly regulated by national legislations. Apart from legislation, some healthcare professionals still need to be convinced about the necessity and the ethical acceptability to preserve fertility in this patient group [10]. The underlying question is whether trans parenting has a negative influence on the gender identity and the sexual orientation of the child [38, 39]. Few studies have addressed this question and conclusive evidence is scarce. Although the results from these studies are reassuring, long-term follow-up studies are undoubtedly needed. None of the studies published so far showed that children suffer to such an extent that would warrant a prohibition of trans parenting [40]. A transgender identity as a reason to interrupt contact between the transgender parent and his or her children, as is the case in some countries, is documented to be harmful for the children [38, 41]. It is shown that a child having a transgender parent may experience more transient and mild harassment than those who do not [38, 41].

Children who were younger at the time of their parent's transitioning, showed to adapt better and maintained healthier relationships with both the transitioning and the non-transitioning parent

in the study of White and Ettner (2007). A less conflicted relationship between child and parents is also predicted by a positive relationship between the two parents [39, 42]. In case of transitioning of the transgender parent before the birth of a child, it is important to disclose the transgender identity of the parent early in childhood, rather than later in the life of the child. The possibility that certain specific circumstances concerning the birth of the child are disclosed by someone else than the parents should be avoided at all-time as this can be traumatic for the child [43].

Conclusion

Fertility and fertility preservation are important topics to discuss before planning any treatment to facilitate a transgender person to live according to the gender they identify themselves with. A patient should be clearly informed upon diagnosis, before starting hormonal treatment or gender-affirming surgery. The first information on fertility preservation should be given by healthcare professionals within the transgender care unit. Next, the patient should be referred to a specialized fertility centre to discuss in more detail his or her options.

The current available options for fertility preservation are very promising. One must however realize that the banking of gametes cannot guarantee future treatment. Upon an apparent child wish post-transitioning, a couple should undergo the screening procedure according to the protocol of the centres for assisted reproduction. Furthermore, not all theoretical reproductive options are possible and not all forms of medically assisted reproduction are available in certain countries. Additionally, medically assisted reproduction, although considered to be safe, is not without health risks and they are often expensive.

The use of the cryopreserved gametes will therefore depend on their quality, success rate of the technique and choice of partner, apart from the centre's policy and national legislation. Fertility in transgender patients also raises the need for appropriate and adapted care before conception, during pregnancy, and after giving birth.

Transgender individuals should be counselled on reproductive issues by professionals prior to initiating treatment in order to have a clear overview of the effects of treatment, the preservation possibilities, and what to expect from it. Transgender people should be referred to specialized centres for assisted reproduction to discuss possibilities. Even if a patient does not always have a clear view on his or her future child wish, it is very important that the patients have access to clear and detailed information so that a well-informed choice can be made.

SECTION 12

Endocrine Responses to Systemic Diseases or Substance Misuse

12.1

Endocrinology of Systemic Disease

12.1.1 The Endocrine Response to Stress

David Henley, Thomas Upton, and Stafford L. Lightman

Introduction—What is Stress?

In the face of a real or perceived threat, organisms mount coordinated and specific hormonal, autonomic, immune, and behavioural responses that allow escape or adaptation [1–3]. Responses that are either inadequate or excessive in terms of specificity, intensity or duration may result in a range of psychological or physical pathologies [2–5]. This concept of 'threat' and the subsequent 'response' is what we typically understand as 'stress'; however, as this construct is so broad and difficult to define [2] 'stress' can be very difficult to investigate or study objectively [6].

The concept of homeostasis emerged in the early twentieth century [4] as the ideal steady state for all physiological processes. Stress may be considered the state where this ideal is threatened. More easily appreciated however are those factors, both intrinsic and extrinsic, that challenge homeostasis (termed stressors) and the complex physiologic, hormonal, and behavioural actions that restore balance, the stress response [1]. The importance of endocrine systems in the stress response was emphasized by the pioneering work of Hans Selye and others [7] who described the need for multiple, integrated systems responding in a coordinated fashion following stressor exposure. It was noted that exposure to noxious stimuli caused non-specific activation of the hypothalamic–pituitary–adrenal (HPA) and sympathoadrenomedullary (SAM) axes. Continued exposure resulted in lasting and damaging effects on various endocrine, immune, and other systems although recovery was possible provided the stress was terminated [8]. Other potential stressors exist including exertion, physical extremes, trauma, injury, and psychological stress. Psychological stressors are some of the most potent stimuli of the endocrine stress response particularly when they involve elements of novelty, uncertainty, and unpredictability. The anticipation of a potentially stressful event may be as potent an activator of the stress response as the event itself [8].

Anatomy and Physiology of the Endocrine Response to Stress

The HPA and SAM axes are the principal endocrine effector arms of the stress response (Figure 12.1.1.1). However, several other hormone axes and neurotransmitter systems are either directly stress-responsive themselves, or act to modulate these systems.

The HPA Axis

Corticotropin-releasing hormone (CRH) promotes synthesis and release of anterior pituitary adrenocorticotropin (ACTH) [9]. Hypophysiotropic CRH neurons project from the paraventricular hypothalamic nucleus (PVN) to the median eminence. CRH is also widely distributed throughout the central nervous system (CNS) where it has important effects on behaviour and cognitive processing. Within the brainstem, interactions with sympathetic and parasympathetic centres influence autonomic functioning while within limbic and para-limbic regions, such as the amygdala, CRH influences the expression of mood and anxiety-type behaviours [10]. Arginine vasopressin (AVP), synthesized in parvocellular cells of the PVN, acts synergistically with CRH to stimulate the release of ACTH [10].

ACTH acts directly on the adrenal cortex to promote release of glucocorticoids into the circulation [1, 3, 10]. Glucocorticoids, in general, have two fundamental roles in the stress response. First, during stress free periods, basal levels prepare the organism for future stress exposure. The circadian rise occurs prior to the onset of daily activity and thus in humans starts around 3:00 a.m. This

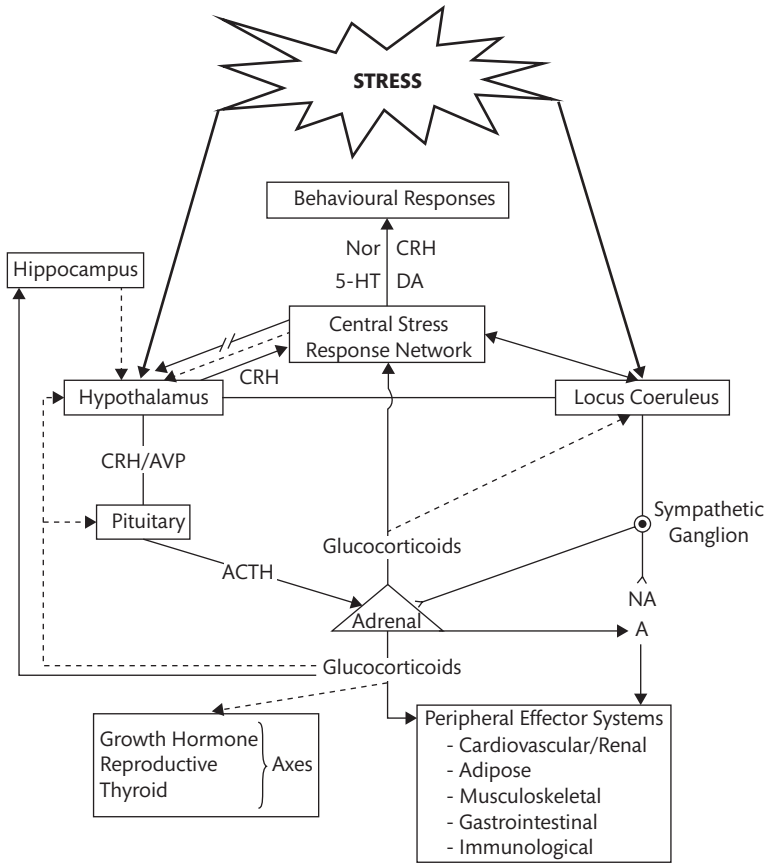

Figure 12.1.1.1 Chronic stress response. Simplified overview of the chronic stress response and its two main effector arms, the hypothalamic–pituitary–adrenal axis and the sympathoneural/sympathoadrenomedullary system. Note the glucocorticoid feedforward and feedback regulatory loops, reciprocal interaction of CRH, and the locus coeruleus, together with the putative central stress response network in effecting peripheral and central adaptive responses. Components of the central brain stress response network include: parvocellular neurons in the paraventricular nuclei, central nucleus of the amygdala, bed nuclei of the stria terminalis, Barrington's nucleus, ventral tegmental area, dorsal raphe, locus coeruleus and the A1/A2 medullary noradrenergic cell groups. CRH, corticotropin-releasing hormone; AVP, arginine vasopressin; ACTH, adrenocorticotrophin; NA, noradrenaline; A, adrenaline; 5-HT, 5-hydroxytryptamine (serotonin); DA, dopamine. Solid lines indicate stimulation; dashed lines indicate inhibition; broken line indicates indirect projections.

anticipatory activity results in energy storage and conservation by promoting glucose and fat uptake, opposing energy utilization, and thus prepares the organism for the activities of the next waking day. Glucocorticoids also prime the immune system for future activation and promote memory formation of previous stressors so that repeat exposure to the same or similar stressor results in a rapid and efficient response [11].

The second role of the HPA response is to modulate events at the time of stress exposure itself. Initially glucocorticoids enhance the cardiovascular effects of catecholamines and AVP, promote energy provision and utilization, influence and enhance appropriate stress-related behaviours, and stimulate certain aspects of the immune response [11]. However, and very importantly, once the stress response has been initiated some of the principal actions of glucocorticoids are to suppress and restrain the activity of these systems, in particular the SAM and immune responses. In doing so, glucocorticoids help regulate a stress response that is appropriate in terms of intensity and duration, ensuring responses are 'switched off' when the stress has been successfully dealt with [2, 11].

Glucocorticoid secretion is controlled by a complex feedback system that involves direct inhibitory action on the hypothalamus and anterior pituitary, reducing releasing hormone (CRH and ACTH) production and consequently limiting glucocorticoid release into the circulation. A further level of feedback occurs at the hippocampus, a site that is also important in memory formation. A subset of hippocampal neurons project to the hypothalamus where they release the neurotransmitter γ-aminobenzoic acid (GABA), inhibiting CRH release, thus contributing to negative feedback effect on cortisol secretion [1].

In the brain, the glucocorticoid receptor (GR) and the mineralocorticoid receptor (MR) are both involved in the feedback system. GRs are found throughout the brain but are most abundant in hypothalamic CRH neurons and pituitary corticotrophs, while MR expression is highest in the hippocampus. GR is occupied during periods of intermediate to high glucocorticoid secretion (e.g. during the circadian peak and following stress) while the high affinity MR is extensively bound even during periods of basal secretion [12]. Therefore, MR is thought to regulate tonic neurocognitive HPA activity while GR (in coordination with MR) mediates the response to stress.

Three time domains of corticosteroid feedback have been described [13]. Fast, rate sensitive feedback occurs within seconds

to minutes, during the period of increasing plasma corticosteroid concentrations, and probably controls the rate and magnitude of ACTH and corticosteroid response to stimuli. This is likely mediated by membrane associated MRs via rapid, non-genomic mechanisms [14]. Disruption of fast feedback has been demonstrated in ageing humans and in depressed patients, and thus may have a role in the maintenance of homeostasis [14]. Intermediate feedback (2–10 hr) limits the response of the system to repeated stimulation within a relatively short period of time, while slow feedback (over hours to days) may have the same role during prolonged stress [13].

Circadian and Ultradian Rhythms of HPA Activity

ACTH and cortisol fluctuate in their secretory activity. The classic circadian (24-h) rhythm describes the pattern of HPA activity with plasma hormone concentrations falling to nadir around midnight, before rising in the early hours of the morning, reaching a peak soon after waking. Concentrations gradually fall again throughout the day toward the nadir. However, the circadian rhythm is subserved by an underlying ultradian (less than 24-h) rhythm of secretory pulses which can only be detected by frequent blood sampling.

Mathematical modelling shows the episodic secretion of ACTH and cortisol is an inherent feature of the pituitary–adrenal axis [15]. Modulation of the amplitude of both ACTH and cortisol secretory pulses gives rise to their respective nyctohemeral rhythms [16]. Under physiological conditions ACTH secretion is characterized by episodic pulses of activity separated by intervals of low basal (non-pulsatile) secretion.

Cortisol is synthesized and secreted from zona fasciculata cells of the adrenal cortex in response to ACTH stimulation. There is a high temporal concordance between ACTH and cortisol secretion peaks, with the latter lagging those of ACTH by 10 min [16–18] (Figure 12.1.1.2). Secretory bursts of both hormones are episodic in that they are independent events produced randomly over time [16, 19]. Sexual diergism in ACTH pulsatility has been demonstrated with males showing greater pulse frequency (18 vs. 10 per 24-h), mean peak amplitude and area under the 24-h profile [20]. Cortisol secretory bursts occur more frequently in the early hours of the morning (shortly before waking) and least frequently during late afternoon [19].

The pulsatile, ultradian rhythms of the HPA axis arise as a consequence of dynamic feedback and feedforward loops and the interactions of glucocorticoids at the molecular level [21]. Corticosteroid pulsatility is important in that it provides an optimally sensitive HPA axis equilibrium with scope for digital, in addition to analogue, signal for tissue GRs [22]. Hippocampal GR and MR receptors translocate rapidly from the cytoplasm to the nucleus and bind DNA in response to a corticosteroid pulse [23]. Within a 1-hour interpulse interval, GR dissociates rapidly from DNA and disappears from the nucleus, in contrast MR remains bound to DNA. Therefore, changes in pulse frequency will have differential effects on MR and GR binding to DNA. Given the variety of cellular transcription factors and molecular chaperones there is scope for multiple cell specific responses to different digital signals [21].

The Sympathoneural and Sympathoadrenomedullary Axis

The hallmark sympathetic 'fight or flight' response is characterized by global activation of the SAM system. Typical features include accelerated heart rate, increased blood pressure, and rapid breathing. Fear, vigilance, sensory arousal, and motor activation often occur with trembling, goose bumps, and piloerection.

The sympathetic nervous system originates from nuclei in the lower brainstem that use noradrenaline as their principal neurotransmitter (Figure 12.1.1.1). Noradrenergic nuclei, centred on the locus coeruleus (LC), project downward to the intermediolateral columns of the spinal cord. Cell bodies send preganglionic fibres to the paraspinal ganglia chain from where postganglionic fibres give rise to sympathetic nerves that supply the heart, blood vessels, lungs, gut, kidneys, and other organs. These nerves principally release noradrenaline from terminals close to their site of action. Other preganglionic fibres innervate the adrenal medulla, regulating release of adrenaline into the general circulation.

Catecholamines, the effector hormones of the system, act through specific cell surface receptors whose wide distribution account for their rapid effect on multiple physiological processes [1, 3]. Catecholamine surges promote glucose release, immune activation, and increased blood flow to essential organs while inhibiting non-essential activities like digestion. Together this produces a 'state of emergency' which can rapidly attend to sudden changes in physiological balance [3]. The SAM response has the ability to trigger purely in anticipation of a stressful event and interact with other stress-responsive systems [3]. Interaction may occur either through neural connections or as a consequence of increased blood flow that allows rapid transport of other messengers (such as hormones and cytokines) to their respective sites of action [3].

Acute Stress

The stress response system has evolved as both an early warning system capable of recognizing potential or existing threats, and as a response system that can initiate and drive the necessary processes required to escape or confront the threat. The response is dynamic, beginning rapidly with brain and behavioural activation, followed quickly by physiological activation. Positive-feedback and feedforward loops enhance and reinforce these processes as well as recruiting other effector arms of the stress response. Slower acting hormone systems moderate the response by effectively providing a brake and ensuring the stress response is appropriate in both intensity and duration [11, 24].

Changes in the environment that represent either real or potential threats are recognized by parts of the brain responsible for receiving, integrating, interpreting, and then relaying information on to areas responsible for coordinating the necessary response. Brain activation occurs within milliseconds and proceeds over seconds to minutes as the response continues to unfold. Stereotypical orienting behaviour gradually gives way to more goal-directed behaviour that is specific to the stressor being faced and the environment in which it is occurring [24].

Activation of the autonomic nervous system occurs within seconds and is enhanced by withdrawal of parasympathetic activity. Within minutes of the onset of this cascade of events, the appearance of ACTH signals recruitment of the HPA axis into the process [1, 10]. Cortisol levels begin to rise within 2–5 min [25], and levels peak about 15–20 minutes after the onset of the stress [26] (Figure 12.1.1.3). Early actions of the HPA system provide additional energy resources, while slower gene-related effects over minutes to hours restrain ongoing actions of the stress response which, if left unchecked, may prove to be unsustainable [27].

Chronic Stress and the Brain

There is a marked change in the hypothalamic response to chronic stress with a greater role for AVP [28]. In addition to colocalization of AVP and CRH in neurosecretory axon terminals [29] there are increases in hypothalamic AVP synthesis, proportion of CRH neurons coexpressing AVP, and in the ratio of AVP to CRH immunoreactivity in neurosecretory vesicles. AVP stimulated ACTH secretion is less sensitive to glucocorticoid feedback than is CRH [30]. Pituitary changes with chronic stress paradigms include a reduction in CRH receptor numbers and sustained elevations in V1b (AVP) receptor mRNA [29]. It appears in some chronic stress paradigms that CRH has a permissive role whereas AVP is the dynamic mediator of ACTH secretion.

It is important for survival that the HPA axis responds adequately during chronic stress. Rodent stress models reveal three basic patterns of response, depending on the type of stress [31]: (1) desensitization of ACTH responses to sustained stimulus, but hyper-responsiveness to a novel stress despite elevated plasma glucocorticoid levels; (2) corticotroph hyper-responsiveness to a novel stimulus, with no desensitization to the primary repeated stress; (3) small and transient increases in basal ACTH, followed by marked hyporesponsiveness to novel stimuli. The level of response is determined by the differential regulation of CRH and AVP. The increase in AVP during chronic stress (where glucocorticoid negative feedback downregulates CRH and ACTH responses) appears to be an important mediator of ACTH release upon new demand.

In the presence of increased plasma glucocorticoid levels during chronic stress, decreased sensitivity of glucocorticoid feedback is critical for the maintenance of ACTH responses. It appears that the increase in number of pituitary V1b receptors is the main determining factor for the responsiveness of the corticotroph during adaptation to chronic stress [31].

Involvement of the limbic system in HPA axis regulation is complex (Figure 12.1.1.1). The role of limbic structures is both region- and stimulus-specific; they all express both GR and MR and they all exert their effects via subcortical intermediaries [32]. Typically, the hippocampus and anterior cingulate/prelimbic cortex inhibit stress-induced HPA axis activation, whereas the amygdala and possibly the infralimbic cortex may enhance glucocorticoid secretion [32]. Furthermore, the HPA axis is also subject to glucocorticoid-independent inhibition from neuronal sources. For example, the PVN is richly innervated by GABAergic neurons from the bed nucleus of the stria terminalis, medial preoptic area, dorsomedial hypothalamus, and lateral hypothalamic area. However, the degree to which these GABAergic inhibitory circuits respond to neural vs. glucocorticoid inhibition has not been fully elucidated [32].

The concept of a **central stress response network** [25] recruited by glucocorticoids in chronic stress defines a critical role for extrahypothalamic CRH neuronal cell groups, in particular the amygdala. Elevated glucocorticoid concentrations acting in a feed-forward manner at the amygdala increase CRH expression and secretion, which is tightly coupled to hypersensitivity of the HPA axis to stressors. CRH acts on receptors in structures throughout the brain, especially monoaminergic cell groups that widely innervate the forebrain, resulting in behavioural changes (e.g. more cautious, more ready to be diverted from tasks at hand, adopt alternative strategies, enjoy rewards and remember fearful situations) that make the organism chronically exposed to stress more capable of adapting to the stressful conditions (Figure 12.1.1.1).

Reciprocal neural connections exist between CRH and the LC/noradrenergic neurons of the central stress system, with each one stimulating the other [4] (Figure 12.1.1.1). Chronic stress increases CRH content in the LC. Thus, CRH may induce mechanisms that result in HPA axis facilitation via increased catecholaminergic input to CRH cells, increasing the capacity for CRH response to acute stress during periods of chronic stress when the corticosteroid feedback signal is high [30].

Clinical Manifestations of Chronic Stress

Throughout the history of medicine, reference has been made to the influence of stress, particularly in the form of negative emotions and psychological distress, on physical health [6]. Relevant examples include psychiatric conditions (depression and post-traumatic stress disorder) [1], coronary heart disease (CHD), immune-mediated conditions including asthma, chronic diseases such as osteoporosis, diabetes, and dementia, as well as premature death [1, 6]. Why some individuals manifest stress as psychiatric illness when others are either more prone to physical disease or even resistant to the effects of stress exposure is not well understood.

There is a protective role for the stress response in the short term [2]. The associated learning and adaptation (a process that requires plasticity of brain responses) that follows stress exposure is critical to the longer-term health and survival of the individual. However, when these responses occur in excess of the body's requirements or continue for longer than necessary, damaging effects occur [2].

Psychosocial Stress

There is an association between socioeconomic status (SES) and health at every level of the SES hierarchy [33]. The Whitehall study of CHD mortality [34] found employment grade was a stronger predictor of subsequent risk of CHD death than any other major coronary risk factor. Depression and depressive symptoms are both inversely related to SES status and depression is linked to health outcomes, particularly CHD [33]. There are two mechanisms by which higher placement in the SES hierarchy can reduce stress and its somatic consequences: (1) by diminishing the likelihood that individuals will experience negative events; (2) through greater social and psychological resources to cope with stressful life events, therefore being less susceptible to the subjective experience of stress [33].

Mood Disorders

Melancholic depression has been described as the prototypic example of chronic activation of the stress system (both HPA axis and SAM) [4]. Cortisol secretion is increased, plasma ACTH response to exogenous CRH decreased and autopsy studies show marked increase in the number of PVN CRH and AVP neurons [1]. Depression is also associated with increased pituitary vasopressinergic responsivity and the LC of depressed patients contains elevated CRH concentrations [35]. Repeated stress that causes frequent surges in blood pressure and catecholamine release is associated with accelerated atherosclerosis and an increased risk of myocardial infarction. Patients with melancholic depression develop varying degrees of atherosclerosis and cardiovascular disease [1] and depressed people with chronic HPA hyperactivity may have reduced life expectancy predominantly as a result of increased cardiovascular mortality [1, 6, 36]. Patients with melancholic depression may develop metabolic syndrome, osteoporosis and Th_1 immunosuppression [1] consistent with chronic hyperactivation of the stress system. Hypercortisolism is also associated with other mood and affective disorders including anorexia nervosa, chronic anxiety, obsessive-compulsive disorder, chronic alcoholism, and other situations such as childhood sexual abuse [1]. Hyperactivity of the LC and other central noradrenergic centres have been shown to influence anxiety and behavioural arousal, with dysregulation of this system postulated as contributing to the pathogenesis of mood disorders, particularly depression, and with noradrenaline levels being an important predictor of outcome in major depression [1].

Animal experiments of chronic stress provide evidence that glucocorticoid overexposure affects the hippocampus with respect to neuronal viability and function—decreased neurogenesis, degenerative loss in pyramidal neurons, reduced dendritic branching and atrophy [35, 37]. This led to the so-called glucocorticoid cascade hypothesis [35] where stress-induced HPA activation and elevated glucocorticoid levels were purported to act in a feedforward manner causing hippocampal damage, resulting in disinhibition of glucocorticoid negative feedback, further rise in glucocorticoid levels and accumulating damage to the hippocampus. This has been supported in principle by the fact that patients with Cushing's disease exhibit both hippocampal atrophy and depression, both of which are reversed with treatment. In addition, depressed patients experience cognitive dysfunction consistent with hippocampal damage and antidepressant treatment may enhance neurogenesis [38, 39]. However, although reduced hippocampal volumes have been seen on MRI scans of depressed patients, significant histologic damage has not been found on post-mortem studies [35]. Thus, despite compelling animal data linking stress-induced hypercortisolism with modulation of neurogenesis in the pathogenesis of depression, evidence for translation to human depression is inconclusive, and is an active area of ongoing research. HPA dysregulation appears well before clinical symptomatology and is a predictor of treatment resistance in depression. Failure to normalize HPA axis responses with treatment is a strong predictor of relapse [40].

Obesity and the Metabolic Syndrome

Chronic stress has been linked to obesity and the metabolic syndrome (characterized by the combination of central obesity, insulin resistance, dyslipidaemia, and hypertension [41]). Glucocorticoids regulate adipocyte differentiation and stress-induced excess cortisol is associated with increased abdominal fat accumulation [41]. In humans, chronic stress-induced increases in cortisol, catecholamines, and the inflammatory cytokine IL-6 in combination with associated suppression of the growth hormone-, gonadal- and thyroid-axes, produces a hormonal milieu conducive to the development of visceral obesity, hypertension, atherosclerosis, osteoporosis and immune dysfunction [41]. Corticosteroids stimulate behaviours that are mediated by dopaminergic mesolimbic 'reward' pathways and the central stress response network [25]. Glucocorticoids stimulate caloric intake and consumption of 'comfort foods' which may result in metabolic feedback signals that dampen brain stress responses [25]. In the current era of chronic social stress, together with the availability of high calorie palatable foods (acquired with ever decreasing physical effort), this adaptive mechanism proposed to enable many species to survive may be occurring at a significant (maladaptive) metabolic cost to contemporary humans.

Sleep Disorders

In animal models with varying degrees of sleep deprivation there is a consistent pattern of cognitive impairment, namely in learning and retention [42]. This is associated with increased brain levels of pro-inflammatory cytokines (IL-1β mRNA), hippocampal oxidative stress, and structural changes. Clinical studies have confirmed elevated evening cortisol and day time growth hormone levels with increased sympathetic nervous activity in both total and partial sleep deprivation [43]. Resultant increased insulin resistance and reduced glucose tolerance increases diabetes risk. This is further compounded by dysregulation of the neuroendocrine control of appetite, promoting obesity.

Obstructive sleep apnoea (OSA) represents a chronically stressed state. OSA is characterized by intermittent upper airway obstruction and subsequent hypoxia during sleep. A cyclical sequence of events consisting of upper airway obstruction, progressive hypoxaemia, autonomic, and electroencephalogram (EEG) arousal occurs. This will prompt the individual to open and clear the airway to reverse the asphyxia, followed by successive relaxation of the airway and subsequent constriction, resulting in fragmented sleep [44]. Morbidity and mortality from OSA are primarily due to cardiovascular disease. OSA is also associated with insulin resistance and the metabolic syndrome.

HPA axis dysfunction in OSA that is altered with continuous positive airways pressure (CPAP) therapy [18]. Obese male subjects with moderately severe or severe OSA had ACTH and cortisol levels measured every 10 minutes over 24 hours both pre- and 3 months post-CPAP under basal conditions [18]. Hormone secretory characteristics estimated from multiparameter deconvolution analysis found no change in the number of predicted secretory episodes, secretion pulse height, or frequency. However, there was an increased mean pulse mass pretreatment due to a longer duration of the individual secretory episodes, and a significant reduction in pulsatile and total ACTH and cortisol production post-CPAP [45]. This is consistent with impaired fast feedback affecting pulse duration [14] and may be due to metabolic/hypoxic insults on the hippocampus, alterations in hippocampal MR expression due to SAM hyperactivity or result from an AVP effect on ACTH pulse duration. Following the single breath 35% CO_2 stress test [26], there was a markedly exaggerated cortisol response to CO_2 pre-CPAP which was reduced to normal levels after treatment supporting HPA axis

hyper-responsiveness in untreated OSA [45]. It is therefore likely that the activation of the stress system in OSA contributes to the metabolic complications of this condition.

Other Effects

CRH hypersecretion and HPA axis activation influences the activity of many organ systems. CRH hyperactivity is associated with gastro-intestinal symptoms such as pain, increased gut motility, and diarrhoea—typical features of the irritable bowel syndrome, a condition commonly associated with stress [1]. Similarly, glucocorticoids inhibit the growth axis and it has been postulated that the severe growth retardation associated with psychosocial abuse or deprivation during childhood is, in part, related to chronic HPA axis activation [1].

By contrast, chronic hypoactivation of the HPA axis may also result in disease states. Post-traumatic stress disorder, chronic fatigue syndrome and atypical depression [1, 36] are associated with CRH hypoactivity and reduced cortisol production. Similarly, immune dysregulation is an important consequence of altered HPA axis activity. Differential levels of hypothalamic CRH in the high CRH-producing Fischer and lower CRH-producing Lewis rats are associated with enhanced immune response and resistance to infections and tumours in the Lewis rats, but also an increased susceptibility to some autoimmune conditions [6]. In human studies, rheumatoid arthritis appears to be associated with HPA axis hypoactivation [46] with blunted cortisol diurnal rhythms and reduced ACTH and cortisol levels.

HPA Response in Critical Illness and Major Surgery

Critical illness and major surgical procedures are examples of extreme stressors that result in marked elevation of circulating glucocorticoid concentrations. In spite of this, high concentrations of ACTH in these patients appears only to be transient [47]. High frequency plasma sampling reveals ongoing coordinated and pulsatile ACTH/cortisol interactions remain [48], albeit with lower ACTH pulse amplitude [49]. The altered dynamics of the HPA axis in these situations are likely explained by combinations of increased sensitivity of the adrenal to ACTH [50], altered corticosteroid-binding globulin function [51], and reduced cortisol metabolism [52].

Adjuvant glucocorticoid supplementation to improve mortality in patients with septic shock has been controversial for decades. Two large clinical trials [53, 54] attempting to answer this question provide conflicting evidence with regard to mortality but some suggestion of short-term benefit in terms of improved shock resolution and shorter duration of mechanical ventilation. Clearly there remains much that is unknown about the dynamics of the stress response in critical illness.

Summary

Stress may be considered as a real or perceived threat to homeostasis. The two primary arms of the stress response are the HPA axis and the SAM systems. These two systems are interlinked and regulated by complex feedback and feedforward processes. The acute stress response is protective and promotes survival in the short term. However, prolonged activation of the stress response is implicated in the pathogenesis of illness, in particular mood and affective disorders, but also obesity, metabolic syndrome, and obstructive sleep apnoea.

12.1.2 Endocrinology in the Critically Ill

Greet Van den Berghe and Lies Langouche

Introduction

Critical illness is any condition requiring support of failing vital organs without which death would ensue. It is characterized by striking alterations in the hypothalamic-anterior-pituitary axes that follow a bi-phasic neuroendocrine response to critical illness. Acutely, an actively secreting pituitary together with the development of target-organ resistance results in low concentrations of peripheral effector hormones. These endocrine alterations may reduce energy and substrate expenditure, likely beneficial for short-term survival [1]. About 30% of critically ill patients do not recover within a few days, and enter a chronic phase of critical illness during which they remain dependent on vital-organ support. The high mortality observed during this prolonged phase is usually attributed to non-resolving failure of multiple organ systems and vulnerability to infectious complications, rather than to the type or severity of the initial disease for which patients were originally admitted to the intensive care unit (ICU). During the prolonged phase of illness, low serum levels of peripheral effector hormones are caused by uniform suppression of the neuroendocrine axes, primarily of hypothalamic origin. The prolonged phase of critical illness is further characterized by persistent hypercatabolism, despite feeding, which leads to a substantial loss of lean body mass in the presence of relative preservation of adipose tissue. This 'wasting syndrome' is likely to compromise vital functions and delay recovery, and as such contribute to the increased morbidity and mortality.

The different patterns of the neuroendocrine responses between the acute and prolonged phase of critical illness indicate the importance of a thorough understanding of the pathophysiology underlying these neuroendocrine changes. Indeed, erroneous extrapolation of the changes observed in the acute-disease state to the prolonged phase of critical illness has misled investigators to apply certain endocrine treatments that unexpectedly increased rather than decreased mortality [2, 3].

The Somatotropic Axis

Growth hormone (GH) is essential for growth during childhood, and for several mainly anabolic functions throughout life. The release of GH is stimulated by the hypothalamic GH-releasing hormone (GHRH), and is inhibited by somatostatin. Ghrelin, produced both in peripheral tissues and in the hypothalamic arcuate nucleus, is the third key factor in the complex physiological control of pulsatile GH release. The pulsatile nature of GH release, with peak serum levels alternating virtually undetectable troughs, is important for its metabolic effects. Apart from its direct actions, GH also exerts indirect effects that are mediated mainly through stimulation of insulin-like growth factor 1 (IGF-1) production, of which the bioactivity in turn is regulated by several IGF-binding proteins (IGFBPs).

The Somatotropic Axis in Acute Critical Illness

The first hours to days after an acute insult, such as surgery, trauma, or infection, are hallmarked by a dramatically changed GH profile. The GH pulse frequency is increased, and peak levels and interpulse concentrations are high. Concomitantly, a state of peripheral GH resistance develops, believed to be triggered by cytokines. Serum concentrations of IGF-1, GH-dependent IGFBP-3, and the acid-labile subunit (ALS) of the ternary complex are low during the acute phase of critical illness, in spite of the clearly enhanced GH secretion. An enhanced clearance of IGF-1, in part related to elevated circulating levels of small IGFBPs such as IGFBP-1, IGFBP-2, and IGFBP-6, also contributes to its low serum levels. These events are preceded by a decrease in serum growth hormone-binding protein (GHBP), reflecting reduced level of GH receptor expression in peripheral tissues [1, 4].

It remains unclear which factor ultimately controls the stimulation of GH release in response to acute stress. Nevertheless, it can be inferred that reduced negative feedback inhibition, caused by reduced expression of the GH receptor and subsequent low levels of circulating IGF-1, is the primary event inducing the abundant release of GH in the acute phase of illness. The high GH levels may then exert direct lipolytic, insulin-antagonizing, and immune-stimulating actions, resulting in increased fatty acid and glucose levels in the circulation, whereas the indirect, IGF-1-mediated effects of GH are attenuated. This would prioritize essential substrates such as glucose, free fatty acids, and amino acids toward survival rather than costly anabolism, which is mainly mediated by IGF-1 and considered less vital at this time. Therefore, from a teleological point of view, the response within the GH axis to acute illness seems highly appropriate in the struggle for survival.

The Somatotropic Axis in Prolonged Critical Illness

When recovery is not achieved within a few days and patients enter a prolonged phase of critical illness, the non-pulsatile GH fraction remains somewhat elevated, but although the number of pulses is still high, the pulsatile release of GH is strongly suppressed [1]. Nocturnal GH serum concentrations are scarcely elevated compared with the healthy, non-stressed condition, and substantially lower than in the acute phase of stress. Furthermore, although GH resistance may be partially reversed in the chronic phase, as indicated by increased serum levels of GHBP, the levels of IGF-1, IGFBP-3, and ALS are even lower in prolonged critically ill patients [1]. Furthermore, the pulsatile fraction of GH secretion correlates strongly with circulating levels of IGF-1, IGFBP-3, and ALS in this phase, meaning that the smaller the GH pulses, the lower the circulating levels of GH-dependent IGF-1 and ternary-complex-binding proteins. This clearly no longer represents a state of GH resistance, but rather suggests that loss of pulsatile GH release contributes to

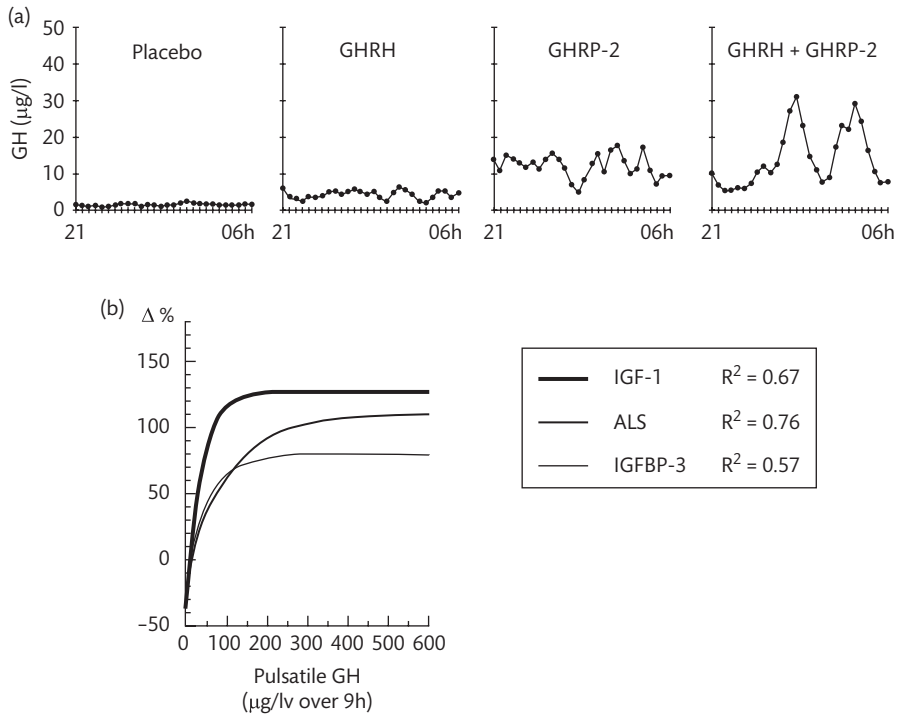

Figure 12.1.2.1 Effects of a growth hormone secretagogue on the somatotropic axis in prolonged critical illness. (A) Nocturnal serum GH profiles with continuous infusion of placebo, GHRH, GHRP-2 or GHRH + GHRP-2. (B) Exponential regression lines between pulsatile GH secretion and the changes in circulating IGF-1, ALS, and IGFBP-3.

the low levels of IGF-1 and binding proteins. Since the robust release of GH in response to GH secretagogues (GHSs) (Figure 12.1.2.1) excludes a possible inability of the somatotropes to synthesize GH, the origin of the relative hyposomatotropism is likely located within the hypothalamus. Furthermore, the release of GH in response to GHRH injection appears to be less pronounced than to GHRP-2 injection in prolonged critical illness, suggesting that hypothalamic deficiency or inactivity of endogenous GHRP-like GHSs is a more plausible cause of the hyposomatotropism than is GHRH deficiency [1]. However, both elevated and decreased concentrations of plasma ghrelin have been reported in critically ill patients [5, 6]. Of note, both studies only quantified total ghrelin, whereas the active—acetylated was clearly decreased [7].

The chronic relative GH deficiency is believed to contribute to the pathogenesis of the 'wasting syndrome' that characterizes prolonged critical illness. This is suggested by the observation that low serum levels of IGF-1 and ternary-complex-binding proteins are closely correlated to biochemical markers of impaired anabolism, such as low serum osteocalcin and leptin concentrations during prolonged critical illness [1].

Therapeutic Interventions: Treatment with GH During Critical Illness

Based on the assumption of sustained GH resistance in the presence of normal pituitary function during the catabolic condition of prolonged critical illness, pharmacological doses of GH were administered in an attempt to restore anabolism in ICU patients. However, a large multicentre study found that, instead of improving outcome, this intervention increased both morbidity and mortality [3]. Since it is clear now that the GH resistance of acute illness is at least partially resolved in the prolonged phase, it is likely that administration of such high doses may have evoked toxic side effects, exceeding any possible beneficial effect of this therapy. Indeed, high doses of GH can induce supranormal IGF-1 levels, excessive fluid retention, hypercalcaemia, and pronounced insulin resistance with hyperglycaemia.

Another treatment option might be the combined administration of GH and IGF-1, which are additive in their anabolic actions and neutralize each other's side effects [8]. Also, treatment with hypothalamic-releasing factors may be more effective and safer. Indeed, infusions of GHSs not only restored the pulsatile GH secretion, but also evoked an increase of IGF-1, IGFBP-3, and ALS, which is indicative of a restored peripheral responsiveness [1]. Evidence supporting a beneficial role of GHS comes from animal studies reporting that ghrelin supplementation reduces catabolic loss in critical illness. [9].

The Thyroid Axis

Thyroid hormones (TH) play a key role in the regulation of energy and substrate metabolism, and are essential for the stimulation of normal growth and development. The hypothalamic thyrotropin-releasing hormone (TRH) stimulates the pituitary to produce thyroid-stimulating hormone (TSH). TSH in turn drives the thyroid gland to synthesize and secrete TH. Deiodinases (D) are

responsible for the peripheral activation of thyroxine (T_4) to either the biological active tri-iodothyronine (T_3) (D1 and D2) or to the inactive reverse T_3 (rT_3) (D3). TRH and TSH secretion are controlled by negative feedback from the TH.

The Thyroid Axis in Acute Critical Illness

Early after the onset of severe physical stress, there is a rapid decrease in serum levels of T_3 and an increase of rT_3 levels, predominantly because of altered peripheral conversion of T_4 due to reduced D1 activity and increased D3 activity (Figure 12.1.2.2). TSH and T_4 levels are elevated briefly and subsequently return to normal, though in the more severely ill patients T_4 levels may also decrease (Figure 12.1.2.2). Although mean serum levels of TSH are normal, the normal nocturnal TSH surge is absent. Low T_3 levels persist beyond TSH normalization, a constellation referred to as 'the low T_3 syndrome'. The magnitude of the T_3 reduction within 24 hours reflects the severity of illness and correlates with mortality. Cytokines might play a role in the pathogenesis of the low T_3 syndrome. Other factors include low concentrations of TH binding proteins and inhibition of TH binding by compounds such as fatty acids and bilirubin, and low selenium levels which reduce deiodinase activity [10].

The thyroidal alterations observed during acute critical illness are strikingly similar to those seen with fasting. As critically ill patients suffer from poor nutritional intake, part of the observed thyroidal alterations could be evoked by this illness-induced fasting.

A large randomized controlled trial (RCT) reported that late initiation of parenteral nutrition, thereby generating a large caloric deficit, was associated with faster recovery and fewer complications, as compared with early full feeding [11]. Circulating levels of TSH, total T_4, T_3 and the T_3 to rT_3 ratio were all further reduced by late parenteral nutrition support [12]. Statistically, the further reduction in circulating T_4 with late feeding reduced part of the outcome benefit of nutrient restriction, whereas the further reduction of T3/rT3 ratio statistically explained part of the outcome benefit. The authors concluded that peripheral inactivation of T_3 with nutrient restriction during critical illness could be a beneficial adaptation, whereas the central lowering of T_4 could be deleterious. The benefit

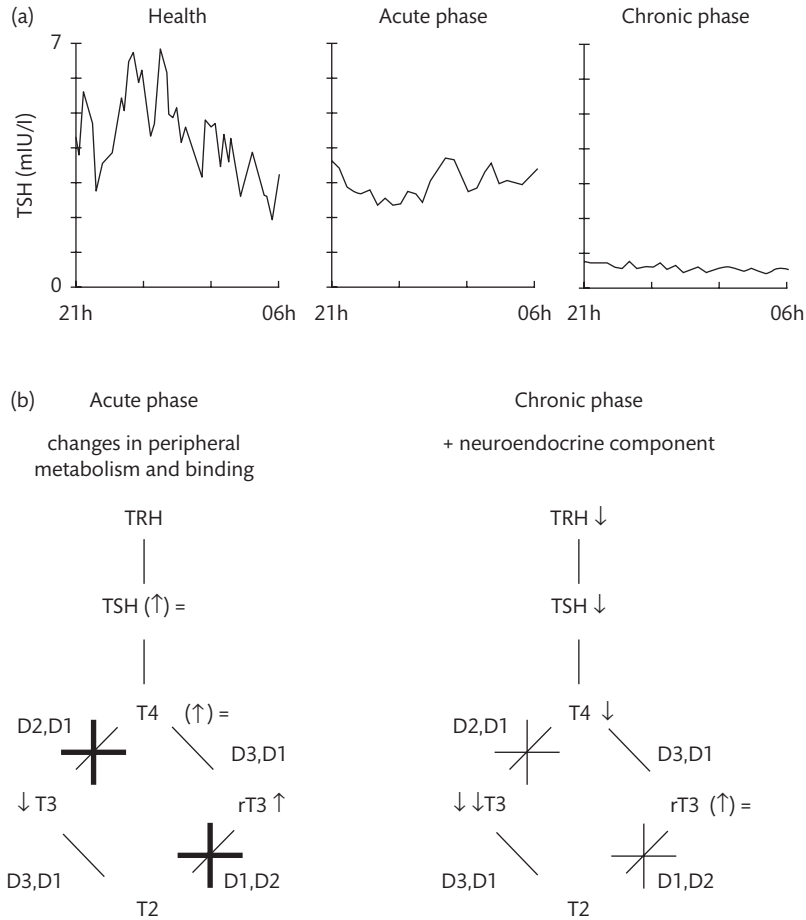

Figure 12.1.2.2 The thyroid axis in critical illness. (a) Nocturnal serum concentration profiles of thyrotropin (TSH) in critical illness are abnormal and differ between the acute and prolonged phase. (b) Overview of the major changes within the thyroid axis during the acute and prolonged phase of critical illness (black: normal regulation, grey: alterations induced by critical illness).

of the fasting-induced reduction in T_3 could, besides less energy expenditure, also optimize bacterial killing capacity via a direct impact of high D_3 activity locally within granulocytes [13, 14].

The Thyroid Axis in Prolonged Critical Illness

Patients who remain in the ICU and enter a prolonged phase of critical illness, now receiving full enteral and/or parenteral nutrition, show a different set of changes within the thyroid axis. In addition to the absent nocturnal TSH surge, the pulsatility in the TSH secretion pattern is dramatically reduced (Figure 12.1.2.2), with even lower serum levels of both T_3 and T_4. In human and an animal model of critical illness, reduced TRH expression in the hypothalamus occur, indicating a predominantly central origin of the suppressed thyroid axis [15, 16] that can be reactivated by TRH administration [17] (Figure 12.1.2.3). Furthermore, reduced GH secretagogue action may also be involved, as the pulsatility of the TSH secretion pattern is only improved when TRH is infused together with GHRP. Interestingly, simultaneous infusion of TRH and GHRP-2 not only increased TSH, T_4, and T_3 levels, but also prevented the rise in rT_3 seen with TRH alone (Figure 12.1.2.3). These results suggest that peripheral deiodinase activity is under joint control of the somatotropic and thyroid axes [1, 18].

The regulation of TH action at the level of the thyroid hormone receptor (TR) is also changed during prolonged critical illness. Alternative splicing gives rise to two TR isoforms, with TR-1 being a bona fide T_3 receptor, and TR-2 acting as a dominant negative isoform. An inverse correlation was observed between the T_3/rT_3 ratio and the TR-1/TR-2 ratio in liver biopsies of prolonged critically ill patients. Furthermore, sicker and older patients presented with higher TR-1/TR-2 ratios compared to less sick and younger ones [19]. Furthermore, in peripheral tissues such as muscle, lung, and liver-residing macrophages, D2 expression is upregulated [20–22]. These findings indicate that during prolonged critical illness, peripheral tissues seems to adapt to the low T_3 levels by increasing cellular sensitivity and local tissue levels.

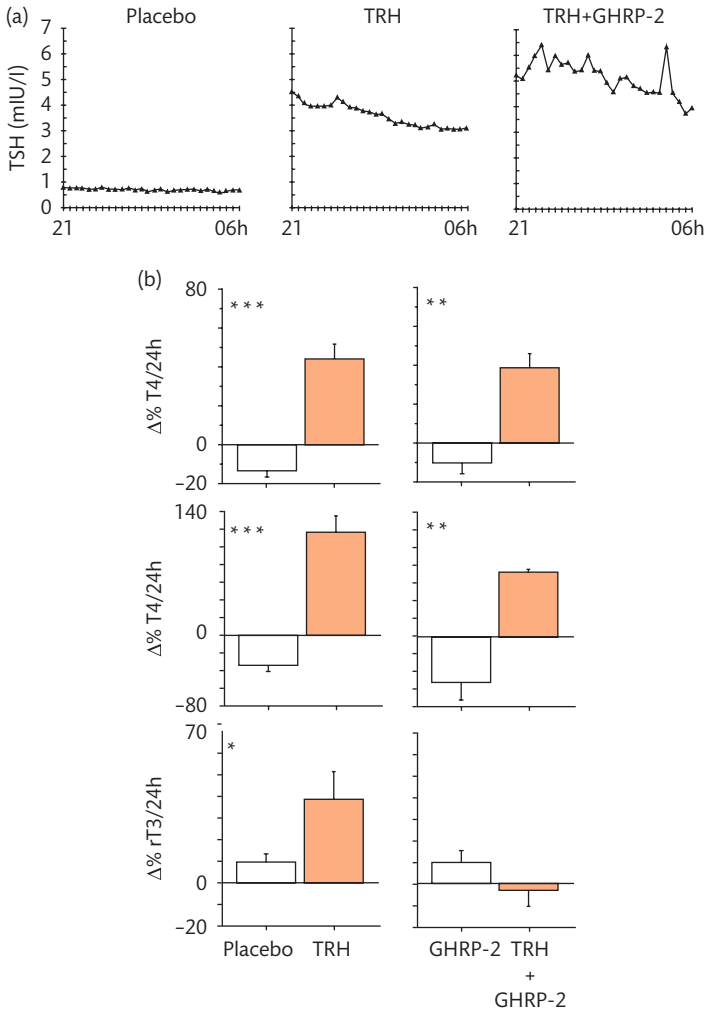

Figure 12.1.2.3 Effects of TRH and GHRP-2 on the thyroid axis in prolonged critical illness. (a) Nocturnal serum TSH profiles with continuous infusion of placebo, TRH, or TRH + GHRP-2. (b) Continuous administration of TRH, alone or together with GHRP-2, induces a significant rise in serum T_4 and T_3 within 24h. Reverse T_3 is increased after infusion of TRH alone, but not after co-infusion with GHRP-2.

Neuroendocrinology of Prolonged Critical Illness: Effects of Exogenous Thyrotropin-Releasing Hormone and Its Combination with Growth Hormone Secretagogues. *The Journal of Clinical Endocrinology & Metabolism* (1998) 83 (2): 309–319, doi:10.1210/jcem.83.2.4575

Therapeutic Interventions: Treatment with Thyroid Hormone or Releasing Factors During Prolonged Critical Illness

The acute changes within the thyroid axis, uniformly present in all types of acute illnesses, and concomitant fasting, is considered a beneficial and adaptive response that does not warrant intervention. Nevertheless, it remains controversial whether and when correction of the low serum and tissue concentrations of T_3 in critically ill patients is beneficial. Pioneering studies using T_4 administration have so far failed to demonstrate clinical benefit within the ICU [23], although this is likely due to the impaired conversion of T_4 to T_3 caused by reduced D1 activity. Short-term intravenous T_3 administration to patients during elective coronary bypass grafting has been shown to improve postoperative cardiac function [24], but the used doses resulted in supranormal serum levels. Administration of replacement T_3 doses during paediatric cardiac surgery improved postoperative cardiac function [25]. However, a benefit of T_3 treatment in iatrogenic, dopamine-induced hypothyroidism does not provide evidence of clinical benefit for low T_3 levels that are characteristic of prolonged critical illness.

Rather than administration of TH, a safer method for treatment of illness-associated hypothyroidism may be the infusion of hypothalamic-releasing factors, since this preserves the normal feedback systems. Indeed, by continuous infusion of TRH in combination with a GH secretagogue, not only TH levels were restored to normal physiological levels, but also markers of hypercatabolism were reduced [1].

The Gonadal and Lactotropic Axis

Hypothalamic gonadotropin-releasing hormone (GnRH) is secreted in pulses and stimulates the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the pituitary. In women, LH mediates ovarian androgen production, whereas FSH drives the aromatization of androgens to oestrogens in the ovary. In men, LH stimulates the testicular production of androgens, whereas the combined action of FSH and testosterone supports spermatogenesis. In turn, sex steroids exert negative feedback control on GnRH and gonadotropin secretion. Several other hormones and cytokines are involved in the complex regulation of the gonadal axis [26]. Prolactin is produced and secreted by the pituitary in a pulsatile and diurnal pattern. The main function of prolactin is to stimulate lactation, but it is also presumed to have immune-enhancing properties. Physiological regulation of prolactin secretion is largely under the control of dopamine, although it can be modulated by several other prolactin inhibiting and releasing factors [27].

The Gonadal and Lactotropic Axis in Acute Critical Illness

As most female patients in the ICU are in the menopausal stage, clinical data on the changes within the female gonadal axis are scarce. Acute physical stress in men causes an immediate fall in serum testosterone, even though LH levels are elevated. This observation suggests an immediate suppression of anabolic androgen production in Leydig cells, as an attempt to reduce energy consumption and conserve substrates for more vital functions. The exact cause remains unclear, but again, inflammatory cytokines might play a role [1]. Acute physical stress causes prolactin levels to rise, which may contribute to altered immune function during critical illness. This increase is possibly mediated by vasoactive intestinal peptide, oxytocin, and dopaminergic pathways, but also cytokines or as-yet uncharacterized factors may be involved [1].

The Gonadal and Lactotropic Axis in Prolonged Critical Illness

When critical illness prolongs, more dramatic changes develop within the male gonadal axis. Circulating levels of testosterone become extremely low, while mean LH concentrations and pulsatile LH release are suppressed. Exogenous GnRH is only partially and transiently effective in correcting these abnormalities, suggesting also peripheral alterations within the male gonadal axis. Indeed, an increased aromatization of adrenal androgens to oestrogens in critically ill patients has been observed [28].

In the prolonged phase of critical illness, the pulsatile fraction of prolactin release becomes suppressed and mean serum prolactin levels are reduced compared to the acute phase. Exogenous dopamine further suppresses prolactin secretion and concomitantly aggravates T-lymphocyte dysfunction and impaired neutrophil chemotaxis [1, 2]. This suggests that the blunted prolactin secretion contributes to the immune suppression or increased susceptibility to infections associated with prolonged critical illness.

Therapeutic Interventions: Sex Steroid Substitution Therapy During Critical Illness?

It remains unclear whether the profound hypoandrogenism seen in male critically ill patients reflects adaptation or pathology. Pioneering studies evaluating the use of androgens in prolonged critical illness failed to demonstrate any conclusive clinical benefit [29, 30]. Exogenous pulsatile GnRH administration in prolonged critically ill men partially overcomes the hypogonadotropic hypogonadism. Moreover, when GnRH pulses were given together with GHRP2 and TRH infusion, target-organ responses, and anabolic effects followed. Despite its immune-enhancing properties, prolactin is currently not available for therapy. Further studies are required to evaluate the therapeutic potential of TRH-induced prolactin release for optimizing immune function during prolonged critical illness.

The Adrenal Axis

Diurnal cortisol release from the adrenal cortex is induced by adrenocorticotropic hormone (ACTH or corticotropin) which is produced by the pituitary under the control of the hypothalamic corticotropin releasing hormone (CRH). In turn, cortisol exerts negative feedback control on both CRH and ACTH. Although only free cortisol is biologically active, more than 90% of circulating cortisol is bound to binding proteins such as corticosteroid-binding globulin (CBG) and, to a lesser extent, albumin.

The Adrenal Axis in Acute Critical Illness

In the early phase of critical illness, the diurnal variation in cortisol secretion is lost and cortisol levels rise in response to the

severity of illness, although plasma ACTH concentrations are already low when admitted into the ICU [31]. In addition to the hypercortisolism, CBG levels are substantially decreased, resulting in proportionally much higher increases in free cortisol. The stress-induced hypercortisolism suppresses anabolism and promotes catabolism, to ensure acute provision of energy to vital organs such as the brain. In addition, it offers hemodynamic advantages in the fight-and-flight reflex by induction of fluid retention and sensitization of the vasopressor response to catecholamine, and it protects against excessive inflammation by suppression of the inflammatory response.

An appropriate activation of the hypothalamic–pituitary–adrenal axis and cortisol response to critical illness appears to be essential for survival, since both very high and very low cortisol levels have been associated with increased mortality.

The Adrenal Axis in Prolonged Critical Illness

In the prolonged phase of critical illness, hypercortisolism is usually sustained, but serum ACTH levels remain low (Figure 12.1.2.4). The dissociation of ACTH and cortisol release suggests a change in adrenal sensitivity to ACTH or the emergence of ACTH-independent pathways such as cytokines, neuropeptides, or vasoactive factors [32]. However, it was recently demonstrated that daytime cortisol production was only mildly elevated, whereas nocturnal production was even suppressed [31, 33]. Moreover, cortisol breakdown was substantially reduced attributable to suppressed expression and activity of A-ring reductases in the liver 11β-hydroxysteroid dehydrogenase type 2 in kidney [31].

Whether the persisting elevation in cortisol is exclusively beneficial remains uncertain. In theory, it could increase the susceptibility to infectious complications, impair wound healing and myopathy, complications that are frequently observed during prolonged critical illness. Teleological, sustaining elevated cortisol levels could be an energy-sparing mechanism during sustained stress. However, this may reduce ACTH levels through negative feedback which in turn might induce adrenal atrophy, which predisposes to adverse outcome. In severely ill critically ill patients, plasma cortisol levels are no longer high beyond 4 weeks in the ICU, at a time when ACTH levels are also low [34]. Post-mortem examination of adrenal glands harvested from

Dotted lines represent regulation that is still speculated and needing additional research. Question marks represent an unknown part of the pathway.

prolonged critically ill patients reveal distorted architecture, lipid droplet depletion, and suppressed ACTH-regulated gene expression suggesting that sustained lack of ACTH may contribute to the risk of adrenal insufficiency in long-stay ICU patients [35].

Therapeutic Interventions: Treatment with Thyroid Hormone or Releasing Factors During Prolonged Critical Illness

In patients with previously diagnosed primary or central adrenal insufficiency, or previously treated with systemic glucocorticoids, glucocorticoid treatment should be started or continued during critical illness. A condition labelled 'relative' adrenal failure also has been suggested by experts, indicating a 'relative exhaustion' or 'insufficiently activated' adrenal cortex, insufficient to cope with the level of stress of septic shock. However, the results of clinical trials of high doses of glucocorticoids in critically ill patients are conflicting with some reporting beneficial [36, 37], ineffective [38, 39], or harmful outcomes [2]. Glucocorticoid treatment downregulates expression of the glucocorticoid receptor, and thus glucocorticoid sensitivity, in the liver but not in muscle [40]. Therefore, steroid-induced side effects such as insulin resistance and catabolism, may develop in muscle, whereas suppression of the hepatic glucocorticoid receptor may be harmful as observed in an animal model [41]. Another controversial issue regarding 'relative' adrenal failure in acute sepsis is the dose and duration of treatment once it has been initiated. Indeed, high dose long-term glucocorticoid administration will conceivably worsen the loss of lean tissue, increase the risk of polyneuropathy and myopathy, extend the ICU dependence, and increase the susceptibility to potentially lethal complications.

The term 'relative' adrenal insufficiency therefor became quite controversial. In the recently published guidelines on the diagnosis and management of critical illness-related corticosteroid insufficiency, the task force was unable to reach agreement on how to reliably diagnose such insufficiency [42]. The ACTH stimulation test is unreliable because of a 40% increased cortisol distribution volume in critical illness [31, 34].

Implications for Clinical Practice

The anterior pituitary responds biphasic to severe stress of illness and trauma (Figure 12.1.2.5). In the acute phase it is actively secreting, but target organs become resistant and concentrations of most peripheral effector hormones are low. In contrast, prolonged critical illness is characterized by a uniform suppression, predominantly of hypothalamic origin, of the neuroendocrine axes. These alterations contribute to low serum levels of the respective target-organ hormones. Although the differentiation between beneficial and harmful neuroendocrine responses to critical illness is difficult, it is important before considering any therapeutic intervention. The hypercatabolic reaction during acute critical illness is probably beneficial and, as such, provides no evidence that supports intervention. In prolonged critical illness, however, sustained hypercatabolism may compromise vital functions, cause weakness, and delay or hamper recovery. Theoretically, during this phase, a strategy of therapeutic intervention to correct these abnormalities could improve survival. In view of the adverse outcome of single hormone treatment strategies, high doses of either GH or glucocorticoids appeared to aggravate insulin resistance and hyperglycaemia that usually develop during critical illness. Importantly, although it had long been widely accepted that stress-induced hyperglycaemia might be beneficial to organs that largely rely on glucose for energy supply but do not require insulin for glucose uptake, strict blood glucose control with intensive insulin therapy has shown otherwise when maintained for at least a few days and avoiding excess hypoglycaemia [43, 44].

Although co-infusion of GHRP, TRH, and GnRH at least partially restores the three pituitary axes and reinitiates anabolism, the effect on survival remains unknown. However, the interaction among the different endocrine axes underlines the importance of jointly correcting all hypothalamic–pituitary defects rather than applying a single hormone treatment. However, evidence from appropriately designed and powered clinical trials is still lacking, making these and other interventions in the critically ill still experimental.

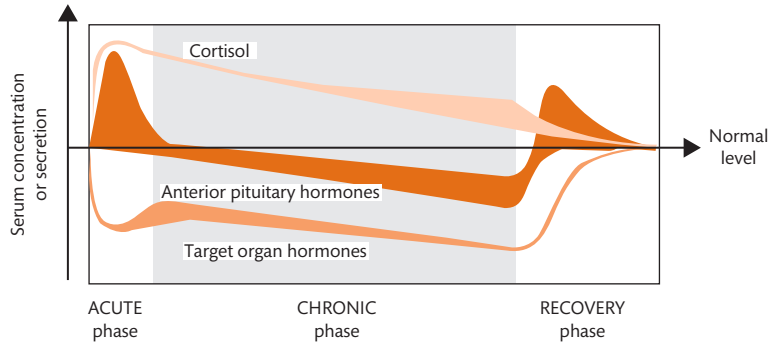

Figure 12.1.2.5 Simplified concept of the pituitary-dependent changes during the course of critical illness. In the acute phase, the secretory activity of the anterior pituitary is maintained or amplified, whereas anabolic target-organ hormones are inactivated. Cortisol levels are elevated. In the prolonged phase, impaired hormone secretion from the anterior pituitary allows the respective target-organ hormones to decrease proportionally over time, with cortisol being a notable exception. The onset of recovery is characterized by restored sensitivity of the anterior pituitary to reduced feedback control.

12.1.3 Hormones and the Kidney

Melissa Nataatmadja, Yeoungjee Cho, and David W. Johnson

Introduction

Chronic kidney disease (CKD) is a major, growing, global public health problem that affects approximately 10–15% of the world's population [1]. Since the kidneys play a critical role in the synthesis, elimination, and actions of a variety of hormones (Table 12.1.3.1), endocrine abnormalities are common in CKD. This chapter will review the common endocrine systems affected in kidney disease.

Renin–Angiotensin–Aldosterone System

The renin–angiotensin system (RAS) plays a vital role in the maintenance of blood pressure homeostasis. Within the kidney, the juxtaglomerular apparatus synthesizes renin, which converts angiotensinogen to angiotensin I [2]. Angiotensin I is in turn converted by angiotensin converting enzyme (ACE) to angiotensin II, which binds to angiotensin II type 1 (AT1R) and type 2 receptors (AT2R) to promote vasoconstriction, renal sodium retention, and secretion of aldosterone, vasopressin, and endothelin [2]. Inappropriate intrarenal RAS activation, usually without elevated plasma renin activity or plasma angiotensin II levels, has been observed in a variety of animal models of kidney disease [2]. Consequently, it has been hypothesized that the beneficial effects of RAS-modifying medications, such as ACE inhibitors and angiotensin receptor blockers (ARB), on CKD progression and proteinuria may occur largely at a local intrarenal level [2].

CKD patients, especially those with advanced renal disease, may experience worsening of their renal function and/or hyperkalaemia following commencement of an ACE inhibitor or ARB, especially if they are poorly hydrated, unwell, known to have bilateral renal artery stenosis, or taking certain medications (e.g. diuretics or non-steroidal anti-inflammatory drugs [NSAIDs]). Current guidelines permit a reduction in estimated glomerular filtration rate (eGFR) of up to 25% within the first month or an increase in serum potassium of up to 6 mmol/L before consideration should be given to reducing or ceasing RAS blockers [3].

Aldosterone, a mineralocorticoid produced by the adrenal glands, activates the apical epithelial sodium channel (ENaC) in the distal nephron to facilitate sodium reabsorption by the principal cells and reduced potassium reabsorption and increased H^+ excretion by the α-intercalated cells [4]. It has also been shown to contribute to kidney damage in CKD, including tubulointerstitial fibrosis and inflammation, glomerulosclerosis, podocyte injury and mesangial cell proliferation [4]. These effects occur independently of angiotensin II and are accentuated in the presence of salt loading [4]. 'Aldosterone breakthrough', with elevated levels of aldosterone, can be observed in patients receiving ACE inhibitor or ARB therapy, and the addition of mineralocorticoid receptor blockers can successfully reduce proteinuria and blood pressure, although these effects are counterbalanced by increased risks of hyperkalaemia and gynaecomastia [5]. Consequently, the role of mineralocorticoid receptor blockers in preventing CKD progression currently remains uncertain [5].

Table 12.1.3.1 Commonly affected hormones in kidney disease

Hormones synthesized by the kidney	Hormones catabolized by the kidney	Hormones that act on the kidney

Erythropoietin and Anaemia of Renal Disease

Anaemia is present in approximately 50% of patients with CKD and the vast majority of patients with end-stage kidney disease (ESKD). It is usually normocytic and normochromic and is associated with left ventricular hypertrophy, cardiovascular events, excess hospitalizations, reduced quality of life, and mortality. The main cause is deficiency of erythropoietin (EPO), a 34 kDa glycoprotein hormone that is produced by type 1 cortical fibroblasts within the kidney [6]. This hemopoietic growth factor regulates the proliferation and differentiation of erythroid progenitor cells through binding with EPO receptors on endothelial cell surfaces and induces stimulation of Jak2 tyrosine kinase and subsequent activation of multiple cellular pathways leading to inhibition of apoptosis [6]. Prior to its availability in the late 1980s, up to 25% of dialysis patients were transfusion-dependent [7].

In addition to EPO deficiency, a number of other factors may contribute to anaemia in patients with CKD, including absolute or functional iron deficiency, gastrointestinal bleeding, uraemia, hyperparathyroidism, inflammation, nutrient deficiencies (vitamin B_{12}, folate, vitamin C, and carnitine), ACE inhibitors, ARBs, aluminium overload, and erythropoiesis-stimulating agent (ESA)-induced antibody-mediated pure red cell aplasia [7]. Elevated serum hepcidin levels, perhaps due to increased expression by inflammatory cytokines and reduced renal clearance, may also contribute to anaemia of CKD by binding to ferroportin (FPN1), a cellular iron exporter expressed in reticuloendothelial system macrophages and duodenal enterocytes, resulting in internalization, loss of function, reticuloendothelial cell iron blockade, impaired dietary iron absorption, and ultimately functional iron deficiency [7].

The use of ESAs has become commonplace in the treatment of anaemia associated with CKD and can be administered either subcutaneously or intravenously (if the patient is if receiving haemodialysis). Human recombinant EPO (alpha, beta, omega, and delta) may be synthesized in human or animal cells and differ based on their carbohydrate moieties, though all have a similar half-life of 6 to 8 hours intravenously and 19–24 hours subcutaneously [8]. More recently, long acting ESAs have been developed, including darbepoetin alpha (half-life 25 hours if intravenous and 48 hours if subcutaneous) and continuous erythropoiesis receptor activator (CERA—half-life approximately 130 hours), which allow less frequent dosing [8]. While cost and ease of administration may influence the choice of ESA used, there is low certainty evidence that the use of different ESAs may make little or no difference to anaemia correction or adverse events [9].

The haemoglobin target to aim for with ESA treatment of anaemia of CKD has been the subject of considerable debate. The accumulated trial evidence to date suggests that targeting normal or high haemoglobin levels reduces the need for blood transfusion, does not have any other clear benefits on patient-level outcomes, and increases the risks of stroke, hypertension and vascular access thrombosis [10]. It remains uncertain whether the increased risk of adverse outcomes at normal or near-normal haemoglobin levels following ESA therapy is related to haemoglobin level, ESA dose-related toxicity, or other factors (e.g. greater iron requirements, inflammatory state, or concurrent illness). Consequently, the current Kidney Disease Improving Global Outcomes (KDIGO) Guideline recommendations state, 'in initiating and maintaining ESA therapy, we recommend balancing the potential benefits of reducing blood transfusions and anaemia-related symptoms against the risks of harm in individual patients (e.g. stroke, vascular access loss, hypertension) [11]. Specifically, the guidelines recommend initiating ESA therapy when the haemoglobin concentration is less than 100 g/L where correctable causes of anaemia have been addressed, that the haemoglobin target concentration with ESA use should not be greater than 130 g/L and, in general, the target should not be greater than 115 g/L [11]. As a result, most nephrologists will now use alternative treatments for anaemia (such as iron supplementation) first and thereafter resort to ESA administration with the primary goal of avoiding blood transfusion without raising haemoglobin levels too high.

Emerging novel therapies, such as orally active hypoxia inducible factor (HIF) stabilizers, EPO mimetic peptides and activin receptor ligand traps (e.g. sotatercept), may offer new treatment approaches for anaemia of CKD in the future [8].

Sexual Dysfunction

Sexual dysfunction is a highly prevalent, but under-recognized, complication of CKD [12]. The cause of sexual dysfunction in these patients is likely multifactorial in nature, due to not only their CKD, but also to comorbid illnesses and complications of CKD, such as diabetes, hyperprolactinemia, hyperparathyroidism, sex hormone imbalances, autonomic neuropathy, cardiovascular and peripheral vascular disease, veno-occlusive dysfunction, depression, and medication side effects [12, 13].

Box 12.1.3.1 Sex hormone abnormalities in men with CKD

- Reduced free and total testosterone
- Reduced Leydig cell response to HCG
- Normal sex hormone-binding globulin
- Elevated total plasma oestrogen
- Normal oestradiol
- Elevated LH
- Reduced LH per secretory burst
- Elevated follicle stimulating hormone (FSH) (lesser degree than LH, so LH/FSH increased)
- Reduced inhibin
- Appropriate increase in LH and FSH to clomiphene (competitive oestrogen/testosterone receptor blocker → prevents negative feedback to hypothalamus)

Male Sexual Dysfunction

Sexual dysfunction in CKD is likely due to a combination of structural and functional hypogonadism. Men with CKD exhibit detectable abnormalities in the pituitary–gonadal axis, even when GFR is only mildly reduced (see Box 12.1.3.1) [12]. Reduced free and total testosterone levels are observed in early CKD, and worsen with progressive falls in GFR [12]. These low testosterone levels also contribute to osteoporosis, anaemia, and reduced muscle mass [12]. Men with CKD have a blunted Leydig cell response to testosterone stimulation by human chorionic gonadotrophin (HCG) [12], and there is evidence for an inhibitory factor in uremic serum that is able to block the luteinizing hormone (LH) receptor at the level of the Leydig cells [12]. This blunted Leydig cell response usually resolves following kidney transplantation, although institution of dialysis treatment generally fails to normalize pituitary–gonadal disturbances and these abnormalities usually progress [12].

Men with CKD also experience impaired spermatogenesis, with decreased ejaculate volume, oligo- or azoospermia, impaired sperm maturation, and low sperm motility [12]. In addition, there may be interstitial fibrosis and calcification within the testes and seminiferous tubules and a failure of Leydig and Sertoli cells to show compensatory hypertrophy and hyperplasia [12]. Though oestrogen is usually elevated in ESKD, oestradiol levels are usually within the normal range despite elevated LH, suggesting functional gonadotrophin deficiency or resistance [12]. Follicle-stimulating hormone (FSH) elevation in men with ESKD is more variable compared to LH elevation. Increased elevation of FSH likely reflects a greater degree of damage to the seminiferous tubules and, thus, lower levels of inhibin production by Sertoli cells to feedback on FSH [12], and is associated with a lower recovery of spermatogenic function post-renal transplantation [12].

Erectile dysfunction in men with CKD is often related to vascular disease (including disease of cavernosal, proximal iliac and pudendal arteries causing effective 'steal' syndrome), autonomic neuropathy and multiple commonly used medications (see Box 12.1.3.2).

Clinical management of sexual dysfunction in CKD involves a thorough assessment for possible causes and contributors, and a multipronged treatment approach. Potentially reversible factors, such as medication effect, must be excluded, and non-organic aetiology (such as depression) should be considered and addressed. Anaemia should be corrected, hyperparathyroidism treated, and nutritional state optimized [12]. ESAs may enhance sexual function and normalize the pituitary–gonadal axis in CKD, with some studies demonstrating reduced serum LH and FSH concentrations, reduced prolactin levels, and increased plasma testosterone levels [12]. In addition, zinc supplementation has been shown in increase testosterone levels in haemodialysis patients [12].

Box 12.1.3.2 Common medications used in CKD that are implicated in male erectile dysfunction

- Alpha blockers
- Beta blockers
- Methyldopa
- Clonidine
- Antidepressants
- Metoclopramide

Testosterone replacement in uremic men does not usually produce a significant improvement in libido, sexual potency, or erectile function [12], although it is successful in increasing testosterone levels and reducing LH and FSH [14]. Potential benefits must be weighed up against risks, including adverse effects on lipid profile, hepatotoxicity, polycythemia, prostatic enlargement, and risk of prostate cancer.

Phosphodiesterase-5 inhibitors (PDE5i), such as sildenafil, are frequently used as first line therapy for erectile dysfunction with normal libido [15]. Although PDE5is increase testosterone and reduce LH and FSH release, they are generally not effective in restoring libido and potency [15, 16]. Its use is contraindicated in patients using nitrates, and should be used with caution in patients with coronary artery disease, and haemodialysis patients prone to hypotension.

Alprostadil treatment, vacuum devices, and penile prostheses may be useful in those patients with neurogenic or vascular causes of impotence [12].

Renal transplantation likely provides the best treatment for male sexual dysfunction through restoration of the normal hypothalamic-pituitary axis, normalization of levels of gonadotrophin releasing hormone (GnRH), LH release, testosterone, and prolactin, and improvements in sperm density and motility (though not morphology) [12]. Improvements in libido and global sexual dysfunction are variable post-kidney transplantation in both male and female recipients [12].

Female Sexual Dysfunction

Women with CKD also display disturbances in the pituitary–gonadal axis at an early stage (see Box 12.1.3.3), and sexual dysfunction becomes increasingly common as CKD progresses.

Box 12.1.3.3 Sex hormone abnormalities in women with CKD

- Failure to increase basal body temperature at expected time of ovulation
- Absence of preovulatory LH and oestradiol surge
- Elevated LH and FSH
- Appropriate increase in LH and FSH to clomiphene (competitive oestrogen/testosterone receptor blocker → prevents negative feedback to hypothalamus)
- Reduced oestradiol

The most common disturbance of reproductive function seen in women with CKD is menstrual disturbance and amenorrhea. Although the preovulatory LH and oestradiol surges are often absent, administration of clomiphene increases LH and FSH secretion, suggesting an intact negative oestradiol feedback pathway [12]. Anovulation and infertility are common in patients with CKD and ESKD [17] and frequent anovulation leads to failure of progesterone secretion by the corpus luteum. Thus, for women who wish to resume menses, a progestogen agent can be administered towards the end of the menstrual cycle, and for women with menorrhagia, administration of a progestogen throughout the menstrual cycle can terminate flow [12]. Over time, chronic proliferation of the endometrium due to frequent anovulation and lack of cyclical progestational endometrial changes may predispose to endometrial hyperplasia and malignancy [17]. Intermittent use of a prostagen may be implemented to avoid this and these patients should be followed by a gynaecologist.

Women also report decreased libido and reduced ability to achieve an orgasm [12]. Oestrogen-deficient patients may experience improved sexual desire and restoration of normal menses, as is the case in patients without CKD, although concerns remain about adverse cardiovascular, cerebrovascular, and malignancy-related side effects. Sildenafil, while possibly useful for women with isolated sexual arousal disorder, does not appear to be useful in those women with decreased libido [18]. Vaginal atrophy and dyspareunia can occur due to chronically low oestradiol levels, and local oestrogen treatments and lubricant use may be useful for symptom management [19].

As is the case for men, clinical management of sexual dysfunction in women with CKD should include optimization of dialysis, treatment of anaemia and hyperparathyroidism, review of medications, and exclusion of non-organic causes. Renal transplantation reverses most hormonal abnormalities in premenopausal women, and can restore regular menstrual cycles [12].

Successful pregnancy while receiving dialysis treatment is uncommon, with low conception rates (2%) and increased risks of miscarriage, intrauterine death, low birth weight and premature delivery [20]. Frequent, long dialysis sessions, such as in nocturnal dialysis, aiming for >36 hours per week increases the likelihood of a successful pregnancy [20]. Kidney transplantation is the most effective means of restoring both sexual desire and fertility in women with CKD [12].

Prolactin

Hyperprolactinemia is common in patients with ESKD, and is primarily due to increased production, with some reduced renal clearance and secondary hyperparathyroidism [12]. The clinical significance of hyperprolactinemia in men with CKD is poorly understood, and the effects of this on libido and sexual potency are inconsistent [21]. In women with CKD, hyperprolactinemia may contribute to sexual dysfunction and galactorrhoea [12].

Prolactin secretion in patients with CKD is resistant to suppression by dopamine infusion or oral L-dopa, and is similarly resistant to stimulation by arginine infusion, thyrotropin-releasing hormone infusion, and insulin-induced hypoglycaemia [12]. Bromocriptine, though effective in reducing prolactin levels, rarely results in restoration of normal menses in women with CKD, and is poorly tolerated due to its side effect profile [12]. Suppression of parathyroid hormone (PTH) with calcitriol has been shown to reduce prolactin and increase testosterone levels [22], although the reported effects on sexual function are mixed [12].

Growth Hormone and Insulin-Like Growth Factor

In the setting of CKD and kidney function impairment, growth hormone (GH) levels are elevated due to increased pituitary release as well as reduced renal metabolic clearance [23]. The elevated GH levels do not translate to a greater GH effect. There is GH resistance which arises from reduced tissue expression of GH receptors and from impairment in the signalling of the GH receptor [23]. The levels of insulin-like growth factor (IGF), as quantified by immunoassays, are generally normal in CKD. However, the biological activity of IGF-1 is reduced. The bioactivity of IGF is influenced by a family of IGF-binding proteins (IGFBPs), the production of which is increased and the clearance of which is reduced in CKD [23, 24].

Growth restriction is a common complication of paediatric CKD and is associated with altered GH/IGF-1 function, altered renin–angiotensin system programming, and renal structural abnormalities, such as low nephron count [25]. The pubertal height gain in children with CKD is approximately 65% that of healthy children [25]. Recombinant human GH (rhGH) is a commonly used treatment in affected patients, with increase in height being positively associated with older age, higher GFR and higher pretreatment growth rate [25]. Following kidney transplantation, rhGH has been used to effectively increase 'catch up' growth with no reported increases in allograft failure rate or adverse events, although routine use is not recommended [26]. The use of rhGH should be avoided in critically ill patients, where it has been associated with significant increases in mortality through an unclear mechanism [27]. Other risks of rhGH use include increased risks of idiopathic intracranial hypertension and type 2 diabetes, for which patients with CKD are already at increased risk.

Low serum IGF-1 concentration has been associated with body composition changes, muscle wasting, low bone mineral density, and increased mortality risk in patients with CKD, although replacing IGF-1 has not been shown to attenuate this risk [28]. While rhIGF-1 treatment has been demonstrated to produce an increase in growth velocity in children with GH-receptor deficiency or antibodies, its usefulness in patients with CKD is less clear given their state of IGF-1 resistance. Combination therapy of rhGH and rhIGF-1 is effective for growth promotion in uremic animal studies, but has not yet been evaluated in human studies [28].

Thyroid

Thyroid abnormalities, including hypothyroidism, goitre, thyroid nodules, and thyroid malignancies, are more common patients with CKD or kidney transplants compared to the general population [29, 30].

Patients with CKD appear to be at particularly increased risk of developing subclinical hypothyroidism and manifest a variety of thyroid axis abnormalities, including blunted response to

thyrotropin-releasing hormone (TRH), and disturbed diurnal variation of thyroid-stimulating hormone (TSH) with reduced or absent evening peaks and shorter and smaller pulsatile releases [30]. Reduced GFR also leads to impaired iodide excretion, total body iodide accumulation and reduced thyroid hormone production [31]. Despite reduced total thyroxine (T_4) levels, free T_4 is usually normal in patients with ESKD, likely due to reduced binding to serum carrier proteins as a result of elevated inflammatory cytokines (e.g. IL-1β and TNF-α), uremic toxins (e.g. indoxyl sulphate and hippuric acid) and concomitant medications (e.g. furosemide, NSAIDs, and heparin) [31]. Dialysis does not produce any significant effect on thyroid hormone metabolism [32]. Total and free triiodothyronine (T_3) are also often reduced despite preserved clearance of T_3 due to decreased conversion of T_4 to T_3 [30]. This may represent a metabolic adaptation to conserve energy and minimize protein-nitrogen catabolism, such that thyroid hormone therapy should not be used except in patients with diagnosed hypothyroidism [33]. Hypothyroidism may in turn increase the risk of CKD through effects on cardiac output, peripheral vascular resistance, and intrarenal vasoconstriction, resulting in reduced renal plasma flow and GFR [30]. In those patients with true hypothyroidism, thyroid hormone replacement may play a role in slowing the decline of kidney function in patients with CKD [30] and may even result in an increase in GFR over time [30]. Treating hypothyroidism may also mitigate some of the excess cardiovascular risk associated with CKD [30]. When using thyroid hormone replacement in patients with CKD, it is important to note that T_3 and T_4 may be bound in the gastrointestinal tract by commonly used CKD medications, such as kayexalate [34] and aluminium-based phosphate binders [35].

Hyperthyroidism occurs in patients with CKD with a similar frequency to that observed in the general population. However, biochemical features of hyperthyroidism may be masked due to reduced T_4 binding to carrier proteins and reduced T_4 conversion to T_3, such that a normal or low T_3 may not exclude hyperthyroidism [36].

CKD may also coexist with thyroid disease in the case of autoimmune disease, such as Hashimoto's thyroiditis and Grave's disease, which may be associated with glomerulonephritis [30]. In addition, some thyroid disease treatments have been associated kidney disease. Propylthiouracil has been linked to the development of antineutrophil cytoplasmic antibody (ANCA)-positive glomerulonephritis, while radioiodine may induce membranous nephropathy [30].

In patients with thyroid malignancies or hyperthyroidism where treatment with radioactive iodine is warranted, it is important to note that renal impairment interferes with body excretion of radioactive iodine Na^{131} and a prolonged half-life is seen in both dialysis-dependent and non-dialysis-dependent patients with ESKD due to reduced clearance [31]. Thus, patients receiving maintenance haemodialysis and peritoneal dialysis require significant reductions in dosage to avoid complications of excessive radiation [30].

Insulin Resistance

Insulin resistance increases the risk of developing kidney disease, while the kidney plays an important role in glucose homeostasis. Renal gluconeogenesis accounts for approximately 40% of all gluconeogenesis and 20% of overall endogenous glucose release in the body [37]. Like hepatic gluconeogenesis, renal gluconeogenesis is not appropriately suppressed by insulin in patients with diabetes [38].

Kidney disease also predisposes to insulin resistance and diabetes, and insulin resistance exists even in the early stages of kidney disease [39]. This is mainly due to reduced peripheral target tissue sensitivity to insulin, and patients with CKD often exhibit elevated glucose levels during fasting despite hyperinsulinemia [39]. Glycogen synthase activity is preserved, despite an attenuated increase in insulin-stimulated glucose transport from muscles [40]. *In vitro* studies of skeletal muscle from uremic patients have indicated that skeletal muscle receptor number, insulin binding, β-subunit receptor autophosphorylation, and tyrosine kinase activity are preserved, suggesting that the observed peripheral insulin resistance is likely due to a post-receptor defect in the insulin pathway [39]. There are many other factors commonly present in patients with CKD that interfere with the action of insulin, and may be amenable to treatment with synbiotics, medications, or dialysis, resulting in improved glucose tolerance [39]. Some of these include: (1) metabolic acidosis (reduces post-receptor signalling in insulin-signalling pathway); (2) vitamin D deficiency (involved in stimulating expression of insulin receptors); (3) secondary hyperparathyroidism (may result in suppressed insulin-stimulated glucose uptake via the cAMP pathway); (4) hyperuricaemia (reduces glucose uptake by peripheral tissues via reduced insulin-mediated nitric oxide release); and (5) gut dysbiosis (leads to bacterial production of uremic toxins, including indoxyl sulphate and p-cresyl sulphate, which alter insulin signalling) [39].

Insulin resistance is a major risk factor for cardiovascular morbidity and mortality in patients with CKD, especially when combined with other risk factors, such as smoking and physical inactivity [39]. As a result, early and intensive management of diabetes and impaired glucose tolerance should be performed in appropriate individuals, together with risk factor modification.

CKD Mineral and Bone Disorder, Hyperparathyroidism, and Vitamin D

CKD mineral and bone disorder (CKD-MBD) has been defined by the KDIGO Guidelines group as any one or a combination of the following: (1) Laboratory abnormalities of calcium, phosphorus, PTH or vitamin D metabolism; (2) Bone abnormalities in turnover, mineralization, volume, linear growth or strength; and (3) Calcification of the vasculature or other soft tissues [41]. The condition occurs early in the course of CKD, affects the vast majority of patients as kidney disease progresses and is a strong, independent predictor of bone fracture, CKD progression, cardiovascular disease, and death [42].

Secondary hyperparathyroidism is common in patients with CKD and is characterized by elevated serum FGF-23, PTH and phosphate levels, normal or low serum calcium levels, and low serum $1,25(OH)_2D_3$ concentrations, with increased bone resorption [43, 44]. FGF-23, a phosphaturic hormone produced by osteoblasts and osteocytes, precedes other laboratory biomarkers of CKD-MBD and rises exponentially as eGFR declines [44]. FGF-23 binds and forms a complex with its receptor, FGFR1, in the presence of

Klotho, a transmembrane protein, to promote decreased proximal tubule expression of sodium-phosphate cotransporters (leading to increased phosphate reabsorption and hyperphosphataemia), decreased kidney $1,25(OH)_2D_3$ synthesis and decreased PTH gene expression and parathyroid cell proliferation [43, 44]. Uncontrolled hyperparathyroidism can lead to osteodystrophy, vascular calcification and calciphylaxis (uremic calcific arteriolopathy), and is associated with increased morbidity and mortality [43, 44].

Treatment of secondary hyperparathyroidism in patients with CKD consists of efforts to lower PTH and control serum calcium and phosphate levels using dietary modification, medications, and dialysis. While using a variety of medications to correct serum PTH, phosphorus, and calcium levels is currently considered standard medical care, a recent systematic review and meta-analysis of randomized trials found that such drug effects on these biochemical markers were imprecisely correlated with cardiovascular and all-cause mortality and were consistent with the possibility of no association [45]. Thus, it remains uncertain as to whether any of the currently recommended interventions are of net clinical benefit [46].

Calcium-based phosphate binders have traditionally been used as first line treatment to reduce serum phosphate concentrations due to their low cost and availability. Unfortunately, their use has been associated with hypercalcaemia, vascular calcification, and calciphylaxis [47]. Aluminium-based binders have been associated with significant side effects, including aluminium-induced bone disease, microcytic anaemia, and dementia, although some investigators have argued that aluminium binders have only played a secondary role to aluminium–contaminated dialysis water and that no cases of aluminium binder-associated toxicity have been reported in the era of ultrapure dialysis water quality [48]. Nevertheless, some guidelines recommend that aluminium-based binders should be used only for short periods of time with close monitoring [49]. Non-calcium phosphate binders, including lanthanum carbonate, sevelamer hydrochloride, and sucroferric oxyhydride, are effective at lowering phosphate, although their use is often restricted by higher cost and difficult access in many healthcare systems [47]. A recently published network meta-analysis of randomized trials of phosphate binders in adults with CKD reported that there was no evidence that phosphate binder treatment reduced mortality compared with placebo [50]. However, patients treated with sevelamer had a lower mortality than those treated with calcium binders, although it remained uncertain whether this reflected a benefit of sevelamer, a harm of calcium or both [50].

Active vitamin D compounds (calcitriol and its prodrugs) increase gut absorption of calcium and phosphorus and reduce PTH synthesis by activating the parathyroid vitamin D receptor. These drugs can cause hypercalcaemia and hyperphosphataemia and so serum calcium and phosphate levels must be monitored. There is however no evidence that these agents alter patient-level outcomes [42, 51].

Calcimimetics, such as cinacalcet, modulate the calcium sensing receptor (CaSR) resulting in reduced PTH levels by increasing sensitivity to calcium [52]. A cumulative meta-analysis of randomized controlled trials demonstrated that cinacalcet reduced the need for parathyroidectomy by approximately 50%, but did not improve cardiovascular or all-cause mortality [52]. Cinacalcet is therefore especially useful for patients who are awaiting parathyroid surgery, or those who are not medically stable enough to receive a parathyroidectomy. Hypocalcaemia is a common side effect and should be monitored.

Prescription of bisphosphonates for the purpose of managing CKD-MBD and reducing bone resorption should be avoided, except as a bridge to definitive management of secondary hyperparathyroidism, as they may cause low-turnover bone disease and have also been reported to be nephrotoxic [53]. Moreover, the benefits and harms of bisphosphonates in patients with CKD have not been clearly established [53].

Parathyroidectomy, usually with preservation of remnant gland or autotransplantation of parathyroid tissue, is indicated in severe secondary hyperparathyroidism, typically with PTH levels >100pmol/L, or tertiary hyperparathyroidism when medical management has failed. It remains the most effective treatment for secondary or tertiary hyperparathyroidism and, in appropriate candidates, may reduce morbidity and mortality [54].

12.1.4 The Endocrinology of Liver Disease

Jacob George and Mohammed Eslam

Introduction

The liver plays a fundamental role in metabolic regulation and energy homeostasis. Thus, it is also an inevitable target of endocrine diseases with intimate reciprocal feedback mechanisms. Liver and endocrine diseases are both common in the general population and hence it is to be expected that diseases of both frequently coexist and modulate the phenotypic manifestations or progression of the other. Of particular interest, the common liver diseases, non-alcoholic fatty liver disease, viral hepatitis and haemochromatosis have unique extrahepatic endocrine manifestations while the liver is frequently a target of a variety of endocrinopathies, including hypothyroidism, hypercortisolaemia, polycystic ovarian syndrome (PCOS), hypopituitarism, growth hormone deficiency, and hypogonadism. In the following chapter, we summarize this bidirectional relationship (Table 12.1.4.1).

Endocrine Associations of Common Hepatic Diseases

Metabolic associated fatty liver disease-Associated Endocrine Disorders

Metabolic associated fatty liver disease (MAFLD) afflicts more than 20–30% of the world population, paralleling the dramatic escalation in global obesity prevalence [1]. Thus, MAFLD is a leading cause for end-stage liver disease, cancer, and liver transplantation in Western countries [1]. The association between MAFLD and the endocrine system is bidirectional. MAFLD is seen in association with a variety of endocrinopathies, while conversely MAFLD increases the risk for multiple endocrine disorders.

Diabetes

The close association between MAFLD and diabetes is robust, so much so that which is the chicken and which is the egg cannot be easily discerned. A recent large prospective study including around 133 000 Taiwanese non-diabetic subjects who had two or more health examinations during 1996–2014 concluded that MAFLD diagnosed by ultrasonography was significantly and independent of other common risk factors such as age, sex, family history of diabetes (T2DM) or obesity, associated with a twofold increase in incident T2DM [2]. This result was confirmed in a recent meta-analysis of 20 observational studies comprising around 117 000 non-diabetic individuals diagnosed with MAFLD by either ultrasonography or abnormal serum liver enzymes, indicating an almost twofold increase in incident T2DM over a median follow-up of five years [3].

Consistently, data demonstrating a reduced incidence of T2DM after improvement or resolution of MAFLD provide strong evidence for a causal relationship between MAFLD and glucose abnormalities [4, 5]. The first study of large cohort of South Korean individuals (n = 13 000) demonstrated a significant reduction in the risk of incident T2DM in individuals in whom fatty liver resolved over time. The association was independent of other potential confounding factors. A second study included ~4000 non-diabetic Japanese subjects followed for 10 years. Improvement of MAFLD based on ultrasonography was again independently associated with a nearly 70% risk reduction of incident T2DM [5]. Notably, the severity of MAFLD was associated with an increased risk of T2DM. Finally, in a recent study of 396 non-diabetic patients with biopsy-proven MAFLD, subjects with advanced liver fibrosis stages 3–4 were at higher risk of T2DM, compared to those with fibrosis stages 0–2 (51% vs. 31%), over a mean follow-up of 18.4 years. Among subjects with fibrosis stages 0–2, fat score was an independent and principal predictor of T2DM risk. Notably, histological features of steatohepatitis were not associated with T2DM risk.

The converse association of T2DM with MAFLD has also been convincingly demonstrated. For example, the prevalence of MAFLD is high among patients with T2DM ranging from 45% to 75% in hospital-based and 30% to 70% in population-based series. Furthermore, patients with T2DM have higher risk of steatohepatitis and for the development of serious liver-related complications (cirrhosis, liver failure, and hepatocellular cancer (HCC)) [6].

Pathophysiological mechanisms linking MAFLD and T2DM is the shared abnormal metabolic milieu seen that is the substrate for both diseases. This includes overnutrition and certain dietary factors such as consumption of an energy dense Western-type diet low in fibre and high in processed foods that can lead to insulin resistance (IR) and low grade systemic chronic inflammation. Peripheral IR leads to ectopic intramuscular lipid accumulation and reduced muscle glucose uptake while hepatic IR promotes hepatic lipid deposition; both coordinately linked to the development of T2DM and MAFLD. Furthermore, a Western-type diet leads to disturbed intestinal permeability with leakage of microbial and other content into the portal circulation leading to the activation of multiple pro-inflammatory innate immune receptors such as toll-like receptor (TLR)2 and TLR4 and inflammasomes, that triggers the development of T2DM, and as

Table 12.1.4.1 Summary of the main interactions between liver and endocrine disorders

Endocrine disease	Hepatic manifestations	Liver disease	Endocrine manifestations
Thyroid dysfunction		**MAFLD**	
Hyperthyroidism	Elevation of liver enzymes Jaundice: uncommon Few case reports of fulminant hepatitis		Diabetes mellitus Hypothyroidism Polycystic ovarian syndrome Osteoporosis
Hypothyroidism	Hepatic steatosis Gallbladder stones Elevated AST Myxoedema ascites		
Antithyroid drugs	Elevation of liver enzymes Idiosyncratic reaction can lead to fulminant hepatitis		
Adrenal dysfunction		**Hepatitis C**	
Addison's disease (adrenal insufficiency)	Mildly elevated aminotransferases		Insulin resistance and diabetes mellitus Thyroid disorders including autoimmune thyroiditis, hypothyroidism, and thyroid cancer Osteoporosis Gonadal dysfunction
Cushing's syndrome (adrenal excess)	Features of metabolic syndrome including hepatic steatosis		
Sex hormones		**Hereditary hemochromatosis**	
Oestrogens	Cholestasis. Hepatic peliosis Hepatic adenomas Focal nodular hyperplasia, Haemangiomas. Budd–Chiari syndrome		Diabetes Hypopituitarism Hypogonadism Thyroid dysfunction Adrenal dysfunction Parathyroid defects Osteoporosis
Androgens	Elevated aminotransferase levels cholestasis Adenomas Rarely hepatocellular carcinoma		

well hepatic IR and lipid deposition. Alterations in gut microbiota and changes to the activation of cytokine/adipocytokine cascades are another potential player in the pathogenesis.

Based on the aforementioned details, ideally, any therapeutic target for MAFLD, should not only improve liver injury, but also ameliorate the associated systemic metabolic milieu to reduce the risk of MAFLD-related extrahepatic disorders, such as diabetes and cardiovascular disease. Further randomized controlled studies will be required to determine if we need to change current clinical practice guidelines and incorporate screening for MAFLD in T2DM patients and vice versa.

Thyroid Disease

Hypothyroidism, a condition characterized by the failure of the thyroid to produce enough thyroid hormones (THs), has been strongly associated with MAFLD. A recent retrospective, case-control study found that the prevalence of hypothyroidism was higher in biopsy-proven MAFLD compared to controls (21% vs. 9.5%; P <0.01). Notably, the prevalence was even higher in patients with steatohepatitis than those with simple steatosis (25% vs. 12.8%, P = 0.03) [7]. This finding was confirmed in a larger study of patients with hypothyroidism (n = 2000) that suggested that overt and subclinical hypothyroidism are both associated with an increased risk of MAFLD, independent of other potential confounding by known metabolic risk factors [8].

On the other hand, clinical hypothyroidism may be an independent risk factor for the development of MAFLD. A recent cross-sectional study of 425 subjects with biopsy-proven MAFLD suggested that the presence of low-normal thyroid function and subclinical hypothyroidism are independent predictors of steatohepatitis and advanced fibrosis [9]. Another prospective study from the Rotterdam cohort based on 9419 individuals with a median follow-up of around 10 years assessed for the presence of MAFLD by ultrasonography. This work concluded that increased levels of free T_4 were associated with a decreased risk of MAFLD, independent of other possible confounding factors. Subjects in the lowest free T_4 tertile had a 1.31-times greater risk of developing MAFLD, compared to those in the highest tertile. Consistently, those individuals with increased thyroid-stimulating hormone (TSH) levels were at a greater risk of developing MAFLD [8]. Hence, screening of patients with MAFLD with annual TSH and vice versa, screening patients with hypothyroidism for MAFLD should be considered.

Mechanistically, a recent study has suggested that hypothyroidism induces MAFLD through hepatic and extrahepatic mechanisms [10]. A mild reduction in THs leads to impaired insulin secretion, suppression of lipolysis, and increased shuttling of fatty acids to the liver, where they induce MAFLD. Surprisingly this study also suggested that a severe reduction in serum TH levels could protects against the development of MAFLD via a

constitutive suppression of lipolysis [10]. Further, mechanistic studies will be required.

Polycystic Ovarian Syndrome (PCOS)

Numerous studies have suggested that patients with PCOS are at increased risk of MAFLD. A recent retrospective longitudinal cohort study assessed NAFLD rates in 63 120 women with PCOS and 121 064 age- and BMI-matched patients utilizing a primary care database in the United Kingdom. This study concluded that patients with PCOS have a 2.23-fold increased risk of MAFLD [11]. Consistently, a recent meta-analysis that incorporated 7 studies from 6 different countries demonstrated that patients with PCOS had a 3.93-fold increased risk of MAFLD, independent of BMI [12]. Notably, most of the current evidence suggests that IR, rather than androgen excess mediates the association. The prevalence of MAFLD among women with PCOS has been shown to vary in different countries ranging from 32.9%, 71%, and 73.3% among Chinese, Australian, and Brazilian women with PCOS, respectively [11]. Though, it is less clear, the converse also seems to be true. Again, these data suggest that screening for the presence of MAFLD among women with PCOS should be considered.

Osteoporosis

Osteoporosis is a prevalent complication in patients with chronic liver disease, especially in end-stage disease, where a prevalence rate of up to 55% has been reported. Osteoporosis in liver disease has been particularly linked to chronic cholestasis, MAFLD, alcoholism, and haemochromatosis.

Several cross-sectional and case-control studies involving both male and female adults and adolescents have found an association between MAFLD and low bone mineral density or osteoporosis [13]. A recent retrospective study involving 7797 Chinese men aged 40 years or older demonstrated that the presence of MAFLD diagnosed by ultrasonography was associated with a 2.5-fold increased risk of osteoporotic fractures [14]. Alarmingly, this risk association has also been reported in the paediatric MAFLD population [15]. Notably, in that study, the degree of bone mineral density loss correlated with increasing severity of MAFLD, being higher in patients with steatohepatitis compared to those with simple steatosis. However, these data should be interpreted with caution, due to the limited sample size (n = 38).

The pathophysiological links between MAFLD and low bone mineral density are not completely understood. However, both disorders share common risk factors such as low levels of physical activity, obesity, IR, T2DM, vitamin D_3 deficiency, and chronic systemic inflammation. Many of these common risk factors are also present in patients with chronic cholestasis, alcoholism, and haemochromatosis.

Elucidation of the core molecular pathways and mechanisms between liver and bone disorders would help to identify novel therapeutic targets to ameliorate both conditions. Further prospective studies and on other ethnicities (as most current reports are from Asia) are required before any recommendation to change current guidelines on screening can be recommend. However, collectively, the findings argue for increased awareness of osteopenia/osteoporosis and the importance of monitoring and evaluation for this among patients with MAFLD.

Hepatitis C-Associated Endocrine Disorders

Hepatitis C (HCV) infects ~3% (170 million) of the world's population [16]. Of these, 70–80% develop chronic disease with a risk of developing liver complications including cirrhosis and cancer, with an estimated liver-related mortality of 350 000 people per year [17]. HCV can be considered not only as a hepatotropic virus, but also a systemic disease with diverse extrahepatic manifestations, including endocrine disorders—mainly IR and type 2 diabetes mellitus, but also thyroid disease and gonadal dysfunction [18].

IR and Type 2 Diabetes Mellitus

Multiple levels of evidences suggest a strong link between HCV and IR/T2DM [19]. T2DM is more prevalent in those with HCV-related cirrhosis than those with cirrhosis resulting from conditions other than chronic hepatitis C (CHC). Consistently, a large study included 9841 subjects from the third National Health and Nutrition Examination Survey (USA) showed that patients with HCV have a threefold higher risk of developing T2DM. Similarly, a longitudinal study demonstrated that patients with HCV were 11 times more likely to develop T2DM than those without HCV infection. Even, in the context of organ transplantation, T2DM is more frequent in liver and kidney transplantation among HCV-infected compared with HCV non-infected patients. Conversely, the prevalence of HCV infection in patients with T2DM ranges from 5% to 12% and is higher than in the general population [19].

CHC patients are also at increased risk of IR and impaired glucose tolerance, the key pathophysiological underpinning T2DM, first demonstrated by Hui and colleagues [20]. Insulin resistance is present in 30–70% of individuals with CHC and is interestingly associated with peripheral (muscle and adipose tissue), rather than hepatic IR [21]. HCV-related IR correlates with an increased risk of liver fibrosis, liver cirrhosis-related complications, such as portal hypertension and variceal bleeding, HCC, high serum HCV RNA levels, and an impaired response to interferon-based therapy before the current era of direct-acting antivirals (DAA) for HCV cure [22–24]. Notably, cure of HCV infection with either Peg-IFN/RBV or with DAAs is associated with an amelioration of IR [25].

Several molecular pathways have been implicated in mediating HCV-induced IR and T2DM. This includes enhanced intrahepatic and systemic expression of pro-inflammatory cytokines, changes in adipocytokines and generation of reactive oxygen species that possibly influence insulin signalling and increase both hepatic and peripheral (muscle and adipose tissue) IR. Furthermore, HCV-induced hepatic steatosis can promote an increase in lipid oxidation and endogenous glucose production, and hinder glucose disposal by skeletal muscles by decreasing glucose oxidation [19].

Thyroid Disorders

Thyroid disorders are among the most frequent endocrine extrahepatic manifestation of HCV; this prevalence is further increased in patients with HCV-induced cryoglobulinemia. Circulating thyroid autoantibodies such as antithyroglobulin antibody (AbTG), antithyroid peroxidase antibody (AbTPO), and antithyroid microsomal antibody (ATMA) are detected in 80–85% of cases and are higher than their prevalence in the general population. Autoimmune thyroid disease is the most frequent HCV-related

endocrine disorder, with hypothyroidism present in about 30% of HCV-infected patients. The mechanisms of HCV-related autoimmune thyroid disease is not fully understood, but is suggested to be a consequence of T-cell-mediated autoimmunity.

Of historical interest, before the era of DAA's, interferon therapy for HCV was associated with an increased risk of thyroid dysfunction; up to 25–30% of HCV patients developed autoimmune thyroid diseases (both hypo- and hyperthyroidism) during Peg-IFN/RBV treatment, and about half of these patients need thyroid hormone replacement therapy. Data are limited on whether DAAs have any effect on thyroid function.

A higher prevalence of papillary thyroid cancer has also been reported in CHC patients, especially in those with autoimmune thyroid disorders. A recent meta-analysis suggests that HCV increases the risk of thyroid cancer 2.86-fold after adjusting for the heterogeneity of the included studies. Longitudinal follow-up studies are however required to determine outcomes [26]. Assessment of TSH and thyroid autoantibodies, thyroid ultrasonography, and cytology are part of the diagnostic work-up of HCV-related thyroid disease.

Osteoporosis

Several studies have suggested that HCV-infected patients have an increased risk of osteoporosis compared to uninfected patients. A recent report of around 2500 HCV-positive patients from the Swiss cohort suggest that HCV was associated with a 1.43-fold increased risk of osteoporosis/fracture [27]. Notably, this association does not seem to be dependent on persistent HCV RNA and was not ameliorated by viral eradication. Consistently, a meta-analysis that included 362 285 participants suggested that HCV infection is associated with a pooled relative risk for osteoporosis of 1.53 [26]. This risk is exacerbated in HIV/HCV coinfected patients who exhibit a threefold increased risk of fracture incidence compared with uninfected controls, and a 1.2–2.4-fold increased fracture risk compared with HIV mono-infected individuals.

Sex Hormones

Though information is scanty, there are reports that suggest an association between CHC and sexual dysfunction; this was more prevalent in males compared to females. Consistent with this observation serum sex hormones were reported to be altered in HCV-infected patients and a high-prevalence of sexual dysfunction (28–74%) has been reported in multiple studies. The mechanisms of this association are unclear, but several hypotheses have been postulated. These include altered hypothalamic-pituitary function that might play a role in sex hormone regulation and, consequently, the impairment of sexual function. Psychological factors also might play a role; given the well know association of HCV infection with socioeconomic disadvantage [28]. In the past, the use Peg-IFN/RBV treatment was associated with an increased risk of sexual dysfunction, but this does not seem to be replicated in the era of interferon free DAA-based therapy.

On the other hand, there are several lines of evidence that indicate that women of reproductive age (premenopausal) have a more favourable HCV natural history, with slower fibrosis progression and a higher response rate to Peg-IFN/RBV-based antiviral therapy. This is consistent with human and experimental evidence indicating a protective role for oestrogens against the development of liver fibrosis and cancer [29] that is opposite to the effect of testosterone.

Hereditary Haemochromatosis

Haemochromatosis (HH) is a genetic disorder of iron overload that results, if untreated, in end-organ damage including of the liver and many endocrine organs. The latter includes diabetes, hypopituitarism, hypogonadism, thyroid dysfunction, adrenal dysfunction, parathyroid defects, and osteoporosis.

The reported prevalence of diabetes among patients with HH varies according to the method of HH diagnosis. It was originally reported to be present in 40–63%, but with the improvement of earlier diagnosis and treatment, the prevalence of T2DM is approximately 13–23%. The pathophysiology of diabetes associated with HH is not clear, but seems to be multifactorial. Iron overload can induce hepatic dysfunction leading to hepatic IR; excess iron can also lead to pancreatic β-cell oxidative stress and apoptosis, with insulin-deficiency. Notably, phlebotomy, which is the gold standard treatment for HH, has a variable impact on diabetes control. In early HH, patients who have not developed complications/organ damage, normalization of glucose tolerance leads to an improvement of insulin secretory capacity. In contrast, no significant improvement is noticed in HH patients with cirrhosis or diabetes [30].

Hypogonadism is the most frequent non-diabetic-endocrinopathy in HH patients with prevalence ranging from 10 to 100%. The vast majority of individuals present clinically with features of androgen deficiency, including loss of libido and impotence, reduced body hair, rarely testicular atrophy, and gynaecomastia with or without altered fat distribution. The main laboratory characteristics reported in male hypogonadic HH patients are subnormal testosterone levels with low or inappropriately normal basal gonadotropin concentrations and a blunted or no response of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) to luteinizing hormone-releasing hormone (LHRH) administration, indicating primary pituitary dysfunction. Similar studies in females are limited by sample size. When the diagnosis is confirmed, the recommended treatment is testosterone replacement in males and cyclical oestrogen and progesterone therapy in fertile females. Mechanistically, the original defect seems to be principally at pituitary level, with iron deposition leading to abnormal hormonal secretion. Iron deposition induced defects in hypothalamic or gonadal dysfunction with and without pituitary defects have also been reported.

Though panhypopituitarism, as well as a single tropin defects, has been reported in HH, it is relatively uncommon and a recovery of the pituitary–thyroid and adrenal axes following therapeutic phlebotomy has been reported. Similarly, it was suggested from autopsy studies that iron tends to deposit in the thyroid gland in HH patients. However, cases of thyroid dysfunction occur rarely and are usually observed at an end-stage of the disease where subjects already have cirrhosis and/or other endocrine disorders. Excess iron can also deposit in the adrenal glands, but data on adrenal dysfunction in HH patients is limited; they seem to have preserved glucocorticoid function [30].

Decreased bone mineral density and osteoporosis are relatively common in HH patients, with osteoporosis prevalence in approximately 25–34% and osteopenia in 40–79%. While parathyroid dysfunction has been suggested as a potential causative factor, it is more likely that the effect is multifactorial. Notably, improvements in bone mineral density have been reported with decreases in serum of ferritin [30].

Hepatic Manifestations of Endocrine Disorders

Thyroid Function

The association between liver and thyroid function is bidirectional. Several liver diseases have varying effects on thyroid hormone metabolism. Conversely, alterations in thyroid function can lead to liver dysfunction. The THs thyroxine and triiodothyronine regulate hepatocyte metabolic rate, development, and function. On the other hand, the liver is the main site for thyroid hormone metabolism and hence plays a key role in regulating their systemic effects. Consequently, thyroid or liver dysfunction may alter the functions of the other. Furthermore, some diseases such as infiltrative disorders and autoimmune affect both organs concomitantly [31].

Hyperthyroidism

Thyrotoxicosis is commonly associated with some degree of liver injury, which can be classified as hepatocellular or cholestatic. Clinically, it manifested by elevations in aminotransferase levels and occurs in about a third of patients. Similarly, elevations of alkaline phosphatase are reported in two third of cases while elevations in γ-glutamyl transpeptidase are observed in less than 20% of patients; progression of liver damage is infrequent. Jaundice is an uncommon presentation and if present, is usually secondary to the systemic effects of thyrotoxicosis, such as heart failure or septic shock. A few case reports have described fulminant liver failure as the initial manifestation of thyrotoxicosis. Histologically, mild liver injury with centrilobular cholestasis is observed and abnormalities return to normal with the treatment of thyroid disease. Mechanistically, the effects are likely due to hypoxia, oxidative stress, and increases in bile acid production.

Hypothyroidism

Hypothyroidism can cause hepatic steatosis, gallbladder stones, and elevated aspartate aminotransferase levels of muscular origin. It can also cause myxoedema ascites, a high protein concentration ascites; severe ascites is a very rare complication. Liver histology is usually normal, and only rarely has fibrosis been described; cholestasis has been reported. Nevertheless, liver manifestations usually regress to normal with thyroid hormone replacement therapy.

Antithyroid Drugs and Liver Abnormalities

Alterations of liver function have also been observed with antithyroid drugs. Hepatotoxicity and increased aspartate aminotransferase and alanine aminotransferase is observed more frequently with propylthiouracil, and is dose dependent. This idiosyncratic reaction that can develop at any time and the course is usually benign, despite cases of fulminant hepatic failure have been reported. In the United States, propylthiouracil is the second leading cause of non-acetaminophen–associated drug-induced liver injury requiring liver transplantation.

Adrenal Dysfunction and the Liver

Addison's disease (adrenal insufficiency) is associated with mildly elevated aminotransferases, which generally return to normal after appropriate glucocorticoid replacement therapy. The mechanisms for this elevation are unclear, but might be related to changes in body weight. Cushing's syndrome (adrenal excess) is linked with features of metabolic syndrome, including hepatic steatosis, MAFLD, IR, and hypertension. This can also be caused by up-regulation of the renin–angiotensin system.

Sex Hormones and the Liver

Oestrogens

The use of oral contraceptives is associated with hepatic disorders. Oestrogens increase the risk of developing cholestasis, hepatic peliosis, hepatic adenomas, focal nodular hyperplasia, and haemangiomas. Oral contraceptives can also be a risk factor for the development of Budd–Chiari syndrome by contributing to the underlying pro-thrombotic state and reasoning the risk of venous thrombosis (of the hepatic veins). Notably, the incidence of these complications has decreased with the use of currently available contraceptives that have lower doses of oestrogen and progesterone.

Androgens

The risk of liver dysfunction following the use of androgenic hormones is well described and includes elevated aminotransferase or cholestasis that can on occasions be severe. Hepatic adenomas and even hepatocellular carcinoma in association with androgen use has been described.

Conclusion

Liver and endocrine disorders are both common and intimately associated, often with shared pathogenic mechanisms (Figure 12.1.4.1). Hence, it is incumbent on both gastroenterologists and endocrinologists to consider these reciprocal interrelationships in

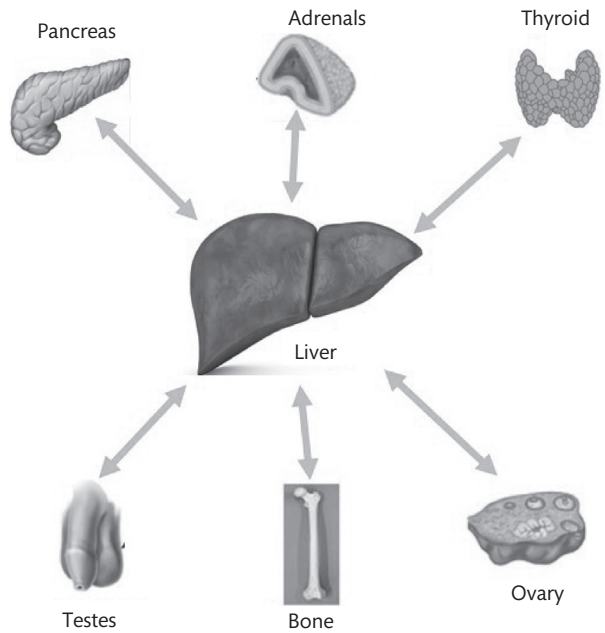

Figure 12.1.4.1 Intimate reciprocal associations and feedback mechanisms between the liver and endocrine organs. Common liver diseases such as non-alcoholic fatty liver disease, viral hepatitis, and haemochromatosis have extrahepatic endocrine manifestations including diabetes, thyroid, gonadal and adrenal dysfunction, and osteoporosis. Likewise, the liver is commonly involved in a variety of endocrinopathies.

daily medical practice, in order to provide better clinical care. It is particularly important to be aware of, and to deal with the hepatic adverse effects of some endocrine therapies, particularly the use of oral contraceptive formulations. Understanding the mechanistic basis of the interrelationships is an avenue for ongoing research that is pivotal for developing novel therapeutic targets, particularly for fatty liver disease. Importantly, prospective studies are required to reveal if we need to change current guidelines on screening for endocrine disease in patients with liver dysfunction and *vice versa*, at least in high risk groups.

12.1.5 Endocrine Abnormalities in HIV Infection

Steven K. Grinspoon and Takara L. Stanley

Introduction

Approximately 37 million people worldwide are living with human immunodeficiency virus (HIV) infection [1]. As access to antiretroviral therapy has improved, the endocrine manifestations of HIV have evolved (Table 12.1.5.1). Whereas untreated individuals may develop undernutrition, wasting, and end-organ effects of opportunistic infections (OIs) such as primary adrenal insufficiency secondary to adrenal destruction, individuals treated with combination antiretroviral therapy (cART) may develop generalized or abdominal obesity, peripheral fat loss, insulin resistance, hyperlipidaemia, and non-alcoholic fatty liver disease (NAFLD). Individuals with treated HIV also have increased risk of cardiovascular disease (CVD) compared to the general population. Some individuals with HIV infection may experience gonadal dysfunction and bone mineral loss. The purpose of this chapter is to review the endocrine manifestations of HIV infection, including pathogenesis and treatment.

Anthropometric Effects of HIV Infection

Depending on the severity of infection and the use of antiretroviral therapy, HIV may have significant effects on body weight, fat distribution, and, in children, growth. These changes often accompany and may contribute to the HIV-associated metabolic and endocrine abnormalities described next.

Wasting and Undernutrition

HIV was originally termed 'slim disease' due to the cachexia that accompanies untreated infection. Before the advent of cART, 'AIDS wasting syndrome', now called HIV-related wasting, was common. Wasting is an AIDS-defining condition, characterized by involuntary weight loss of more than 10% of usual body weight, accompanied by diarrhoea or weakness and fever lasting 30 days in the absence of other illness. The aetiology of wasting is multifactorial and includes immune dysregulation, inflammatory response to HIV and OIs, increased energy expenditure, and protein catabolism [2]. In practice, wasting is less common today but may still be found in individuals with untreated HIV. Additionally, because HIV is prevalent in many areas where malnutrition is also common, HIV infection and malnutrition often coexist in a phenotype similar to wasting but with distinct aetiology [2]. Unsurprisingly, malnutrition predicts poorer outcomes even in treated HIV infection [2].

Changes in Fat Distribution Associated with Combination Antiretroviral Therapy (cART)

With the advent of cART, individuals with HIV infection began to demonstrate changes in body fat distribution, including increased abdominal fat accumulation, dorsocervical fat accumulation ('buffalo hump'), lipoatrophy of the face and limbs, and,

Table 12.1.5.1 Major endocrine abnormalities in HIV infection

	Untreated HIV and/or advanced disease	cART-treated HIV
Body composition	Wasting and/or malnutrition	Generalized obesity and/or visceral fat accumulation, dorsocervical fat accumulation, facial and peripheral lipoatrophy
Adrenal function	Possible primary or secondary adrenal insufficiency	Typically normal
GH/IGF-1 axis	GH resistance	Relative GH deficiency
Gonadal function	Hypogonadism and menstrual irregularities, greater prevalence in untreated or advanced disease. Increased SHBG	
Thyroid function	Subclinical hypothyroidism (non-auto-immune); increased TBG	
Bone density and calcium homeostasis	Reduced BMD and increased fracture risk. High prevalence of vitamin D deficiency. Risk of osteomalacia with TDF, efavirenz, or severe vitamin D deficiency. Increased risk of osteonecrosis	
Glucose metabolism	May be altered due to pancreatic process	Increased risk of glucose intolerance and diabetes
Lipid metabolism	Increased triglyceride, decreased LDL, increased de novo lipogenesis	Same as untreated, plus increased LDL
Cardiovascular disease	Unknown	Increased
Other	Increased prevalence of non-alcoholic fatty liver disease	

Figure 12.1.5.1 Facial fat atrophy (a), abdominal and breast lipohypertrophy with gluteal fat atrophy (b), and dorsocervical fat accumulation (c) in individuals with HIV infection.

Modified with permission from Grinspoon S, Carr A. Cardiovascular risk and body-fat abnormalities in HIV-infected adults. *N Engl J Med.* 2005;352(1):48–62. (38), Copyright © 2005 Massachusetts Medical Society. All rights reserved.

less commonly, multiple discrete lipomas. These changes, often termed 'HIV lipodystrophy', do not represent a single syndrome but rather are characterized by differing degrees of lipoatrophy and lipohypertrophy in individual patients. For example, patients may experience peripheral fat atrophy, abdominal fat accumulation with visceral fat gain and central subcutaneous fat loss, or a combination of both (Figure 12.1.5.1). Additionally, studies of cART initiation consistently show increases in weight and fat mass with treatment. Although weight gain with cART is associated with lower mortality for those who are initially of normal weight or less [3], generalized obesity is increasingly common in cART-treated patients [4].

The aetiology of altered fat accumulation in HIV is multifactorial. Older agents in the protease inhibitor (PI) and nucleoside reverse transcriptase inhibitors (NRTI) classes exert direct effects on adipocyte differentiation, glucose metabolism, and mitochondrial function. With newer antiretroviral agents, extreme phenotypes of lipodystrophy are less common, but generalized obesity is of increasing concern [4]. Randomized studies generally have not demonstrated substantial benefits of one antiretroviral regimen over another with respect to preventing ongoing fat gain, although weight gain appears to be more significant with integrase inhibitors [4].

Ectopic fat accumulation in other areas, including the liver, muscle, and epicardium, is also common in HIV and may contribute to adverse metabolic profile. NAFLD appears to be common in HIV and may be related in part to use of antiretrovirals with mitochondrial toxicity [5, 6].

Chronic inflammation and immune activation in HIV may contribute to abnormal fat deposition and altered adipocyte function. Additionally, HIV viral proteins alter adipocyte function and may contribute to lipohypertrophy [4]. The increased dorsocervical fat and visceral fat accumulation seen among many cART-treated patients are similar to the phenotype of Cushing syndrome, but neither facial atrophy nor laboratory evaluation of these patients is consistent with true Cushing syndrome.

As described next, visceral fat accumulation is associated with reduced GH levels, dyslipidaemia, insulin resistance, and impaired glucose metabolism. In addition, patients with HIV and associated changes in fat distribution demonstrate elevated C-reactive protein (CRP) and decreased adiponectin compared to patients without such changes [7], as well as increased intramyocellular lipid and hepatic steatosis, all of which may also contribute to increased cardiometabolic risk. The medical and surgical interventions used for obesity in the general population may also be appropriate and effective in HIV but require further study [4].

Effects of HIV on Growth and Body Composition in Children

Children and adolescents with HIV often have decreased height-for-age and weight-for-age, and growth failure in children with HIV is associated with disease progression and mortality [8, 9]. Combined antiretroviral therapy (ART) improves but may not normalize growth in children with HIV, particularly in the context of coexisting malnutrition [9]. Abdominal fat accumulation and/or peripheral fat atrophy are also described in children receiving antiretroviral therapy. As in adults, the severity of these changes depends on the antiretroviral agents used as well as the appropriateness of paediatric dosing.

Growth Hormone/IGF-1 Axis

Physiology of the GH/IGF-1 Axis in HIV Infection

GH secretion is commonly altered in individuals with HIV, often related to changes in body composition. Patients with HIV-associated weight loss often demonstrate elevated GH levels and reduced IGF-1, consistent with GH resistance. Endogenous overnight GH secretion in this population is inversely associated with fat mass, and IGF-1 levels are directly associated with caloric intake. In contrast, patients with HIV and abdominal fat accumulation may have

decreased GH production. Men with HIV and abdominal fat accumulation demonstrate reductions in both mean overnight endogenous GH secretion and peak GH levels following GH-releasing hormone (GHRH)/arginine stimulation testing as compared to both healthy volunteers and men with HIV and normal body composition. As a result, a large percentage of men with HIV infection and visceral fat accumulation demonstrate relative GH deficiency. Although fewer studies describe GH secretion in women with HIV, increased abdominal adiposity is a negative predictor of peak stimulated GH in women as well. The aetiology of relative GH deficiency in individuals with HIV infection and abdominal fat accumulation is multifactorial and includes increased somatostatin tone, increased free fatty acids, and decreased ghrelin.

Growth Hormone Therapy for AIDS Wasting

In patients with AIDS, lean body mass may decline significantly and disproportionately to weight. Moreover, lean body mass correlates with survival. High-dose GH has been used as an anabolic therapy to increase lean mass in patients with wasting. Numerous studies of recombinant human GH (rhGH) at supraphysiologic doses of 0.1 mg/kg, or at a fixed dose of 6 mg, demonstrate increases in lean mass along with corresponding improvement in muscle function and/or exercise capacity. The relatively high doses of GH in these studies are thought to be necessary to overcome the GH resistance found in individuals with wasting. However, these supraphysiologic doses may also result in numerous side effects, including hyperglycaemia, arthralgia, and fluid retention, limiting long-term use of GH in this population.

Augmenting GH for Abdominal Fat Accumulation in HIV Infection

Though not currently approved by regulatory agencies in Europe or the United States for this indication, GH has been shown to reduce visceral fat in patients with HIV-associated abdominal fat accumulation. However, use of rhGH exacerbates insulin resistance, limiting its use in HIV-associated visceral adiposity.

An alternative strategy to increase GH levels in individuals with HIV-associated visceral adiposity is through use of GHRH analogue. In theory, GHRH may have two advantages over the use of rhGH: it maintains GH pulsatility, thus more closely mimicking physiologic secretion, and it preserves the negative feedback of IGF-1 on pituitary GH release. A large study of synthetic GHRH (tesamorelin) daily for six months demonstrated a 15% reduction in visceral fat, decreased triglyceride and total cholesterol, and increased high density lipoprotein (HDL), without changes in fasting or 2-hour glucose or insulin measured by oral glucose tolerance test [4]. A 6-month extension demonstrated that beneficial effects on visceral fat and lipids were maintained over 12 total months of treatment, without effect on insulin sensitivity, but that patients who discontinued treatment had rapid reaccumulation of visceral adipose tissue. In some countries, tesamorelin has received regulatory approved for use to reduce visceral adiposity in HIV-infected adults [4]. Although supraphysiologic levels of IGF-1 are uncommon with tesamorelin use, monitoring of IGF-1 is useful before and 6–12 months after initiation of therapy to confirm physiologic dosing [4].

GH/IGF-I Axis in HIV-Infected Children

Untreated children with HIV tend to exhibit GH resistance, sometimes accompanied by reductions in IGF-1 [10]. With cART, GH resistance improves, and both IGF-1 and IGFBP-3 generally increase; improvements in IGF-1 are associated with increases in lean body mass [10]. As in adults, adolescents with HIV-associated visceral adiposity demonstrate decreased GH response to GHRH-arginine testing [11]. Therapies targeting the GH axis have not been studied widely in children.

Gonadal Function

Pubertal Progression in Children with HIV

In conjunction with poor growth, children with HIV may have delay in pubertal progression [8]. Immune activation and chronic inflammation likely contribute to pubertal delay, whereas inadequate or delayed cART, OIs, and concomitant malnutrition are exacerbating factors [8]. Later age at cART initiation, lower CD4+ T-cell count, and higher viral load are associated with greater delays [8]. Pubertal delay may contribute to the reductions in bone mineral density seen in children and adults with HIV.

Gonadal Function in Men

Hypogonadism is common in men with untreated HIV, particularly in the advanced stages of disease and among patients with HIV-associated weight loss. In an early study, 6% of asymptomatic HIV-infected men demonstrated hypogonadism compared to 50% of men with CDC-defined AIDS [12]. The prevalence of hypogonadism in men with HIV who are receiving effective cART is much lower than in untreated men but still higher than the general population [13]. On average, men with HIV have lower morning free testosterone levels, and the slope of decrease in free testosterone with age is similar among men with and without HIV [13]. Of note, sex hormone binding globulin (SHBG) is elevated by 40–50% in individuals with HIV. Screening for hypogonadism in HIV should occur in the morning, using either a reliable free testosterone assay or calculation of bioavailable testosterone through assessment of total testosterone and SHBG. Hypogonadism should be confirmed with a second assessment.

The mechanisms underlying hypogonadism in men with HIV are shown in Box 12.1.5.1. Hypogonadism is most commonly pituitary

Box 12.1.5.1 Mechanisms of gonadal dysfunction in HIV

Primary hypogonadism
Infiltrative disorders of the testes
Cytomegalovirus
Toxoplasmosis
Kaposi's sarcoma
Germ cell neoplasm
Lymphoma
Idiopathic

Secondary hypogonadism
Severe illness
Malnutrition
Infiltrative disorders of the pituitary/hypothalamus
Cytomegalovirus
Toxoplasmosis
Lymphoma
Adenohypophyseal necrosis
Medications (megestrol acetate, glucocorticoids)

or hypothalamic in origin, related to an effect of severe acute illness or undernutrition on gonadotropin production. Less commonly, men with HIV may develop primary hypogonadism due to anatomic destruction of testicular tissue by opportunistic infection. Hypothalamic and/or pituitary destruction from opportunistic infection (e.g. cytomegalovirus (CMV)) severe enough to cause panhypopituitarism and gonadal failure have also been reported in a small number of patients. Medications may also suppress the pituitary gonadal axis. Megestrol acetate suppresses gonadotropin secretion because of its glucocorticoid-like properties, and ketoconazole may cause primary hypogonadism by inhibiting enzymes in testicular steroidogenesis.

Androgen Therapy in Men with HIV Infection

Hypogonadism in men with HIV is associated with decreased lean body mass and diminished exercise capacity as well as increased indices of depression. Physiologic testosterone replacement increases lean mass and improves patient report of overall quality of life, appearance, and well-being. In men with HIV-associated abdominal fat accumulation, testosterone levels may also be decreased, but testosterone therapy in this population has no effect on visceral adiposity in spite of reductions in total and subcutaneous abdominal fat mass [14].

In addition to monitoring testosterone levels, laboratory monitoring during testosterone administration should include prostate specific androgen (PSA) measurement, HDL, which may decrease during therapy, and haematocrit, which may increase. Among patients who achieve stable weight and/or experience improved virologic control, discontinuation of testosterone, and reassessment of gonadal function by morning measurement of bioavailable testosterone level may be appropriate, as androgen concentrations may improve with nutritional and immunologic recovery.

Gonadal Function in Women with HIV Infection

Amenorrhea is common among women with advanced HIV disease, with the prevalence approaching 40% in women with severe HIV-related wasting. In women without an AIDS-defining illness, oligomenorrhea may be up to ten times more prevalent and amenorrhea up to seven times more prevalent than in HIV-negative controls [15]. Compared to the HIV-negative population, women with HIV have lower oestrogen levels and higher SHBG levels [16] and may have earlier menopause.

In addition, androgen deficiency is highly prevalent among women with HIV, particularly among those with wasting. In a cohort of women studied prior to the cART era, over 50% of women with wasting and more than one-third of normal weight patients demonstrated serum free testosterone concentrations below the lower limit of normal for healthy age-matched women. A more recent cohort also demonstrates lower testosterone and dehydroepiandrosterone sulphate (DHEA-S) concentrations in women with HIV compared to controls. Importantly, androgen deficiency in women with HIV is associated with decreased bone mineral density and may also be associated with increased cardiovascular risk [16]. The aetiology of the androgen deficiency is unknown but may relate to intra-adrenal shunting away from androgen production toward cortisol synthesis; in women with HIV-related wasting, DHEA-S levels are low compared to controls and correlate with decreased androgen levels.

Multiple studies have investigated physiologic transdermal testosterone replacement (150–300 mcg daily) in women with HIV, with some studies showing improvements in lean body mass, bone mineral density at the hip, sexual function, and depression indices. Transdermal testosterone has not received regulatory approval for the treatment of androgen deficiency in women with HIV. DHEA supplementation has also been investigated as a means of increasing testosterone and dihydrotestosterone as well as improving mood, but the safety profile and effects of DHEA on body composition are not known [17].

Adrenal Function

Adrenal function is typically normal in individuals with effectively treated HIV, but the adrenal axis may be affected in advanced HIV disease. In these cases, subclinical impairment of adrenal function is more common than frank adrenal insufficiency. Adrenal impairment is most often associated with anatomic destruction of the adrenal glands or anterior pituitary due to OIs, or to use of medications that suppress adrenal function. In contrast, increased cortisol concentrations may also be seen in HIV-infected patients, typically due to stress activation of the hypothalamic–pituitary–adrenal axis or intra-adrenal shunting toward cortisol synthesis.

Adrenal Insufficiency

Although adrenal insufficiency is rare in individuals with virologic control from cART, adrenal impairment is relatively common in patients with progressive HIV infection or AIDS. Impaired adrenal reserve may precede clinical adrenal insufficiency, as asymptomatic men with HIV demonstrate progressively increased plasma corticotropin (ACTH) concentrations over time in spite of normal cortisol responses to synthetic ACTH [18]. Individuals with advanced HIV disease are at higher risk for frank adrenal insufficiency. In a relatively large study of 93 patients with AIDS or AIDS-related complex (ARC), 4% of patients exhibited clinical adrenal insufficiency, whereas 54% had subnormal cortisol responses to synthetic ACTH indicating marginal adrenal reserve [19]. Adrenal insufficiency in individuals with HIV is most often related to tissue destruction of the adrenal glands by OIs (Box 12.1.5.2). Cytomegalovirus (CMV), mycobacterium avium intracellulare (MAI), and cryptococcus may damage adrenal tissue. Glandular destruction does not typically exceed more than 50% of adrenal tissue, however, and is therefore unlikely to result in frank adrenal insufficiency in most cases. Kaposi sarcoma, lymphoma, and haemorrhage may also cause adrenal damage in advanced HIV. Secondary adrenal insufficiency related to pituitary infiltration from disseminated toxoplasma gondii, cryptococcus, and CMV has also been reported in patients with AIDS.

Assessment and Treatment of Adrenal Insufficiency

Routine assessment of adrenal function is not indicated in asymptomatic individuals with HIV but should be performed in patients with advanced disease who have significant fatigue, inanition, hypotension, or hyponatraemia. Patients with known disseminated CMV or MAI are at increased risk. Testing should proceed with either a morning cortisol concentration or with cosyntropin administration (0.25 mg of ACTH 1–24). The cosyntropin test is misleading,

Box 12.1.5.2 Mechanisms of adrenal dysfunction in HIV

Primary adrenal insufficiency
Cytomegalovirus
Mycobacterium tuberculosis
Mycobacterium avium intracellulare
Cryptococcus neoformans
Kaposi's sarcoma
Haemorrhage
Lymphoma

Secondary adrenal insufficiency
Adenohypophyseal necrosis
Cytomegalovirus
Toxoplasmosis gondii
Lymphoma
Medications (megestrol acetate, ketoconazole, rifampin, opiates, ritonavir, glucocorticoids)

Hypercortisolism
Stress response to illness
Intra-adrenal shunting toward cortisol synthesis
Cytokine modulation
Glucocorticoid resistance
Medications (concurrent use of ritonavir and fluticasone)

however, if secondary adrenal insufficiency is of relatively acute onset, in which case testing with metyrapone or insulin tolerance testing is indicated. Of note, the insulin tolerance test should not be performed in certain circumstances, for example if patients are older, or have known heart disease or seizures. Long-term therapy includes mineralocorticoid and glucocorticoid replacement in primary adrenal insufficiency and glucocorticoid administration alone in secondary adrenal insufficiency.

Medication Effects

Medications such as megestrol acetate, ketoconazole, rifampin, and opiates are known to affect adrenal function. Ketoconazole inhibits multiple cytochrome-P450 dependent steroidogenic enzymes, including the side chain cleavage and 11-hydroxylase enzymes, and decreases cortisol synthesis in a dose dependent manner. Fluconazole and itraconazole are much less likely to cause adrenal insufficiency. Rifampin, an antituberculous agent, increases the metabolism of cortisol and may precipitate adrenal insufficiency in the setting of known hypoadrenalism or decreased adrenal reserve. In addition, megestrol acetate, a synthetic progestational agent approved for use as an appetite stimulant in patients with HIV-related wasting, decreases adrenal function through a glucocorticoid-like effect on the hypothalamic–pituitary–adrenal (HPA) axis. Chronic use of megestrol acetate may result in Cushingoid symptoms, and rapid withdrawal of megestrol acetate may cause adrenal insufficiency. Furthermore, megestrol acetate use can aggravate underlying glucose intolerance and diabetes mellitus in patients with HIV.

Hypercortisolism, HPA Activation, and Glucocorticoid Resistance

Individuals with HIV may demonstrate increased cortisol levels. Although this is most often due to a stress response to illness, studies have also demonstrated intra-adrenal shunting toward cortisol synthesis, potentially due to 17,20 lyase dysfunction. Cytokine modulation of the HPA axis is another potential mechanism for hypercortisolism in patients with HIV. Anomalous cases of clinical adrenal insufficiency with normal or elevated cortisol concentrations have also been reported in individuals with HIV in association with glucocorticoid resistance due to abnormal glucocorticoid receptors [20]. Finally, Cushing's syndrome has been described in individuals with HIV concurrently taking fluticasone and ritonavir, secondary to ritonavir's inhibition of CYP3A4, which prevents metabolism of fluticasone. Discontinuation of fluticasone in this setting can lead to severe adrenal insufficiency. Interactions between ritonavir and other steroids have also been reported.

Thyroid Function

Abnormal thyroid function may accompany HIV, although subtle laboratory abnormalities are more common that overt hyper- or hypothyroidism. Thyroid binding globulin (TBG) levels increase in both adults and children with HIV, correlating positively with severity of illness. Several studies indicate that subclinical hypothyroidism, indicated by elevated thyroid-stimulating hormone (TSH) with normal T_3 and T_4 levels, is also relatively common in individuals with HIV, with prevalence ranging from 3% to 12% [21]. Antithyroid peroxidase antibodies are commonly negative in these patients [21], arguing against an autoimmune aetiology. In addition to subclinical hypothyroidism, the prevalence of isolated low free thyroxine levels (without increased TSH) may also be increased in HIV infection [21]. Paediatric data demonstrate a high prevalence (approximately 20%) of isolated low free T_4 in children with HIV, with free T_4 levels directly associated with CD4+ count [22]. Development of hyperthyroidism due to Graves' disease has also been reported in individuals with HIV several months following initiation of cART, potentially as a late manifestation of immune reconstitution [21].

In patients with advanced HIV disease, overt hypothyroidism may result from infiltration of the pituitary or thyroid by OIs. *Pneumocystis jirovecii* may cause a pneumocystis thyroiditis characterized by painful gland enlargement; depending on the extent of necrosis, thyroid function may remain normal, or patients may develop hypothyroidism, sometimes preceded by a brief period of hyperthyroidism [21]. In addition, the severity of HIV disease, as well as undernutrition and weight loss, may lead to thyroid function test abnormalities similar to those in non-thyroidal illness (i.e. 'euthyroid sick syndrome'). In advanced HIV, however, both T_3 and reverse T_3 (rT_3) tend to be reduced in direct association to serum albumin and surrogate measures of muscle mass, in contrast to the rT_3 elevations typically found in non-thyroidal illness.

Bone Health, Calcium, and Vitamin D

Calcium and Vitamin D

Vitamin D insufficiency is relatively common in individuals with HIV, as in the general population, and vitamin D deficiency may be associated with more rapid disease progression [23]. People with HIV share many risk factors for vitamin D deficiency with the general population, and, additionally, some types of cART reduce vitamin D. Use of efavirenz, a non-nucleoside reverse

transcriptase inhibitor (NNRTI), is associated with vitamin D deficiency [24]. In addition, *in vitro* studies demonstrate that PIs inhibit both 25-hydroxylation and 1-alpha hydroxylation, while also mildly inhibiting 24-hydroxylation, with a net effect of decreasing 1,25 dihydroxyvitamin D production [25]. Guidelines recommend checking 25-hydroxyvitamin D levels in individuals with HIV and risk factors for deficiency, including dark skin, malnutrition, or malabsorption, obesity, efavirenz use, and chronic kidney disease [26].

Severe HIV infection may be associated with hypocalcaemia, with mechanisms including malabsorption, vitamin D deficiency, abnormal protein binding, medication effects, hypomagnesaemia, and altered parathyroid function. The intestinal tract of patients with advanced HIV is often the target of OIs, which may result in malabsorption of calcium and vitamin D. Hypocalcaemia associated with severe illness most often results from hypoalbuminemia and abnormal protein binding.

Bone Density and Fracture Risk in HIV Infection

Bone mineral density (BMD) is decreased in both children and adults with HIV [27, 28]. In children, lower BMD appears to be related to increasing severity of disease as well as decreased height-for-age, weight-for-age, and IGF-1 levels [27]. In adults, decreased bone density has been associated with decreased gonadal steroids, decreased vitamin D levels, lower IGF-1, lower body mass index (BMI) and/or weight loss, visceral fat accumulation, duration of HIV, and increasing severity of disease. In a large longitudinal analysis, decreased BMD over time was predicted by low body weight, albumin, corticosteroid use, and menopause, whereas strength training was protective [29]. With regard to the effect of antiretrovirals on bone density, one NRTI, tenofovir disoproxil fumarate (TDF), has a clear effect to reduce bone density. Additionally, PIs 'boosted' with ritonavir appear to decrease BMD to a greater degree than other regimens [26].

Reduced BMD in individuals with HIV translates into increased fracture risk. In an epidemiologic study in a large healthcare system, women with HIV were more likely to sustain vertebral and wrist fractures than non-HIV-infected patients, and men with HIV were more likely to sustain any fracture compared to non-HIV-infected patients. The overall fracture prevalence in the combined cohort was 2.87 fractures per 100 persons in the HIV-infected group vs. 1.77 fractures per 100 persons in the uninfected controls [30]. A study of Canadian women demonstrated a similar increase in risk, with women with HIV 1.7 times more likely to sustain low-impact fractures than uninfected women [31].

Screening and Treatment of Osteopenia and Osteoporosis in HIV

Strategies for screening and management of osteopenia and osteoporosis are shown in **Box 12.1.5.3** [26]. For individuals with HIV and osteopenia or osteoporosis, contributing endocrine conditions or medications should be considered. Hypogonadism may contribute to reduced bone density, and physiologic testosterone replacement in women with HIV and reduced androgen levels significantly increased bone density over 18 months. For individuals receiving TDF, switching to tenofovir alafenamide (TAF) significantly improves BMD by 2–3% after 144 weeks [32]. The bisphosphonates alendronate and zoledronic acid have also proven safe and effective to increase BMD in patients with HIV [26]. There have not yet been studies assessing the effects of exercise, androgen, or bisphosphonate on fracture risk in the HIV-infected population.

Box 12.1.5.3 Summary of recommended management of bone health in HIV [26]

Screening

25-hydroxyvitamin D deficiency

Indications: low BMD, history of fracture, or major risk factor(s) for vitamin D deficiency, including efavirenz use, dark skin, malnutrition or malabsorption, obesity, or chronic kidney disease

Frequency: per clinical judgement

Fracture risk assessment by FRAX score

Indications: men 40–49 yo and premenopausal women ≥40 yo without major risk for fragility fracture

Frequency: every 2–3 years, or with development of a new clinical risk factor

Bone density assessment with DXA

Indications: (1) men 40–49 yo and premenopausal women ≥40 yo with intermediate- or high-risk stratification by FRAX; (2) all postmenopausal women; (3) all men ≥50 y; (4) all adults with major fragility fracture risk factors regardless of age

Frequency: Consider repeat every 1–2 years if advanced osteopenia, every 5 years if moderate osteopenia, or up to every 15 years if normal bone density

Management

Lifestyle optimization

Interventions: Increased weight bearing exercise, smoking cessation, avoidance of excessive alcohol use, fall prevention

Indications: All patients with HIV

Calcium and vitamin D optimization

Interventions: (1) Calcium: ensure 1000 mg daily for men 50–70 yo, or 1200 daily for women ≥51 yo and men ≥71 yo; (2) Vitamin D: ensure 1000 IU daily if 25-hydroxyvitamin D levels normal; if insufficient or deficient, treat with higher doses until serum 25-hydroxyvitamin D >75 nmol/L (30 ng/ml)

Indications: All patients with HIV

Treatment of osteoporosis

Intervention: (1) If possible, discontinue or prescribe alternatives for medications that cause bone loss, including glucocorticoids and TDF. (2) Alendronate or zoledronic acid

Indications: Bisphosphonates should be prescribed according to country- or region-specific guidelines for treatment of osteoporosis in the general population

Osteomalacia and Osteonecrosis

Osteomalacia may occur in individuals using efavirenz or TDF or in those with severe vitamin D deficiency [26]. Additionally, individuals with HIV are at risk for osteonecrosis, typically occurring at the femoral head [33]. Though the mechanisms are unknown, case-control studies demonstrate a significantly increased risk with exposure to antiretroviral medications [33]. Other identified risk factors include alcohol consumption, use of corticosteroids, a prior AIDS-defining illness, and low CD4+ count. Although the absolute incidence of osteonecrosis remains relatively low, estimated at approximately 0.2 to 0.6 cases per 100 person-years, individuals with HIV appear to have increased risk over the general population [34].

Salt and Water Balance

In general, patients on effective cART are not expected to have abnormalities in fluid balance or electrolytes, although these may occur in advanced illness. Recent evidence suggests more subtle perturbations of the renin angiotensin aldosterone system (RAAS), however, with increased aldosterone in individuals with HIV compared to non-infected individuals [35]. RAAS activation appears to be associated with visceral adiposity and insulin resistance in HIV, although more study is needed to determine if therapeutic targeting of RAAS improves body composition or metabolic health.

Sodium

Sodium and water balance may be disturbed in advanced HIV disease, most commonly manifesting as hyponatraemia secondary to syndrome of inappropriate antidiuretic hormone secretion (SIADH). Certain medications such as vidarabine, miconazole, and pentamidine are associated with hyponatraemia of unknown aetiology. Hypernatraemia and nephrogenic diabetes insipidus have been reported with foscarnet therapy and also in association with CMV infection of the hypothalamus.

Potassium

Diarrheal OIs may lead to hypokalaemia in patients with advanced HIV disease. In addition, TDF has been associated with development of renal Fanconi's syndrome, with accompanying hypokalaemia, hypophosphatemia, and acidosis. Foscarnet therapy for CMV has also been associated with hypokalaemia, hypomagnesaemia, and hypophosphatemia.

Lipid Metabolism

HIV is associated with abnormalities in lipid metabolism, with decreased HDL and decreased low-density lipoprotein (LDL) occurring early in the disease [36]. Triglyceride levels also increase in HIV infection in conjunction with increased *de novo* hepatic lipogenesis [36]. These lipid abnormalities are seen in children as well as adults. In patients receiving cART, hypertriglyceridemia may be more pronounced, particularly in patients with altered fat distribution (Figure 12.1.5.2) [37]. Moreover, in contrast to patients with untreated HIV, in whom LDL is often low, patients receiving cART may demonstrate an increase in LDL to pre-HIV levels or beyond [36, 38]. The lipid profile often depends on the specific components of the antiretroviral regimen, with some PIs demonstrating particularly adverse effects. In one large cohort comparing antiretroviral naïve patients to those on different cART regimens, use of PI and NRTI was associated with 27% prevalence of hypercholesterolemia (total cholesterol ≥ 6.2 mmol/L) and 40% prevalence of hypertriglyceridemia (triglyceride ≥ 2.3 mmol/L), compared to 8% and 15% prevalence, respectively, in antiviral naïve patients [39]. A significant effect of PIs on lipids is also seen in paediatric cohorts. Newer classes of cART, such as integrase inhibitors and fusion inhibitors, as well as newer agents in the NRTI, PI, and NNRTI classes, may have fewer adverse effects on lipid profile.

Individuals with HIV should have lipid panels obtained at the initiation of care and routinely thereafter [40]. As in the general population, lifestyle changes and exercise are an important initial treatment strategy for dyslipidaemia, and formal exercise programmes effectively reduce triglyceride and total cholesterol in individuals with HIV [41]. If an individual is receiving a cART regimen with particularly adverse effects on lipid, such as a regimen with 'boosted' PI, switching to another regimen with more favourable lipid effects can be considered if feasible. If pharmacotherapy is needed, medical treatment of dyslipidaemia in HIV-infected patients currently follows the same principles as treatment of lipid abnormalities in the general population, although the known increase in cardiovascular risk in HIV may argue for more aggressive treatment. Interactions between lipid-lowering agents and antiretrovirals may alter therapeutic options [41, 42]. For instance, many PIs are metabolized by CYP3A4, affecting HMG-CoA reductase concentrations. Lovastatin and simvastatin are contraindicated with many PIs. Rosuvastatin may also interact with specific PIs and may require dose adjustment. Pravastatin and pitavastatin are not metabolized by CYP3A4 and may be given safely [43]. A study comparing treatment in HIV-infected vs. uninfected individuals showed similar LDL-lowering benefit in both groups [43]. In addition, studies suggest that statins improve endothelial function in HIV-infected patients [42] and reduce non-calcified plaque volume and high-risk plaque features. A multinational study investigating the benefit of statins on primary CVD prevention in the HIV-infected population is ongoing.

Many patients with HIV demonstrate significant hypertriglyceridemia (>500–900 mg/dl or >5.65–10 mmol/L), which can be treated with gemfibrozil or fenofibrate [41]. Omega-3 fatty acids may also be effective.

Glucose Homeostasis

In HIV-infected individuals naïve to antiretrovirals, glucose abnormalities are rare and caused most often by pancreatic damage and reduced insulin secretion from pentamidine administration or hyperglycaemia from megestrol acetate. For individuals treated with cART, however, impaired glucose tolerance is relatively common, particularly in patients with HIV-associated fat redistribution. In one cohort, 35% of patients with HIV lipodystrophy had impaired glucose tolerance (IGT), and 7% had frank type 2 diabetes that had been previously undiagnosed (see Figure 12.1.5.2) [37]. A more recent study demonstrated a 14% prevalence of diabetes in a large group of HIV-infected individuals receiving cART (with or without lipodystrophy) compared to a 5% prevalence in uninfected controls [44]. With the development of newer antiretroviral agents, the incidence of diabetes appears to be decreasing in HIV, suggesting that much of the dysglycaemia in HIV is due to specific medication effects.

With the high prevalence of IGT and diabetes in HIV-infected individuals, evaluation of glucose homeostasis is important in this population, particularly in patients with changes in fat distribution. Notably, haemoglobin A1c values may underestimate glycaemia in HIV-infected individuals, particularly those receiving NRTIs, such that fasting glucose may be a more accurate method for diagnosing diabetes in this population [45]. As in the general population, lifestyle modification is first line for individuals with glucose intolerance and early diabetes. Additionally, if an individual is receiving

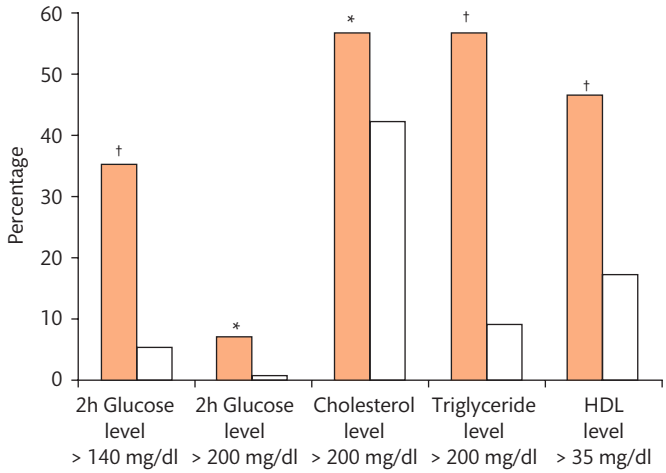

Figure 12.1.5.2 Percentages of impaired glucose tolerance, diabetes, and elevated lipids in a cohort of individuals with HIV lipodystrophy (dark bars) vs. Framingham controls (white bars) matched for sex, age, and BMI. *p <0.05, †p <0.001 for comparison of unadjusted odds ratios between groups.

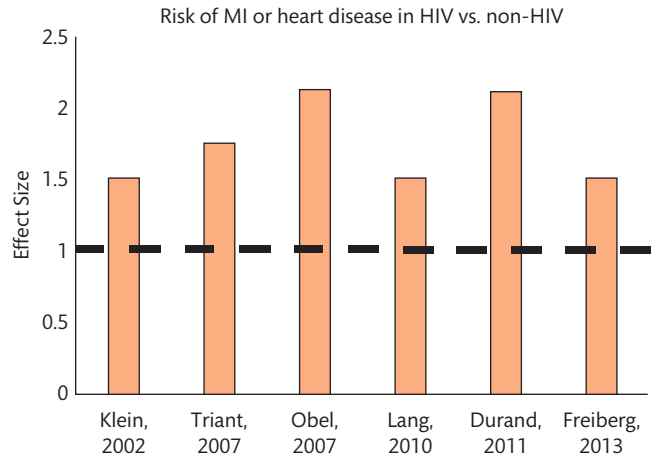

Figure 12.1.5.3 Relative risks for myocardial infarction (MI) or heart disease in various cohort studies in individuals with HIV infection compared to those without. In all studies, the HIV group was comprised, at least in part, of individuals treated with cART [47, 50–54]. The dotted line at 1 would indicate no increased risk conferred by HIV.

lopinavir/ritonavir, zidovudine, or stavudine, all of which have particularly adverse effects on glucose homeostasis, a switch in cART could be considered if feasible. For treatment of insulin resistance and diabetes in HIV, metformin is first line and may also modestly improve body composition and cardiovascular risk. Metformin may interact with dolutegravir, requiring reduced metformin dose. In patients with peripheral lipoatrophy, thiazolidinediones (TZDs) are an alternative potential strategy to both improve insulin resistance and increase limb fat, but use of TZDs is limited due to adverse cardiovascular effects as well as weight gain. The other antidiabetic agents available for general use (sulfonylureas, glucagon-like peptide 1 (GLP-1) analogues, gliflozins, dipeptidyl peptidase 4 (DPP-IV) inhibitors, and meglitinides) can also be used [45], although currently none of these is extensively studied in the HIV population. For all of these agents, drug monographs should be consulted to assess for cytochrome P450 interactions that would affect antiretroviral concentrations. Insulin therapy is the preferred second-line medication, following metformin, if HbA1c is over 8.5% [45].

Cardiovascular Risk

Numerous studies have demonstrated increased rates of coronary heart disease and approximately twice the rate of myocardial infarction in HIV-infected individuals compared to the general population (Figure 12.1.5.3). Although increased CVD risk relates in part to traditional risk factors such as dyslipidaemia, dysglycaemia, and smoking, HIV-related mechanisms such as immune activation, increased microbial translocation, and virus-mediated changes in cholesterol metabolism also seem to play a large role [46]. In a large veterans' cohort in the United States, the hazard ratio of myocardial infarction was 1.48 (95% confidence interval 1.27–1.72) in individuals with HIV after adjusting for comorbidities, substance use, and traditional risk factors as measured by Framingham Risk Score [47]. Multiple markers of immune activation, including soluble CD163 and soluble CD14, are elevated in HIV and strongly associated with increased CVD risk [46]. These markers decrease with cART but remain elevated above levels found in non-infected controls. Additionally, serum markers of microbial translocation are elevated in HIV and are associated with measures of subclinical atherosclerosis, suggesting that impaired gut integrity in HIV may contribute to chronic inflammation and CVD risk [46]. Trials to reduce immune activation and inflammation in hopes of decreasing CVD risk are an active area of investigation in HIV. Some evidence has suggested that certain antiretroviral agents may increase the risk of CVD, but there is not clear evidence that newer cART regimens increase risk. A study of continuous cART versus an intermittent regimen based on CD4+ count demonstrated higher cardiovascular risk in the intermittent regimen [48], in association with higher systemic inflammatory markers [49]. These results suggest that sustained cART, by achieving viral suppression and reducing systemic inflammation, may actually lower CVD risk, but further research is needed.

Given the adverse cardiometabolic effects of HIV just described, effective treatment of risk factors for cardiovascular disease is crucial for HIV-infected patients. As in the general population, prevention strategies include smoking cessation as well as screening and treatment for dyslipidaemia, hypertension, and disordered glucose metabolism [42].

Summary

HIV is associated with a number of endocrine abnormalities, largely dependent on the stage of disease and the medications used for therapy. In individuals with advanced HIV disease or AIDS, OIs and the medications used to treat them often play a role by damaging endocrine organs and altering hormone synthesis. Weight loss is a predictor of mortality in this group, and clinicians should be aware of strategies to increase lean body mass, including

physiologic androgen replacement and potentially GH. In contrast, HIV-infected individuals treated with cART may present quite differently, with visceral adiposity, relative GH deficiency, hyperlipidaemia, and altered glucose homeostasis. In these patients, management of hyperlipidaemia, impaired glucose metabolism, and CVD risk is of primary concern. HIV-infected patients generally demonstrate decreased bone density, increased prevalence of subclinical thyroid disease, and increased cardiovascular risk as evidenced by increased myocardial infarction rate as well as increased carotid intima-media thickness. Children with HIV also demonstrate many of these abnormalities and may also present with growth failure, particularly in severe disease.

12.1.6 The Endocrinology of Anorexia Nervosa

Karen K. Miller

Introduction

Sir William Gull, a personal physician to Queen Victoria, coined the term 'anorexia nervosa' in the 1860s to describe a syndrome of wasting in young female patients, for which he could discern no organic cause, such as tuberculosis, which was a common cause of such signs and symptoms at the time [1]. He surmised that anorexia nervosa was of primary psychiatric origin—a construct that persists today. The most recent psychiatric diagnostic criteria (published in 2013) are delineated in the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (*DSM-5)*, which defines anorexia nervosa as a disorder characterized by food restriction leading to low weight, an intense fear of gaining weight or becoming fat (or persistent behaviours designed to prevent weight gain), and altered body image (such that the patient is convinced that she is

overweight when she is not). With the recognition that there are a wide range of physical manifestations of this psychiatric syndrome, these revised diagnostic criteria relaxed the weight criteria and removed the amenorrhoea requirement that had been included in the prior diagnostic criteria [2]. Moreover, DSM-V added a number of additional diagnostic criteria, including 'atypical anorexia nervosa', in which patients share the psychiatric characteristics of anorexia nervosa, but without low weight [2].

Anorexia nervosa is a common disorder, particularly in adolescent girls and young women. It has a prevalence of 0.3 to 3% in women [3] and it ranks third in prevalence among chronic disorders in adolescent girls [4]. However, it should be noted that the disorder also affects older women and men, though much less frequently. Therefore, very little is known about the endocrine complications of the disorder in these groups, and this chapter will focus on endocrine dysregulation in girls and women with anorexia nervosa.

Anorexia nervosa is biologically a disorder in which chronic starvation affects multiple endocrine systems, including classic hypothalamic–pituitary, adipokine, and satiety pathways. Much of this dysregulation is adaptive to the starved state and reverses with nutritional recovery. However, it remains relevant because the psychiatric disorder is chronic in approximately 50% of women [5], and because endocrine dysregulation can have long lasting consequences on skeletal, and other aspects of, health.

Hypothalamic–Pituitary Axis Dysregulation

Electrolyte disturbances, particularly **hyponatraemia** and hypokalaemia, occur in 20% of women with anorexia nervosa [6]. Hyponatraemia can be caused by syndrome of inappropriate antidiuresis (SIAD) and/or primary polydipsia and rarely results in seizures. **Diabetes insipidus** has also rarely been reported. Hypokalaemia is associated with purging behaviours (self-induced vomiting, laxative overuse, and/or diuretic use). See Table 12.1.6.1 [7].

Table 12.1.6.1 Endocrine dysfunction in women and adolescent girls with anorexia nervosa

	Women and adolescent girls with anorexia nervosa	Implicated in bone loss
Hypothalamic amenorrhoea	✓	✓
GH resistance	✓	
↑GH	✓	
↓GF-1	✓	✓
Hypercortisolaemia	✓	✓
Appetite hormone dysregulation	✓	
↑PYY	✓	✓
↓Leptin	✓	
↑Ghrelin	✓	

Abbreviations: IGF-1, insulin-like growth factor I; PYY, peptide YY.

Non-thyroidal illness is a common complication of this disorder [8]—and is adaptive to the starved state. For this reason and because of the potential for levothyroxine abuse to induce weight loss, levothyroxine therapy should only be prescribed for frank hypothyroidism.

Hypothalamic amenorrhoea is a common—but not universal—complication of anorexia nervosa and results in relative oestrogen, androgen, and progesterone deficiency. Our understanding of the interplay of starvation, the hypothalamic–pituitary–gonadal axis and fat stores has advanced since the 1970s, when Drs Frisch and McArthur published their seminal work describing a 'minimum weight for height' required for menarche [9]. In the same decade, Boyar *et al.*, published important work demonstrating luteinizing hormone (LH) apulsatility in women with anorexia nervosa, which recovered to normal with weight gain [10]. However, Dr Boyar's group also noted that this seemingly clear construct, in which starvation results in near total cessation of gonadotropin-releasing hormone (GnRH) secretion by the hypothalamus, does not capture the complexity of the hypothalamic–pituitary–gonadal (HPG) axis in women with anorexia nervosa. In addition to the absence of GnRH—and therefore LH—pulsations, they described a number of other patterns, including LH pulsatility only at night, as seen in normal late puberty [10]. They also demonstrated that the severity of derangement of LH pulsatility is not directly related to the length of time the patient has been suffering from the disease or the degree of low weight. Moreover, they demonstrated that weight gain did not reliably result in return of menses [11]. In fact, approximately 15% of women with anorexia nervosa remain amenorrhoeic despite weight gain to a 'healthy' level [12]. Whether the lack of recovery of reproductive function in such women reflects hypothalamic or pituitary atrophy due to prolonged suppression, a resetting of the HPG axis, continued psychologic stress, lack of sufficient fat mass despite weight gain and/or other factors, is unknown.

The importance of adequate fat mass to initiate and sustain normal reproductive function has mostly focused on the adipokine leptin, a 16 kDa peptide secreted by adipocytes which is permissive (necessary) for normal reproductive function. Leptin is an anorexigenic hormone. However, its primary function appears to be as a signal of inadequate energy stores to the reproductive, and other, systems. Evidence in humans of leptin's key role in regulating reproduction include that congenital leptin deficiency is complicated by hypogonadotropic hypogonadism [13]. Rodent data demonstrate that leptin deficiency is a critical link between starvation and hypothalamic amenorrhoea. In an elegant study, Ahima *et al.* showed that whereas acute starvation delayed the rodent equivalent of ovulation (oestrous), simultaneous administration of leptin to 'normal' blood levels (levels characteristic of non-starved mice) resulted in normal reproductive function [14]. Although, mean serum leptin levels are lower in women with anorexia nervosa who experience amenorrhoea than in those without amenorrhoea [15], there is considerable overlap in individual levels between these two groups. This demonstrates the considerable complexity and variable intraindividual vulnerability of the female reproductive system to stress and also highlights the lack of utility of leptin levels in clinical practice when, for example, setting weight goals for recovery in women with hypothalamic amenorrhoea due to anorexia nervosa [15]. In a study of eight healthy-weight women with hypothalamic amenorrhoea (BMI 18.8–24.4 kg/m^2), leptin administration resulted in ovulatory cycles

in three. However, because of the resultant weight loss (to be expected because leptin is an anorexigenic hormone) [16], it cannot be used in women with anorexia nervosa in whom nutritional repletion must be the primary goal. Other putative mediators of reproductive function have been studied. Although the role of kisspeptin, the endogenous ligand for the hypothalamic kisspeptin receptor, has not been studied in women with anorexia nervosa, acute administration of kisspeptin increases gonadotropin release in healthy-weight women with hypothalamic amenorrhoea [17].

In addition to hypo-oestrogenaemia, the effects of hypogonadism in women with anorexia nervosa also include androgen and progesterone deficiency. Both testosterone and free testosterone levels are reduced in women with anorexia nervosa, with a further reduction in free testosterone in women with the syndrome who also take oral contraceptives [18]. Low androgen levels result from a reduction of ovarian, not adrenal, precursors [19], consistent with the diagnosis of hypothalamic amenorrhoea, though there are conflicting data as to whether adrenal pre-androgen levels are normal or low in girls and women with anorexia nervosa [18, 20]. When considering the end organ effects of hypothalamic amenorrhoea in girls and women with anorexia nervosa, the effects of oestrogen, progesterone, and androgen deficiencies should all be considered. If one extrapolates from men with regard to the effects of testosterone deficiency, one could surmise that women with relative androgen deficiency might experience decreased muscle mass and bone mineral density (BMD), and depressed mood. However, testosterone levels are ten to 20 times lower in healthy women than men and therefore direct extrapolation is not possible. A small randomized study of low-dose transdermal testosterone (300 mcg daily) administration demonstrated increases in lean body mass but not BMD [21], and a cross-sectional study demonstrated an inverse association between severity of depression and anxiety symptoms and free and total testosterone levels [22, 23]. However, a small, randomized, placebo-controlled trial of low-dose transdermal testosterone showed no improvement in weight, eating disorder cognition or depression symptom severity. Therefore, there is no evidence that testosterone administration ameliorates such symptoms. Moreover, there are no FDA-approved testosterone preparations that deliver appropriate female doses, and the long-term effects of testosterone replacement therapy in women are unknown.

GH resistance is another endocrinopathy observed in girls and women with anorexia nervosa. That GH levels are relatively high in association with acute and chronic fasting was first reported in a classic paper by Roth *et al.* in 1963 in *Science*—the same publication in which the insulin tolerance test was described [24]. Later it was shown that despite the relatively high GH concentrations in women with anorexia nervosa (basal levels four times higher and pulsatile release 20-times greater than in healthy controls) [25], insulin-like growth factor 1 (IGF-1) levels (total and bioactive) are relative low, consistent with a state of resistance at the level of the liver to the effects of GH [26]. This is because nutrition and insulin are required for IGF-1 production by GH in the liver [27].

Hypercortisolaemia is present in approximately one-third of girls and women with anorexia nervosa, as originally shown by Boyar and colleagues [8]. Some studies have shown that hypercortisolism may not be dexamethasone-suppressible and can, but does not always, reverse with restoration of weight. Despite low weight, the consequences of hypercortisolaemia in girls and women with anorexia nervosa share some similarities with those with Cushing's syndrome, with disproportionate accumulation of trunk fat during recovery [28] and bone loss [29], the latter remained significant after controlling for months of amenorrhoea, age, and IGF-1 levels (though low body weight, a determinant of both high cortisol and low BMD was not included in the statistical models). A positive result of hypercortisolaemia—perhaps mediated by the relative increase in trunk fat observed—is that girls with anorexia nervosa and relatively higher cortisol levels are more likely to regain menses during the following year [30].

Satiety Pathway Dysregulation

Some appetite-regulating hormone pathways are also dysregulated in girls and women with anorexia nervosa (Table 12.1.6.1). One would expect low levels of anorexigenic hormones and high levels of orexigenic hormones in individuals with low weight, and in some cases, this is what is seen in girls and women with anorexia nervosa. For example, serum leptin levels are relatively suppressed, as would be predicted from low fat mass and anorexigenic effects of leptin [31, 32]. Moreover, as one would expect in a low-weight population, mean systemic levels of ghrelin, an orexigenic hormone, are elevated in girls and women with anorexia nervosa [33–35]. However, there are some contradictory studies, including one which demonstrated low mean ghrelin levels in women with binge-purge-type anorexia nervosa [36] and another which reported a greater reduction in ghrelin levels during a euglycemic hyperinsulinaemic clamp than controls [37]. The authors hypothesized that this exaggerated response contributes to a feeling of satiety in such women and as such could be contributing to the maintenance of the disorder.

Moreover, contrary to what would be predicted in a low-weight, low-caloric-intake state, mean systemic levels of peptide YY (PYY), an anorexigenic gut hormone, is high both in girls and women with anorexia nervosa compared with controls [38, 39]. The cause and result of this elevation are unknown and raise the possibility that NPY-PYY appetite system dysregulation may contribute to the pathophysiology of anorexia nervosa. In support of this unproven hypothesis, PYY levels correlate with the degree of eating disorder thinking and behaviour [40], suggesting a possible relationship between the psychologic features of anorexia nervosa and PYY levels.

Bone Loss

The global endocrine dysregulation delineated earlier contributes to severe bone loss in women with anorexia nervosa—both those with classic low-weight anorexia nervosa and those with normal-weight atypical anorexia nervosa (Table 12.1.6.2). The vast majority of women with low-weight anorexia nervosa have Z-scores and or T-scores of less than or equal to –1.0, and 40% have osteoporosis [41]. In addition, BMD in such women declines by a mean 2.5% annually [42]. Bone loss occurs disproportionally at primarily trabecular sites (e.g. lateral and posteroanterior (PA) spine), and only 15% of women with anorexia nervosa have normal BMD at all skeletal sites [6]. This results in a non-spinal fracture rate seven times expected [43], and 30% of such women report a history of at least one fracture [6]. Healthy adolescence is characterized by a substantial increase in BMD and an increase in markers of bone metabolism, which is not experienced by girls with anorexia nervosa [44],

Table 12.1.6.2 Therapies for low bone mineral density in adolescent girls and women with anorexia nervosa

Therapy	Age	*n*	Change in BMD	Treatment length (months)	Refs
Oral oestrogen/progestin	16–42	48	No change versus placebo	19 (mean)	[55]
	12–21	50	No change versus placebo	12	[56]
	18–38	60	No change versus placebo	9	[57]
	11–17	112	No change versus placebo	12	[58]
Physiologic oestrogen replacement	12–18	110	Increase in spine BMD versus placebo (2.6% versus 0.3%). Stable hip BMD versus decline in placebo (0.004% versus −1.2%)	18	[59]
Recombinant human IGF-1	18–38	60	Increase in spine BMD versus placebo (1.1% versus −0.6%)	9	[57]
Recombinant human IGF-1 plus oral contraceptive	18–38	60	Increase in spine BMD versus placebo (1.8% versus −1.0%)	9	[57]
Testosterone	19–49	77	No change versus placebo	12	[21]
DHEA	14–28	61	No change in lumbar BMD in either DHEA or oral oestrogen/progestin group. Similar increase in hip BMD (1.7%) in both DHEA and oral oestrogen/progestin group, but change was not significant after controlling for weight gain	12	[20]
DHEA plus oral contraceptive	13–27	94	Maintenance of spine and hip BMD versus decrease in placebo group	18	[61]
Oral bisphosphonates	12–21	32	No change versus placebo, although both groups gained weight and increased spine and hip BMD	12	[69]
	19–49	77	3–4% increase in spine BMD and 2% increase in hip BMD versus placebo	12	[21]
Teriparatide	32–58	32	Increase in spine BMD versus placebo (6% versus 0.6%). No change in hip BMD versus placebo	6	[70]
Weight gain and resumption of menses	18–40	75	1.8% increase in hip BMD, 3.1% increase in spine BMD compared with baseline	12	[43]

DHEA, Dehydroepiandrosterone; hIGF1, human insulin-like growth factor 1.

Adapted with permission from Schorr M, and Miller KK. The endocrine manifestations of anorexia nervosa: mechanisms and management. *Nat Rev Endocrinol*. 2017;13(3):174–86.

resulting in low BMD compared to healthy girls [45] and an elevated fracture risk [46]. In one study 70% of amenorrhoeic, 67% of eumenorrheic, and 65% of women on oral contraceptive pills with atypical anorexia nervosa (psychiatric symptoms characteristic of anorexia nervosa in the absence of low weight) had a BMD Z score <−1 at least one skeletal site [46]. Prior low weight and/or amenorrhoea conferred a high risk for low BMD, whereas having a history of neither appeared to be relatively protective [47].

Bone microarchitecture and strength (as modelled by finite element analysis) are also adversely affected in adolescent girls and women with anorexia nervosa [48–52], before dual energy X-ray absorptiometry (DXA) shows evidence of low BMD [51]. Recovery of bone mass does occur with weight recovery, particularly in adolescents in whom intervention is early and adults who recover menses with their weight gain [42]. However, nutritional restoration is not easy to achieve for many girls and women suffering from this psychiatric disorder, and even when it does occur, persistent low BMD is common [53]. In addition, weight recovery may take years to achieve. These factors provide a rationale for early intervention—to restore weight and normal neuroendocrine function, as well as to develop therapeutic strategies to prevent and treat skeletal compromise.

Bone metabolism in women with anorexia nervosa is characterized by an uncoupling of bone formation (which is low) and bone resorption (which is high) [31], which provides clues to the pathophysiology of the disease and a rationale for putative treatment strategies. In adolescent girls with anorexia nervosa, the characteristic increase in bone turnover (bone formation and resorption) observed in adolescence—and leading to rapid bone accrual toward peak BMD—is not present [54]. These differences in bone turnover in girls versus adults with anorexia nervosa highlight very real differences in skeletal physiology in these groups that inform preventative and therapeutic choices (i.e. findings in one age group cannot be generalized to the other).

Given the well-known link between oestrogen-deficiency and bone loss during menopause, hypogonadism in anorexia nervosa is an excellent candidate for an important contributing factor to bone loss in girls and women with anorexia nervosa—and an obvious therapeutic target. In fact, in amenorrhoeic low-weight women with anorexia nervosa, the mean spine T-score in amenorrhoea group was −1.9 compared to −0.9 in women with comparable low weight but without amenorrhoea [15]. This suggests that gonadal steroids are important for skeletal integrity in the setting of low weight and that nutritional deprivation plus gonadal steroid deficiency is particularly detrimental to bone. Whether there is a component of relative androgen and/or progesterone deficiency or whether it is simply oestrogen-deficiency that contributes to bone loss is unknown. In adolescent girls and women with anorexia nervosa, oral replacement strategies that involve oestrogens and progestins (both postmenopausal hormone therapy [55] and oral contraceptives) [56–58] have demonstrated unimpressive results. The former appears to be entirely ineffective [55], whereas the latter may stem

bone loss but does not increase BMD [57]. This is contrast to the effects of transdermal oestrogen and progestin at replacement doses (100 μg of 17β-oestradiol with cyclic progesterone transdermally in older adolescents (with a bone age ≥15 years), which was shown in a randomized, placebo-controlled study to result in significant increases in BMD, though it did not result in normalization of BMD [59]. Low-dose testosterone administration stimulates bone formation in women with anorexia nervosa [21, 60], but does not increase BMD [21]. Dehydroepiandrosterone (DHEA) administration to adolescent girls with anorexia nervosa resulted in increases in BMD that were explained by increases in weight [20], but a subsequent study of DHEA plus ethinyl oestradiol plus a progestin demonstrated spine and total body BMD stability compared to placebo, which was associated with bone loss [61].

As might be expected, duration of illness (time since onset of anorexia nervosa) and body mass index are inversely associated with BMD. Muscle mass (as measured in most studies as lean body mass by DXA) is the body composition parameter that most strongly correlates with BMD [44]. Weaker associations are seen with total fat mass, but bone marrow fat, which is high in anorexia nervosa, is strongly inversely associated with BMD [62]. Whether this provides a clue to the mechanisms underlying bone loss in anorexia nervosa is unknown. It is possible that the increase in bone marrow fat is mechanistically related with endocrine dysregulation resulting in mesenchymal stem cell precursor differentiation toward the adipocyte, rather than osteoblast pathway. Alternatively, impaired osteoblastogenesis may be the cause, not result, of accumulation of bone marrow fat.

Although components of nutritional intake have not been implicated in bone loss in anorexia nervosa, there is controversy about the impact of vitamin D deficiency. In studies in both girls and women with anorexia nervosa, mean vitamin D and calcium intake have been shown to comparable to healthy controls of comparable age (in part due to the ingestion of supplements) and low vitamin D levels have even been shown to be more common in healthy controls. The conclusions drawn from these studies are that vitamin D deficiency is unlikely to be an adequate explanation for the lower BMD observed in anorexia nervosa [63, 64]. However, when vitamin D deficiency is present, it may contribute to bone loss. In one study, a majority of females with anorexia nervosa had 25-hydroxy-vitamin D levels, and very low levels (<12 ng/ml) were associated with lower hip BMD than those with vitamin D levels ≥ 20 ng/ml [65]. Moreover, in another study, improvements in spine BMD with weight restoration occurred only in individuals who had vitamin D levels ≥ 30 ng/ml This suggests that it is important to ensure normal vitamin D levels to optimize improvements in bone health with weight gain or pharmacologic therapies [66].

GH is well-known to be anabolic to bone, primarily responsible for linear growth and important for maintenance of bone mass in adults. However much of GH's bone-anabolic actions are mediated through IGF-1, systemic levels of which are reduced in anorexia nervosa due to the state of GH resistance. Evidence of a detrimental effect of relative IGF-1 deficiency on BMD in anorexia nervosa include an association of IGF-1 levels with markers of bone formation [44] and bone microarchitectural parameters [49]. Recombinant human IGF-1 (rhIGF-1) replacement therapy is effective at increasing BMD in women with anorexia nervosa but not to normal (1.4% at the spine—2.8% when combined with oral contraceptives) over 9 months [57]. Of note, rhIGF-1 is not FDA-approved to treat low BMD in women with anorexia nervosa, and studies in adolescents with anorexia nervosa are lacking.

Bone loss is a well-known complication of hypercortisolaemia in women and men with Cushing's syndrome. Whether hypercortisolaemia is driven in part by relatively higher ghrelin levels is unknown. Moreover, whether the functional hypercortisolaemia observed in anorexia nervosa contributes to the bone loss observed in this syndrome has not been fully determined. However, there is evidence of such an effect from studies. For example, overnight frequent samples for cortisol negatively correlate with BMD in both women and girls with anorexia nervosa [29, 67]. It is unknown how to translate these observations into a therapeutic strategy other than to work toward nutritional and psychiatric recovery, which result in normalization of cortisol levels.

There is also a complex interplay between bone loss and appetite hormone dysregulation. Most studies suggest indirect effects. For example, although there is little evidence that hypoleptinaemia directly causes bone loss, normalization of leptin may improve BMD through normalization of reproductive function. In contrast, PYY levels are elevated in women and girls with anorexia nervosa and strongly inversely associated with BMD, even after controlling for weight [68], raising the question of whether there may be direct effects. However, no studies establishing causality have been published.

Other traditional pharmacologic and non-pharmacologic interventions developed to treat postmenopausal osteoporosis have also been tested in girls and women with anorexia nervosa. Antiresorptive and anabolic agents have been studied in small, randomized, placebo-controlled studies. Risedronate increases BMD in women with anorexia nervosa, but one year of therapy does not normalize BMD [21]. In contrast, alendronate was not found to be effective at increasing BMD in adolescent girls with anorexia nervosa after controlling for weight gain [69]. This is yet another example of the non-generalizability of results in adults and adolescents. It is important to note that bisphosphonates are not FDA-approved for use in girls or women with anorexia nervosa, and although the limited data available are reassuring about teratogenicity of bisphosphonates, they should be avoided in individuals at risk of becoming pregnant in the near future. Anabolic therapies have particular appeal in anorexia nervosa because of the decrement in bone formation observed. A pilot study demonstrated increases in BMD at the spine 6–10% with 6 months of teriparatide as compared with placebo [70]. Although these data are very promising, teriparatide is not FDA-approved for the treatment of low BMD in anorexia nervosa, and an FDA warning states that teriparatide should not be used in patients at risk for the development of osteosarcoma, including adolescents. Finally, although weight-bearing exercise appears to improve BMD in women who are have recovered from anorexia nervosa [71], exercise is deleterious for skeletal health in low-weight women with anorexia nervosa [72], likely because it exacerbates the negative energy balance.

Conclusions

Endocrine complications of chronic starvation, as seen in girls and women with anorexia nervosa, are myriad and include SIAD,

hypothalamic amenorrhoea (resulting in relative oestrogen, androgen, and progesterone deficiency), GH resistance (with resultant relative IGF-1 deficiency) and hypercortisolaemia, as well as alterations in anorexigenic and orexigenic hormone levels and pathways. These endocrine consequences of starvation contribute to bone loss, which is nearly universal in girls and women with anorexia nervosa. A multidisciplinary approach to psychiatric and nutritional rehabilitation, with a physician, therapist, and nutritionist, is the key to recovery from this psychiatric disease. The combination of weight restoration and psychiatric recovery results in normalization of endocrine axis dysregulation in many, but not all, patients. Recovery of skeletal health often accompanies weight recovery, especially if it is accompanied by recovery of reproductive function. However, some degree of BMD impairment may persist after recovery from anorexia nervosa, and the disorder is chronic in many patients. Therefore, further research into preventative and treatment strategies for bone loss in girls and women with anorexia nervosa is warranted.

12.2

Endocrine Complications of Substance Misuse

12.2.1 Endocrinology and Alcohol

Marc Walter and Margit G. Proescholdt

Introduction

Alcohol has widespread effects on the endocrine system, potentially impairing endocrine function. Endocrine impairment is more obvious and frequent in those who have developed alcoholic liver disease. Endocrine dysfunction not only results from hepatic failure or chronic malnutrition, but also from direct, toxic actions of alcohol on the endocrine organs as well as impairing regulation at the hypothalamic–pituitary level. In the absence of liver disease, the adverse effects of alcohol on the endocrine organs are mostly reversible upon reduction or cessation of alcohol consumption. There is increasing evidence that the endocrine system itself may play a crucial role in the pathogenesis of addictive behaviour.

Studies on alcohol–endocrine interactions in humans are difficult and often report inconclusive or controversial results. Difficulties arise from the highly heterogenic groups of alcohol-dependent persons differing in amount and duration of alcohol consumption, periods of abstinence, confounding variables (e.g. age, gender, nutritional status, smoking, concomitant drugs) and comorbidities (e.g. liver disease), respectively. The mechanisms of alcohol–endocrine interactions are poorly understood, due to multifactorial causes of disease and the complexity of endocrine regulation. However, a better understanding of the impact of alcohol on the endocrine system is required to guide public health recommendations on alcohol consumption.

Hypothalamic–Pituitary–Adrenal (HPA) Axis and Alcohol-Induced Hypercortisolism

Excessive alcohol intake increases cortisol secretion acutely and chronically and is primarily mediated through the activation of hypothalamic corticotropin-releasing hormone (CRH). In addition, hepatic dysfunction may result in an impaired peripheral clearance of cortisol and thus contribute to the hypercortisolaemic state in chronic alcoholism. As a consequence, some patients with chronic alcohol consumption may develop a physiologic, non-neoplastic hypercortisolism (formerly pseudo-Cushing's syndrome) with clinical and endocrine features that may be indistinguishable from true Cushing's disease (pathologic, neoplastic hypercortisolism), which is usually caused by either an adrenocorticotrophic hormone (ACTH)-secreting neoplasm or adrenal neoplastic disease.

Due to the similar clinical and endocrine features, differentiation of alcohol-induced hypercortisolism from true Cushing's syndrome may be difficult; therefore, a thorough history and clinical examination are often considered best. Possible endocrine findings in alcohol-induced hypercortisolism are described in **Box 12.2.1.1**. Importantly, both the physical and the endocrine abnormalities improve after discontinuation of alcohol use. Thus, abstinence from alcohol not only is curative but also an important diagnostic tool [1].

Box 12.2.1.1 Alcohol-induced hypercortisolism (formerly pseudo-Cushing's syndrome)

May be indistinguishable from true Cushing's syndrome
History and physical examination best way to differentiate from true Cushing's syndrome
Endocrine abnormalities resolve with discontinuation of alcohol use

Endocrine findings

- ↑ late-night salivary cortisol and urinary corticosteroids
- Mostly normal or ↑ plasma ACTH
- Rarely adrenal nodular disease and subnormal plasma ACTH
- Often abnormal overnight dexamethasone suppression test
- Abnormal dexamethasone-CRH test during active alcohol consumption
- Likelihood of no ACTH response to DDAVP (in contrast to true Cushing's syndrome)

↑: increased.
DDAVP, desmopressin acetate; ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone.

Hypothalamic–Pituitary–Gonadal (HPG) Axis and Alcohol

HPG Axis and Alcohol in Men

Chronic alcohol abuse may affect all levels of the hypothalamic–pituitary–gonadal (HPG) axis resulting in hypogonadism. The full spectrum of hypogonadism (testicular atrophy, loss of libido, impotence, infertility), osteoporosis, decreased muscle, anaemia, altered immune function, depressed mood, and decreased vitality, may occur [2, 3].

Alcohol-induced (AI) hypogonadism arises from direct (toxic) and indirect effects on the gonads and on the hypothalamic–pituitary unit [3]. AI hypogonadism is more frequently observed in advanced alcoholic liver disease [4]. The prevalence of sexual disorders ranges from 8 to 58%. Abnormal sperm parameters (morphology, semen volume), and altered sex hormones are frequent findings [4, 5] (Box 12.2.1.2). In a recent study of young Danish men, reduced semen quality occurred with only 5 drinks/week, and was most pronounced in heavy drinkers (>25 drinks/week) [6].

Box 12.2.1.2 Alcohol-induced gonadal dysfunction in men

Sexual disorders
Altered sperm parameters
Feminization in advanced liver disease

Endocrine findings

- Acute alcohol exposure
  - LH, testosterone, and oestradiol ↓
- Chronic alcohol exposure
  - Testosterone*, free testosterone, and FAI → or ↓
  - LH, SHBG, oestradiol, and androstenedione → or ↑
- Abstinence
  - Testosterone and free testosterone → or ↑, LH ↑

↑: increased; →: normal; ↓: decreased
*: ↓ testosterone mostly seen in alcoholic liver disease
LH, luteinizing hormone; SHBG, sex hormone-binding globulin; FAI, free androgen index (testosterone/SHBG ×100).

Sex hormones levels are variable [4, 7–11] (Box 12.2.1.2). Blood testosterone levels are mostly normal in the absence of liver disease. By contrast, levels of luteinizing hormone (LH) are frequently inappropriately high or low indicating disturbance of adenohypophyseal feedback [7]. In the absence of significant hepatic or gonadal injury, abstinence may improve gonadal dysfunction [5, 12].

Feminization, as distinct from hypogonadism is manifested by gynaecomastia, female body habitus changes, spider angioma, palmar erythema, and changes in body hair patterns. Feminization is seen rarely in the absence of chronic alcoholic liver disease. Feminization results from the combined effects of altered enterohepatic circulation of biliary excreted steroids from portal hypertension, and increased conversion of testosterone to androstenedione, oestradiol, and oestrone [13].

A clinical evaluation of hypogonadism should always include a thorough history of alcohol consumption, information on the negative effects on the male reproductive system and the potential reversibility from abstinence.

HPG Axis and Alcohol in Women

In **premenopausal women**, chronic heavy alcohol use may contribute to a multitude of reproductive disorders, such as menstrual cycle irregularities, amenorrhoea, anovulation, loss of libido, early menopause, and increased risk of spontaneous abortions [14]. During early adolescence, alcohol consumption may delay puberty and adversely affect the maturation of the female reproductive system [15]. Binge drinking may be most detrimental at certain times, namely puberty. It can impair the cyclical selection of follicles for maturation, ovulation, implantation, and subsequent survival of the blastocyst [16].

Studies investigating effects on sex hormones are challenging because of the variation in hormone levels throughout the menstrual cycle. A recent large study observed higher luteal oestrogen and sex hormone-binding globulin (SHBG) concentrations and lower levels of free testosterone among women who consumed alcohol compared with non-drinkers. In this study, there were no significant associations between alcohol consumption and plasma androgen, oestrone, or oestradiol levels in the follicular phase [17]. However, the role of AI alterations of sex hormones on the female reproductive system is still unclear. Further studies are needed to clarify the relationships and underlying mechanisms.

In **postmenopausal women**, plasma oestradiol levels are elevated in alcoholic liver disease as well as in 'moderate' drinkers (1 to 28 drinks/week) in the absence of liver disease. However, so far, a firm relationship between 'moderate' alcohol consumption (no more than 1 drink/day) and oestrogen levels has not been established. By contrast, single dose alcohol administration to postmenopausal women on oestrogen replacement therapy (ERT) increases serum oestradiol levels markedly, which may increase the risk of breast cancer. Following a single oral dose of ethanol (0.75 g/kg bodyweight), serum oestradiol levels increased by 22% when oestradiol was administered by transdermal patch (0.15 mg), and by 300% by oral administration (1 mg/day), respectively [18]. Notably, ERT has been implicated in breast cancer and the risk of breast cancer is increased in postmenopausal women with concomitant alcohol use [19]. Therefore, postmenopausal women on ERT with concomitant

alcohol use should be informed about the increased risk for breast cancer and motivated to reduce alcohol intake.

Alcohol and Breast Cancer

Alcohol consumption is a risk factor for breast cancer in women. However, the underlying pathophysiological mechanisms are unclear. Recent hypotheses include perturbation of oestrogen metabolism and response, induction of mutagenesis by carcinogenic products of alcohol metabolism (i.e. acetaldehyde), and stimulation of oxidative damage through ethanol metabolism [20].

A causal association has been established between alcohol consumption and cancers of the oral cavity, pharynx, larynx, oesophagus, liver, colon, rectum, and breast. This association is highest for breast cancer than for any other type of cancer [21]. There is a 7–10% risk increase for each 10 g alcohol consumed per day (premenopausal and postmenopausal women). It has been suggested that breast tissue is more vulnerable to the carcinogenic effects of alcohol compared to other organs [20]. A recent meta-analysis has reported an odds ratio for breast cancer of 1.085 (95% confidence interval [CI] 1.015–1.160) for low-level (<21 g/d) drinkers, 1.374 (95% CI 1.319–1.431) for hazardous-level drinkers, and 1.336 (95% CI 1.228–1.454) for harmful-level (>40 g/d) drinkers [22]. There is evidence that early-life exposure to alcohol may contribute to the lifetime risk of breast cancer, implying a need for increased awareness and counselling regarding alcohol use among adolescent girls and young women [20].

Hypothalamic–Pituitary–Thyroid (HPT) Axis and Alcohol

Thyroid dysfunction is a frequent finding in alcohol-dependent patients. The mechanisms include direct toxic effects of alcohol and its metabolism on the thyroid gland, as well as central effects on the hypothalamus and/or pituitary gland [23]. AI thyroid dysfunction usually normalizes during abstinence.

The most consistent clinical and endocrine findings are described in Box 12.2.1.3 [14, 24]. In individuals where thyroid dysfunction persists into abstinence, other non-alcohol-related thyroid diseases should be excluded (e.g. autoimmune thyroid disease). In patients with pre-existing hyperthyroidism, acute alcohol intoxication may mimic a thyrotoxic crisis warranting immediate analysis of thyroid hormones and adequate medical treatment.

Box 12.2.1.3 Alcohol-induced thyroid dysfunction

Usually absence of overt clinical signs of hypothyroidism
Thyroid volume ↓, thyroid fibrosis ↑

Endocrine findings

- Usually normal basal TSH
- T_4 → or ↓, T_3 and fT_3 ↓
- Deiodination of T_4 to T_3 ↓
- Normalization of peripheral thyroid hormones during abstinence
- Frequently blunted TRH test, may persist into abstinence

T_4, total thyroxine; T_3, total triiodothyronine; fT_3, free triiodothyronine; TSH, thyroid-stimulating hormone; TRH, thyrotropin-releasing hormone.

Water and Electrolyte Balance and Alcohol

Water and electrolyte balance can be substantially disturbed by alcohol consumption. While regulation of fluid balance and electrolyte homeostasis is highly complex, this section will focus on the effects of alcohol on arginine vasopressin (AVP), the main regulator of blood and urine osmolality.

AVP levels are profoundly altered by alcohol during acute and chronic alcohol ingestion as well as during alcohol withdrawal and abstinence. Acute alcohol ingestion results in a biphasic AVP response. During ascending plasma alcohol concentrations, AVP levels decrease leading to increased diuresis of free water. During descending plasma alcohol concentrations, AVP levels increase, resulting in decreased diuresis [25]. The effects of chronic alcohol consumption on AVP levels are unclear. Overhydration from increased AVP levels occur during withdrawal. Despite increased AVP levels, plasma, and urine osmolalities may be normal, contrary to what would be expected in AVP-induced overhydration. Higher AVP levels relative to serum sodium levels may result from a lowering of the threshold for osmotic stimuli. Increased AVP levels return to normal within 4 to 10 days. By contrast, plasma AVP levels are reduced in long-term abstinent alcoholics in whom the free water clearance is increased, indicating there is persistent alterations in hormonal regulation of electrolyte and water balance [25, 26].

Since alcohol withdrawal may be associated with overhydration, fluid management, particularly during withdrawal should be undertaken with caution. In addition, alcohol withdrawal may cause substantial disturbances in electrolyte homeostasis, thus, blood electrolytes should be monitored closely [25].

Beer Potomania

'Beer potomania' is a specific hypo-osmolality syndrome related to massive consumption of beer. It carries a high risk of an osmotic demyelination syndrome (ODS) resulting from rapid correction of hyponatraemia [27]. Because beer has very little sodium (<2 mmol/L), the low osmole intake results in an excess of electrolyte-free water but no solute for diuresis. If AVP levels at admission are not decreased, patients are likely to quickly convert to a state of low antidiuretic hormone (ADH) secretion. Exogenous solute intake may then lead to a brisk diuresis resulting in a rapid increase of serum sodium which in turn may lead to ODS. To prevent ODS, fluid management within the first 48 hrs is crucial. Common findings and recommendations for management of beer potomania are described in Box 12.2.1.4. ODS may manifest clinically 2 to 3 days after the initial insult, therefore, the patient's management must be defined at admission [27].

Hypertension and Alcohol

Alcohol consumption and hypertension (HT)—HT defined as systolic blood pressure (BP) >140 mmHg or diastolic BP <90 mmHg—is among the top five risk factors responsible for the growing global non-communicable diseases (NCD) burden [28]. Notably, chronic heavy drinking is among the most common reversible causes of HT and heavy drinking causes approximately

Box 12.2.1.4 Clinical findings and management of beer potomania

Typical history and clinical findings
- Excess beer drinking, recent binge drinking or illness
- Severe hyponatraemia (100–120 mmol/L), hypokalaemia
- Blood urea nitrogen ↓, urine Na^+ ↓
- Brisk diuresis in response to solute intake
- Mild neurologic symptoms (confusion)

High risk upon rapid serum sodium correction
- Osmotic demyelination syndrome (ODS)
- Symptoms range from mild confusion to coma and death

Management*
- Intensive care status
- Restrictive and careful fluid management
- Serum Na^+ every 2 hrs
- Serum Na^+ ↑ in first 24 hrs <10 mmol/L
- Serum Na^+ ↑ in first 48 hrs <18 mmol/L
- If necessary relower Na^+ levels

↓: decreased; ↑: increased; Na^+: sodium level
*: for more detail see: Sanghvi SR, *et al.* Beer potomania: an unusual cause of hyponatraemia at high risk of complications from rapid correction. *American journal of kidney diseases: the official journal of the National Kidney Foundation.* 2007;50(4):673–80.

16% of HT cases worldwide [29]. The underlying mechanisms are not well understood [30].

Whereas 1–2 drinks/day may have a neutral effect on long-term BP, regular alcohol intake at doses greater than 2 drinks/day increases BP in a linear dose-response relationship. More than 2 drinks/per day, each additional alcoholic drink will raise BP by 1.5 mm Hg and the relative risk (RR) for HT being 1.7 for 50 g alcohol/day and 2.5 for 100 g alcohol/day [29]. By contrast, acute alcohol intake causes peripheral vasodilatation causing a fall of BP. Hypotension may also develop in those with AI autonomic neuropathy and/or late-stage cardiomyopathy [30]. Reduction of alcohol intake lowers BP in a dose-dependent manner with an apparent threshold effect at two 2 drinks/day. The strongest effect was found in people who drank more than 6 drinks per day and reduced their intake by about 50% [28]. Upon cessation or significant reduction of alcohol intake, BP falls within 2–4 weeks. The effects on BP reduction are similar to that of other health behaviour changes such as physical activity, weight loss, and diets. Therefore, implementation of effective alcohol interventions in people who drink more than 2 drinks/day would be an effective means to reduce the disease burden from both alcohol and hypertension, particularly in countries with a substantial alcohol–attributable risk [28].

Growth Hormone/Insulin-like Growth Factor-1 Axis and Alcohol

Growth hormone (GH), is essential for the growth of all tissues in the body and acute and chronic alcohol exposure has various effects on the GH/IGF-1 axis.

Alcohol interferes with the normal, pulsatile release pattern of GH with the major secretory episode occurring during the first period of slow-wave sleep (SWS), inducing a significant and dose-dependent decrease of the nocturnal GH surge. While studies show a robust relationship between sleep disturbances and decreased GH secretion, alcohol-dependent individuals release less GH during SWS compared to normal control subjects [31]. GH responses to various challenges, e.g. apomorphine (dopamine receptor agonist), diazepam (allosteric modulator of $GABA_A$ receptor), sumatriptan (serotonin receptor agonist) are reduced not only in early, but also in long-term abstinence (1–2 years), indicating persistent impairment [14, 31].

The liver is the major source of IGF-1 which mediates the anabolic actions of GH. The regulation of IGF-1 in the liver by GH is inhibited by glucocorticoids. IGF-1 synthesis is reduced in long-term alcohol users with and without evidence of significant liver disease leading to progressive loss of muscle protein [32].

Parathyroid Hormone and Alcohol

Parathyroid hormone (PTH) regulates serum calcium levels through its effects on bone, kidney, and intestine. The activation of vitamin D by PTH increases calcium absorption by the intestine. PTH is stimulated by decreased serum calcium, and mild decreases in serum magnesium, whereas severe decreases in serum magnesium concentrations result in an inhibition of PTH.

Vitamin D deficiency is a common finding in alcohol-dependent patients, indicating a necessity for substitution. PTH levels are usually within the normal range but show a negative correlation with vitamin D levels. Calcium levels in general are also within the normal range. A recent study shows a negative correlation between calcium levels and alcohol craving, implying calcium supplementation as a potentially useful intervention to reduce craving and relapse in alcohol dependence. However, the role of calcium in addictive behaviour as well as the pros and cons of vitamin D and calcium supplementation in alcohol-dependent patients are still under debate and future studies are needed for clarification [33].

Chronic alcohol ingestion is often associated with a disturbance of electrolyte homeostasis (calcium, magnesium, phosphorus, and potassium), which is mainly due to poor intake, vomiting, diarrhoea, and increased urinary loss. Severe hypomagnesaemia results both in reduced secretion of PTH and end-organ (in bone and kidney) resistance to PTH, leading to hypocalcaemia und hyperphosphatemia. Transient hypoparathyroidism secondary to magnesium deficiency can be reversed by magnesium supplementation alone which corrects the calcium abnormalities [34].

Bone Disease and Alcohol

Alcohol is one of the leading risk factors for male osteoporosis, whereas in women it is an infrequent risk factor.

The alcohol-associated decrease in bone mass and strength is mainly due to an imbalance in bone remodelling with a predominant decrease in bone formation. The pathophysiology of alcohol's effects on bone is not fully understood, multifactorial in nature, includes direct and indirect mechanisms and is influenced by many confounders and comorbidities [35, 36].

Current evidence suggests that the doses (U-shaped relationship), duration of alcohol use, and the type of alcoholic beverage consumed influence bone loss. Whereas light alcohol consumption (8–10 g alcohol/day) is without effect, that of moderate alcohol consumption (2–3 drinks/day) may be positive or negative depending on sex, age, and hormonal status, and the type of beverage consumed. By contrast, chronic heavy drinking (100–200 g of alcohol/day) unequivocally reduces bone mass and bone mineral density. Alcohol consumption greater than 4 drinks/day in men and 2 drinks/day in women may increase fracture and trauma risk. Alcohol may delay the healing of fractures and associated complications. There is evidence from animal studies that binge drinking may influence bone remodelling. Thus, teenagers with binge drinking may decrease their peak bone mass and be at risk for later skeletal pathophysiology [36].

Furthermore, chronic alcohol abuse can rarely lead to aseptic osteonecrosis (ON), mainly of the femoral head, but also of other locations such as the knee. ON appears to be a late bone complication mainly seen in patients with late-stage liver disease. Therapy of choice for ON of the femoral heads is total hip arthroplasty [35]. For bone health, the European Foundation for Osteoporosis, and the National Osteoporosis Foundation of the United States has recommended that alcohol consumption be limited to 1 drink/day for women and 2 drinks/day for men [36].

Diabetes Mellitus and Alcohol

Since T1D usually manifests in childhood and adolescence, alcohol is more likely to affect the development and course of T2D although patients with T1D may benefit from limiting alcohol intake [37].

Current evidence suggests a J-shaped relationship between alcohol intake and the risk of developing T2D. Accordingly, maximum daily alcohol doses of 22 g in men and 24 g in women lowers the risk, whereas higher alcohol doses increased the risk for T2D both in women and men [37]. Potential mechanisms include decreased fasting insulin and HBA_1 concentrations among non-diabetic subjects and improved insulin sensitivity among women.

There is also strong evidence that alcohol may increase diabetes-induced complications ('double trouble' [37]) (See Table 12.2.1.1 online only) [37].

The American Diabetes Association recommends not more than 2 drinks/day for diabetic men and not more than 1 drink/day for diabetic women [29]. When pharmacologic treatment includes metformin, patients are to avoid consuming excessive amounts of alcohol because of the increased risk of a potentially life-threatening lactic acidosis.

Role of the HPA Axis in the Development and Maintenance of Alcohol Use Disorders

Changes in the activity of certain brain hormones have long been suggested to play an important role in the development and maintenance of addictive behaviour although proof of causality is still outstanding [38]. Whereas many neuroendocrine hormones have been implicated in addictive behaviour, the following section focuses on the HPA axis.

The HPA axis is one of the main stress response pathways and extensive research has shown that problematic alcohol use and dependence result in serious perturbations of the HPA axis. The effects of alcohol on the HPA axis are modulated by vulnerability factors (genetic factors, early-life environment, current stress, gene-environment interactions) and alcohol use-associated factors (dose, recent drinking history, expectancies) [39]. The dynamic interactions between alcohol and HPA axis function vary with respect to the stages of progression towards alcohol dependence, withdrawal, and recovery [39–42]. Table 12.2.1.2 (online only) shows the alcohol-associated changes on HPA axis regulation and their potential impact on development and maintenance of addictive behaviour. Altogether, there is ample evidence that the HPA axis—with particular emphasis on the CRH system—plays a key role in facilitating and maintaining substance use disorders and may therefore qualify as a major target for treatment.

Summary

Alcohol can impair endocrine function by affecting regulation at all levels of the endocrine system. Since endocrine regulation is particularly important during puberty and adolescence, binge drinking behaviour places this group at risk for later diseases. The dysregulation of the endocrine system particularly of the HPA axis may play a role in the development and maintenance of addictive disorders. Endocrine dysfunction is potentially reversible by abstinence in the absence of liver disease. The level of evidence supporting claims that low to moderate alcohol consumption may have positive effects on certain diseases, is not high due to methodological concerns [43].

Current recommendations are aimed at limiting regular alcohol intake to not more than one drink/day for women and not more than two drinks/day for men. Non-drinkers should not be advised to begin drinking (paucity of outcome data, abuse risk) and problem drinkers should be advised to abstain permanently or significantly reduce their alcohol intake and seek professional help therefore [29].

12.2.2 Use and Abuse of Performance-Enhancing Hormones in Sport

Peter Sonksen and Richard I.G. Holt

Introduction

Anecdotes suggest that attempts to improve athletic performance in both man and animals date from the times of ancient Greece and Rome and probably before. The status of an athletic winner has always been sufficient to encourage people to cheat and in recent times winners have been rewarded with generous sponsorships and can accumulate great wealth.

Fair play and ethical behaviour are among the fundamental principles of 'Olympians' laid out in the Olympic Charter [1] which aims to achieve a hypothetical 'level playing field' where winning reflects true ability, dedication, and training rather than mastering the science for using performance-enhancing substances to cheat—the process known as 'doping'. Doping not only damages the integrity of sport but may cause significant harm to athletes. The origin of the term 'doping' is uncertain; some sources suggest that it was originally derived from the African Kaffirs word 'dop', an alcoholic drink made from grape skins that was used as a stimulant in battle, while others believe it came from the slang term for opium.

The true prevalence of doping is unknown and reports vary widely from 1% to 90% because of the secrecy surrounding it. The huge financial rewards for professional sportsmen and women and the need for corporate sponsors and TV broadcast act as a great temptation to cheat. When coupled with the ever-increasing pharmacopoeia of performance-enhancing substances, the athlete's drive to win may create an overwhelming urge to use prohibited substances.

The International Olympic Committee (IOC) Medical Commission

It was the deaths of the Danish cyclist Knud Jensen at the Rome Olympiad in 1960 and the British cyclist Tommy Simpson before the cameras in the 1967 Tour de France that made people sit up and realize that something had to be done to control the misuse of substances in the quest of winning. The IOC, aware of the growing problem, first placed the responsibility for dealing with this on the Sports Federations but when it was clear that this was ineffective, formed a 'Medical Commission' in 1967. The remit was to oversee the introduction of an effective antidoping system. The IOC Medical Commission established a list of banned substances that was regularly updated as 'The Prohibited List'. The Medical Commission also developed procedures as well as methods for detecting drugs and certifying the process. It was not until 1982, however, that the first dedicated IOC laboratory was created in Los Angeles with a grant from the organizing committee for the 1984 Olympic Games.

This laboratory was accredited by the IOC in November 1983 and detected one adverse analytical finding of an anabolic steroid (methandienone) at the Winter Olympic Games at Sarajevo in February 1984 and 12 positives at the Los Angeles Summer Games of 1984.

The IOC Laboratories and the 'Prohibited List'

Subsequently the IOC established and accredited a network of antidoping laboratories around the world. Each laboratory had to participate annually in a 'Quality Assurance' programme where they had to analyse a set of 'blind' samples and come up with the right answers. Failure to do so resulted in immediate suspension and the need for re-accreditation. This laboratory network was effective and the sports federations had to use these laboratories while running and paying for their own testing programmes.

The Creation of the World Anti-Doping Agency (WADA) and the Court of Arbitration for Sport (CAS)

The IOC system was not without critics, the main issue being the potential conflict of interest between the organizers of the Olympic Games and the system run to prevent doping. This led to the creation of WADA in 1999, composed and funded equally by the sport's movement and national governments. WADA took over responsibility for managing the network of IOC laboratories as well as producing the annually updated list of banned substances and methods.

To resolve legal disputes in elite sport, the CAS came into being in June 1984. Initially created and funded by the IOC and reformed in 1994 to make it independent of the IOC, CAS was verified in 2003 by a Swiss Federal Tribunal. It is the 'high court' for all sporting disputes, including doping violations.

The World Anti-Doping Agency List of Prohibited Substances

Initially when WADA was created and took over the official list of prohibited substances, they said that they would only include substances (and methods) that had been proven to be performance enhancing but it was not long before they adopted a more pragmatic approach, previously used by the IOC.

The decision to include a substance or method in the prohibited list depends on the substance meeting two of three criteria:

- The substance or method enhances sporting performance or has the potential to do so
- The substance or method may cause harm to the athlete or has the potential to do so
- The substance or method violates the spirit of sport

The discovery of new performance-enhancing drugs often arises after athletes have discovered desirable properties often using a version of the 'trial of one' methodology [2]. Once others have started using them and confirmed their efficacy, their use spreads by word-of-mouth and clandestine publications. Others are detected by laboratories through routine analysis of urine samples by mass spectrometry as a part of dope testing and their ergogenic properties are assumed by their spreading popularity.

A good recent example of this is meldonium. Developed in Latvia, it was initially used by Russian troops in Afghanistan to improve endurance and subsequently adopted by athletes. In 2015, when meldonium started appearing in athlete's urine samples, it was not known to be performance enhancing but was added to the list of substances monitored by WADA. Its use by athletes became extensive, largely in the Eastern European bloc countries [3]. At the 2015 Baku European Games, 13 medallists or competition winners were taking meldonium and most of the athletes taking meldonium did not declare it. It was subsequently added to the WADA list of banned substances operational from 1 January 2016. On 7 March 2016, the former number one tennis player Maria Sharapova announced that she had failed a drug test due to the detection of meldonium; she received a 2-year ban from the International Tennis Federation [4].

Some drugs are banned always, while others are only banned in competition while others are only banned in certain sports. A summary of the 2018 section dealing with endocrine-related substances is reproduced in **Box 12.2.2.1**.

Box 12.2.2.1 Summary of hormones and drugs appearing on the 2018 WADA list of prohibited substances

Substances and methods prohibited at all times

S1 anabolic agents:

1 Anabolic androgenic steroids (AAS)
   - a Exogenous AAS
   - b Endogenous AAS when administered exogenously

2 Other anabolic agents: including but not limited to: clenbuterol, SARMs

S2 peptide hormones, growth factors, related substances, and mimetics:

1 Erythropoietins (EPO)
   - 1.1 EPO receptor agonists
   - 1.2 Hypoxia-inducing factor (HIF) activating agents
   - 1.3 GATA inhibitors
   - 1.4 TGF-beta (TGF-β) inhibitors
   - 1.5 Innate repair receptor agonists

2 Peptide hormones and hormone modulators
   - 2.1 Chorionic gonadotrophin (CG) and luteinizing hormone (LH) and their releasing factors
   - 2.2 Corticotrophins and their releasing factors
   - 2.3 Growth hormone (GH), its fragments and releasing factors

3 Growth factors and growth factor modulators

S3 β-2 agonists:

Except:

- Inhaled salbutamol—restricted amount
- Inhaled formoterol—restricted amount
- Inhaled salmeterol—restricted amount

S4 hormone and metabolic modulators:

1 Aromatase inhibitors
2 Selective oestrogen receptor modulators (SERMS)
3 Other antioestrogen substances
4 Agents modifying myostatin function
5 Metabolic modulators
   - 5.1 Activators of the AMP-activated protein kinase (AMPK)
   - 5.2 Insulins and insulin-mimetics
   - 5.3 Meldonium
   - 5.4 Trimetazidine

Endocrinology and Doping

Testosterone and Anabolic Androgenic Steroids

Testosterone and anabolic androgenic steroids (AAS) are among the most commonly misused performance-enhancing drugs representing 43% of Adverse Analytical Findings in WADA-accredited laboratories in 2016, although this may be just because they have been easier to detect. AAS misuse is not confined to elite athletes and indeed use by amateur bodybuilders and weightlifters for appearance purposes outnumbers elite athletes. It is estimated that 6.4% of men and 1.6% of women have taken AAS.

The effects of testosterone in animal husbandry has been long known but it was Charles Édouard Brown-Séquard who is usually credited with the preparation and use of a watery testicular extract that he found to improve strength and well-being in himself and other older men [5].

The next important event was the isolation and synthesis of testosterone independently in 1935 by the German Adolf Butendant and the Croatian Leopold Ruzicka, for which they were awarded The Nobel Prize in Chemistry in 1939 [6]. There were rumours that testosterone was used for performance-enhancement and aggression in the German Army but there are no facts to support this. Likewise, there is no evidence that testosterone was used in the 1936 Olympic Games in Germany. The first well-documented use of testosterone as a performance-enhancing drug was with the German rowing team in 1952 [7].

Testosterone use in athletics was also suspected in 1952 at the Summer Olympics in Helsinki. The Soviet Union competing for the first time at the Olympics dominated weightlifting and hearsay attributed this to testosterone. This suspicion was later confirmed when a Soviet doctor told a US colleague that they were experimenting with testosterone [8].

Because of unwanted virilizing side effects, there was a drive by the pharmaceutical industry to alter the molecule to improve its therapeutic profile—altering the pharmacokinetics and increasing the anabolic effects while reducing the androgenic effects. This resulted in many new anabolic steroids, methandrostenolone (Dianabol) developed by CIBA being one of the first. Within 2 years 'almost every world-class athlete knows of its performance-enhancing possibilities' [8]. Synthetic androgens predominantly have one of two substitutions on the D ring of native testosterone, either esterification at the 17-β-hydroxy group or alkylation at the 17-α position (**Figure 12.2.2.1**). Many variations on the structure of testosterone has led to a long list of so-called designer steroids.

In the late 1990s, topical preparations of testosterone became available. Many further manipulations of the basic steroid structure have been undertaken to alter the anabolic and androgenic actions as well as to avoid detection by increasingly sophisticated antidoping technology. The extent of this can be judged by the list of known variants in the latest WADA Prohibited Substances list [9].

State-Sponsored Doping

State-sponsored doping in the former German Democratic Republic (GDR) has been well documented by Franke and Berendonk, including secret files recovered from the Stasi following the unification of Germany [10]. In the 1960s the GDR was a relatively obscure country with a 'Cold War' image and dominated by the 'Iron Curtain'. GDR politicians decided that they could enhance their international prestige through athletic success. They instituted a system of early selection of potential athletes and systematic doping. They used mainly a chlor-substituted version of methandrostenolone (Oral-Turinabol). In 1968 they started administering Oral-Turinabol to women athletes as well as to men. In the 1972 Olympic Games this small country with only 17 million people were placed third in the medal tables (66 medals) behind the United States (99 medals) and the Soviet Union (94 medals); next was West Germany (62 million people) with 40 medals. In swimming at the Olympic Games in Montreal in 1976 GDR athletes won Gold in 11 of the 13 events.

Monitoring the performance of their athletes closely and adjusting doping protocols allowed trainers to study not only how performance improved with dosage but also how long the improved performance lasted after the anabolic steroid was discontinued. They were then skilled at maximizing performance while ensuring that their athletes did not test positive when competing in major events outside GDR. After one GDR athlete tested positive in 1977 a rule was introduced that all athletes needed to provide a urine sample that would be tested and need to be found 'clean' in a central laboratory (actually accredited by the IOC) before being allowed to compete abroad [10].

Interestingly, while this was occurring in the GDR, there was considerable debate about whether anabolic steroids were performance enhancing. The science was hampered because undertaking double-blind placebo-controlled trials in elite athletes is considered unethical.

Other methods were therefore needed to determine 'efficacy' of potential performance-enhancing drugs. In the GDR, trials of one and carefully executed case–control studies were the most frequently used methodologies and provided the most persuasive evidence. Despite the scepticism shown by Western scientists, the benefits were realized by athletes whose performance improved dramatically. For example, between 1956 and 1980, the winning distance in the Olympic women's shot put increased from 15.28 m to 22.41 m (**Figure 12.2.2.2**). Since the introduction of effective testing in the early 1980s, the winning distance in the women's shot put has fallen progressively to the point where the winner in Rio de Janeiro in 2012 would not have made the final in Moscow in 1980 and has plateaued since then.

A further episode of state-sponsored doping occurred more recently at the Winter Olympic Games in Sochi and as a result 111 of 389 Russian athletes were banned from the 2016 Summer Olympic Games in Rio de Janeiro and all their Paralympic athletes from the Paralympic Games: in addition because the IOC were not satisfied with the corrective measures required, Russia was banned from the 2018 Winter Olympic Games in South Korea [11].

Why Do Athletes Misuse Anabolic Androgenic Steroids?

AAS increase muscle mass and strength [12] through several mechanisms including the stimulation of protein synthesis, recruitment of satellite cells, production of cytokines, and increase in androgen

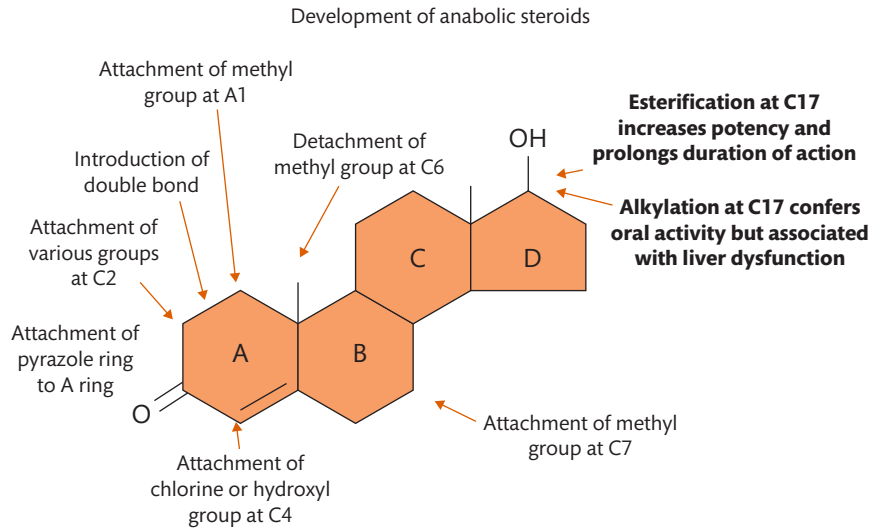

Figure 12.2.2.1 Development of androgenic anabolic steroids. As the half-life of testosterone is short, manipulations at the C17 position of the D ring have led to compounds that are either more potent and longer lasting (esterification) or orally acting (alkylation), marked in bold. Further alterations have been tried to alter the relative androgenic and anabolic actions.

receptor number. Clinical trials have shown that AAS improve both muscle mass and strength in a dose-dependent manner and these effects are additive to resistance training alone. The full potential of AAS, however, has almost certainly not been realized in these trials because of the limited doses used because of medical and ethical concerns about potential side effects. By contrast, doping athletes are reported to take combinations of AAS in doses that are up to 30 times higher than the physiological replacement dose. Although there is little hard evidence that AAS are performance enhancing, since performance in many athletic sports is dependent on lean body mass and strength, it is likely that they do have ergogenic effects.

There are many websites and printed manuals giving details about the use and supply of AAS. Steroid use usually involves techniques such as 'cycling' and 'stacking'. AAS appear to lose effectiveness with time through adaptation of the androgen receptor and athletes have learned to obtain greater benefit through using the steroids intermittently in a cycle over 5–10 weeks. Stacking involves the use of two or more steroids concomitantly to obtain a synergistic effect.

Adverse Effects of Androgenic Anabolic Steroids

The most marked side effect of AAS use is virilization. In both men and women these manifests as acne, an increase in body hair and male pattern baldness. In men, prostate enlargement may occur leading to urinary hesitancy and poor flow and there are concerns about long-term risk of prostate cancer. Gynaecomastia may develop as excessive testosterone is converted to oestradiol under the action of the aromatase enzyme. In women the virilizing effects are more marked including hirsutism, a decrease in breast size, clitoromegaly, and enlargement of the larynx causing deepening of the voice; these changes can be permanent.

Administration of AAS may reduce fertility through suppression of luteinizing hormone (LH) and follicle-stimulating hormone

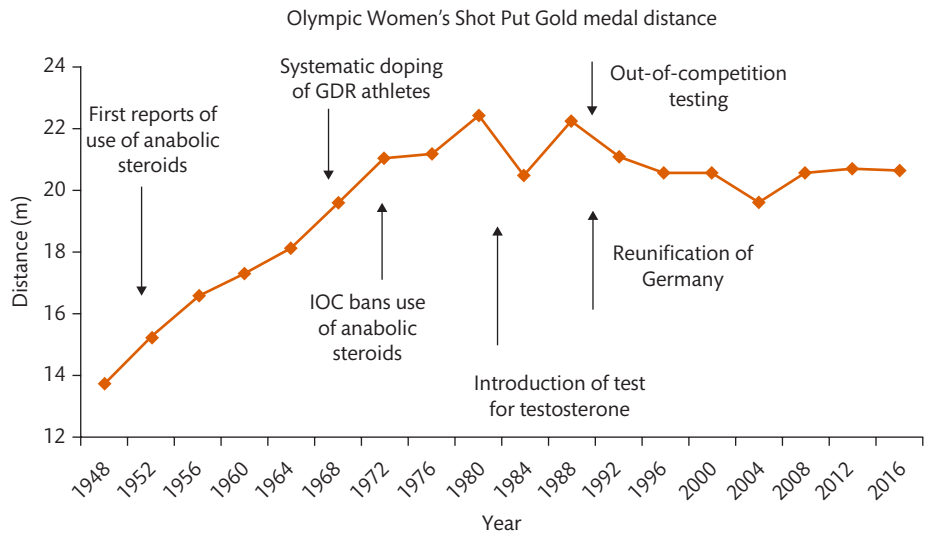

Figure 12.2.2.2 The winning distance in the women's Olympic Shot Put since 1948.

(FSH) secretion. In men sperm count falls and testicular atrophy may occur. In women there is reduced endogenous oestrogen production, ovulation is impaired, and irregular or absent menstrual cycles may ensue. These effects on reproduction function are prolonged taking many months to return to normal after AAS discontinuation.

Hepatotoxicity can occur with orally administered AAS due to a 'first pass' effect on the liver and cholestasis can progress to hepatocellular necrosis. The incidence of myocardial infarction is increased in young men taking AAS as is the risk of developing hypertrophic cardiomyopathy in genetically predisposed individuals. AAS misuse is also associated with the development of dyslipidaemia. The concentration of high-density lipoprotein (HDL) cholesterol is reduced while the concentration of low-density lipoprotein (LDL) cholesterol increases. The use of AAS may be associated with increased irritability, aggressiveness, and rarely mania. Dependency may develop in long-term users and depression may occur after AAS withdrawal.

Detection of AAS Misuse

Detecting AAS and many other drugs in urine is relatively simple and effective for two reasons: first, they are 'foreign' substances and should not be there at all and secondly, their metabolism and pharmacokinetics often mean that they can be traced for some time in urine.

Clenbuterol

Clenbuterol, a long-acting β2 agonist, is used as a partitioning agent in cattle where it promotes dietary intake towards muscle growth at the expense of fat [13]. It is an anabolic agent and a drug of abuse in sport. Eating contaminated meat can lead to the accumulation of levels in the human body that will provoke an adverse analytical finding [14]. It is also a bronchodilator and used to treat asthma in many countries (but not in the United Kingdom). B2 agonists are favourites of cross-country skiers where often they race at low environmental temperatures and may develop cold-induced bronchoconstriction. Clenbuterol is on the WADA list of prohibited substances and has a very long half-life in the body. In 1992 Katrin Krabbe of the GDR, along with two teammates, tested positive for clenbuterol and this effectively ended her career [15].

Growth Hormone

Growth hormone (GH) was initially promoted as a performance-enhancing drug in the first edition of *The Underground Steroid Handbook* authored by Dan Duchesne in 1982. It described GH as the newest and most potent anabolic substance of interest to athletes. This was seven years before the results of the first two double-blind controlled trials of GH administration to people with GH deficiency were published in the peer-reviewed scientific literature. These showed (among other things) the dramatic effects of GH on body composition [16, 17]. By then, however, it had become widely known in elite sport as a 'doping agent' often used in combination with testosterone. This was dramatically demonstrated to the world by the sprinter Ben Johnson in the Seoul Olympic Games of 1988 when he beat his arch rival Carl Lewis to win Gold in the 100 metres only to lose the medal a few days later when his urine tested positive for the anabolic steroid stanozolol; he later admitted in court to have taken GH as well [18].

In addition to the confession of Ben Johnson, other events pointed to its widespread misuse. For example, athletes have been caught smuggling vials of GH into countries where games are held [19] and pharmacy burglaries and hijacking of supply trucks have often seen specific targeting of GH.

Why Do Athletes Abuse Growth Hormone?

GH is best considered, like clenbuterol, as a 'partitioning agent' ('something which when included in an animal's nutrition increases the proportion of food energy that goes into the production of meat rather than fat') and results in changes in body composition with increases in lean tissue and matching reduction in fat mass. This is achieved through stimulation of protein synthesis at the expense of increased lipolysis [13]. Most of normal linear growth is determined by GH and IGF-I while androgens, oestrogens and other steroid hormones contribute little before puberty [13]. Post-puberty, GH, IGF-I, testosterone, and oestrogens are responsible for building and maintaining body composition. Excess GH and/or testosterone results in increased lean body mass in a dose-dependent manner. As strength is closely related to lean body mass it is easy to see why both testosterone and GH are misused by elite athletes to enhance performance although properly controlled trials to demonstrate this in athletes are very scarce since they are limited by ethical constraints.

In addition to regulating body composition, GH together with insulin are critical for the storage and timely release of metabolic fuel from depots and used in sport [13, 20–23].

The side effects of GH use are uncommon and occur only after prolonged use. These include a myopathy and development of diabetes.

Detection of Growth Hormone Misuse

GH misuse has been and still is difficult to detect. By 1989 the IOC recognized the need for a GH test and somewhat reluctantly for the first time put money into research for a method to detect GH misuse. There are now two methods available and approved by WADA, but both lack sensitivity and are probably only catching a small minority of those doping with GH.

The first method works by demonstrating an abnormally high ratio of the 22 kD isoform of GH to total GH. Recombinant GH (rhGH) contains only the 22 kD isoform and when injected leads to the suppression of all other isoforms that are normally present [21]. The second approach is based on two GH-sensitive 'markers' (IGF-I and P-III-NP), which when included in a discriminant function, are able to detect the prior use of GH for up to 14 days [22]. The tests are complimentary; the isoform test, introduced at the Athens Olympic Games of 2004, has a short 'window of opportunity (24 hours)' and is most potent when used for 'out of competition testing' while the marker method, introduced at the London Olympic Games of 2012, can detect prior GH use for longer. At the 2012 London Paralympic Games, two athletes tested positive by the 'marker' method who were not detected by the 'isoform' test. The athletes subsequently admitted that they took GH and were disqualified. This finding indicates that either they took rhGH more than 24 hours before they were tested, or they had taken 'pituitary-derived' GH which is not picked up by the isoform test since it still contains several isoforms. Pituitary-derived GH is believed to be available on the black market but although those misusing it may avoid testing positive by the isoform test, they will be at risk of contracting Jacob–Creutzfeldt disease.

Insulin-Like Growth Factor-I (IGF-I)

Although IGF-I is synthesized by most cells in the body, the majority of circulating IGF-I is produced by the liver under the control of GH and insulin. It has profound effects on cell proliferation and differentiation in many tissues as well as metabolic effects broadly like insulin. Unlike insulin, however, IGF-I stimulates protein synthesis whereas insulin's protein anabolic actions are mediated through inhibition of protein breakdown [24].

No doubt supplies are available on the black market and it may well be used as a performance-enhancing peptide and is on the WADA list of prohibited substances. In a double-blind randomized controlled study in 30 male and 26 female recreational athletes, recombinant human IGF-I (rhIGF-I) combined with IGF Binding Protein-3 (rhIGFBP-3) improved aerobic performance, as assessed by maximal oxygen consumption (VO_2 max), by 7%. In contrast to GH, there was no significant change in body composition [25].

Insulin

Insulin's major function is to control glucose, fat, and protein metabolism and in its absence type 1 diabetes develops with uncontrolled breakdown of body protein and fat to fuel gluconeogenesis and ketogenesis. Insulin normally regulates glucose metabolism primarily by inhibiting hepatic glucose production from glycogenolysis and gluconeogenesis (the 'Chalonic' action of insulin [26]). Contrary to common assumptions glucose entry into cells is primarily dependent on the glucose concentration in the blood stream and extracellular fluid and is only influenced by insulin at very high concentrations of insulin. Glycogen content of muscles is an important component of athletic performance in many sports. Infusions of insulin at rates sufficient to raise insulin concentrations to the high physiological levels and concomitant infusions of glucose to maintain normoglycaemia results in increases in muscle glycogen proportional to the rates of glucose infusion required to maintain normoglycaemia [27] (Figure 12.2.2.3). The use of insulin in such a way in people without diabetes was banned by the IOC in Nagano at the Winter Games in 1998.

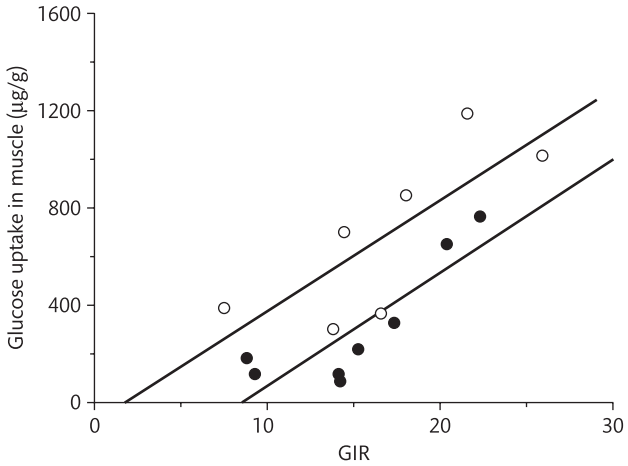

Figure 12.2.2.3 Relationship between glucose uptake in muscle glycogen and glucose infusion rate and the effects of insulin.

Erythropoietin

Receptor Gene Mutation and Blood Transfusion

Erythropoietin (EPO) is a hormone produced by the peritubular cells in the proximal tubules of the kidney and stimulates erythrocyte production by the bone marrow. Of interest to sport and doping is a family with a mutation in the EPO receptor who have erythrocytosis with asymptomatic polycythaemia due to continued bone marrow stimulation. The original phenotype (Eero Antero Mäntyranta) was a successful Finnish cross-country skier winning seven Olympic Medals [28, 29].

Prevalence of Erythropoietin Administration

Blood doping was first prohibited by the IOC in 1985. Before the ban was introduced, it was openly and commonly used by middle and long-distance runners as well as cyclists. Since its prohibition, there have been several high-profile cases involving athletes who have used either EPO or blood transfusion. These include Niklas Axelsson who tested positive for EPO in 2000 and Tyler Hamilton who used a homologous blood transfusion in 2004. The Spanish Operación Puerto in 2006 investigated allegations of blood doping in hundreds of athletes while several members of the Astana Team in the 2007 Tour de France tested positive for homologous blood transfusion leading to the withdrawal of the team. The German speed skater and fivefold Olympic Gold medallist Claudia Pechstein was banned for two years in 2009 for alleged blood doping.

Why do Athletes Abuse Erythropoietin?

Exogenous EPO, which is available as a recombinant protein or as an analogue, is abused by endurance athletes as the increase in red blood cells improves oxygen transport to muscles. Its administration results in a slow and sustained increase in erythrocyte volume, which is associated with improved performance. Endogenous EPO production can be induced by training at high altitude and this leads to a similar increase in erythrocyte volume and performance. However, only about 50% of competitive athletes respond to altitude training and it is notable that non-responders do not improve the aerobic capacity.

An alternative method used by athletes to expand erythrocyte volume is autologous or homologous blood transfusion. Blood is removed and erythrocytes are harvested, stored, and then reinfused later. In contrast to EPO administration, following a blood transfusion, the erythrocyte volume is only increased for a few weeks

Adverse Effects of Erythropoietin and Blood Transfusion

The main adverse effect of an increased erythrocyte volume is an increased risk of thrombotic events. However, there are also additional risks of infection associated with blood transfusion, particularly when this occurs in an unregulated fashion. Mismatched blood transfusions have occurred with serious consequences.

Detection of Erythropoietin Misuse

EPO testing (like that for GH) is difficult. The earliest test of EPO misuse was based on detecting immuno-specific bands in urine subjected to isoelectric focussing. This method separates natural EPO from synthetic varieties based on charge carried by the molecules. This method was first trialled in the Sydney Olympic Games in 2000 and has since been further refined and validated. It remains the mainstay of EPO misuse detection. This is used together with a blood test that examines the profile of red cells looking specifically at the proportion of young reticulocytes.

The Athlete's Biological Passport

Introduced by WADA in 2013, the athlete's biological passport involves individual athlete's 'profiling' of several biological variables in blood samples and the building of a statistical model representing each athlete. If a given sample produces a concentration of one or more key variables that are outside the 'normal limits' of their individual statistical model then that is considered a positive or can be used to monitor a suspicious athlete more closely. There are still concerns about the sensitivity and the reliability of the method [30]. There are plans to add an 'endocrine module' covering GH and other growth factors.

Synergistic Performance-Enhancing Properties of Testosterone, Growth Hormone, and Insulin

Although generally considered the most important, testosterone is not the only hormone regulating body composition and strength. GH plays an equal if not a more important role [13]. In fact, testosterone, GH and insulin work together in determining and regulating body composition while GH and insulin are the key substances regulating the flow of nutrients needed before, during and after an athletic event [20, 31].

Because of the ethical difficulties in giving GH or testosterone to athletes for research purposes and despite strong evidence of their anabolic effects, very little good evidence exists of their performance-enhancing properties. The one excellent randomized and well-controlled study in 96 recreational athletes carried out by Meinhardt *et al*. in Australia showed a 3.9% increase in sprint capacity with GH alone and an 8.3% increase when GH was coadministered with testosterone in men [32]. One short-term randomized and controlled study (6 days) in abstinent anabolic steroid-dependent men of average age 32 years showed a significant effect of GH on strength, peak power output, fat-free mass index and VO_2 peak [33]. In elderly unathletic men, Giannoulis *et al.* used a double-blind randomized placebo-controlled trial that looked at placebo versus GH alone, testosterone alone or testosterone and GH combined and found positive effects of GH alone on a number of exercise-related end points but more marked effects when GH was combined with testosterone [34].

Weissberger *et al*. using a randomized double-blind placebo-controlled design examined the effects of three months subcutaneous GH alone versus placebo on body composition and some strength and functional measures in elderly patients awaiting and undergoing total hip replacement. Preoperative GH treatment resulted in improvements in lean body mass and skeletal muscle mass that were sufficient to offset postoperative losses seen in the placebo group. The data showed also that GH preserved or improved muscle strength and walking ability [35].

12.2.3 Effect of Opioids on Adrenal and Reproductive Endocrinology

Eleni Armeni, Ashley B. Grossman, and Bernard Khoo

History of Opioids

Derived from the ancient Greek word *ὀπός*, which can be translated as vegetable juice, opium refers to the dry latex derived from the Opium Poppy (*Papaver somniferum*). References to the use of the Opium Poppy because of its medicinal properties can be found in ancient Greek, Egyptian, early Roman as well as Indian and Chinese texts [1, 2]. Widely available nowadays, opioids represent a class of drugs consisting of opiates (opioids derived from *P. somniferum)* like opium, morphine, diamorphine, codeine and pethidine, and synthetic/semi-synthetic opioids like methadone, fentanyl, tramadol, buprenorphine, and oxycodone [3].

Endogenous Opioids

Endogenous opioids are neuropeptides produced in the brain which interact with opioid receptors. Opioid receptors can be classified as follows.

- **μ-receptors (mu):** These are localized in the brainstem and medial thalamus. They are further divided into μ1-receptors, which regulate analgesia, and μ2-receptors, which regulate euphoria, pruritus, sedation, vomiting, respiratory depression, anorexia, and physical dependence.
- **κ-receptors (kappa):** These are localized in the limbic and other diencephalic areas, brain stem, and spinal cord. They are largely involved in the regulation of pain in women as well as the regulation of POMC secretion in the arcuate nucleus [4] and the gonadotropin-releasing hormone (GnRH) pulsatility clock [5].
- **δ-receptors (delta):** These receptors are found in highest densities in the olfactory bulb, neocortex, nucleus accumbens, and the caudate putamen in the brain, as well as spinal sites where they are associated with the regulation of spinal analgesia.

- **Nociceptin/orphanin FQ receptor (N/OFQ receptor):** This is a receptor which shares 60% homology with the classical opioid receptors and is the most recently discovered member of the opioid receptor family. It is widely distributed in the central nervous system (CNS), especially in the amygdala, subthalamic nucleus, hypothalamus, substantia nigra, and thalamus. The N/OFQ receptor appears to have a pro-nociceptive effect and also regulates immune function [6].

The main subtypes of endogenous opioids are endorphins, enkephalins, and dynorphins, endomorphins, and nociceptin/orphanin FQ. Endorphins are derived from the prohormone pro-opiomelanocortin (POMC), as shown in Figure 12.2.3.1: β-endorphin is involved in pain control via μ-receptors and to a lesser extent via **δ-receptors**. Other products of POMC processing include adrenocorticotrophic hormone (ACTH) which acts on the adrenal cortex inducing steroidogenesis and cortisol release; α-melanocyte-stimulating hormone (MSH) exerts its effect on melanocytes inducing pigmentation, on immune/inflammatory cells resulting in anti-inflammatory and antipyretic effects as well as on the central nervous system regulating food intake, energy homeostasis, and erectile activity. γ-MSH exerts an anti-inflammatory response on macrophages and regulates the autonomic nervous system.

Enkephalin-related peptides are derived from proenkephalin (PENK), which produces one copy of leu-enkephalin, six copies of met-enkephalin, an octapeptide and a heptapeptide [7, 8]. The *PENK* gene is expressed mainly in the posterior pituitary, in neuronal axon terminals as well as in neuronal and non-neuronal system tissues such as the gastrointestinal, the visual systems, and the placenta [7]. Enkephalins bind and activate μ-receptors and δ-receptors.

Dynorphin peptides are potent endogenous ligands, for example β-neoendorphin, dynorphin, leu-enkephalin, rimorphin, and leumorphin, which are derived from the prodynorphin peptide (PDYN). Dynorphins are highly selective for the κ-receptor, inducing analgesia, psychomimesis, dysphoria, and diuresis as well as psychostimulant effects [9].

The pronociceptin peptide (PNOC) is processed into N/OFQ is the endogenous ligand for the N/OFQ receptor. N/OFQ has a pro-nociceptive/antiopioid effect and regulates immune function. N/OFQ also stimulates ACTH and cortisol release, and enhances the effects of stress on these hormones [6, 10].

Endomorphin-1 and -2 are endogenous opioid peptides derived from a recently discovered propeptide, proMexneurin [11]. The endomorphins have a potent antinociceptive effect on acute and neuropathic pain *in vivo* via μ-receptors.

Exogenous Opioids

As noted earlier, opioids have been used for thousands of years as first-line drugs to manage pain of various severity. Commonly prescribed opioids include codeine, fentanyl, hydrocodone, hydromorphone, methadone, morphine, oxycodone, oxymorphone, and tapentadol. These opioids can be classified according to their duration of action, as follows: (a) rapid onset, like fentanyl; (b) short-acting, like codeine, buprenorphine, oxymorphone,

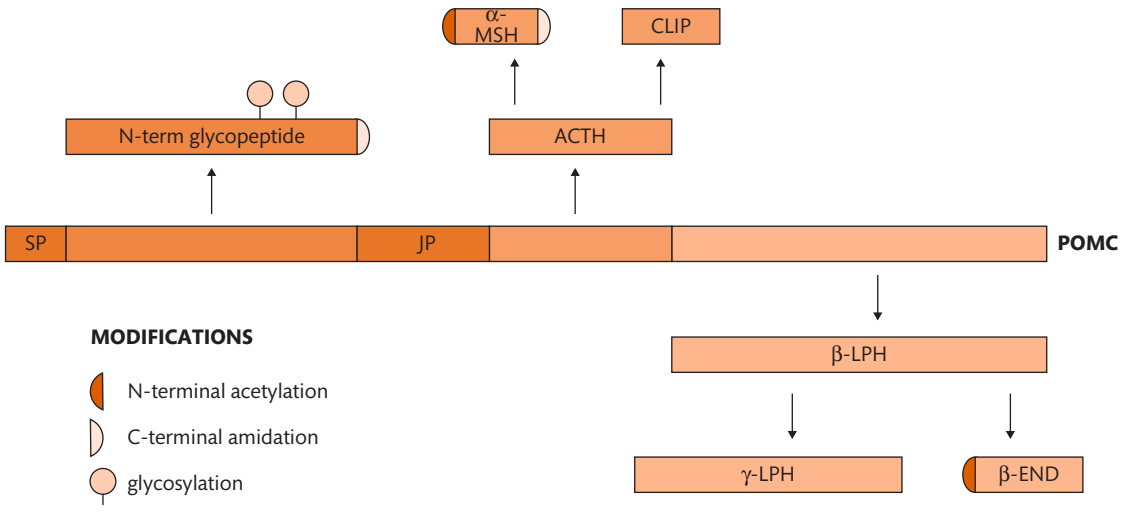

Figure 12.2.3.1 Pro-opiomelanocortin gene expression and post-translational modification.

oxycodone, hydrocodone and morphine; (c) long-acting, including transdermal fentanyl, methadone, extended-release oxycodone, extended-release oxymorphone or extended-release morphine [12, 13]. Their effects are exerted through activation of the opioid receptors either as agonists or partial agonists. Current efforts are underway to develop analogues with selective actions that have enhanced analgesic activity and reduced effects on the respiratory system. Strategies currently being used include exploiting biased signalling, targeting multiple or heterodimerized opioid receptors, modifying drug availability to receptors according to pH, and allosteric enhancement of endogenous opioid activity [14]. At present it is unclear how much the desirable effects of opioids can be disentangled from their potential for addiction using these strategies.

The possibility of substance abuse and dependency should always be considered during opioid treatment. Prior to initiation of opioid treatment, clinicians should carefully estimate the lowest effective dose and uptitrate the dose gradually. Appropriate justification regarding possible benefits and risks is necessary when administering doses equal or higher than 50 mg of morphine equivalents per day. Doses higher than 90 mg of morphine equivalents per day should be avoided. Immediate-release rather than long-acting opioids should be preferred when initiating opioid therapy for chronic pain [15].

The overreliance on the use of prescription opioids for the management of acute and chronic pain has reached epidemic proportions. Where patients are unable to obtain legal supplies of prescription opioids such as oxycodone there is substitution with illegally obtained opioids, such as fentanyl, which leads to increased risks of overdose and continued addiction [16]. The risk of addiction is dose-dependent and associated with chronic therapy (more than 3 months). This risk has been estimated as 5.5% in patients treated with a very low dose of non-prescribed opioid (<20 morphine equivalents daily) [17]. In addition, chronic treatment with methadone and buprenorphine is licensed for opiate use disorder; these are effective at reducing mortality and facilitating recovery, but entail the continuing side effects of opioid therapy [18]. Endocrine side effects of opioids are therefore increasingly encountered by physicians. The following summarizes the effects of opioids on two clinically important endocrine systems. For more information regarding the effects of opioids on other endocrine systems, see [19].

Effects of Opioids on the Hypothalamo–Pituitary–Adrenal (HPA) Axis

The HPA axis is a key pathway for the regulation of the body's response to stress. Endogenous opioids represent another such stress response pathway with a role in modulating pain [20], and also act to modulate the HPA axis. It is therefore not surprising that exogenous opioid treatment modulates the HPA axis. As noted earlier, POMC is processed to ACTH and β-endorphin, which inhibits POMC/ACTH release. The endogenous opioids β-endorphin and dynorphin are thought to regulate the POMC neurons via postsynaptic μ-receptors and presynaptic μ-, κ-, and δ-receptors [21]. Similarly, activation of opioid receptors by exogenously administered opioids inhibits POMC neurons postsynaptically and decreases the biosynthesis of POMC [22]. Consequently, there is a suboptimal ACTH and cortisol response to a corticotrophin-releasing hormone (CRH) stimulus in volunteers given morphine [23], but they may also suppress the hypothalamic release of the other ACTH-releasing factor vasopressin. Opioids also directly act on the adrenal gland as judged by inhibition of dehydroepiandrosterone sulphate (DHEAS) production [24, 25].

Acute administration of opioids suppresses ACTH, β-endorphin, and cortisol levels at baseline and secretion in response to CRH [23]. Patients under chronic treatment with both oral or transdermal opioid analgesics present with various degrees of cortisol deficiency [26–28]. The prevalence of secondary adrenal insufficiency in patients treated with opioids has not been systematically evaluated. A small cross-sectional analysis evaluated the potential association between long-term opioid analgesia and the HPA axis, confirming low cortisol levels and suboptimal response to synthetic ACTH(1–24) (*Synacthen*) in up to 6.25% of treated cases [29]. Similarly, adrenal insufficiency is estimated to occur in approximately 15% of patients treated with chronic intrathecal opioid administration [30].

In addition to the inhibitory effect on cortisol production, exogenous opioid treatment alters the circadian rhythm of the HPA axis, and appears to have a 'flattening' effect with more marked inhibition of morning cortisol levels relative to afternoon cortisol levels [31], However, while opioid peptides significantly inhibit the HPA axis [32], the endogenous 'tone' is not responsible for the circadian rhythmicity of ACTH and cortisol. The high doses of naloxone required to demonstrate endogenous opioid tone suggest the presence of non-μ receptors [33]. Prenatal exposure to opioids results in altered regulation of the HPA axis in offspring, according to animal studies, and more specifically: (a) changes in the baseline secretion of ACTH; (b) altered ACTH secretion by the hypothalamus following physiological and psychological stressors; (c) alterations to the activation of the glucocorticoid receptor [34]. The long-term impact of any alterations to HPA axis function in children born to opiate users is unknown.

The impact of opioids on the HPA axis seems to be reversible, with small studies describing increases in cortisol levels following successful withdrawal from opioid treatment. However, further longitudinal studies are required to determine the time course response of the HPA axis following the withdrawal of opioid administration [35].

No agreed clinical guidelines for the assessment and treatment of hypoadrenalism in opioid users exist. The following recommendations are therefore based on the authors' clinical experience and allied guidance on hypoadrenalism.

1. The clinical manifestations of hypoadrenalism can be non-specific (e.g. tiredness, weight loss, nausea, anorexia, hypotension). Therefore, adrenal function should be routinely evaluated in patients chronically treated with opioids, using 9 am cortisol levels, with repeated blood tests every 3–4 months.
2. 9:00 a.m. serum cortisol levels less than 100 nmol/L are strongly suggestive of adrenal insufficiency and in this case, replacement should be initiated. A 9:00 a.m. cortisol level higher than 380 nmol/L generally indicates normal adrenal function and does not require further investigation, but note that thresholds may be assay-dependent [36].
3. The cortisol response to *Synacthen*, according to locally established cut-offs, can be used to establish the diagnosis of hypoadrenalism in cases where the 9:00 a.m. cortisol level is

between 100 and 380 nmol/L. Insulin tolerance or glucagon stimulation tests are rarely required.

4. The specific characteristics of local cortisol assays [36], concomitant use of exogenous glucocorticoids (e.g. those used in management of chronic back pain), or presence of conditions affecting cortisol binding globulin such as oral oestrogen therapy or pregnancy, should be considered when interpreting the results.
5. Glucocorticoid replacement can be provided as short-acting corticosteroids (e.g. immediate-release hydrocortisone in 2–3 divided doses) or as longer acting agents (e.g. prednisolone given once a day) [37].
6. If the patient presents with clinical signs of acute hypoadrenalism, parenteral hydrocortisone should be administered in accordance with guidance on the acute management of hypoadrenalism [38].
7. The response of the HPA axis to withdrawal of opiates can be monitored by regular 9 am serum cortisol levels or short *Synacthen* tests as needed, with withdrawal of glucocorticoid support when euadrenalism is established.

Influence of Opioids on the Function of the Hypothalamo–Pituitary–Gonadal (HPG) and Prolactin Axes

The adverse impact of opiates on gonadal function has long been known. Referring to opium, Charles Alexander Bruce, a British explorer, described the effects on people in India as follows in 1843: 'This vile drug has kept, and does now keep down the population: the women have fewer children than those of other countries . . . the enfeebled opium-eaters of Assam, who are more effeminate than women' [39]. Hypogonadism is present in 21% of female and 75% of male patients on long-term treatment with opioids [40].

The endogenous opioid system influences the function of the HPG axis through interactions with hypothalamic and pituitary hormones, as well as directly on the gonads. One key mechanism involves suppression of pulsatile GnRH secretion during times of physiological stress, specifically via POMC processing, β-endorphin release, and activation of μ-opioid receptors. A second mechanism involves the termination of GnRH pulses via dynorphin, κ-receptors, and the so-called KNDy neurons in the arcuate nucleus which secrete kisspeptin [5]. A third, more indirect, mechanism involves inhibition of dopaminergic pathways, leading to de-repression of prolactin secretion [41] which in turn leads to a suppression of gonadotropin secretion [42].

With respect to male patients, acute administration of opioids leads to suppression of luteinizing hormone (LH) secretion, demonstrating their tonic inhibitory effect on GnRH pulsatility [43]. Naloxone antagonism leads to stimulation of LH and testosterone secretion [44]. The opiate effect on pituitary hormone secretion is reversible following administration of opioid antagonists. Opioid-induced androgen deficiency is diagnosed as low levels of testosterone in patients on treatment with opioids. Long-term opioid treatment reduces testosterone [45], a dose-dependent effect that is not influenced by the type of administered opioids (i.e. commonly prescribed opioids, heroin, or methadone) [46]. The impact of the dose was particularly pronounced in men treated with short-acting opioids. A longer duration of opioid action increases the risk of androgen deficiency more than 3-fold when compared with administration of short-acting agents [47]. With respect to erectile function, there are direct inhibitory effects, as the occurrence of erectile dysfunction is independent of serum testosterone levels in people taking opioids [48]. It is thought that central μ-receptors inhibit the oxytocinergic neurons in the paraventricular nucleus of the hypothalamus, directly inhibiting penile erection [49].

Endogenous opioid tone varies during the menstrual cycle, due to phase-dependent β-endorphin tone, opioid receptor expression/binding affinities, and the key influences of oestrogen and progesterone on endogenous opioid tone itself. Indeed, endogenous opioid tone plays a key role in the transition between stages of the menstrual cycle. In the early follicular phase, the endogenous opioid tone is low, enabling high-frequency pulsatile GnRH secretion. As oestradiol levels rise in the mid-follicular phase, leading to increased endogenous opioid tone and less frequent GnRH pulsatility, in turn leading to increased LH pulse amplitude which prepares the way for the ovulatory LH 'spike'. Luteal secretion of progesterone induces a high endogenous opioid tone, consequently reducing the frequency of GnRH and LH pulses (once every 5–6 hours instead of once an hour during the follicular phase). With menses, progesterone and oestradiol levels fall, endogenous opioid activity declines, leading to a restart of high-frequency pulsatile GnRH secretion in the follicular phase [50]. The effect of opioids (and opioid antagonists) on HPG axis function in animal models is blunted in prepubertal animals, suggesting that the effect of opioids on the HPG axis may differ according to the stage of sexual development [19].

Stress conditions (e.g. excessive exercise, weight loss, anorexia nervosa) have been speculated to increase endogenous opioid tone which in turn suppresses GnRH pulsatility, gonadotrophin, and oestradiol secretion. One hypothesis is that this drives the 'functional hypothalamic amenorrhoea' that is observed in such patients. However, the success of opioid antagonism as a therapy for this condition is variable: in one study, naloxone blockade was not successful in restoring cycles in patients with weight-related amenorrhoea [51], but in other hands naltrexone restored cycles in approximately 50% of patients [52]. It seems that weight-related amenorrhoea, and presumably the related exercise-induced amenorrhoea, are not opioid-dependent as they are naloxone insensitive, at least in short-term studies, although hyperprolactinaemic amenorrhoea may be opioid-mediated [51].

Interestingly, dysregulation of the endogenous opioid system appears to have a key role in polycystic ovarian syndrome (PCOS). Increased endogenous opioid activity has been linked with a reduction in GnRH pulsatility and elevated LH/follicle-stimulating hormone (FSH) ratios. Moreover, enhanced opioid activity stimulates pancreatic insulin secretion, inhibits insulin clearance by the liver and decreases peripheral insulin sensitivity, hence contributing to the hyperinsulinaemia observed in PCOS. This hyperinsulinaemia in turn synergizes with LH to induce hyperandrogenism, and also reduces hepatic sex-hormone-binding globulin (SHBG) production leading to elevated free androgens and the hyperandrogenic manifestations of PCOS. Elevated endogenous opioid tone is also conjectured to drive other issues seen in PCOS such as depression and poor sleep quality. Administration of opioid antagonists, like

naloxone and naltrexone, may help reverse the hormonal imbalances observed in PCOS cases [42, 53].

As a result of this complexity of regulation, the effects of opioid treatment in women can vary largely throughout the reproductive life of the woman as well as within the menstrual cycle. Exogenous opioid peptides suppress LH and FSH secretion when given acutely to normal and postmenopausal women [54]. Exogenous opioids have been shown to be associated with a reduced FSH/LH ratio, and with a lower age threshold of FSH/LH ratio inversion (a marker of menopause) indicating a shorter duration of fertility [55]. Naloxone increases LH pulse frequency in women; unlike the regulation of the HPA axis, as this is naloxone-sensitive it is presumably μ-receptors that mediate the effect [56]. Administration of the opioid antagonist naltrexone has positive effects on both the HPG and HPA axes, by inducing elevation of LH levels as well as levels of ACTH and cortisol, respectively [42].

Endogenous opioids are also known to directly influence oocyte maturation, preimplantation embryo development, endometrial, and myometrial function. β-endorphin and met-enkephalin are present within ovarian follicular fluid and influence oocyte maturation in a paracrine fashion by binding to δ-, κ-, and μ-receptors. Granulosa cells also express μ-receptors which is thought to stimulate angiogenesis. Endometrial fluid contains β-endorphin and met-enkephalin produced presumably by endometrial tissues. μ-receptors in the endometrial tissues are known to regulate oestradiol receptor expression. At least in animal models, morphine can inhibit the development of preimplantation embryos and reduce uterine receptivity to implantation. Opioids also inhibit/relax myometrial contraction, which is important for sperm transport in the uterus and Fallopian tubes [42]. However, the exact impact of exogenous opioids on oocyte maturation, fertilization, embryonic development, and implantation in humans is as yet unknown.

Finally, animal studies report adverse effects on the reproductive system of newborns following intrauterine exposure to opioids. Prenatal exposure to an opioid environment induces pre- and postnatal alterations of the hormonal milieu, and potentially changes of sexually dimorphic brain regions regulating reproductive and play behaviour [34].

No agreed clinical guidelines for the assessment and treatment of hypogonadism in opioid users exist. The following recommendations are therefore based on the authors' clinical experience and allied guidance on hypogonadism.

1. Physicians treating patients who are using opioids chronically should routinely enquire after symptoms and signs of potential hypogonadism during clinical reviews. For male patients, diminished libido, decreased frequency of morning erections and erectile dysfunction are the most specific symptoms [57]. For female patients, oligo- or amenorrhoea together with symptoms of hypo-oestrogenization (hot flushes, sleep disturbance, dyspareunia) are the most specific symptoms [58].
2. If hypogonadism in a male patient is suspected, evaluate with two separate fasting measurements of 9am testosterone with LH/FSH and prolactin levels. Determination of free testosterone by equilibrium dialysis where available or by Vermeulen calculation utilizing simultaneous measurements of SHBG and albumin may be helpful in the assessment of cases where patients have extremes of SHBG concentration, such as in obesity (which lowers SHBG), or with liver disease (which tends to increase SHBG) [57].
3. If hypogonadism in a female patient is suspected, evaluate with oestradiol, LH/FSH and prolactin levels. Human chorionic gonadotropin (HCG) testing is mandatory to exclude pregnancy.
4. Consider pituitary imaging with MRI to exclude a substantial hypothalamic/pituitary lesion if the blood tests indicate a secondary hypogonadism or hyperprolactinaemia [59].
5. If opioid-induced hypogonadism is confirmed, hormone replacement with testosterone [57] or oestrogen ± progestogen [59] should be considered.
6. Patients with long-standing hypogonadism should be assessed for osteopenia/osteoporosis with dual-energy X-ray absorptiometry (DEXA) and treated accordingly [59].
7. We recommend that physicians collaborate with pain control and addiction specialists to withdraw, if possible, patients from chronic opioid use prior to attempts at conception and/or fertility treatment to mitigate their effects on fertility, conception, and prenatal development, as well as on the HPA axis.

Effects of Opioids on the Posterior Pituitary and Sympathoadrenal System

Exogenous opioid peptides, contrary to earlier expectation, inhibit the release of vasopressin in the human [60], in agreement with animal studies showing a direct inhibitory effect on release from the hypothalamus. The significance of this induced free water diuresis in chronic opiate users remains unclear but seems unlikely to have a major impact. Similarly, opioids inhibit the release of adrenaline and noradrenaline from the sympathoadrenomedullary system, probably at κ- or δ-receptors. There appears to be an endogenous opioid tone which chronically inhibits these systems and which is more active during any form of physical or mental stress-induced activation [61–63]. Again, the significance of this in terms of chronic opioid use is undetermined.

Conclusions

Endogenous opioid pathways are fundamental to the regulation of many endocrine axes, the most clinically important of which are the HPA and HPG axes. Chronic opioid users are at high risk of developing hypoadrenalism and hypogonadism, but even short-term use may lead to suppression of the HPA and HPG axes and cause diagnostic confusion [64, 65]; therefore, physicians and other health workers involved in their treatment should ensure that a robust screening and treatment protocol is in place.

SECTION 13

Endocrinology of Cancer

13.1

Endocrine Disorders Caused by Cancer or its Treatment

13.1.1 Metastatic Disease in Endocrine Organs

Thomas G. Papathomas and Vania Nosé

Introduction

Endocrine organs are classified into primary and secondary based on whether a hormone-secreting organ synthesizes the relevant hormone(s) as a primary function or not. This chapter will focus on metastatic disease in major endocrine organs, including adrenals, pituitary, thyroid and parathyroid glands, from malignancies other than haemato-lymphoid neoplasms. Their presence is best regarded as generalized involvement rather than metastatic spread. Herein, we discuss the prevalence and importance of recognition of metastases in endocrine organs and highlight various aspects of endocrine organ-specific metastatic disease.

Prevalence of Metastatic Disease in Major Endocrine Organs

The prevalence of metastatic malignancy varies in the clinical setting (see Table 13.1.1.1):

- common in the **adrenals** in patients with lung carcinoma
- uncommon in the **pituitary gland** in patients with breast and lung carcinomas
- rare in the **thyroid gland** in patients with renal cell and lung carcinomas
- very rare in the **parathyroid glands** in patients with breast carcinoma

Importance of Recognition of Metastatic Deposits in Endocrine Organs

Recognition of metastatic disease in endocrine organs is important for various reasons (see Figure 13.1.1.1).

Metastases might:

- be discovered as an incidentaloma in an unconfined anatomical space without any pressure effects (e.g. adrenal metastases)
- occur as a mass in an unconfined, or relatively unconfined, space producing pressure effects, e.g. on the optic chiasm causing homonymous hemianopia (e.g. pituitary metastasis)
- present as a space-occupying lesion in a relatively confined anatomical space, such as the superior mediastinum (e.g. thyroid metastases)
- present with endocrine gland insufficiency, which is usually detected at an advanced stage given the large reserve of function of endocrine organs (e.g. pituitary and adrenal metastases)
- be functional secreting a hormone or other substance relevant to the primary neoplasm (e.g. small cell carcinoma of lung origin or pancreatic neuroendocrine tumour metastases)
- cause the host tissue to secrete excessive amounts of hormone because of their presence (e.g. transient hyperthyroidism due to thyroid parenchyma destruction and hormone release)
- be mistaken clinically for a primary neoplasm of the gland in which they are found causing diagnostic and management difficulties (e.g. metastatic origin from an occult primary)
- be discovered on histopathological examination within a primary endocrine tumour (i.e. tumour-to-tumour metastasis)

Table 13.1.1.1 Prevalence of metastases in major endocrine organs

	Relatively common primary sites	Relatively rare primary sites
Adrenal glands	Lung, gastrointestinal tract	Kidney, breast, skin (melanoma)
Pituitary gland	Breast, lung	Kidney, prostate, gastrointestinal tract, skin (melanoma), thyroid
Thyroid gland	Kidney, lung	Breast, gastrointestinal tract
Parathyroid glands	Breast	Skin (melanoma), lung, kidney, thyroid

The Adrenal Gland

The adrenal gland is the fourth commonest anatomic site for metastatic deposits after lung, liver, and bone, whereas per unit weight is the most frequently involved site [1, 2].

The most common primary tumour metastatic to the adrenals arises from the **lung** [3–5]. Based on a 30-year period retrospective **systematic review** of 464 patients with adrenal metastasis at Queen Mary Hospital in Hong Kong [3], **lung cancer** (35.4%) was the most frequent followed by malignancies originating from upper gastrointestinal (GI) tract (26.4%), hepatobiliary (10.7%) and pancreas (6.9%), lower GI tract (5.4%), kidney (4.3%) and breast (2.9%). Data emerging from a **multicentric European study** including 317 patients indicated the leading sources of adrenal metastasis, as follows: **lung** (46.7%), lower GI tract (13.6%), kidney (11.7%), breast (3.5%) and skin (melanoma; 3.5%) [4]. The difference in the relative prevalence of primary tumours has been attributed to the geographic origin and/or source of data [4, 5].

In contrast to autopsy-based data [6], metastatic melanoma to the adrenal gland is a rare ante-mortem diagnosis [3, 4, 7]. This is usually associated with evidence of systemic disease and overall poor prognosis with almost one-fifth of cases being of unknown primary origin [7, 8].

Primary adrenal tumours can rarely receive metastatic deposits with **lung cancer** being the most frequent donor neoplasm in tumour-to-tumour metastatic setting [9–12].

Most adrenal metastases are identified at staging or follow-up of patients, who are either oligo-metastatic or suffering from widespread metastatic disease [1, 3, 5]. Isolated metastasis after surgical removal of a primary tumour is a rather infrequent event [3, 13]. Less than 2% of renal cancer patients who develop a metachronous metastasis will present with a solitary adrenal metastasis [14] being consistent with data deriving from the **Japanese Society of Renal Cancer** [15]. Albeit, cases of isolated metastasis have been increasingly reported in the medical literature, highlighting the unpredictable behaviour of diverse tumour types with a variable propensity for metastatic spread. When bilateral and extensively effacing the adrenal parenchyma, latent or overt adrenocortical insufficiency can be detected. Concomitant involvement of pituitary gland and unilateral adrenal destruction can also result in secondary insufficiency, while abdominal pain is another rare presentation due to intra-abdominal haemorrhage and haemoperitoneum [3].

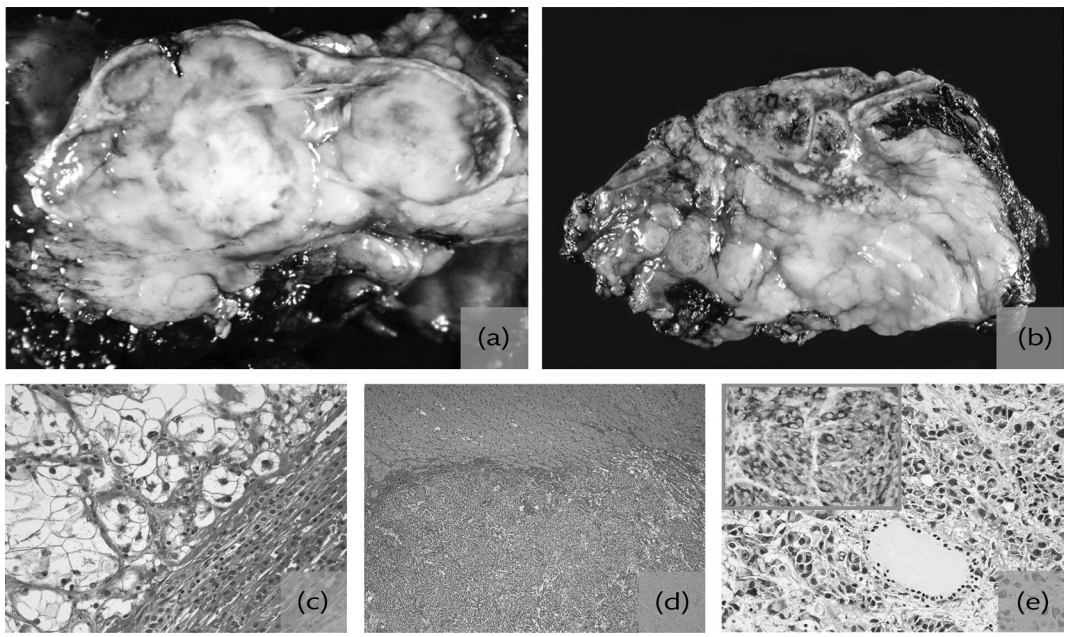

Figure 13.1.1.1 Transverse sections of adrenals either extensively replaced by confluent pale-white metastatic deposits of lung adenocarcinoma (a) or moderately expanded by two metastases of renal cell carcinoma, having a variegated appearance (b). Renal cell carcinoma metastatic to the adrenal gland simulating a primary adrenal tumour (c) and medullary thyroid carcinoma metastatic to the adrenal (d). Metastatic melanoma extensively effacing the thyroid gland parenchyma (e), which was confirmed on immunohistochemical grounds, i.e. S100, MELAN-A and HMB-45 (e; inset).

The Pituitary Gland

Pituitary tumours are intrasellar neoplasms with **pituitary adenomas** being the most common constituting up to 15% of all intracranial tumours, while tumours metastatic to the pituitary gland being rather rare [1]. Per data stemming from the **German Pituitary Tumour Registry**, the former account for 84.6% and the latter for 0.6% of 4122 surgical cases [16]. Only 0.4% of intracranial metastatic tumours are confined to the pituitary gland according to the **Brain Tumour Registry of Japan** [17], being consistent with previously published data supporting rare involvement of the pituitary gland by intracranial metastatic disease [18].

Based on a systematic review with pooled individual patient data analysis, He *et al.* [19] calculated the incidence of pituitary metastasis based on stratified patient populations, as follows: 0.87% among all intracranial metastases; 1.9% among all autopsied cancer cases; 11.56% among all breast cancer patients who had hypophysectomies and 12.83% among all autopsied breast cancer patients. This study confirmed **breast** and **lung cancer** as the most common primary malignancies accounting for two-thirds of the cases, while highlighted cancer of unknown primary (CUP) in approximately 3% of cases. To extend, it was shown that the odds ratio of a breast cancer patient having pituitary metastasis is ~7 times greater than a patient suffering from a different primary cancer.

Breast and lung are the commonest primary sites of metastatic origin in the rare tumour-to-tumour metastatic context [20].

Pituitary metastasis occurs mostly in patients suffering from systemic dissemination and less frequently being the only site of metastasis or the first manifestation of a latent primary tumour, as documented in 10% up to 40% of cases [17, 19, 21]. Although these tumours are clinically silent, a subset of patients is having pituitary-related symptoms [19, 21]. Diabetes insipidus remains the most frequent symptom at presentation, reflecting higher prevalence of metastatic deposits in the posterior lobe possibly due to lack of direct arterial blood supply to the anterior counterpart. Anterior hypopituitarism, pan-hypopituitarism, cranial nerve palsies, visual disturbance, and headaches can also occur. Extraordinary presentation of acromegaly due to somatotroph hyperplasia elicited by a metastatic GHRH-producing pancreatic neuroendocrine tumour has been documented [22].

The Thyroid Gland

Intrathyroidal metastasis is a relatively uncommon event in clinical practice, i.e. <0.2% of thyroid malignancies [23, 24]. Based on a systematic review and meta-analysis involving a total of 514 patients, Straccia *et al.* [23] evaluated the type of metastatic spread and the localization of the primary tumour. The overall rate of metachronous metastases was estimated at 69%, while the overall metastatic rate from organs located in the infradiaphragmatic region was 53%. **Renal cell carcinoma** was the most frequent malignancy followed by lung carcinoma, breast carcinoma, and colorectal adenocarcinoma. The **International Head and Neck Scientific Group** [24] confirmed the order of frequency in the *clinical series* and highlighted **lung cancer** as the most common primary tumour in the *autopsy series*. Both studies documented CUP in 2% of cases. Along these lines, Hegerova *et al.* [25] identified 97 patients over a 30-year period at the **Mayo Clinic** (Rochester, USA) with **kidney** (22%) and **lung** (22%) constituting the most frequent primary sites.

In accordance with a predilection of spread to endocrine tumours [26], metastatic disease can rarely involve primary thyroid tumours with follicular adenoma and papillary thyroid carcinoma being the commonest benign and malignant recipient respectively [27]. **Renal cell carcinoma** is the most common donor neoplasm followed by malignancies originating from lung, breast, and lower GI tract [27, 28].

Although most patients with a diagnosis of intrathyroidal metastasis have a prior history of malignancy, occult primary accounts for approximately 30% of cases [23]. Metastatic deposits can be asymptomatic or present with unspecific symptoms at an advanced stage, such as dysphagia, hoarseness, pain, and airway compromise. Extensive destruction of thyroid parenchyma can cause changes in thyroid function and regarded as symptom of advanced stage disease [23, 24].

The Parathyroid Glands

Metastatic disease to the parathyroid glands is rare, and poorly documented. Given evidence emerging from thyroidectomies performed for cancer and autopsy data, Shifrin *et al.* [26] suggested that metastatic involvement might be probably underreported [29, 30]. Approximately 4% of the former cases as well as ~12% of patients with various disseminated malignancies harboured metastatic infiltrates when multiple parathyroid glands were sampled [1, 30]. In a series of 392 consecutive parathyroidectomies performed for primary hyperparathyroidism, only one metastatic cancer was detected [26].

Per the **2017 WHO classification of endocrine neoplasia** and based predominantly on post-mortem data, the most common primary site is **breast** followed by skin (melanoma), lung and kidney [1, 26, 30]. Regarding cancer arising from the thyroid gland, the incidence rate of parathyroid involvement is ranging from 0.4% to 3.9% and with only a small subset corresponding to true metastasis [31, 32].

Metastatic disease can involve normal parathyroid tissue, hyperplastic parathyroid glands, and parathyroid adenomas. The patients might be asymptomatic or present with a mass in the neck, clinical signs of parathyroid disease and/or disseminated systemic metastasis. To exemplify, Torregrossa *et al.* [33] reported a metastatic renal cell carcinoma without clinical signs of parathyroid disease and/or disseminated metastasis. In the hyperplastic setting, Venkatraman *et al.* [34] described an incidental discovery of metastatic lung adenocarcinoma within a parathyroid gland resected for surgical management of primary hyperparathyroidism, while Shifrin *et al.* [35] a metachronous metastasis of neuroendocrine thymic carcinoma to a hyperplastic parathyroid gland in a patient with multiple endocrine neoplasia type 1 syndrome and widespread metastatic disease.

13.1.2 Paraneoplastic Endocrine Syndromes

David W. Ray

Introduction

Production of hormones usually occurs in specialized endocrine glands. Such hormone production is typically under control from higher centres, ultimately the brain, and also subject to complex negative feedback. This results in tight regulation of circulating hormone levels, and affords a mechanism for influencing diverse tissue function throughout the body. Inappropriate hormone production by non-endocrine tissue causes a spectrum of rare syndromes which are important as they are not only a management challenge, but also because they shed light on the regulation of tissue-specific gene expression with widespread ramifications for understanding human physiology. In addition, inappropriate expression of a peptide may be useful as a tumour marker, as for example human chorionic gonadotrophin (hCG) or α-fetoprotein. This chapter will address the basic mechanisms of ectopic hormone production and will further discuss specific clinical syndromes.

The Origin of Ectopic Hormones

The use of sophisticated techniques has revealed that hormones may be expressed 'ectopically' in a variety of normal tissues other than in specialized glands [1]. It is, therefore, less than surprising that tumours arising from these tissues can give rise to ectopic hormone producing syndromes. If the hormone production in the tumour remained under physiological control ectopic hormone production would not pose a clinical problem. Sometimes aberrant control has an obvious mechanism, for example, lack of specific neural connection, physical distance from a portal system or absence of receptors for hormonal modulators of gene expression.

Dysdifferentiation Theory

This proposes that neoplastic change occurs in progenitor cells, rather than terminally differentiated ones [2]. The transformed progenitor cell subsequently undergoes differentiation but at each stage experiences a partial block. If this theory holds it would predict a tumour with a mixed population of cells at different stages in development. Depending on how the blocks to normal differentiation were arranged a majority of cells may develop into an endocrine cell type, and give rise to a typically endocrine-type tumour. This model may explain why certain hormones tend to be produced by certain tissues, since the tumour would retain some features of its parent tissue and would tend to transcribe the same genes as its parent tissue though may express these aberrantly (Figure 13.1.2.1).

Extrapituitary expression of the adrenocorticotrophic hormone (ACTH) gene (*POMC*) is described in detail next as a model for ectopic hormone syndromes. Ectopic ACTH syndrome shares many features with other ectopic hormone syndromes, and as many of the underlying mechanisms of expression are common they have a wider application.

Ectopic ACTH Syndrome

The human *POMC* gene is encoded in three exons on chromosome 2. The first exon is non-coding, the second contains the signal peptide which targets the protein product to the regulated secretion pathway and the third exon encodes the majority of the mature protein, including ACTH. In pituitary corticotroph cells, the only cells in health that express the gene at high level, the mature mRNA from the *POMC* gene is of 1200 nucleotides. A third *POMC* transcript has also been described which is longer than the pituitary form (about 1500 nucleotides). This arises from a site, or multiple sites, within the 5' flanking region of the human *POMC* promoter. This mRNA species therefore includes the entire coding region of the peptide, and it does appear to give rise to a secreted peptide product. This 'long' form of the *POMC* mRNA is found in extrapituitary tissues and tumours.

Dysdifferentiation hypothesis for ectopic hormone production

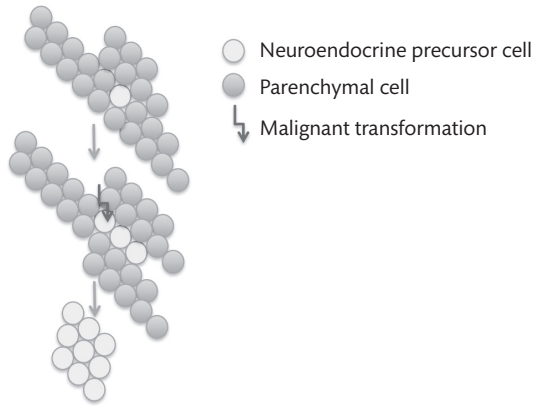

Figure 13.1.2.1 Dysdifferentiation results in aberrant gene expression. The malignant transformation of a progenitor cell results in a clonal population of cells that have undergone atypical differentiation. These cells share some features with their progenitor cells and may continue to express genes associated with these immature, incompletely differentiated cells. Malignant transformation of a cell can lead to persistent, or enhanced, hormone gene expression in the clone of proliferating cells.

Regulation of *POMC* Gene Expression

Expression of the *POMC* gene appears to be predominantly controlled at the level of gene transcription [3]. Expression of the *POMC* gene in the anterior pituitary corticotroph cell requires the action of a tightly restricted transcription factor, a member of the T-box family, termed Tpit [4]. This factor acts with the homeodomain protein PitX1 and promotes recruitment of SRC family coactivators to the *POMC* promoter, leading to enhanced gene transcription [5].

Corticotropin-releasing hormone (CRH) acts on pituitary corticotroph cells to increase cyclic adenosine monophosphate (cAMP) accumulation and activates mitogen-activated protein kinases. There is also evidence of activation of the orphan nuclear receptor nerve growth factor–induced clone B (or Nur 77) [6] leading to enhanced *POMC* transcription through the recruitment of SRC coactivators to nerve growth factor–induced clone B [5, 7]. As nerve growth factor-induced clone B and Tpit act synergistically, this suggests the formation of a regulatory complex on the *POMC* promoter with Tpit, NGFI-B and SRC coactivators [5]. It is important that expression of Tpit promotes corticotroph cell differentiation and that its expression is more limited than that of *POMC*. Therefore, there is no Tpit expression in hypothalamic *POMC*-expressing neurons, suggesting that Tpit is specific for corticotroph-specific expression of *POMC*; other mechanisms are responsible for expression elsewhere. Tpit expression has been found specifically in human pituitary corticotroph adenomas [4].

Glucocorticoids repress transcription of the *POMC* gene by binding to two DNA elements in the 5′ flanking region of the promoter. The more proximal element, an imperfect palindrome 63 nucleotides upstream from the transcription start site, is thought to bind three glucocorticoid receptor molecules in an unusual trimer formation [8–10]. This conformation of receptors on DNA directs repression of transcription rather than enhancement. Further upstream, between −480 and −320, there is another glucocorticoid-regulated element, suggesting that these two DNA elements interact to achieve the full effect of glucocorticoid repression [11]. It is interesting that Tpit expression, essential to the corticotroph cell type and to *POMC* expression, is not affected by glucocorticoids, in contrast to *POMC*, which is repressed [12]. Because Tpit is not part of the mechanism allowing glucocorticoid repression of *POMC*, the lack of Tpit in ectopic ACTH syndrome causing tumours cannot explain the failure of glucocorticoid repression characteristic of the disorder. However, the mechanism underlying *POMC* induction by CRH in some well-differentiated carcinoid tumours causing ectopic ACTH syndrome is not yet defined. Although the expression of nerve growth factor–induced gene B and Tpit in such tumours is not definitively addressed, other pathways, such as mitogen-activated protein kinase activation, cAMP activation, and induction of c-fos may be important.

A number of other hypothalamic factors act on the pituitary corticotroph to influence *POMC* expression. However, their modes of action are not well defined. In particular, arginine vasopressin stimulates *POMC* expression rather weakly but augments CRH action. The intracellular pathways activated by arginine vasopressin appear to be protein kinase C dependent, but arginine vasopressin also potentiates the action of CRH on cAMP generation [13].

Evidence points to intrapituitary factors as important modulators of corticotroph function. One such factor is the proinflammatory cytokine leukaemia inhibitory factor, which signals through the Janus kinase/signal transducers and activators of transcription pathway [14]. Leukaemia inhibitory factor has been shown to act on the *POMC* gene through a specific response element that overlaps with the −166 CRH response element. In addition to stimulating *POMC*, transcription leukaemia inhibitory factor also appears to trigger a 'switch' in cell phenotype from proliferative to synthetic [15].

However, many other peptide growth factors and cytokines are capable of activating cAMP, mitogen-activated protein kinase and Janus kinase/signal transducers and activators of transcription signalling cascades and thus are potentially capable of regulating *POMC* expression in non-pituitary tissue. Although extrapituitary tissues lack expression of corticotroph-specific transcription factors, activation of common signalling cascades might be expected to result in *POMC* gene expression. In extrapituitary tissues, the *POMC* gene may be modified to render it transcriptionally silent. One such irreversible modification is DNA methylation. The loss of methylation in tumour tissue may allow transcription of the gene to be activated by the common signalling pathways described previously. There is some evidence that such changes in DNA methylation do occur in cell line models of ectopic ACTH syndrome [16]. It seems likely that *POMC* expression per cell is less in most extrapituitary tumours compared with the pituitary corticotroph, but this relative inefficiency of expression is compensated for by the greater number of cells expressing the gene in extrapituitary tumours.

Pathophysiology

ACTH immunoreactivity has been recognized to show size heterogeneity for many years, with the presence of high-molecular-weight forms being detected in human plasma. The ectopic ACTH syndrome was the first recognized of the ectopic hormone syndromes. In its most florid form it is rare, affecting 4.5% of patients with small cell lung cancer in one study, but there is evidence of derangement in the hypothalamic–pituitary–adrenal axis in most patients with small cell lung cancer. Analysis of tumour tissue surprisingly suggested the presence of immunoreactive ACTH, even in the absence of clinical features of hormone excess [17]. The ACTH was present predominantly in a high-molecular-weight form, of approximately 20 kDa, but this purified material could be cleaved to mature ACTH (4.5 kDa) by the action of trypsin. Further work identified the presence of immunoreactive ACTH-like peptide in a variety of normal tissues, suggesting that extrapituitary ACTH expression was less 'ectopic' than inappropriately regulated. The ACTH immunoreactivity was found to have no biological activity, and was assumed to be 'big' ACTH. However, identification of predominantly high-molecular-weight forms of ACTH in the circulation of patients with clinically apparent Cushing's syndrome does suggest that the precursors of ACTH may have some activity at the ACTH receptor.

POMC Processing

The *POMC* gene leads to the generation of a pre-pro-hormone, *POMC*. This protein undergoes a series of proteolytic cleavages at dibasic amino acid residues to give rise to a series of small molecules including ACTH, melanocyte-stimulating hormone (MSH) and β-endorphin. In the anterior pituitary ACTH is cleaved by the action of a specific protease termed PC1 (for pro-hormone

convertase type 1). In the rodent intermediate lobe melanotroph the *POMC* molecule undergoes more comprehensive digestion to give smaller fragments, MSH, β-endorphin and corticotrophin-like intermediate lobe peptide (CLIP) as a result of cleavage by pro-hormone convertase type 2 (PC2).

In the majority of extrapituitary tumours causing the ectopic ACTH syndrome processing of the pre-pro-hormone is incomplete. Therefore, the ectopic ACTH syndrome is characterized by the presence of high-molecular-weight forms of ACTH in the circulation [18]. It is likely that the extent of processing correlates with the degree of neuroendocrine differentiation of the tumour, and hormonal manifestations are probably only seen in tumours with significant hormone processing capacity. This lack of processing could result from a lack of the specific cleavage enzymes, PC1 and PC2, which are expressed only in specialized endocrine tissue, or with a switch from a regulated secretory pathway to a constitutive one. A number of small, highly differentiated, slow-growing tumours, typically bronchial carcinoid, have been characterized to process *POMC* in the neurointermediate lobe manner, giving rise to small fragments in the circulation, such as CLIP, and β–MSH. These have been used to aid diagnosis in some cases of Cushing's syndrome, although the series are too small to confidently extrapolate from.

Dysregulation of *POMC* Expression in Extrapituitary Tumours

In contrast to expression of the *POMC* gene in pituitary corticotroph cells, which is repressed by glucocorticoid as just discussed, expression in extrapituitary tumours is characteristically resistant to glucocorticoid [19]. This is the basis of the high-dose glucocorticoid suppression test used to distinguish eutopic from ectopic sources of ACTH in Cushing's syndrome. As the test has approximately 10% false-positive and 10% false-negative it has largely been superseded by sophisticated imaging and inferior petrosal sinus sampling for differential diagnosis. With the availability of recombinant corticotrophin-releasing hormone responses of extrapituitary tumours to this peptide have been measured. In general, only pituitary corticotrophs stimulate *POMC* expression in response to corticotrophin-releasing hormone, but exceptions are increasingly being identified.

Clinical Manifestation

The diagnosis of Cushing's syndrome and differential diagnosis of ACTH-dependent Cushing's syndrome are described elsewhere. Briefly, dynamic endocrine testing is required to diagnose Cushing's syndrome, and detection of ACTH using a sensitive two-site immunoradiometric assay (IRMA) makes the diagnosis of ACTH-dependent Cushing's syndrome. A variety of dynamic endocrine and imaging protocols are used to identify a pituitary or extrapituitary source of the ACTH excess. These all have variable sensitivity and specificity. The most reliable test is bilateral inferior petrosal sinus sampling, which, if performed when the patient is hypercortisolaemic, has an accuracy approaching 100%.

Most occult tumours are carcinoid, phaeochromocytoma, or medullary thyroid carcinoma and originate in the neck, chest, or abdomen (Box 13.1.2.1). Computed tomography (CT) or magnetic resonance (MR) scanning can be used to detect chest tumours in those patients with a normal chest radiograph. There have been some reports of success in using radioactive In-labelled octreotide scanning to identify occult neuroendocrine tumours, although experience is still limited. The development of new imaging techniques may identify previously occult primary tumours, with ^{11}C-methionine PET-CT imaging being used in a limited number of patients to good effect [20]. However, this requires highly specialized facilities for the synthesis of the labelled aminoacid, and its use. This should be regarded as a research tool until larger series of ectopic ACTH patients have been reported.

Management

Treatment is focused on two objectives. The first is control of the endocrine manifestation and the second is management of the underlying tumour. Individual patients will present with different priorities. The ideal treatment is curative resection of the primary tumour, which achieves both objectives. If this is not possible, due to a small, elusive primary tumour, patients with small, occult primary tumours may be managed by chemical or surgical adrenalectomy, and in many cases the primary tumour will not be life threatening. Patients with extensive carcinoma, for example, small cell carcinoma, in whom ACTH excess coexists, are best managed by chemotherapy, which indirectly reduces ACTH expression. The presence of clinical hypercortisolaemia in small cell lung carcinoma is linked to poor prognosis but chemotherapy should be tailored for the cell type and tumour stage regardless of the presence of hormone excess. The exception to this is those cases with florid Cushing's syndrome in whom a tissue diagnosis has yet to be obtained. In these individuals, it is prudent to start adrenolytic treatment with metyrapone while concluding investigation. In patients with aggressive Cushing's syndrome adrenalectomy is lifesaving.

Syndrome of Inappropriate Antidiuretic Hormone (ADH) Secretion (Schwartz–Bartter Syndrome)

Pathophysiology

The syndrome of inappropriate antidiuresis (SIADH) is the most common cause of hyponatraemia. It may be caused by a wide range of underlying disorders, but in three broad groups. These comprise malignancies, neurological disorders, and lung diseases. The latter two conditions cause hyponatraemia as a result of hypothalamic vasopressin, whose secretion comes under aberrant control from either neuronal inputs or circulating humoral factors. The first results from vasopressin expression in non-hypothalamic-pituitary tissue. The result of either source of overproduction is hyponatraemia with apparently inappropriate renal sodium excretion.

Box 13.1.2.1 Types of tumours causing ectopic adrenocorticotropic hormone secretion

- Small cell lung carcinoma
- Carcinoid tumours (bronchus, thymus, small intestine)
- Pancreatic islet cell tumour
- Pheochromocytoma
- Medullary carcinoma of the thyroid
- Carcinomas (breast, gastrointestinal tract [oesophageal, gastric, colorectal], ovarian, cervical, prostate)

Box 13.1.2.2 Tumours associated with syndrome of inappropriate antidiuretic hormone secretion

Tumour
• Small cell lung carcinoma
• Pancreas
• Duodenum
• Urethra
• Prostate
• Bladder
• Lymphoma and other

The vasopressin gene is expressed in a number of separate neuronal nuclei, and also in peripheral tissues in health. Regulation of vasopressin expression is dependent on site. For example, hyperosmolality increases vasopressin expression in the supraoptic nucleus and the magnocellular division of the paraventricular nucleus, but vasopressin mRNA in other sites, including the suprachiasmatic nucleus, is unaltered. Vasopressin expression in the suprachiasmatic nucleus, in contrast, is under diurnal regulation. Androgens upregulate expression of vasopressin in the striae terminalis, and glucocorticoids suppress expression in the parvocellular division of the paraventricular nucleus. Differential regulation, even within such anatomically closely related sites likely results from differential expression of hormone receptors in the cells, and different neuronal afferents. Vasopressin gene transcription is under positive regulation by cAMP and protein kinase C pathways. Much less is known about regulation of vasopressin outside the central nervous system (CNS), but glucocorticoids were shown to suppress its expression in a small cell lung carcinoma cell line.

Ectopic secretion of vasopressin occurs in squamous cell carcinoma, small cell carcinoma, neuroblastoma, and in undifferentiated carcinoma. A wide variety of non-tumour causes for the SIADH has also been defined (Box 13.1.2.2). In one series 16% of patients with small cell lung carcinoma had hyponatraemia (less than 130 mmol/L) at diagnosis, compared to 0% of patients with non-small cell carcinoma. Hyponatraemia was found to be an independent predictor of poor prognosis in extensive stage disease. *In vitro* studies found 7 of 11 tumours in culture produced vasopressin, 9 of 11 atrial natriuretic factor and 5 of 11 both hormones. All the cells studied from patients with hyponatraemia produced either one of the two hormones [21].

Box 13.1.2.3 Clinical features of hyponatraemia

- Headache
- Lethargy
- Weakness
- Nausea/vomiting
- Mood swings
- Confusion
- Drowsiness
- Hyporeflexia
- Positive Babinski's sign
- Convulsions
- Coma

Clinical Manifestation

Hyponatraemia presents with features of neuropsychiatric dysfunction in most cases (Box 13.1.2.3). The elderly and the young are more likely to be symptomatic than others. The absolute sodium concentration is less reliable as a predictor of symptoms than the rate of fall of sodium concentration, although almost all symptomatic patients will have a plasma sodium less than 120 mmol/L, and plasma sodium concentration greater than 125 mmol/L rarely have symptoms related to hyponatraemia specifically. Clinical features include lethargy, fatigue, impaired conscious level, coma, seizures, and psychosis. Hyponatraemia may cause death as a result of cerebral oedema, uncontrolled seizures, and the consequences of coma. Although in most cases mild hyponatraemia (over 125 mmol/L) is regarded as a straightforward condition which may not require specific treatment, hyponatraemia should not be regarded as benign.

A set of diagnostic criteria must be fulfilled before a secure diagnosis may be reached (Box 13.1.2.4). In practice it is useful to perform a bedside evaluation of the patient's extracellular fluid volume. This measure is tightly related to the total body sodium. Patients who have hyponatraemia in the absence of oedema or hypovolaemia are a select group who, in the absence of other endocrine, psychiatric, or pharmacological cause, are defined as having SIADH. Plasma atrial natriuretic factor (ANF) is usually decreased in this group. The underlying cause is then sought. Neurological, lung, drug-related, and miscellaneous causes result in dysregulation of vasopressin regulation in the hypothalamus, and should not, therefore, be regarded as true ectopic hormone secretion states. In contrast, a variety of tumours have been shown to be aberrantly secreting vasopressin, and considerably more to be expressing the vasopressin gene inappropriately. There is evidence from T_1-weighted MR scans of the pituitary that such ectopic vasopressin secretion results in central suppression of vasopressin synthesis.

On the basis of salt and/or water loading tests four subgroups of SIADH have been defined, but as these subgroups do not partition with underlying cause this classification is not useful in routine practice.

Management

The management of this disorder falls into two parts. The first is diagnosis and treatment of the underlying cause, and the second is removal of excess, free body water. Discussion of specific therapy of the variety of underlying tumours is beyond the scope of this account, but surgical cure or debulking, chemotherapy, and radiotherapy have all been applied. In general, the circulating vasopressin concentration bears a direct relationship to tumour bulk within a patient, but little relationship across a patient cohort, presumably reflecting intertumour differences in cellular differentiation. Decisions about the acute correction of hyponatraemia are complicated by the occurrence of both pontine and extrapontine myelinolysis as consequences of therapy. The risk of myelinolysis is linked to the rate of change in sodium concentration. Therefore, a prudent approach is always justified. In symptomatic patients, treat with frusemide and hypertonic saline until convulsions cease and conscious level improves. This is usually achieved by a rapid increase in sodium concentration of 10% (approximately 10 mmol/L). After such initial emergency treatment patients are best managed by water restriction. In asymptomatic patients, the condition

Box 13.1.2.4 Diagnostic criteria for the syndrome of inappropriate antidiuretic hormone secretion

- Hyponatraemia
- Inappropriately increased urine osmolality (>100 mOsm/kg)
- Persistent sodium excretion in urine (>20 mmol/L)
- Normal renal, thyroid, and adrenal function
- No hypovolemia, oedema, or diuretic use

is almost always chronic. These patients should be treated by water deprivation in the first instance regardless of the sodium concentration as treatment is likely to hold greater dangers than persisting hyponatraemia. Water restriction results in a decrease in urinary sodium excretion, often to less than 10 mmol/L, indicating that these patients do have intact mechanisms for sodium conservation.

A number of pharmacological approaches will antagonize the action of ADH on the renal tubule. The most commonly used is demeclocycline, in divided doses up to 1200 mg daily. In addition, lithium carbonate is effective but is harder to use and a more toxic alternative. These agents induce a state of nephrogenic diabetes insipidus, and so encourage loss of water. Alternatively, oral sodium supplementation, up to 3 g daily, with frusemide, 40–80 mg daily, results in net loss of free water. The entry of specific V2 receptor antagonists to the clinic offers a new approach to management. This especially relevant to patients with tumoural synthesis of ADH, in particular small cell bronchogenic carcinoma, in whom curative therapy is not possible. The vasopressin receptor antagonists (Vaptans) increase free eater clearance by blocking the action of ADH at the renal tubule. Conivaptan is available in the United States, and is used as an intravenous agent, while in Europe Tolvaptan used orally. Initial studies focused on short-term use, and demonstrated efficacy, but now longer-term follow up is available, showing therapeutic response out to 4 years [22]. A number of specific cautions have been raised including the need to exclude patients who are hypovolaemic, and not to use with other interventions targeting hyponatraemia, including fluid restriction. Monitoring of serum sodium is required, to avoid over-rapid correction, and there are drug interaction liabilities through CYP3A4, including grapefruit juice. The issues around long-term use of vaptans relate to drug cost, and the risk of overcorrection, requiring careful monitoring of serum sodium.

Humoral Hypercalcaemia of Malignancy (HHM)

Hypercalcaemia is a common complication of malignancy. It may result from the lytic effect of bony metastases, or the effect of tumour-derived humoral factors.

Pathophysiology

The humoral syndrome has been explained by the isolation and characterization of a peptide hormone, parathyroid hormone-related protein (PTHrP). This hormone is closely related in amino acid sequence to parathyroid hormone (PTH) in its N-terminal region (amino acids 1–34), but after residue 34 the two peptides have unique sequences. The discovery of PTHrP as the circulating mediator of hypercalcaemia in malignancy allowed the discarding of earlier theories about ectopic production of PTH as the cause. There are isolated reports of ectopic PTH production by tumours, but these are excessively rare.

PTHrP is seldom detectable in the circulation of normal subjects, but its expression has been shown in a number of normal tissues. PTHrP may be regarded as the product of the diffuse paracrine system, and may have evolved to perform quite different physiological roles compared to the structurally related PTH. Under these circumstances it is hard to call production of PTHrP from a tumour arising from any tissue truly ectopic, as no definite eutopic source for the peptide has been defined. However, humoral hypercalcaemia of malignancy (HHM) is most conveniently considered with the group of ectopic hormone secretion syndromes.

PTH and PTHrP share a common receptor, which they recognize through their homologous N terminals. The PTH/PTHrP receptor mediates the action of both peptides in bone and kidney, and is a member of the G-protein-coupled seven transmembrane receptor family. The common receptor explains how PTHrP is able to generate cAMP in membrane preparations of PTH-sensitive renal tubule, and further why the humoral hypercalcaemia of malignancy (HHM) syndrome resulted in hypercalcaemia with hypophosphataemia. In the past there was controversy about 1,25-dihydroxyvitamin D levels in primary hyperparathyroidism versus HHM. PTHrP and 1,25-dihydroxyvitamin D appear to be loosely correlated in HHM, suggesting that PTHrP shares with PTH the capacity to induce 1α-hydroxylase. Occasional reported discrepancies stem from the action of other tumour-derived, circulating factors, or from the metabolic consequences of malignancy.

PTHrP may also play a role in hypercalcaemia related to osseous metastases, in that even the hypercalcaemia associated with bony metastases has a significant humoral component. Further, expression of PTHrP by primary tumours is a predictor of development of bony, metastatic disease. Thus, the local production of PTHrP by bone micrometastases may facilitate bony invasion and destruction [23].

Hypercalcaemia in Haematological Malignancy

Hypercalcaemia occur in up to 30% of patients with multiple myeloma. Skeletal involvement causes extensive bone destruction with pain, and risk of pathological fracture. Histological evidence suggests that the bone disease is caused by increased osteoclastic activity, in the absence of significant osteoblastic activity. Loss of osteoblastic activity is also supported by the characteristically negative bone scan and suppressed circulating osteocalcin concentration. A number of cytokines, produced by activated immune cells, have been shown to have direct effects promoting bone resorption. Such cytokines include tumour necrosis factor-α, tumour necrosis factor-β, interleukin-1 and leukaemia inhibitory factor (LIF). A superseded generic term for these factors was 'osteoclast activating factor'. However, in three of nine patients with multiple myeloma complicated by hypercalcaemia there was an elevation in circulating PTHrP, suggesting that a mechanism similar to HHM may be operating in at least some patients with haematological malignancy associated hypercalcaemia [24].

Generally hypercalcaemia is rare in lymphoma, with the exception of adult T-cell leukaemia/lymphoma [25]. This disease occurs in Japan and the West Indies and is caused by infection with the human T-cell lymphotropic virus type I (HTLV-I). At least one-quarter of

patients will develop hypercalcaemia, which is associated with suppressed 1,25-dihydroxyvitamin D. Hypercalcaemia predicts outcome, and is implicated in causing patient mortality. There is strong evidence that the hypercalcaemia is mediated by PTHrP, and also by local cytokine production, particularly interleukin-1α.

Clinical Manifestation

Hypercalcaemia is the most common metabolic complication of malignant disease, and is the cause of much morbidity (Box 13.1.2.5). Most cases are due to humoral mechanisms, principally PTHrP, rather than direct damage of bone by malignant cells. This is clear from the observation that even patients who have bone metastases and hypercalcaemia have a poor correlation between extent of skeletal involvement and calcium concentration in the circulation. In clinical practice, the underlying tumour will usually be obvious by the time hypercalcaemia is noted, and the patient is usually obviously ill. Less commonly hypercalcaemia may be due to an occult malignancy, here the diagnosis is made by checking serum intact PTH which is invariably suppressed in true HHM. The presence of a non-parathyroid tumour associated with hypercalcaemia and elevated PTH suggests either concomitant hyperparathyroidism, or true ectopic PTH secretion—a very rare event.

The presentation of hypercalcaemia may be confusing, and may be attributed to the underlying disease process itself. In general, the clinical manifestations of hypercalcaemia correlate with the calcium concentration and the rapidity of its rise. Most people show clinical features when the total calcium concentration exceeds 3.0 mmol/L, and features are almost invariable at concentrations above 3.5 mmol/L. Patients may be non-specifically unwell, they may complain of constipation, nausea, vomiting, confusion, or dehydration. Relatives may be the first to notice a change in concentration, or increased sleeping. Hypercalcaemia often affects the gut with constipation, anorexia, nausea, and vomiting. Hypercalcaemia induces a diuresis, and so may cause profound dehydration, particularly in association with vomiting or drowsiness. The absence of clinical features in a patient with severe hypercalcaemia should prompt measurement of ionized calcium to ensure that the hypercalcaemia is not due to excessive binding of calcium to plasma proteins.

Management

The decision to start treatment depends on the calcium concentration and the presence of symptoms. In general, patients with calcium concentrations below 3.0 mmol/L do not require therapy, and those with concentrations above 3.5 mmol/L do. Those with calcium concentrations between 3.0 and 3.5 mmol/L should be treated if there are symptoms, otherwise a conservative approach is preferred with monitoring of calcium concentrations and checking for development of clinical features. An important further consideration is the underlying malignancy and its prognosis, for example, in a terminally ill patient for whom there is no further specific antitumour therapy possible it may be better to resist attempting to reduce serum calcium concentration but rather make the patient comfortable.

There is little evidence that hypercalcaemia is a significant cause of premature mortality in cancer, but it is a significant cause of morbidity. Even if the underlying malignancy is beyond cure, effective relief of hypercalcaemia can be a most useful palliative intervention.

The initial management consists of general measures designed to increase calcium clearance. Dehydration is very common with significant hypercalcaemia and should be corrected. This is best achieved using an intravenous infusion of 3–4 L of 0.9% sodium chloride given over 24 h. This will typically reduce calcium concentration by about 0.5 mmol/L. Clearly, this form of therapy should be used with caution in older people, and those with impaired cardiac or renal function. Following hydration, intravenous loop diuretics will enhance calcium excretion by inhibiting calcium resorption by the thick ascending loop of Henle. Frusemide 40–80 mg may be used by bolus intravenous injection to supplement saline infusion, but there is little to be gained from higher doses or continuous infusions of diuretic. Diuretics should not be used in the presence of persisting dehydration.

Thiazide diuretics should be withdrawn as they tend to reduce renal calcium clearance, and the patient, where possible, encouraged to keep mobile in order to reduce immobility associated calcium mobilization.

Dialysis, either peritoneal or haemodialysis, against a low calcium dialysate is effective at rapidly reducing serum calcium, and may be particularly useful in renal impairment.

Bisphosphonates are analogues of pyrophosphate which are resistant to phosphatase degradation. Gastrointestinal absorption of bisphosphonates is very poor and so usually they are given by intravenous infusion. The bisphosphonates are rapidly cleared from the circulation and concentrated in bone. They appear to inhibit osteoclast activity, and may induce osteoclast apoptosis. Their duration of action is greatly longer than predicted by their plasma half-life, reflecting their distribution and mode of action.

Usually a single infusion of 30–60 mg of pamidronate is sufficient as initial treatment, pamidronate is more effective than the first-generation bisphosphonate, etidronate, which it has superseded for this indication. Pamidronate often causes myalgia and a transient fever, which can be helped by pretreatment with paracetamol. At a dose of 90 mg pamidronate often causes infusion reactions. Clodronate (300 mg intravenously) is another bisphosphonate which is effective for acute management of hypercalcaemia, and newer bisphosphonates including alendronate, risedronate, and aminobutane bisphosphonate are becoming available. These newer drugs appear to have similar efficacy to pamidronate. The bisphosphonates are usually given by slow intravenous infusion in large volumes (above 500 ml) to prevent nephrotoxicity due to precipitation of calcium bisphosphonate. The calcium response is typically rapid with a steady decline over the first 24 hours and may last from days up to one month. The response to treatment should be monitored by checking serum calcium daily until its concentration reaches a plateau; thereafter, monitoring can be performed weekly, or on recurrence of symptoms.

Box 13.1.2.5 Symptoms and signs of hypercalcaemia

- Polyuria
- Thirst
- Nausea
- Anorexia
- Constipation
- Confusion
- Drowsiness
- Headache
- Coma

Bisphosphonates may be used to maintain normocalcaemia, but treatment must be adjusted individually. It is possible to give bisphosphonates by subcutaneous infusion, or orally, in the domiciliary setting as intermittent intravenous infusions require hospital admission. Either clodronate or alendronate are effective in this role. Oral etidronate appears ineffective in maintenance therapy and may cause osteomalacia when used chronically.

In the past calcitonin and/or mithramycin (now called plicamycin) were used, but these have been largely superseded by the bisphosphonate drugs. Calcitonin inhibits osteoclastic bone resorption and is a very safe drug. Further, it causes a rapid fall in serum calcium, within 6 h of administration. Calcitonin (4–8 U/kg) is given by intramuscular or subcutaneous injection every 6 hours. Unfortunately, the effect of calcitonin is transient, and rarely sufficient to normalize serum calcium. It is occasionally useful in severe hypercalcaemia when a rapid response is needed while awaiting the more sustained bisphosphonate effect.

Gallium nitrate has been used to treat hypercalcaemia; however, it is cumbersome to administer and is nephrotoxic. It is used as a continuous 5-day infusion at a dose of 200 mg/m²/day. The maximal hypocalcaemic effect may not be seen until 3 days after the end of the infusion.

Glucocorticoid treatment, usually intravenous 200–300 mg hydrocortisone per day for 3–5 days, has been used to treat malignancy associated hypercalcaemia, but is usually effective only in lymphoma, multiple myeloma, or granulomatous disease.

Non-Islet Cell Tumour Hypoglycaemia

Pathophysiology

Fasting hypoglycaemia may arise as a consequence of non-islet cell tumour formation. Such tumours do not express insulin, a hormone which appears to be very tightly regulated in its tissue distribution, but the insulin-related molecule IGF-II. The two insulin-like growth factors (IGFs) I and II are members of the insulin family of peptide hormones along with relaxin, and are capable of signalling both through the type 1 IGF receptor or the insulin receptor. IGF-I is the liver-derived circulating mediator of growth hormone (GH) action, and IGF-II may have a more important role in development. In normal subjects IGF-I and IGF-II circulate at much higher concentrations than insulin, and would, if unopposed, cause profound hypoglycaemia due to their actions through the insulin receptor. That this does not occur is due to the presence of high-affinity, high-capacity, circulating IGF-binding proteins, the most important of which is IGF-binding protein-3. The IGFs form a ternary complex with IGF-binding protein-3 and with another liver produced protein, the acid labile subunit (ALS). Formation of this ternary complex between the IGFs and their binding proteins results in very low concentrations of free IGFs and so limits their bioavailability.

A number of tumours, typically of mesenchymal origin, have been identified as the cause of non-islet cell hypoglycaemia (Table 13.1.2.1). The apparent mechanism is overproduction of IGF-II. The circulating IGF-II would be expected to cause few problems if it were effectively sequestered by IGF-binding proteins, but this does not occur [26]. The tumour-derived IGF-II has a higher molecular mass compared with mature IGF-II, as a result of impaired proteolytic processing of pro-IGF-II, and is also often abnormally glycosylated [27]. The high concentrations of IGF-II suppress pituitary GH secretion and so result in reduced hepatic production of the ALS and IGF-binding protein 3 [27]. The high-molecular-weight form of IGF-II derived from the tumour ('Big' IGF-II) binds to IGF protein-3 in a 50 kDa binary complex in contrast to the 150 kDa ternary complex that is usually formed between IGF-I or IGF-II, IGF-binding protein-3, and the ALS. The IGF-II in the 50 kDa complex has increased insulin-like activity compared to the IGF-II containing ternary complex, and because of its smaller size appears to have greater capillary permeability, which results in greater bioavailability of the IGF-II. In addition to the changes caused by suppression of GH secretion (which result in reduced hepatic production of IGF-binding protein-3), the IGF-binding protein-3 produced has a lower affinity for forming the ternary complex with the ALS and IGF-II. This altered affinity also tends to promote IGF-II–IGF-binding protein-3 binary complex formation. Further secondary events also stem from these changes, including increased circulating concentrations of other IGF-binding protein including IGF-binding protein-2 and IGF-binding protein-6.

Table 13.1.2.1 Tumours associated with non-islet cell tumour hypoglycaemia

Carcinoma	Mesenchymal
Hepatocellular, hepatoma	Fibroma, fibrosarcoma
Adrenocortical	Mesothelioma
Pancreatic	Rhabdomyosarcoma
Gastric	Neurofibroma, neurofibrosarcoma
Colon	Leiomyosarcoma
Lung (small cell, squamous)	Others
Kidney	Haemangiopericytoma
Prostate	Haematologic, lymphoma

As pro-IGF-II is complexed just to IGF-binding protein-3 in the 50-kDa binary complex rather than the 150-kDa ternary complex, it has a 30-fold shorter plasma half-life. Therefore, measurement of total IGF-II may not be significantly elevated despite the presence of hypoglycaemia. Serum levels of free IGF-II and pro-IGF-II are both consistently elevated.

Glucocorticoids result in a series of metabolic effects in non-islet cell tumour hypoglycaemia. Prednisolone directly suppresses tumour production of IGF-II, enhances formation of the ternary complex and so relieves hypoglycaemia. Resulting from these changes there is an increase in IGF-I, IGF-binding protein-3, and ALS concentrations. As glucose is normalized, a fall in IGF-binding protein-2 follows. Recombinant human GH also reverses hypoglycaemia and promotes formation of the ternary complex. GH directly increases concentrations of IGF-I, IGF-binding protein-3, and ALS; however, only prednisolone improved the ability of IGF-binding protein-3 to bind to the ALS to form the IGF-I containing ternary complex. Therefore, prednisolone and GH are both effective treatments for non-islet cell hypoglycaemia, but they work in different ways [28].

Clinical Manifestation

The diagnosis is based on the recognition that the patient's symptoms are due to hypoglycaemia, which involves a detailed history,

Table 13.1.2.2 Non-islet cell tumour hypoglycaemia versus insulinoma

	Non-islet cell	Insulinoma
IGF-1	×	×
IGF-2		×
IGFBP-3	¬	×
Insulin	¬	
Glucose	¬	¬
Growth hormone	¬	× or
β-Hydroxybutyrate	¬	¬

IGF, insulin-like growth factor; IGFBP, insulin-like growth factor–binding protein., increased; ¬, decreased; ×, equivocal.

and confirmation of either hypoglycaemia occurring during a symptomatic episode, or fasting hypoglycaemia. Clinical features include hunger, attacks of sweating, pallor, and dizziness relieved by eating and weight gain. The typical biochemical accompaniment to hypoglycaemia is suppressed insulin, suppressed ketone bodies (β-hydroxybutyrate) and suppressed GH. Total IGF-II may be elevated or normal, while free IGF-II and pro-IGF-II are usually elevated. IGF-binding protein-3 and ALS are both suppressed, as a consequence of low GH, and two other IGF-binding proteins IGF-binding protein-2 and IGF-binding protein-6 are both elevated (Table 13.1.2.2).

The majority of tumours are large by the time hypoglycaemia has occurred, and are often easily diagnosed clinically. It may be that the tumour is recognized before the episodes are ascribed as hypoglycaemia. The tumours are typically imaged with a combination of chest radiography, abdominal ultrasound, and CT. Histological confirmation of the diagnosis is by specific immunostaining of a biopsy for IGF-II, or identification of pro-IGF-II in tumour extract.

Management

Effective management requires either surgical excision or debulking of the tumour. This is best achieved by close consultation between surgeon, interventional radiologist, who may have much to contribute by, for example, tumour embolization and oncologist. These tumours tend not to be radiosensitive, although there are isolated case reports of therapeutic response. As these tumours are rare, management is tailored to the individual patient, and is usually based on pragmatic grounds.

As a first course of action, curative resection of the primary tumour should be the aim. This depends on the site of tumour and the physical condition of the patient. Resection of pleural tumours has been reported, but curative resection of hepatoma is difficult unless orthotopic liver transplantation is feasible. Even in cases where curative resection is not possible, debulking accompanied by tumour embolization by an experienced interventional radiologist can result in resolution of hypoglycaemia in the absence of further drug therapy. Even inoperable tumours, such as a limb fibrosarcoma in an elderly patient, can be rendered hormonally inactive by tumour embolization, which offers a rapid and simple resolution of hypoglycaemia.

In patients whose tumours cannot be physically reduced relief of hypoglycaemia can be achieved by using glucocorticoid, usually dexamethasone, either alone or with recombinant human GH [29]. Glucocorticoids reduce tumour production of IGF-II, enhance formation of the ternary complex and increase production of IGF-binding protein-3 and the ALS. GH has no direct effect on the tumour but increases hepatic production of IGF-binding protein-3 and the ALS and enhances sequestration of IGF-II within the ternary complex. Pragmatically glucocorticoids are best used in the initial stages as their effect is of rapid onset, they are easy to administer and are inexpensive. The wide spectrum of glucocorticoid side-effects will make longer-term use of glucocorticoids less desirable. In the medium-term recombinant human GH will provide effective relief of hypoglycaemia, with a better side-effect profile. Disadvantages of GH include the need for daily injections and cost.

Other Ectopic Hormones

The two pituitary hormones prolactin and GH are of interest in that they have a wide extrapituitary expression, and yet are very seldom the cause of clinically significant ectopic hormone syndromes. Prolactin is expressed in decidualized endometrium, T lymphocytes, mammary epithelial cells, skin, sweat glands, and in the brain. It is the same gene that is transcribed in all these cases, rather than the related placental lactogen type gene, but the regulation of the gene appears completely different [30]. Whereas in the pituitary lactotroph cell prolactin is under the transcriptional control of the pituitary specific factor Pit1, in extrapituitary tissues Pit1 is not expressed, and the pituitary promoter of the prolactin gene is in consequence silent. The gene is transcribed from an upstream promoter, which gives rise to a slightly longer mRNA, with a unique 5' end, but after processing results in a protein with the same amino acid sequence. Because the gene is transcribed from a different promoter, the control of gene transcription, its basal rate, and regulation by external signals is different. For example, in T lymphocytes prolactin gene transcription is responsive to the immunophilins including cyclosporin A. The function of this extrapituitary prolactin is subject to debate, and it is not clear why such widespread expression in health is accompanied by such rarity of overexpression in malignant disease, in contrast to ACTH or vasopressin expression. As prolactin receptors are found in such a variety of tissues that cannot be reconciled with an exclusive action on mammary milk production prolactin may well have a more diverse pattern of action than that so far determined.

GH is also found in extrapituitary tissues in health, again in cells of haemopoietic lineage. This expression has been suggested to result in paracrine signalling, although hard data are lacking.

Extrapituitary GH expression causing acromegaly has been described in tumours of the pancreas, lung, and ovary. Ectopic GH-releasing hormone causing acromegaly through somatotroph hyperplasia rather than adenoma formation (occurs in less than 1% of acromegaly cases) may arise from carcinoid tumours of the pancreas or lung, or from phaeochromocytomas (Box 13.1.2.6). Acromegaly due to ectopic production of growth hormone-releasing hormone (GHRH) can be successfully treated using long-acting somatostatin analogues (octreotide or lanreotide).

Box 13.1.2.6 Tumours associated with growth hormone-releasing hormone secretion

- Carcinoid tumours (e.g. bronchial)
- Pheochromocytomas
- Pancreatic islet tumours
- Adrenal adenomas
- Hypothalamic gangliocytomas
- Small cell lung carcinoma

13.1.3 Long-Term Endocrine Sequalae of Cancer Therapy

Claire E. Higham and Robert D. Murray

Introduction

The worldwide incidence of cancer is increasing, and it is predicted that around 20 million people will have a cancer diagnosis by 2025 [1]. In contrast, mortality from cancer is on the decline, dropping by 26% in the United States between 1991 and 2015 [2]. Thus, there are an increasing number of patients living with and beyond cancer (LWBC) who are susceptible to both short- and long-term cancer therapy related side effects.

Long-term endocrine sequelae of cancer therapies occur in up to 50% of childhood cancer survivors and may occur decades after the treatment has been delivered [3]. With over 30 000 patients registered in the United Kingdom as long-term survivors of childhood cancer [4], the importance of developing appropriate models of surveillance, follow-up, and management are clear.

The majority of research into the long-term sequelae of cancer therapies has been performed in childhood survivors, and is dominated by observational studies. Data are now emerging with regards to survivorship in patients treated as adults, where susceptibility to endocrinopathies is thought less prevalent, but still significant

This chapter will focus on describing the long-term endocrine sequelae in children and adults treated for cancer, the underlying pathophysiology, diagnostic, management, and surveillance strategies.

Endocrine late effects include disturbances of growth and puberty, hypothalamo-pituitary (HP) dysfunction, hypogonadism, thyroid dysfunction, benign and malignant thyroid nodules, hyperparathyroidism, and bone effects.

Growth and Puberty

Diagnosis and treatment of cancer during childhood is associated with reduced height velocity and final height. There are several contributors to this including the impact of acute illness, poor nutritional status, and ongoing cancer therapy. In addition, perturbations of the endocrine system, including radiation-induced hypothyroidism, precocious puberty, and growth hormone deficiency (GHD) impact adversely on growth.

Survivors of childhood malignancies who received cranial irradiation achieve final heights significantly below those predicted from parental heights even with irradiation doses as low as 18 Gy. Although radiation-induced GHD is an obvious cause for the abrogated growth it is not universally present in all children with impaired growth velocity, implicating additional mechanisms. A subanalysis of the Childhood Cancer Survivor Study (CCSS) survivors with brain tumours revealed 40% of patients to have a final height below the tenth percentile [5].

Spinal irradiation has a negative impact on growth above that of cranial irradiation alone, and relating directly to a reduction in vertebral height [6]. Greater impairment of spinal growth compared with the limbs results in an increase in leg length to sitting height ratio. This disproportion may be further amplified by growth hormone (GH) replacement therapy as GH impacts favourably on growth of the long bones, whereas the irradiated spine remains relatively resistant [7].

Precocious puberty is common in childhood brain tumour survivors, occurring in up to 12%. This depends on tumour location, presence of hydrocephalus, and low-dose cranial radiotherapy. If the diagnosis is delayed and puberty allowed to progress unabated, this can have significant decrement to final height, particularly when concomitant GHD is present.

Time allowing, catch-up growth is frequently observed once active treatment has been completed and remission achieved.

Pituitary

Deficiency of one or more pituitary hormones is commonly seen following treatment for central nervous system (CNS) tumours and cranial irradiation [8, 9]. It remains unclear whether standard chemotherapy contributes to pituitary dysfunction, with no definitive agent or class of agent implicated. Novel immunotherapy agents, in particular checkpoint inhibitor therapies (anti-CTLA-4, anti-PD1) are associated with hypophysitis and subsequent persistent pituitary hormonal deficiencies [10].

In children and adolescents, tumours such as medulloblastoma, ependymoma, choroid plexus tumour, astrocytoma, low-grade glioma, and primitive neuroectodermal tumour (PNET) may result in HP dysfunction dependent on tumour localization and treatment [11]. The spectrum of brain tumours in the adult population is different (a higher percentage of high-grade glioma and meningioma) and overall survival significantly lower, although those with low-grade gliomas have a more than 70% 5-year survival. Up to 90% develop a variable degree of hypopituitarism post-treatment [12]. In addition, both children and adults treated with irradiation for head and neck carcinomas or CNS tumours distant to the HP region (e.g. retinoblastoma) are at risk if the HP axis is included within the radiation field [11]. Low dose cranial irradiation in children with acute lymphoblastic leukaemia (ALL) or as part of total body irradiation (TBI) in stem cell transplantation is also a risk, although appears less of a concern in adults [13].

Greater than 50% of childhood cancer survivors exposed to cranial radiotherapy will develop at least one pituitary hormone deficiency by 25 years post-exposure. Doses of radiation lees than 30 Gy

are commonly associated with isolated GHD. Higher radiation doses can result in further damage, commonly causing gonadotrophin deficiency with thyroid-stimulating hormone (TSH) and adrenocorticotrophic hormone (ACTH) deficiency less frequent. Diabetes insipidus has not been described as a consequence of HP radiotherapy [14, 15].

Time since irradiation, age at time of radiotherapy, fraction size and radiation schedule are important determinants of subsequent HP function [14, 15].

Growth Hormone Deficiency (GHD)

The somatotropic axis is the most vulnerable to radiation damage. Symptoms and signs of GHD in the LWBC population do not differ from those described in non-cancer populations. In prepubertal children poor growth and development predominates (see Section 7, 'Disorders of Growth and Development and Transition'), whereas weight gain, fatigue, reduced muscle mass, and poor quality of life are indicators in adults. Diagnosis is complex in these individuals as symptomatology may overlap with other cancer related complications [15, 16].

Dynamic testing of the GH axis is generally required in children, adolescents, and adults to confirm the diagnosis; testing should not differ from that in the non-cancer population, with an insulin tolerance test (ITT) being the gold standard. There should be the recognition that if only hypothalamic damage is present post-radiotherapy, then the GHRH-arginine testing may be falsely reassuring [16]. Dynamic testing is not required in patients with two or more additional pituitary hormone deficits.

In those with isolated GHD in childhood after cranial radiotherapy, re-testing of the GH axis is recommended following achievement of final height as partial recovery of the axis is possible and lower thresholds for GH treatment are used in the paediatric population [15–17]. Low IGF-I or IGF-BP3 does not reliably predict GHD post-cancer therapy but may be a surrogate marker for severity [15–17].

GH replacement in prepubertal children with poor growth and documented GHD following cancer therapy is well accepted and generally started 1–2 years following completion of cancer therapy. Adequate treatment improves final adult height, although full height potential may not be achieved as a result of other endocrine dysfunction, chronic illness, and spinal or direct bone irradiation effects. Data concerning the safety of GH in childhood cancer survivors are reassuring with regards to recurrence of primary, or emergence of secondary tumours, although caution and careful monitoring is advised [15–17].

GH replacement therapy in GH-deficient survivors of cancers arising in adulthood remains controversial and there are minimal safety data available. The data that are available are reassuring. The positive impact of GH replacement on quality of life is well described [18, 19].

Cranial irradiation doses of less than 50 Gy can result in precocious or early puberty in children. Both genders are affected with irradiation doses employed in the treatment of brain tumours (25–50Gy), whereas lower doses used for prophylaxis in treatment of ALL results in a predominance of girls developing precocious puberty. The mechanism responsible for early puberty is thought to be a disinhibition of cortical influences on the hypothalamus allowing gonadotropin-releasing hormone (GnRH) pulse frequency and amplitude to increase prematurely. The impact of early puberty in a child with radiation-induced GHD is to foreshorten the time available for GH therapy and thereby restrict the therapeutic efficacy of this intervention. These latter children may therefore require a combination of GnRH analogues alongside GH replacement to optimize their height potential.

Gonadotropin Deficiency

Gonadotropins are the second most frequently affected anterior pituitary hormones following cranial irradiation, although deficiency is uncommon with radiation doses less than 40 Gy. In children and adolescents, deficiency may present with pubertal delay, arrested puberty, or primary amenorrhoea. Adults experience secondary amenorrhea, impairment of libido, and/or erectile dysfunction.

Diagnosis relies on baseline blood sampling of LH, FSH, oestradiol (females) or testosterone (males). These reveal low or inappropriately normal gonadotropins in association with low peripheral total and/or bioactive sex hormones [20].

Treatment with sex hormones in gonadotropin deficient patients is recommended to induce puberty if required, to prevent cardiovascular complications, and reduce loss of bone mass in premenopausal women and men, in line with current guidance [21, 22].

ACTH Deficiency

The ACTH axis is more resilient to irradiation-induced damage than either the GH or gonadotropin axes. There are only occasional reports of ACTH deficiency following TBI (9.0–15.0 Gy) used as preconditioning before bone marrow transplant (BMT) or prophylactic cranial irradiation during treatment of ALL (18–24 Gy) [21]. Even with cranial radiation doses up to 50 Gy only around 3% of children develop ACTH deficiency, though the incidence increases dramatically with doses more than 50 Gy. ACTH deficiency tends to occur late necessitating continued awareness and screening beyond 10 years after treatment of the primary disease [23].

ACTH deficiency leads to non-specific symptoms including fatigue, weight loss, gastrointestinal symptoms (epigastric pain, nausea, and vomiting), and lack of resistance to infection. Symptoms are commonly mistaken as sequelae of the tumour/treatment or as psychological problems. Life-threatening adrenal crisis may develop in stressful situations such as infections or surgery. Morning plasma cortisol measurements within the reference range are reassuring (generally >200 nmol/L, although this is local assay, and reference range, dependent), but only dynamic stimulation testing allows definitive diagnosis of the condition when there is clinical suspicion [8].

Treatment of ACTH deficiency does not differ from standard recommendations for replacement therapy. ACTH deficiency should be diagnosed and treated prior to instigating treatment with thyroxine or GH to prevent triggering an adrenal crisis (reviewed in [8, 15]).

TSH Deficiency

Damage to the TSH axis can develop over time post-treatment, although it is considered the least vulnerable of the anterior pituitary axes to radiation-induced damage. Overt secondary hypothyroidism is uncommon with irradiation doses below 50 Gy [22]. Central hypothyroidism is suspected if there is a low free thyroxine (fT_4) in association with low or inappropriately normal TSH. TSH cannot therefore

be used for screening in central hypothyroidism and a high index of clinical suspicion is required along with consideration of both fT_4 and TSH levels. Slightly elevated TSH levels can occur in central hypothyroidism as a consequence of an alteration in the predominant form of TSH secreted, resulting in an alteration in the ratio of bioactive/immunoreactive TSH. There is no evidence to support routine use of the thyrotropin-releasing hormone (TRH) test or assessment of TSH surge to improve diagnostic sensitivity and specificity [24].

Treatment of central hypothyroidism with l-thyroxine substitution should be according to published guideline. Titration of dose relies on measurement of fT_4 levels rather than TSH. Patients should be screened for adrenal insufficiency before the initiation of l-thyroxine to avoid adrenal crisis [8, 15, 25].

Prolactin

Hyperprolactinemia can occur after cranial irradiation; it is usually mild, transient, and rarely symptomatic, although should be considered as a factor in impaired gonadotropin secretion, if present. It most frequently occurs in adult female cancer survivors treated with high cranial radiation dose. Increasing or very high levels of prolactin are unusual and should prompt pituitary imaging [15].

Thyroid

Thyroid pathology following cancer therapy can relate to abnormalities of TSH secretion (hypopituitarism), a direct effect on the thyroid gland, or a combination of both (for example patients with radiation exposure to the head and neck region as well as the supraclavicular or chest are at risk for both primary and secondary thyroid dysfunction). Thyroid anomalies occur following cancer treatment in childhood and adulthood. Primary thyroid abnormalities are very common, and may present as primary hypothyroidism secondary to thyroid atrophy, autoimmune thyroid disease (hypothyroidism, Graves' disease, Graves' ophthalmopathy), thyroiditis, or thyroid nodules (benign and malignant).

Disorders of Thyroid Function

Direct irradiation of the thyroid gland causes both acute and chronic functional changes. Thyroid volume reduction has been observed during the first 6 months post-treatment and depends on received thyroid dose, with higher doses of radiation more likely to cause primary hypothyroidism (PH). The percentage of thyroid volume receiving more than 30–40 Gy is predictive of PH after radiotherapy and dose-volume constraints might reduce the risk [26].

In contrast, low dose radiotherapy increases the risk for autoimmune thyroid disorders which can manifest as either hypothyroidism (Hashimoto's disease) or hyperthyroidism (Graves' disease). The underlying pathophysiology for this is not well understood [27]. Gender (F > M) race (Caucasian survivors are 2.5× more likely to develop PH) and age at exposure (children and adolescents) are all determinants of developing thyroid dysfunction [28]. Following radiotherapy of more than 20 Gy to the thyroid, it is recommended that thyroid function tests (TFTs) are performed annually, or earlier if symptoms occur [15].

Conventional chemotherapeutic agents may play a role in thyroid dysfunction but this is less clearly defined; being described after the use of high-dose chemotherapy in stem cell transplantation, with alkylating agents, or after combined vincristine-cisplatin usage. Chemotherapy additionally may increase the risk of irradiation-induced hypothyroidism [29].

Newer chemotherapeutic agents such as the multitargeted receptor tyrosine kinase (RTK) inhibitors (e.g. sunitinib and sorafenib), and checkpoint inhibitors (e.g. PD1, PDL-1, and CTLA4 inhibitors) frequently result in thyroid dysfunction, which may require long-term thyroid hormone replacement [10, 30]. Regular monitoring of thyroid function is required during treatment with RTK and checkpoint inhibitor therapies.

Thyroid Nodules and Secondary Thyroid Malignancy

Thyroid nodules are common in the general population. Radiotherapy to the thyroid increases the prevalence of nodules, and the likelihood of thyroid nodules becoming malignant. The interval post-radiotherapy until the development of thyroid nodules and/or thyroid carcinoma is long (15–30 years) with a minimum latency period of 5 to 10 years. The risk is greater with young age at exposure, time since exposure, and dose of radiation received; with peak risk following a radiation dose between 10 and 30 Gy. Risk increases linearly with doses up to 20 Gy and decreases at higher doses of radiation, but remains significantly elevated even above 50 Gy. Most thyroid cancers histologically are papillary, with occasional cases of follicular, carcinoma. Prognosis is generally good, although there may be a significantly inferior survival in younger patients [31].

The appropriate screening for thyroid nodules following radiotherapy remains controversial. Routine ultrasound risks overdiagnosis of benign nodules and associated anxiety in a vulnerable group, whereas thyroid palpation risks missing smaller and more diffuse lesions. The Late Effects of Childhood Cancer Guideline Harmonization Group in collaboration with the PanCareSurFup Consortium argue for an individualized surveillance strategy using a decision aid [32].

Parathyroid

Irradiation involving the neck increases the risk of primary hyperparathyroidism (PHPT). Higher radiation doses result in an increased probability of developing PHPT. PHPT tends to emerge decades after radiation exposure, and later than intrinsic thyroid disease, although the latency between radiotherapy and PHPT might be shorter in patients receiving high-dose radiotherapy for malignancies. Younger age at irradiation and female gender are additional risk factors.

The pathophysiology of primary hyperparathyroidism in this setting is unclear, but diagnosis and management follow standard guidance for primary hyperparathyroidism. A single parathyroid adenoma is often the underlying cause. It is suggested that annual calcium and parathyroid hormone (PTH) measurements are performed in at risk patients [15, 33].

Ovary

Premature ovarian failure (POF) can result from surgical intervention, chemotherapy regimens, and radiotherapy where the field includes ovarian tissue. Combinations of treatment with radiotherapy

and chemotherapy, particularly alkylating agents, imparts a greater risk of POF than either modality alone.

POF occurs in up to 83% of teenage and young adult cancer survivors following chemotherapy, although normal ovarian function may persist for a variable period. Important risk factors are alkylating agents, older age at chemotherapy, and cumulative dose. For example, in 620 young adult women receiving chemotherapy alone; 8%, 10%, 9%, and 5% of patients with Hodgkin's, non-Hodgkin's disease, breast and gastrointestinal cancer respectively developed POF [34].

POF results from direct therapeutic radiation to the ovary, or where the ovary is unavoidably within the radiation field, for example: spinal, abdominal, pelvic, vaginal, bladder, iliac lymph node irradiation, total lymphoid system, whole spine, or TBI. Relative risk of POF depends on radiation dose and age at initial therapy. In prepubertal girls, doses as low as 5 Gy may affect later ovarian function. The average doses required to induce sterility decline with age, being 20.3 Gy in infants, 18.4 Gy at age 10 years, and 16.5 Gy at age 20 years.

Radiotherapy related uterine damage is a further consideration. Radiotherapy can reduce uterine volume or impair growth, cause altered vasculature, and a reduced endometrium, dependent on age at irradiation and dosage received. A dose of 14–30 Gy has been shown to alter uterine vascularization and muscular elasticity, however, lower doses given during TBI can also be detrimental to the uterus. Radiation exposure of the uterus is associated with a markedly increased risk for miscarriage, preterm birth, and low birth weight [35].

Untreated POF leads to symptoms of oestrogen deficiency and prematurely reduced bone mineral density. Standard practice is to replace females with oestrogen plus progesterone (if there is potential for an endometrial lining). Replacement therapy is generally not recommended in those with hormone sensitive tumours, although the evidence to support this remains elusive. Optimal hormone replacement strategies have not been well studied. Regimes range from high doses of ethinyl oestradiol in the oral contraceptive pill to low doses of transdermal oestradiol, and will depend on patient preference and individual risk profile (reviewed in [14]).

Testes

The vast majority of primary gonadal late toxicity is due to chemotherapy and/or radiation, and occurs as a result of toxicity to Leydig cells, germ cells, or both.

Germ cells are extremely sensitive to toxicity from chemotherapy and radiotherapy. Chemotherapeutic agents include alkylating agents such as cyclophosphamide and procarbazine. Impaired fertility and reduced sperm count can occur with cyclophosphamide doses of 200–300 mg/m^2 in prepubertal boys and 100 mg/m^2 in adults. Doses exceeding 6 g in prepubertal boys are associated with the highest risk of azoospermia. It is noteworthy that recovery from azoospermia can occur many years after therapy [36]. Doses of testicular radiotherapy as low as 0.1 Gy have been associated with inhibition of spermatogenesis, which may recover; but doses exceeding 2 Gy most commonly lead to permanent impairment. Patients at risk therefore include those receiving direct testicular radiation, but potentially also those having TBI or pelvic radiotherapy.

Leydig cells are less sensitive to damage from chemotherapy or radiotherapy, with irradiation doses of up to 24 Gy tolerated by prepubertal testes and up to 30 Gy during puberty. Combination chemotherapy and radiotherapy regimens are more likely to lead to testosterone deficiency (e.g. cumulative cyclophosphamide doses of more than 20 mg/m^2 and 14 Gy of testicular radiotherapy). Subclinical testosterone deficiency is relatively common, and under-recognized.

As a consequence of the differential sensitivities of the Leydig and germ cells of the testis; puberty generally progresses normally in children and secondary sexual characteristics are maintained in most adults who received irradiation. Oligo- or azoospermia frequently accompany normal androgenization. Testicular volumes are small reflecting damage to the germinal epithelium, and cannot be relied upon for pubertal staging.

Available guidance suggests at risk patients should be screened using Tanner staging of pubertal development every 6 months until sexual maturity. Adults should be monitored annually for symptoms of androgen deficiency; decreased libido, reduction in spontaneous erections, gynaecomastia, loss of body hair, reduced muscle bulk, hot flushes/sweating, and reduced testicular volume. Diagnosis involves measurement of morning total testosterone and LH/FSH. Borderline results require further investigation with sex hormone-binding globulin (SHBG) and calculations of free testosterone levels.

Adolescents and adult cancer survivors with confirmed hypogonadism should be replaced with testosterone using standard treatment regimes. Monitoring follows standard guidelines [37]. Fertility in both males and females should be considered and early referral to fertility services for assessment is recommended.

Bone

Low bone mineral density (BMD) is well described as a consequence of treatment for childhood, adolescent, and adult cancers. Whether this low BMD contributes to an increased risk of fragility fracture in cancer survivors is less well defined.

Poor bone health in cancer survivors can relate to the original cancer, treatment modalities received, and hormonal deficiencies. Cachexia, anorexia, reduced weight-bearing exercise, and immobility also potentially contribute to low BMD and increased fracture risk. In addition, risk factors for some cancers (e.g. smoking, alcohol excess, type 2 diabetes) are well-recognized lifestyle risk factors for low BMD and fragility fracture. Cancer and the treatment for cancer during childhood and adolescence can halt bone accrual and prevent or delay the attainment of peak bone mass. This has the potential to be associated with increased fracture risk in later life.

Glucocorticoid (GC) use is common to a number of oncology regimens and supportive treatments. Glucocorticoid-induced bone loss and increased fracture risk is well described although understanding of the pathophysiology still remains incomplete [38]. GCs cause rapid onset bone loss, within 30 days as shown in ALL patients, and effects are dose dependent. In general terms, glucocorticoid-induced bone loss is, at least partially, reversible. Risk of fracture in children with ALL treated with GC therapy related to higher GC dose, recent average increase in GC dose and increase in GC dose intensity. Type of GC treatment might also be important, with

dexamethasone causing more bone morbidity than prednisolone ([39, 40] reviewed in [15]).

High-dose methotrexate (doses above 40 000 mg/m^2) in children is associated with osteopathy, bone pain, and increased fracture risk. Animal studies demonstrate reduced osteoblast proliferation, increased osteoclast formation and increased marrow adiposity with methotrexate [15, 41]. Other chemotherapy agents; doxorubicin, etoposide, vincristine, asparaginase, cyclosporin, tacrolimus, 6-mercaptopurine, and cyclophosphamide, have been postulated to cause direct bone toxicity, however, it is difficult to isolate direct effects of chemotherapy from other contributory factors such as glucocorticoids, radiotherapy, and chemotherapy-induced hypogonadism [15, 42].

Cranial radiotherapy in children with ALL is associated with low BMD, initially described as the presence of reduced lumbar volumetric BMD in patients receiving more than 18 Gy of cranial radiotherapy. Subsequent studies demonstrated BMD inversely correlated to the dose of irradiation received. This bone toxicity has been in part attributed to radiation-induced GHD. Furthermore, low total body and lumbar spine BMD was found in children with posterior fossa tumours treated with craniospinal radiotherapy or posterior fossa radiotherapy independent of the presence of GHD or treatment with chemotherapy [15, 43].

Focal radiotherapy in children and adults is associated with increased fracture risk within the radiation field, usually when doses exceed 40 Gy. Rib fractures are common following radiotherapy to the chest for hepatocellular carcinoma, breast, and lung cancers. Pelvic insufficiency fractures have been described in between 1.7% and 89% of patients receiving pelvic radiotherapy [44].

A full understanding of the pathophysiology underlying the direct effects of radiation on bone is still elusive. *In vitro* studies demonstrate radiation-induced reduction in osteoblast number, osteoblast cell cycle progression, and increased apoptosis. Data for osteoclasts are less clear. Both a reduction and increase in osteoclast number and activity have been described [44].

Patients undergoing haematopoietic stem cell transplant are at high risk of reduced BMD and fracture. This risk is multifactorial; use of pretransplantation chemotherapy, glucocorticoids, TBI, endocrine dysfunction, immobilization, and low body mass index (BMI). Bone loss occurs rapidly and mainly within the first year following haematopoietic stem cell transplantation (HSCT). There is some recovery of bone health with time but most patients do not fully normalize BMD and remain at increased risk of fracture [45].

Patients at risk of poor bone health should have an assessment of bone density and fracture risk assessment. Gold standard technique for measurement of BMD is a DEXA scan, although in children and those with small bone volume, QCT may be more appropriate, providing a volumetric rather than areal density. The impact of childhood cancer on ability to attain peak bone mass should be taken into account.

There is little evidence to guide the management of bone health in cancer survivors. Systematic review did not provide overall convincing evidence for the use of physical exercise training in improving BMD in childhood cancer patients [46].

Similarly, in adults, a meta-analysis of exercise programmes in breast and prostate cancer survivors; including over 800 patients, showed no overall benefit demonstrated on lumbar spine, total hip, or femoral neck BMD. There was a trend for a beneficial effect in those undertaking resistance/impact exercise [47].

Vitamin D insufficiency and deficiency have been reported in both childhood/adolescent and adult cancer survivors, although whether this exceeds that of the general background population is controversial. There are no data in cancer populations that replacement with vitamin D improves BMD or reduces fracture risk although standard practice to maximize bone health would be adequate calcium intake (700–1000 mg per day) and cholecalciferol 400–800 IU per day.

Low BMD and bone turnover can be improved in children with ALL and Non-Hodgkin lymphoma using bisphosphonate therapy during or following chemotherapy treatment. However, there are no data with regards to fracture and there are general concerns about using antiresorptive therapy in growing bones and in fertile young women—more long-term studies are required before these therapies can be recommended routinely [48].

Bisphosphonate and denosumab therapy have been shown to improve BMD and in the case of denosumab, reduce fracture risk, in post-menopausal breast cancer patients taking aromatase inhibitors and prostate cancer patients taking androgen deprivation therapy [49]. It is well demonstrated that bisphosphonate therapy improves hip and spine BMD and prevents vertebral fracture in glucocorticoid-induced osteoporosis, although there are no specific studies in patients LWBC.

For HSCT patients, improvements in BMD following 12 months of bisphosphonate therapy have been demonstrated, although again these studies were not sufficiently powered or of sufficient duration to comment on fracture prevention. There are no clinical data currently to support the use of antiresorptive therapy for insufficiency fractures secondary to focal radiotherapy [50].

Conclusion

The number of patients diagnosed and surviving cancer is increasing. Each patient with cancer has a unique phenotype and will receive an individualized treatment regimen, leading to specific risks of acute and long-term effects of cancer therapies, including the endocrine dysfunction described in this chapter. Metabolic disturbance, including diabetes, lipid abnormalities, and increased cardiovascular and cerebrovascular risk are also common sequelae to be considered. Future studies are required to determine contributory factors and biomarkers to identify patients at risk of endocrine and metabolic dysfunction in order to determine appropriate long-term surveillance strategies. Furthermore, randomized controlled trials of preventative and therapeutic interventions in this group are needed to maximize quality of life and minimize the current increased morbidity and mortality in this group.

13.1.4 Endocrine Complications of Biological Cancer Therapies

Carla Moran

Introduction

Improved understanding of cancer biology over the past decade has led to a revolution in the immunotherapy field, with development of drugs targeted towards molecules mediating 'immune-silencing' in the tumour environment [1]. These treatments, collectively termed immune checkpoint inhibitors, are antibodies directed against cytotoxic T-lymphocyte antigen 4 (CTLA-4), programmed cell death protein 1 (PD-1) or its ligand (PD-L1), which work by regulating the natural checkpoints of the immune system. They boost immune antitumour activity, resulting in higher treatment responses and better survival rates in a number of metastatic malignancies, than seen hitherto.

Immunotherapeutic agents can have varying on- and off-target toxicities related to their affinity and specificity, respectively. Toxicities common to all checkpoint inhibitors include fevers, chills, diarrhoea, colitis, skin rash, hepatitis, pneumonitis, eye, and endocrine disorders. Although endocrinopathies are common, they are difficult to detect but, unlike other immune-related adverse events (IrAEs), are rarely life-threatening.

CTLA-4 Inhibitors

Ipilimumab, a fully human monoclonal IgG1 antibody against CTLA-4 potentiates T-cell activation by blocking the interaction between CTLA-4 and the costimulatory ligand B7 expressed on antigen-presenting cells, thus enhancing the T-cell response to tumour (see **Figure 13.1.4.1**) [1]. It was the first checkpoint inhibitor to obtain approval for the treatment of advanced melanoma, but is associated with severe and life-threatening IrAEs in 10–15% of patients [2]. Endocrine adverse events are reported at a relatively low frequency (see **Table 13.1.4.1**), but these side effects last longer than

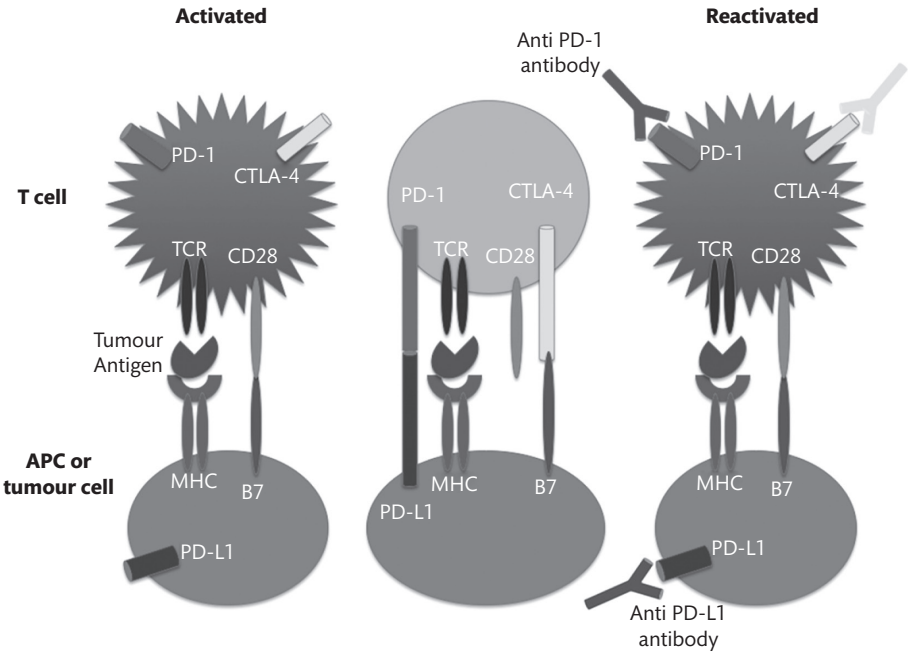

Figure 13.1.4.1 Mechanism of action of immune checkpoint inhibitors. On presentation of tumour antigen to T cells by the MHC complex on antigen-presenting or tumour cells, interaction of costimulatory molecules (CD28 and B7) results in T-cell activation. This process is halted by the interaction of PD-1 with its ligand, PD-L1, and CTLA-4 with B7. The presence of antibodies directed against either PD-(L)1 or CTLA-4 blocks their interaction with their partners on the APC or tumour cell and T-cell activation is therefore perpetuated. Abbreviations: TCR, T-cell receptor; CTLA-4, cytotoxic T-lymphocyte antigen-4; PD-(L)1, programmed cell death 1 (Ligand); CD28, cluster of differentiation 28; APC, antigen-presenting cell; MHC, major histocompatibility complex.

other IrAEs; moreover, although there may be an initial response to steroids, endocrine function does not usually recover.

Tremelimumab is another human monoclonal antibody (IgG2) against CTLA-4 currently being investigated for several types of malignancies. With a similar mechanism of action to ipilimumab, tremelimumab appears to have a similar toxicity profile, with one difference being that the latter has also been associated with Graves' disease (GD) [3].

CTLA-4 Inhibitors and Hypophysitis

Hypophysitis is the most common endocrinopathy associated with CTLA-4 antibody therapy, reported in 2–16% of treated individuals [2, 4–7]. A drug dose response relationship for this side effect has been reported in some [8], but not all, studies [9]. Time of onset is very variable, with hypophysitis reported as early as 3 weeks [5] and as late as 19 months [9], but typically occurring between 6 to 12 weeks (average 8.4 weeks) post-treatment [7]. Older age and male gender may be risk factors [7, 9].

Clinical Presentation, Investigations, and Initial Management of Hypophysitis

Algorithms for surveillance and management of hypophysitis following ipilimumab therapy have been proposed [10, 11]. Given the frequency of hypophysitis following CTLA-4 inhibitor therapy, baseline tests of pituitary function (LH, FSH, testosterone or oestradiol, thyroid-stimulating hormone (TSH), free T_4, adrenocorticotrophic

Table 13.1.4.1 Frequency of endocrine immune-related adverse events in patients treated with immune checkpoint inhibitors

	Hypophysitis	Adrenal insufficiency	Hyperthyroidism	Primary hypothyroidism	Thyroiditis
Anti-PD-1 therapy	0–1.9%	<1%	1–7.8%*	2–13%**	<1–9%
Anti-PD-L1 therapy	<1%	<1%	<5%	9–12%	1%
Anti CTLA-4 therapy	0–18%	<2%	<10%	0–7%	<5%
Combination therapy	0–12%	0–6%	4–12%#	13–22%##	0–16%

* subclinical hyperthyroidism occurs in an additional 13%.
** subclinical hypothyroidism occurs in an additional 13%.

subclinical hypothyroidism occurs in an additional 5.6%.

hormone (ACTH), cortisol at 9:00 a.m.) would be helpful, both to document normal pituitary reserve and for comparison with later hormone measurements should development of hypophysitis be suspected. Thereafter, pituitary function should be evaluated if there are any clinical symptoms or signs suggestive of hypophysitis. However, since specific symptoms are often difficult to elicit, it is reasonable to undertake pituitary function testing prior to each cycle of ipilimumab administration and up to 16 weeks after initial treatment. If hypophysitis is suspected on clinical criteria outside these time points additional hormone measurements should be undertaken.

Most patients (80%) present with non-specific symptoms such as fatigue, muscle weakness, and headaches [5, 9]. Less common presenting symptoms include postural dizziness, weight loss, nausea, anorexia, vomiting, and generalized arthralgia. Hyponatraemia is the commonest reported biochemical abnormality (47–56%) at presentation [9].

TSH and gonadotrophin (luteinizing hormone and follicle-stimulating hormone) deficiency are very common (approximately 80%), as is ACTH deficiency (50–85%). Lack of ascertainment may explain the lower prevalence of growth hormone (GH) (25%) and prolactin deficiency [5, 7, 9]. Diabetes insipidus is very rare.

Visual fields should be tested by confrontation in all patients with suspected hypophysitis, and urgent formal visual field perimetry undertaken if an abnormality is suspected. Imaging of the pituitary gland, ideally by MRI with contrast, should be undertaken in order to determine if the typical appearance of hypophysitis (mild to moderate diffuse enlargement of the pituitary gland and homo- or heterogeneous gland enhancement following contrast administration) is present and also to exclude pituitary metastasis, or other, coincidental pituitary pathology (e.g. adenoma). Compression of the optic chiasm due to an enlarged pituitary gland has not been reported in anti-CTLA-4 induced hypophysitis. The pituitary gland typically decreases in size within 4 to 12 weeks from onset of hypophysitis with such change occurring irrespective of high-dose steroid administration [6, 7]. Most experts do not recommend routine administration of high-dose steroids in immune checkpoint inhibitor induced hypophysitis, however steroid treatment can be considered in selected circumstances, such as severe headache, pituitary enlargement that encroaches on the optic chiasm or associated with visual field defects.

As in conventional hypopituitarism, hormone replacement should be instituted, with particular care taken to exclude concomitant adrenal insufficiency prior to commencing thyroxine. Guidance on management of acute endocrine complications has been published [11]. Rates of recovery of hormone deficiencies are poorly defined; however, recovery of pituitary adrenal axis function is very rare (7, 9) and recovery of TSH and gonadotrophin deficiency is reported in approximately 50% of patients in some series [5, 7, 12].

CTLA4-Inhibitors and Other Endocrinopathies

Thyroid dysfunction was reported relatively infrequently (<10%) but possibly due to regular surveillance and improved detection of subclinical disease, recent studies have recorded thyroid dysfunction in 23% of cases [13]. Overt thyrotoxicosis is rare and is almost always due to thyroiditis, although GD has been reported. Primary adrenal insufficiency is very rare (<2%).

Pathogenesis

The CTLA-4 gene is also an important susceptibility locus for autoimmune endocrinopathies [14] and probably plays an important role in self-tolerance. CTLA-4 is expressed in murine and human pituitary glands, especially cells producing prolactin and TSH. Lymphocytic infiltration of the pituitary gland and development of pituitary antibodies is seen in mice injected with anti-CTLA-4 antibodies [15]. Although the pathogenesis of ipilimumab-induced hypophysitis is unknown, it is possible that administration of anti CTLA-4 antibody to susceptible individuals evokes an autoimmune process targeting the pituitary gland.

PD-1 Antibody Therapy

Programmed cell death-1 (PD-1) is an inhibitory receptor located on immune cells, which, by engaging its ligands (PD-L1 and PD-L2, located on antigen-presenting cells), acts as a negative regulator of immunity, downregulating the T-cell-mediated immune response [16, 17]. Pembrolizumab and nivolumab (humanized monoclonal antibodies targeting PD-1) exploit this mechanism by inhibiting the interaction between PD-1 and PD-L1/PD-L2, thereby perpetuating T-cell activation. In comparison to ipilimumab, they have been shown to exhibit greater clinical efficacy and a more favourable toxicity profile for some metastatic cancers [18–20].

Thyroid Dysfunction Following Anti-PD-1 Therapy

Thyroid dysfunction is common after treatment with PD-1 antibodies (3–39%) and tends to occur early (typically 3–8 weeks) (see Table 13.1.4.1) [21]. Although any form of thyroid dysfunction can occur, overt hypothyroidism (2–13%) seems more common than thyrotoxicosis (0–7.8%) (see Table 13.1.4.1) [13, 21–23].

Thyroiditis is likely to be the dominant cause of thyrotoxicosis; in one retrospective study, thyroiditis was the cause of dysfunction in all hyperthyroid patients and was also the suspected aetiology in the remainder of cases who were hypothyroid at presentation but may have had a preceding hyperthyroid phase [24].

High rates of subclinical thyroid dysfunction were reported by a single UK centre following treatment with either pembrolizumab or nivolumab; subclinical hypo- and hyperthyroidism occurred in 13% of cases, with the overall rate of thyroid dysfunction following anti-PD1 therapy being 39% [13].

Clinical Presentation, Investigations, Initial Management of Thyroid Dysfunction

As for CTLA-4 antibody-mediated endocrinopathies, recommendations for surveillance and management of thyroid dysfunction following administration of anti PD-(L)1 agents have been proposed [10, 11]. At a minimum, baseline assessment of thyroid function (TSH and fT_4) and periodic measurement of TSH and fT_4 (perhaps coinciding with cycles of treatment) is advised, with additional testing at intermediate timepoints if symptomatic.

If thyroid dysfunction develops, thyroid autoantibody status should be checked; in hypothyroidism, positive anti-TPO antibody levels can signify an autoimmune basis; in hyperthyroidism, positive anti-TSH receptor antibody status indicates GD (>95% specificity) rather than thyroiditis. At present, there is no evidence to suggest that thyroiditis or GD should be managed differently to that occurring in the conventional (non-immune checkpoint inhibitor) context.

Hyperglycaemia Following Anti-PD-1 Therapy

Development of diabetes mellitus, including diabetic ketoacidosis, has been described following anti-PD-1 therapy. In some cases biochemical measurements were strongly suggestive of immune-mediated insulin deficiency [25].

PD-L1/PD-L2 Inhibitors

Antibodies targeted against PD-L1 (such as atezolizumab, durvalumab, and avelumab) have shown efficacy against advanced non-small cell lung cancer and urothelial carcinoma [26]. Although their relative efficacy and toxicity has not been compared directly, indirect comparisons suggest endocrine IrAEs associated with atezolizumab are similar to those observed with anti-PD-1 antibody therapy (hypothyroidism 9%, thyrotoxicosis 3.6%, adrenal insufficiency and hypophysitis <1%) [27–30]. Durvalumab causes thyroid dysfunction in 5.5 to 12%, with the higher frequency possibly attributable to concomitant treatment with tremelimumab [31, 32]. Avelumab may have a lower frequency of endocrine IrAEs (adrenal insufficiency 0.5% [33, 34]; diabetes <0.1% [35]).

Pathogenesis

The interaction between PD1 and PDL1 evokes quiescence of autoreactive T cells, thereby maintaining peripheral tolerance and preventing autoimmunity. PD-1 deficient mice of differing genetic backgrounds develop different types of autoimmunity, presumably linked to varying target organ susceptibilities in different strains [34, 35].

Baseline positive thyroid autoantibody status may confer greater risk of anti-PD-1-mediated thyroid dysfunction [36], suggesting that this immunotherapy unmasks a latent autoimmune process in susceptible individuals.

Combination CTLA4 and PD-1 Blockade

The improved overall survival seen in metastatic melanoma after combination therapy with ipilimumab and nivolumab occurs at a cost of more frequent IrAEs [19, 20], and endocrinopathy is no exception. Rates of hypophysitis (4–12%) are higher than those observed following ipilimumab treatment alone, as is the incidence of thyroid dysfunction (30–50%) (see Table 13.1.4.1) [13, 37]. Adrenal insufficiency may also be more common (6.4% vs. 4.3%) (see Table 13.1.4.1).

Summary

It is now clear that immune checkpoint inhibitor agents are highly effective treatments for many advanced cancers. These agents frequently cause IrAEs, with thyroid dysfunction (following PD-(L)1 inhibitor-treatment) and hypophysitis (following CTLA-4 inhibitor therapy) being common. Although these side effects are not generally life-threatening, they can result in significant morbidity if not detected and treated promptly. These therapies provide remarkable insights into susceptibility and development of endocrine dysfunction, but further studies are needed to elucidate pathogenetic mechanisms for different endocrinopathies.

13.2

Hormonal Therapy for Breast and Prostatic Cancers

13.2.1 The Breast

Lactation and Breast Cancer as an Endocrine Disease

Robert Clarke and Alice Greenhalgh

Normal Breast Development

The normal human breast is made up of two main tissue compartments—the stroma and the epithelium. The stroma consists of adipocytes, fibroblasts, blood vessels, inflammatory cells, and the extracellular matrix. Embedded within this stroma, the epithelium consists of several branching ductal-lobular systems forming tree-like structures from single major ducts of which there are estimated to be 12–16 that channel milk to their openings on the nipple [1]. This structure reflects the breast's specialist function to produce milk during lactation in order to feed and sustain offspring. Epithelial cells form terminal ductal lobuloalveolar units (TDLU), where milk is made, and connect to the nipple via a network of ducts. Both ducts and lobules are lined by a single layer of luminal epithelial cells which comprises hormone-sensing and milk-producing cells and their proliferative progenitors. The luminal cells are surrounded by a basal cell layer, consisting mostly of myoepithelial cells with contractile properties, as well as progenitor and multipotent stem cells, which are capable of giving rise to all epithelial cell types.

Human breast development is controlled by the endocrine system, specifically by the ovarian steroid hormones, oestrogen (E) and progesterone (Pg), and by the pituitary hormones prolactin (PRL) and growth hormone. There is evidence that other local and systemic proteins such as growth factors and cytokines play a role in tissue development at various stages.

Regulation of Adult Human Breast Development

Adult development of the human breast is regulated largely by ovarian steroid hormones which are first secreted at puberty. However, there is evidence of a requirement for other endocrine hormones such as growth hormone and PRL secreted by the pituitary gland, and placental lactogen secreted by the placenta during pregnancy. It has also become increasingly apparent that the effects of these systemic hormones are mediated locally by growth factors and cytokines synthesized and secreted by breast cells. In contrast to the endometrium, epithelial proliferation is maximal during the latter half of the menstrual cycle when both oestrogen and progesterone are secreted by the ovarian *corpus luteum*.

Ovarian Steroids: Oestrogen and Progesterone

E and Pg exert their effects following binding to receptors in the nucleus of the cell. The E receptor (ER) and the P receptor (PR) are nuclear receptors that act as ligand-activated transcription factors regulating cellular gene expression by both activation and repression of transcription. The hormone-sensing cells that express the classical ER and the PR are found within the luminal epithelial, but not the myoepithelial or stromal, cells of the human breast.

There are two isoforms of ER: ERα and ERβ, which are encoded by two different genes. ERα has historically been considered to be the most important in the development of the breast due to its expression pattern in the epithelium, its proliferative role, and the total lack of mammary epithelial development when it is knocked out in the mouse. In contrast, ERβ has a more subtle role in differentiation and the regulation of apoptosis, as the mammary gland of ERβ knockout mice develop normally. Unless indicated, ER refers to ERα in this review. There are two closely related isoforms of PR: PR-A and PR-B, both are transcribed from the same gene but with two different promoters. PR-B has an additional sequence of 164 amino acids at the amino terminus compared to PR-A. Both isoforms are equally expressed in breast epithelial cells and can be present as both hetero and homodimers.

E and P Effects on Mammary Development

In experimental studies utilizing ER and PR knockout animals it has been shown that, E regulates ductal elongation [2] and P regulates side branching and lobular development [3]. Other animal studies have demonstrated E to be a mitogenic stimulus during puberty promoting the elongation of the mammary ducts and expansion of the epithelium throughout the fat pad [4]. Mammary epithelial transplantation experiments in mice have also indicated that the growth factor amphiregulin, which is a ligand of the epidermal growth factor receptor, to be an essential mediator of E-induced proliferation during puberty [5].

Following puberty in the mouse, the effect of E on proliferation is weakened, although it is responsible for driving the strong mitogenic effects of P through its regulation of PR expression during this stage of development [6]. P is secreted in the human during the luteal phase of the menstrual cycle when proliferation is highest and therefore is regarded as the main proliferative hormone in both the mouse mammary gland and the normal human breast. P is also required for promoting much of the increase in breast epithelial proliferation during early to mid-pregnancy.

Normal Breast Development

Normal breast development can be grouped into three well-defined stages: embryonic, pubertal, and reproductive.

Embryonic Development

The rudiments of the gland are developed during embryogenesis when a mammary disc forms from the epidermal milk line and the parenchyma begins to invade the underlying mesenchyme. The invading epithelial cells become indented at the epithelial-stromal border, sprouting, and separating into 10–15 branches of epithelial ducts that each open separately onto the epidermal surface at the nipple. As these ducts grow into the mesenchyme they may bifurcate several times and may even form end-vesicles, a primitive form of the lobuloalveolar structures observed in the adult gland. Late in gestation, the skin above this area specializes to form the areolus and nipple from which secretions may be observed at parturition, presumably in response to maternal hormones.

Pubertal Development

In contrast to embryogenesis, all developmental stages of post-embryonic breast development are hormone dependent. Mammary gland development during childhood does little more than keep up with the overall growth of the child until the approach of puberty. Puberty triggers breast growth driven by ovulation and the formation of regular menstrual cycles. The mature gland undergoes cycles of proliferation and apoptosis over the course of each subsequent menstrual cycle. This results in a network of ducts leading from the nipple growing and dividing into bundles of primary and secondary ducts, lined with epithelial cells and ending with morphologically club-like structures called terminal end buds (TEBs). Equally, the mainly collagenous connective tissue of the breast expands and grows to accommodate the branching network of epithelium. It is from the TEBs that the TDLU, also called lobules, form and which comprise the principal, functional milk-producing glandular units of the breast (see Figure 13.2.1.1).

These lobules exist initially as alveolar buds that mature following menarche into a variable number of blind-ending, grape-like, secretory sacs known as acini, alveoli, or ductules which open into the intralobular terminal duct. At maturity, the lobular structure can be

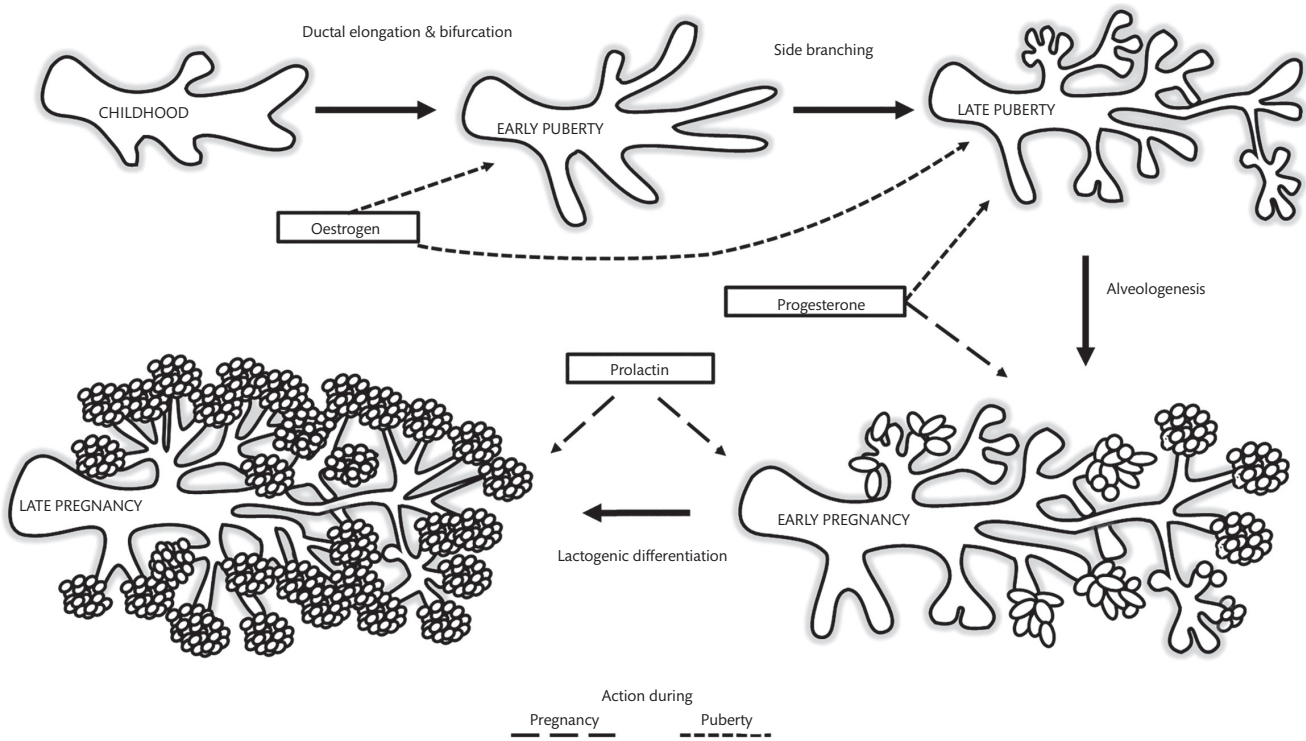

Figure 13.2.1.1 Diagrammatic representation of the lobular structures of the human breast throughout all stages of development.

imagined as resembling a bunch of grapes (see Figure 13.2.1.1). It is during the development of the TDLU that epithelial hyperplasias and carcinomas of the breast are thought to be initiated since this is the site at which they are most often observed histopathologically.

Reproductive Development

Epithelial development continues throughout adolescence and into adulthood. Despite many rounds of mammary remodelling events taking place during puberty and through adulthood, it is not until pregnancy that full mammary epithelial maturation occurs, as the breast progressively transforms into a fully mature functional organ. During pregnancy, mammary stem cells (MaSCs) and progenitor cells proliferate resulting in the formation of new ducts, elongation of the existing ducts, further epithelial branching, and formation and expansion of round hollow structures, which are individually called alveoli [7, 8].

In parallel with this growth and development of the epithelial component, the stromal elements also develop to accommodate this increase in volume and cell number.

The progressive maturation of the breast is regulated by the increased levels of the circulating lactogenic hormones, E, P, and PRL during pregnancy. Other hormones and growth factors are also involved in regulating mammary development during pregnancy. Placental lactogen, amphiregulin, Wnt, RANKL, CXCL12, IGF2, and stromal paracrine factors directly regulate mammary development. Contrastingly insulin, growth hormone, glucocorticoids, and fibroblast growth factors play a more indirect role [9]. Blood placental lactogen has been shown to be strongly correlated with breast growth, with a proposed mechanism of inducing the stem/progenitor cells to proliferate [10].

There are two main phases of human mammary development corresponding to the early and late stages of pregnancy. The early stage is characterized by increased side branching of the ductal tree corresponding to elevated P levels, resulting in the formation of ductules termed acini. P levels rise during the luteal phase of the menstrual cycle but particularly during pregnancy. During the second trimester, the lobules become further enlarged and increase in number. P works cooperatively with PRL to stimulate cellular differentiation at the alveolar sites (during alveologenesis) that are responsible for milk secretion during lactation. P is necessary in the mammary epithelium for side branching and alveologenesis [9], whereas the PRL is required for alveologenesis and milk secretion. The cooperation between P and PRL signalling becomes evident after side branches have been established during mid-pregnancy, when further alveologenesis requires epithelial PRL signalling [10]. This sequential action ensures that the discrete morphological steps occur in an ordered fashion; therefore, allowing all of the ducts to form before the alveoli bud, ensuring they have enough space to unfold and to be drained effectively [6].

The secretory alveoli formed during pregnancy signify the end of mammary gland differentiation. Each alveolus is surrounded by stroma and separated from it via the basement membrane. Secretion of milk by the epithelium during lactation also distends the alveoli and upon infant suckling, there is an increase in bound oxytocin causing the myoepithelial cells to contract releasing milk from the alveolus.

Following weaning, secretion of milk by the epithelial cells ceases and the lobules involute to resemble those present in the non-pregnant gland, although they may retain a larger number of individual alveoli per lobule than before. This intriguing process of expansion and regression, known as involution, can take place across multiple pregnancies during the reproductive lifespan, signifying that the epithelial cells of the mammary gland have substantial regenerative abilities.

A Mammary Stem Cell Niche

There is increasing evidence that mouse and human mammary epithelium is hierarchically arranged; from the multipotent stem cells to the lineage restricted, hormone-sensing, milk-producing, and myoepithelial cells [11–14].

The mammary gland is a dynamic structure, throughout a lifetime many changes in both structure and function occur, including recurring expansions relating to the hormonal changes prompted by the menstrual cycle. In addition, dramatic changes occur during pregnancy, lactation, and involution. MaSC are proposed to be the drivers of the constant mammary tissue remodelling events occurring through cycles of pregnancy, lactation, and involution. This quiescent, self-renewing, population of cells give rise to the differentiated ductal, alveolar, and myoepithelial cells [15].

A MaSC niche theory has been proposed encompassing both cellular and acellular supportive elements surrounding the stem cells. These supporting elements could, for example, include differentiated stem cell progeny their surrounding stromal cells which display cell surface molecules and can deliver soluble factors to regulate stem cell actions.

As previously discussed, the mammary gland is constantly remodelled in response to the female reproductive hormones. A self-renewing population of MaSCs is needed during these cycles of growth to differentiate into new epithelia. Consequently, MaSCs must respond to these hormonal signals; however, oestrogen receptor (ER) and progesterone receptor (PR) are only detected in a subset of luminal epithelial cells and have not yet been identified in the mouse or human MaSC-enriched basal cell population [16, 17]. Three epithelial subsets including basal stem/progenitor, luminal progenitor and mature luminal cells have been characterized so far with ER and PR being found to be enriched in mature luminal cells.

Therefore (ER^+PR^+) luminal cells can be described as essential niche cells that detect circulating hormone levels and signal, via paracrine mechanisms, to other niche populations, and to unipotent or multipotent MaSCs.

Hormones and Breast Cancer

There is a causal relationship between breast cancer and the ovarian steroid hormones. Early menarche, late first-term pregnancy, and late menopause are associated with a heightened breast cancer risk, this is coupled with research showing removing a woman's ovaries significantly reduces the risk of breast cancer. In addition, both hormone replacement therapy (HRT) and oral contraceptives can increase the risk of breast cancer, thus linking steroid hormones with breast carcinogenesis [18]. However, on the other hand, ER/PR+ tumours are associated with a more favourable breast cancer prognosis with receptor expression being most significant predictive marker for endocrine responsiveness [19].

The mammary stem cell theory that steroid receptor-positive cells signal via paracrine mechanisms to adjacent receptor-negative

cells, is supported by the inverse relationship between steroid receptor expression and proliferation in the normal breast [9, 20]. Contrastingly, in breast cancer the number of proliferating cells expressing steroid hormone receptors is increased [21], implying that steroid receptor-positive cells experience an early 'switch' to autocrine signalling mechanisms, or that these cells somehow gain the ability to divide [22]. However, the mechanisms that drive this molecular switch from paracrine to autocrine signalling are as yet unknown making this an interesting area for current research [23, 24].

Conclusions

This is a very interesting time for mammary gland scientists. New signalling pathways are being uncovered that dictate the lineage commitment, coupled with the development of improved humanized mouse models and three-dimensional culture models, the future of mammary gland biology is an exciting one. As new discoveries are made, the cellular targets of breast cancer will become better understood, thus providing oncologists with better tools to predict, prevent, and treat breast cancer.

13.2.2 Endocrine Treatment of Breast Cancer

Amna Sheri and Laura Morrison

Introduction

Endocrine manipulation has been recognized as a treatment modality for breast cancer for over 100 years. Oestrogen is an important promoter in the pathogenesis of breast cancer and endocrine response, is predominantly dependent on the presence of oestrogen receptor (ER), a protein which can be detected in about 70% of primary breast cancers.

A better understanding of the mechanisms that result in oestrogenic deprivation of breast cancer cells has enabled medical therapeutics to be developed which have largely replaced surgical ablative procedures (Box 13.2.2.1). These include hormone manipulation at the cellular level, via competition for ER in the breast tumour, using antioestrogens, such as tamoxifen or more recently selective oestrogen receptor modulators (SERMs), and 'pure' antioestrogens such as fulvestrant.

An alternative approach is to lower systemic oestrogen levels in premenopausal women by the use of luteinizing hormone releasing hormone (LHRH) agonists and in postmenopausal women by the use of aromatase inhibitors. Endocrine agents with more ill-defined mechanisms, such as progestogens, androgens, and corticosteroids can induce endocrine responses.

In patients with ER-positive advanced breast cancer, endocrine treatments generally achieve a response rate of between 20% and 40%. The median response duration to endocrine therapy in advanced disease is about 8–14 months but can last several years.

In patients with early stage ER-positive breast cancer adjuvant tamoxifen therapy given for 10 years delays local and distal relapse and prolongs survival. It also substantially reduces the incidence of contralateral breast cancer. The use of endocrine therapy in a chemopreventive role has been evaluated [1–4].

Antioestrogens

Tamoxifen

Approximately 80% of human breast carcinomas express ER. Tamoxifen is a non-steroidal oestrogen receptor antagonist which inhibits breast cancer growth by competitive antagonism of oestrogen at the receptor site. Its actions are complex due to partial oestrogenic agonist and antagonist effects depending on the specific end organ. It has been in use since its approval in 1978 and, although effective, the partial agonist effects may account for the development of tamoxifen resistance and disease progression after prolonged administration, in addition to specific adverse side effects on the gynaecological tract.

Adjuvant Tamoxifen

In early breast cancer, tamoxifen has been the gold standard of adjuvant endocrine therapy for both premenopausal and postmenopausal breast cancer for over two decades. In an overview of the effects of chemotherapy and hormonal therapy for early breast cancer by the Early Breast Cancer Trialist's Collaborative Group (EBCTG) [5], a 31% reduction in the annual breast cancer death rate with 5 years of adjuvant tamoxifen was reported at 15 years of follow-up. Breast cancer is relatively unusual in that the risk of recurrence remains substantial during the second decade and indeed may continue indefinitely. It is therefore highly significant that trials comparing allocation to a control arm or 5 years of tamoxifen have shown persistent benefits with a reduction in the 15-year probability of death from breast cancer about three times as great as the 5-year probability [1]. The benefit from tamoxifen treatment was confined to those patients with oestrogen receptor-positive cancers. Overall, this gave an 8% reduction in the 5-year mortality for patients with primary operable breast cancer. There was also a 47% reduction in the incidence of contralateral breast cancer at 5 years.

Adjuvant tamoxifen was traditionally administered for 5 years following data from the EBCTG. While earlier data in node-negative patients did not find any advantage in continuing tamoxifen beyond 5 years [6] newer data from two key trials suggests that 10 years of adjuvant treatment is beneficial. The Adjuvant Tamoxifen, Longer Against Shorter (ATLAS) study [7] randomized 12 894 women to 10 or 5 years of tamoxifen. In this study, there was a significant reduction in risk of breast cancer recurrence ($P = 0.02$), breast cancer mortality ($P = 0.01$) and overall mortality ($P = 0.01$) in women with ER-positive disease. Similar results were noted in the aTTom study [8].

Tamoxifen 20 mg/day for 10 years alone or in addition to chemotherapy is now the standard endocrine therapy of choice for early breast cancer in premenopausal women [9].

Side Effects/Toxicity of Tamoxifen

The side effects of tamoxifen are well documented. Short-term effects are usually mild and include hot flushes and altered menses. Tamoxifen acts as an oestrogen agonist on bone, increasing mineral density and thereby potentially reducing the risk of osteoporotic fractures in postmenopausal women. Similarly, it lowers serum cholesterol, potentially decreasing the risk of heart disease. The risk of developing deep vein thrombosis and pulmonary emboli is increased in women taking tamoxifen and caution must be used in patients with prothrombotic risk factors. The ATLAS study built on previous data showing an increased risk of endometrial cancer, due to the oestrogenic stimulation of the endometrium, with a longer duration of tamoxifen. The increased risk was predominantly confined to postmenopausal women who had not undergone hysterectomy and the risk was outweighed by the reduction in breast cancer mortality and recurrence. There were no deaths from endometrial cancer in this study.

Aromatase Inhibitors: Pharmacology

In contrast to tamoxifen, which antagonizes oestrogen at the receptor site, the oral aromatase inhibitors (AI) such as anastrozole), letrozole, and exemestane all reduce serum oestrogen levels in postmenopausal women by preventing the conversion of adrenal androgens into oestradiol and oestrone by the cytochrome P450 enzyme aromatase (Figure 13.2.2.1) [10].

Box 13.2.2.1 Endocrine treatment for breast cancer

- Antioestrogens
  - Tamoxifen
  - Other selective oestrogen modulators: raloxifene, lasofoxifene
  - Steroidal 'pure' antioestrogens: fulvestrant
- Oestrogen deprivation therapies
  - Luteinizing hormone releasing hormone analogues: goserelin
  - Aromatase inhibitors: letrozole, anastrozole, exemestane
- Other agents
  - Progestogens
  - Androgens: medroxyprogesterone acetate. Megestrol acetate
  - Corticosteroids
  - Oestrogens: diethylstilboestrol

While oestrogens are primarily synthesized in the ovary in premenopausal women, following the menopause mean plasma oestradiol levels fall from about 400–600pmol/L to around 25–50 pmol/L. These residual oestrogens come solely from peripheral aromatase conversion, particularly in the subcutaneous fat. Of note, AI are contraindicated in premenopausal women without additional ovarian suppression because the suppression of peripheral aromatase results in a reduced feedback to the hypothalamus and an increase in ovarian stimulation [10].

The currently approved 'third-generation' AI all powerfully inhibit oestrogen synthesis [10]. They are highly specific with almost no effect on cortisol or aldosterone levels. All are administered on a once daily basis.

Clinical Efficacy of AI in Advanced Breast Cancer

A number of clinical trials have now consistently shown improved efficacy of AI over tamoxifen [11–17]. See Table 13.2.2.1.

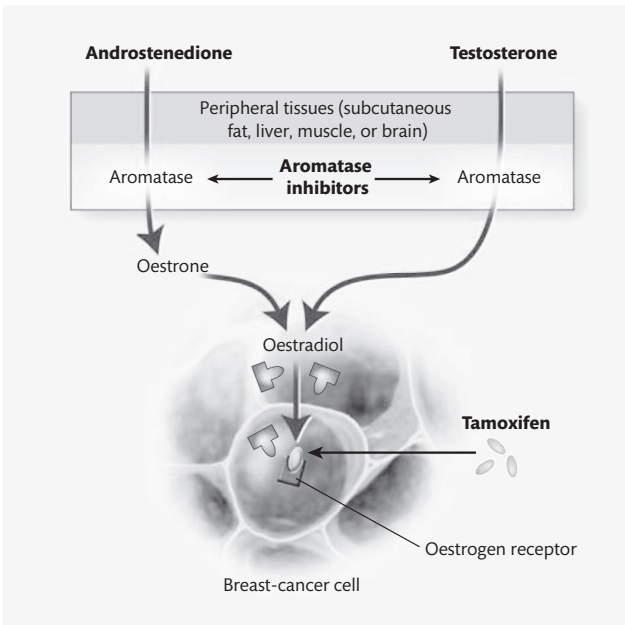

Figure 13.2.2.1 Mechanism of action of aromatase inhibitor and tamoxifen.

Reproduced with permission from Smith IE, Dowsett M. Aromatase inhibitors in breast cancer. *N Engl J Med*, 2003; 348:2431–42.

The largest of these, a randomized double-blind phase III trial in over 900 postmenopausal women with locally advanced or metastatic breast cancer, compared letrozole 2.5 mg with tamoxifen 20 mg daily [15, 16]. Patients treated with letrozole had a significantly higher objective tumour response rate (30% vs. 20%, P <0.001), clinical benefit rate (49% vs. 38%, P <0.001), and prolonged time to disease progression (median time to progression of 9.4 months vs. 6.0 months, hazard ratio 0.72, P <0.0001). Of particular note in this trial, nearly 20% of the patients had received prior tamoxifen in the adjuvant setting; in this subgroup, retreatment with tamoxifen had a low response rate of 8% compared with a 32% response rate with letrozole. The improvements in clinical efficacy for letrozole resulted in an early improvement in survival during the first 2 years [18], although with longer follow-up this difference was lost. This could be explained by the high number (>50%) of patients who prospectively crossed over to the alternate treatment at the time of progression. Significantly more patients benefited from second-line letrozole after progression on tamoxifen than the reverse. There were no significant differences in toxicity between the two treatments [16].

As a result of this data the third-generation AIs have now become the standard of care for first-line endocrine therapy in postmenopausal women with ER-positive advanced breast cancer.

Use of AI in Early Breast Cancer

The establishment of the efficacy and tolerability of AI in advanced breast cancer encouraged the development of a number of trials examining their use in the adjuvant setting.

Trials Comparing Adjuvant Tamoxifen Versus AI

A large meta-analysis undertaken by the (EBCTCG) [19] in 2015 compared the efficacy of tamoxifen versus AI in postmenopausal women with ER-positive early breast cancer. The analysis compared results from nine individual trials and reports on 31 920 women. A significant reduction in breast cancer mortality (RR 0.85) and recurrence, at both distal (RR 0.86) and local (RR 0.74) sites, in women receiving 5 years of AI versus 5 years of tamoxifen therapy (P <0.00001). Ten-year recurrence was 19.1% in the AI group and 22.7% in the tamoxifen group, suggesting a 3.6% 10-year gain of AI over tamoxifen. In terms of side-effect profile, there was a greater incidence of bone fracture in the AI group (8.2% vs. 5.5%; RR 1.30) and this risk was maintained throughout a 10-year follow-up period. There was a lower rate of endometrial cancer in the aromatase inhibitor group (0.4% vs. 1.2%).

Upfront AI Versus Switching Strategies

Earlier studies of tamoxifen versus tamoxifen followed by a switch to an AI demonstrated a survival benefit. However, this was not shown to be superior to commencing on upfront AI. The BIG-198 also looked at commencing on AI upfront followed by a switch to tamoxifen at year 2–3 and this was not inferior to 5 years of AI in this study. This therefore provides some evidence that patients who tolerate an AI poorly can be switched to tamoxifen safely if needed.

Extended Adjuvant Endocrine Therapy with AI After 5 Years of Tamoxifen

Hormone receptor-positive breast cancers have a chronic relapsing nature with risk of recurrence continuing indefinitely and

Table 13.2.2.1 Comparative of first-line trials of aromatase inhibitors versus tamoxifen in advanced breast cancer

Authors (reference)	Comparators	N	Response (%)	Clinical benefit (%)	Median time to progression (months)
Nabholtz *et al.* [12]	Anastrozole Tamoxifen	171 182	21 17	59 46	11.1 5.6
Bonneterre *et al.* [13, 14]	Anastrozole Tamoxifen	340 328	33 33	56 56	8.2 8.3
Mouridsen *et al.* [15, 16]	Letrozole Tamoxifen	453 454	30 20	49 38	9.4 6.0
Paridaens *et al.* [17]	Exemestane Tamoxifen	182 189	46 31	66 49	9.9 5.8

approximately half of all recurrences occurring between 5 and 15 years after surgery despite 5 years of adjuvant tamoxifen treatment. There is, therefore, a rationale for considering extended adjuvant endocrine therapy beyond 5 years. The MA.17 study [20], a double-blind, placebo-controlled trial evaluated whether 5 years of letrozole therapy after completion of 5 years of tamoxifen in postmenopausal women could lead to an improvement in disease-free survival (DFS). The positive results were most marked in patients with lymph node positive disease and those who were premenopausal at presentation.

Duration of AI Therapy

Treatment with an AI for 5 years either as monotherapy or after tamoxifen became the standard of care for postmenopausal women with early, receptor-positive breast cancer.

The MA.17R study, a double-blind, placebo-controlled trial, assessed the efficacy of extending AI therapy to 10 years [21]. The study enrolled 1918 women who had remained disease-free on adjuvant endocrine therapy with any AI. They were randomly assigned to receive placebo or continue receiving letrozole for a further 5 years. Most patients in this study had received 5 years of tamoxifen prior to starting AI so the study effectively compares 10 versus 15 years of adjuvant endocrine therapy. There was a significant improvement in the DFS and a reduction in the incidence of contralateral breast cancer as well as a 1% benefit in distant recurrence. Interestingly there was no difference in overall survival (OS). The extended therapy arm had an increased risk of osteoporotic fractures and this would need to be considered when deciding on the appropriate duration of treatment.

Two other studies, DATA and IDEAL [22, 23] have also looked at extended AI therapy in this group of patients. While the DATA study did show a reduction in DFS in the 6-year group they also noted a higher rate of side effects in the extended therapy arm. The IDEAL study, comparing 2.5 or 5 years of additional AI therapy did not show any significant difference between groups in relation to DFS or OS and

There is therefore a lack of clarity regarding which, if any, subgroups of patients will benefit from extended AI therapy. Decisions about extending therapy to 10 years will be influenced by the relative risk versus the potential toxicities in individual patients and is an area of ongoing research.

Toxicity/Side Effects of AI

In general, the third-generation AIs are well tolerated although symptoms of oestrogen withdrawal are common. The commonest side effects include hot flashes, musculoskeletal stiffness, and vaginal dryness. However, in the clinical trial setting the different side-effect profiles of tamoxifen and AI do not appear to impact on patient's quality of life [24]. Interestingly, the appearance of vasomotor or joint symptoms within the first 3 months of treatment has been associated with a greater decrease in breast cancer recurrence in the Arimidex, Tamoxifen, Alone or in Combination (ATAC) trial [25].

In trials comparing the third-generation AIs with tamoxifen, the adverse events associated with tamoxifen's oestrogenic properties, such as venous thromboembolism and endometrial cancer, were significantly less common in the AI groups [26]. However, an increased risk of osteoporosis and fractures has been observed with the AIs compared with tamoxifen [26, 27]. The American Society of Clinical Oncology (ASCO) guidelines recommend that postmenopausal women who receive an aromatase inhibitor should have their bone mineral density evaluated [28]. It is likely that the introduction of adjuvant bisphosphonates in postmenopausal women will also modify this risk in the future. Increases in cardiovascular events [29] and hypercholesterolaemia [26] have been observed with AIs.

The relatively short follow-up time and overall small numbers of cardiovascular events in these studies make it difficult to draw concrete conclusions about the causality of AIs and cardiovascular events. Given that most women presenting with early breast cancer can now expect long-term survival long-term vigilance of cardiovascular morbidity and mortality in these studies is warranted.

Current Role of AI

Cumulatively, the results of these adjuvant AI trials have led to a substantial increase in the use of AIs in early breast cancer, but also to some uncertainty as to optimal duration of the correct role of AI therapy.

At present the gold standard of care for postmenopausal women is to commence upfront AI as per the ASCO guidelines [30].

Ultimately risks of recurrence and relative toxicities must be considered when considering extended therapy. Who requires a longer duration of therapy is an area of active research.

Oestrogen Deprivation Therapies: Ovarian Ablation/Suppression

In 1896, Beatson published the first report of surgical oophorectomy as a treatment modality for advanced breast cancer in

premenopausal women. This was followed, in the 1920s, by radiotherapy-induced ovarian ablation. Since then ovarian ablation by either means has been used as a therapy for premenopausal patients with advanced breast cancer.

LHRH agonists, are currently used as an alternative to ovarian ablation for the treatment of advanced breast cancer in premenopausal women. The initial stimulation of luteinizing hormone can cause a short 'flare' in disease-related symptoms, followed by a complete inhibition of luteinizing hormone secretion, decreasing oestradiol levels to near castration levels. This effect is reversible on withdrawal of the LHRH agonist. The LHRH agonist goserelin 3.6 mg administered by deep subcutaneous injection every 4 weeks is licensed in the United Kingdom for the treatment of breast cancer.

The EBCTG [5] reviewed several trials involving women with ER-positive or ER-unknown early breast cancer randomized to ovarian ablation or ovarian suppression with an LHRH agonist. There was a definite effect of both ovarian ablation and suppression on recurrence and breast cancer mortality [1]. A more recent meta-analysis [31] focused on trials where oestrogen receptor status was known and used only LHRH agonists as the method of ovarian suppression. A particular benefit was observed when LHRH agonists were used after chemotherapy, either alone or with tamoxifen in women aged 40 years or younger in whom chemotherapy is less likely to induce permanent amenorrhea. Optimum duration of use is unknown.

Ovarian Suppression in Addition to Endocrine Therapy in Premenopausal Patients

A landmark study, the Suppression of Ovarian Function Trial (SOFT) [32] has examined the use of ovarian suppression in women with hormone-receptor-positive early breast cancer. In the SOFT study 3066 premenopausal women were randomized to tamoxifen alone, tamoxifen with ovarian suppression, or exemestane with ovarian suppression. There was no benefit of ovarian suppression across the whole study population however importantly a subgroup analysis did demonstrate benefit in women under 35 years and those who had been deemed high risk of recurrence and undergone chemotherapy. Of the 94% of women under 35 who had chemotherapy 67.1% remained breast cancer free at 5 years in the tamoxifen alone arm versus 75.9% in those who received ovarian suppression with tamoxifen and 83.2% in the exemestane and ovarian suppression group. Ovarian suppression is now recommended in premenopausal patients at high enough risk to receive adjuvant chemotherapy [30].

The Role of AIs in Premenopausal Women

In TEXT [33] premenopausal women were randomly allocated to receive ovarian suppression with either tamoxifen or exemestane. Data from the SOFT and TEXT have been combined to provide a larger study population for further analysis. The combined data demonstrated a relative reduction in risk of disease recurrence, second cancer, or death of 28% and a 34% with exemestane plus ovarian suppression versus tamoxifen with ovarian suppression. These figures compare favourably with results seen in postmenopausal women. Long-term follow-up to determine OS advantage is still pending.

Despite a relatively low adverse event rate and discontinuation level in the study population ovarian suppression is a difficult treatment to tolerate and the percentage of those intolerant to therapy is likely to be much greater in the real-world setting. More data is needed on the tolerance of ovarian suppression in this population. In younger patients receiving adjuvant ovarian suppression this may be given either with tamoxifen or an AI.

Other Agents

Steroidal Pure Antioestrogens: Fulvestrant Pharmacology

Fulvestrant is a novel type of oestrogen receptor antagonist which, unlike tamoxifen, has no known agonist effects. It is administered intramuscularly and does not appear to cause endometrial proliferation and is less likely than tamoxifen to cause thromboembolism. Fulvestrant binds to the oestrogen receptor, but, induces a different conformational shape with the receptor to that achieved by tamoxifen. Due to its unique mechanism of action, fulvestrant delays the emergence of acquired resistance compared with tamoxifen in an MCF-7 hormone-sensitive xenograft model [34].

Clinical Efficacy of Fulvestrant in Advanced Breast Cancer

In a small phase II study in advanced disease, fulvestrant was shown to produce remissions of 2 years in tamoxifen-resistant tumours in postmenopausal women [18]. Clinical data with fulvestrant in advanced breast cancer following resistance to AIs is limited but phase II trials in this setting have reported clinical benefit rates of between 19 and 52%.

The Evaluation of Faslodex versus Exemestane Clinical Trial (EFECT) [35] assessed the efficacy of fulvestrant versus exemestane in patients who had progressed on treatment with AIs and found no significant difference in the effectiveness or tolerability between treatments with a clinical benefit rate of 32.2% and 31.5%, respectively. Both treatments were well tolerated.

A second study (SoFEA) compared progression-free survival in patients who had progressed on an AI, treated with either fulvestrant plus continued anastrozole, or with fulvestrant alone [36]. No benefit was noted of fulvestrant either in combination or alone in this trial population.

An analysis of the SoFEA paper showed a clinical advantage with fulvestrant over exemestane in patients with an ESR1 mutation [37]. This is the subject of ongoing research but provides a potential biomarker to select patients who may benefit from specific treatment options.

The results of these trials will help define optimal sequencing of endocrine therapies, and in particular the effectiveness of fulvestrant alone or in combination with AIs [38].

Progestogens

Synthetic progestogens/androgens, such as medroxyprogesterone and megestrol acetate, have been used in the treatment of advanced breast cancer, although their main benefit is relief of metastatic bone pain. Their mechanism of action is unclear but they are known to cause steroidogenic side effects such as weight gain, and cardiovascular and thromboembolic complications. The new generation of

AIs have clearly been shown to be more effective and less toxic than progestogens and these agents have largely been replaced as breast cancer treatment options.

Androgens and Corticosteroids

Androgens are rarely used for the treatment of advanced breast cancer due to side effects. Less than 10% patients with advanced breast cancer respond to treatment with corticosteroids. However, corticosteroids are often effective at controlling symptoms, such as local oedema, and pain.

Oestrogens

High-dose oestrogen therapy was used in the treatment of advanced breast cancer until the introduction of tamoxifen in the 1970s. A phase II trial has explored the use of high-dose oestrogen therapy in highly refractory, advanced breast cancer [39]. The clinical benefit rate was 40% with a median duration of response of 9 months. Another trial compared low-dose oestradiol 6 mg/day with high-dose 30 mg/day [40] in women with AI-resistant advanced breast cancer. The lower dose was found to be equally as effective as the higher dose but with fewer side effects.

Abiraterone

Abiraterone acetate, an inhibitor of cytochrome P 17 is a key enzyme in androgen and oestrogen biosynthesis. Around 60–70% of breast cancers are thought to be androgen receptor-positive; however, the role of the androgen receptor in breast cancer remains incompletely understood and to date no role for abiraterone has been identified in treating hormone-receptor-positive breast cancer. A large, phase II trial did not demonstrate any difference between single agent exemestane or exemestane, abiraterone, and prednisolone. More work is needed to identify potential roles, if any, for abiraterone in breast cancer.

Endocrine Resistance

Despite adjuvant chemotherapy and endocrine therapy, a proportion of patients with ER-positive breast cancer will still relapse and ultimately die of the disease. Further developments depend on finding methods to prevent and overcome resistance to endocrine therapy.

Endocrine resistance may occur either initially (*de novo*) or subsequently (acquired). Exposure to long-term oestrogen deprivation and subsequent development of acquired resistance may be accompanied by adaptive increases in oestrogen receptor gene expression and intercellular signalling, resulting in hypersensitivity to low oestradiol levels.

HER2

HER2 has been implicated in the development of endocrine resistance. Combining endocrine therapy with agents targeted against HER2 such as trastuzumab or lapatinib has shown advantages in progression-free survival (PFS) and clinical benefit rates, although these are relatively modest [41, 42].

mTOR

The phosphoinositide 3 kinase (PI3K)/AKT/mammalian target of rapamycin (mTOR) pathway has also been investigated in numerous preclinical models.

In advanced breast cancer in postmenopausal women a phase III randomized trial, BOLERO-2 showed improved PFS (15.2 vs. 4.2 months) in patients receiving everolimus plus exemestane compared with exemestane alone [43]. This confirms the preclinical rationale for cotargeting these pathways.

This study led to the approval of everolimus plus exemestane in patients with ER+ve, HER2–ve breast cancer who had progressive disease with non-steroidal AIs.

Everolimus is currently also being evaluated in the adjuvant setting for early breast cancer (NCT01805271).

CDK4/6

Another pathway involving cyclin-dependent kinases 4 and 6 (CDK4 and CDK6) which promote tumour growth has also been implicated in the development of endocrine resistance. In the PALOMA-3 phase 3 study women were randomized to receive either palbociclib, an oral CDK4 and CDK6 inhibitor with fulvestrant or fulvestrant alone [44]. The combination arm showed significantly longer PFS (9.2 months vs. 3.8 months) and was well tolerated in the trial population.

The sister PALOMA-2 study investigated the addition of palbociclib to letrozole in the first-line setting for metastatic or advanced breast cancer and demonstrated improved PFS from 14.5 to 24.8 months [45]. This was the longest PFS ever reported in the first-line setting and has led to the adoption of letrozole + palbociclib as first-line treatment in metastatic breast cancer. Premenopausal women are given Zoladex alongside this combination.

Ribociclib, a CDK 4/6 inhibitor has recently been approved by the US Food and Drug Administration (FDA) for the use in combination with AI in postmenopausal women with hormone-receptor-positive, HER2 negative advanced breast cancer following results from the MONALEESA-2 study. In this study patients received either ribociclib + letrozole or placebo + letrozole. Improvements were seen in PFS and ORR [46].

Further progress will depend on understanding the mechanisms behind the development of endocrine resistance and the compensatory pathways that emerge in individual patients. The identification of biomarkers predictive of response will allow better selection of patients for treatment with specific combinations of targeted and endocrine therapies.

Conclusions

Adjuvant endocrine therapy for early breast cancer has led to significant improvements in both DFS and OS and is generally a well-tolerated treatment. The EBCTG [1] confirmed that 10 years of tamoxifen reduces both the annual recurrence rate and the breast cancer mortality rate.

In postmenopausal patients, AIs either upfront or in sequence offer further incremental benefits over tamoxifen. Ovarian suppression has shown clinical benefit in women aged under 35 and those at high risk of developing recurrent disease. Alongside this AIs have also demonstrated benefits in preventing disease recurrence in younger, premenopausal women in terms when used alongside ovarian suppression. AIs have had a major impact on the treatment of breast cancer and further progress depends on understanding the mechanisms that underlie the development of endocrine resistance.

Clinical trials examining the use of targeted agents as a means to overcome resistance are challenging given that compensatory pathways probably vary over time and from patient to patient. The identification of biomarkers will help to define which tumours are most likely to respond to particular treatments. Key aspects to be addressed in future will be the best trial design with appropriate target selection and patient selection with activation of the relevant target. Ultimately, this should help identify which patients benefit most from specific drug combinations and over the next few years we should learn whether this combination approach, of endocrine therapy with the new generation targeted agents, leads to significant improvements in the treatment and survival of hormone-positive breast cancer.

13.2.3 Hormonal Therapy for Prostate Cancer

Molecular Basis of Efficacy and Therapeutic Bypass

Irina A. Vasilevskaya, Matthew J. Schiewer, and Karen E. Knudsen

Introduction

Despite tremendous advances in diagnosis and treatment, resulting in 51% decline in death rates from 1993 to 2016 [1], prostate cancer (PCa) remains the second leading cause of cancer-related death in American men. The American Cancer Society estimates 174 650 new cases and 31 620 deaths from the disease in 2019. Around 10% of men will be diagnosed with PCa during their lifetime, and for approximately 1 man in 40 this disease will be fatal [1]. As is the case for many cancers, ageing is one of the most significant risk factors for PCa. PCa develops mainly in older men, with a significantly higher frequency in African-American men. Diagnosis rarely occurs in men younger than 40 years old, with the majority of new cases diagnosed between the ages of 65 and 79. Current data suggest that only up to 10% of PCa cases are hereditary especially in early

onset disease [2], while other risk factors proposed in some studies, such as smoking and excess body weight, have not been universally accepted [1–3].

Androgens are indispensable for prostate development and normal function, including normal turnover of prostatic cells [4]. With age, the homeostatic balance between proliferation and cell death can become perturbed, giving rise to several abnormalities. For example, benign prostatic hyperplasia (BHP), occurring mostly in the transition zone of the prostate, is characterized by accelerated proliferation of stromal components and not considered to be a precursor of PCa [5]. Other disorders include proliferative inflammatory atrophy (PIA) and prostatic intraepithelial neoplasia (PIN). These selectively develop in the peripheral zone of the prostate and manifest through proliferation of luminal and basal epithelia (PIA) or hyperproliferation of luminal cells (PIN) [6]. High-grade PIN, in particular, exhibits some biochemical, genetic, and phenotypical characteristics of prostate cancer, and generally is accepted as the main premalignancy of the prostate [7].

The central feature of prostate cancer is a profound dependency on androgens. It was reported in 1941 by Huggins and Hodges that surgical castration, or orchiectomy, lead to significant decrease in primary tumour size and alleviation of symptoms in patients with metastatic prostate cancer. In the following years, feasibility of medical castration using inhibitors of steroid synthesis, which drastically reduce the levels of serum androgens, was established. Treatments leading to depletion of testosterone were appropriately termed androgen deprivation therapy (ADT). With the discovery and characterization of the androgen receptor (AR) as the crucial cellular mediator of androgen function during prostate tumorigenesis and disease progression, another promising avenue to combat PCa by directly targeting AR became the focus of vigorous research. As a result, a new class of therapeutics, androgen receptor antagonists, or antiandrogens, was developed and introduced into clinical usage [8].

Improvements in diagnostic capability, including development of the widely used test for prostate-specific antigen (PSA) in patient sera, contributed to earlier detection of PCa with the majority of new cases reported at the stage of local, organ-confined disease [1]. While localized tumours are successfully treated by either surgery or radiation (5-year survival rate of nearly 100%), patients diagnosed with locally advanced or metastatic disease harbour a less favourable prognosis (30% 5-year survival rate) [1]. As a first line of therapeutic intervention, patients with disseminated PCa undergo ADT alone or in combination with fist-generation antiandrogens (NCCN 2018 [9]). This approach is effective and results in substantial disease regression in the majority of patients. Unfortunately, these treatment strategies are not curative; recurrence is typically observed after 2–3 years and the disease progresses to a lethal stage termed castration-resistant prostate cancer (CRPC). CRPC retains dependency on AR, which is reactivated through multiple mechanisms and is able to sustain PCa growth despite low to undetectable levels of serum androgens [10]. Consequently, treatment of non-metastatic CPRC continues to include ADT, to maintain castrate levels of testosterone, with addition of second-generation AR antagonists (e.g. enzalutamide, apalutamide) or inhibitors of steroid metabolism (abiraterone), whereas combinatorial strategies for metastatic CRPC (mCRPC) include secondary hormonal therapy along with chemotherapy (docetaxel), immunotherapy (sipuleucel-T) or Radium-223 (NCCN 2018 [11]). Importantly, resistance to secondary hormonal therapy develops in mCRPC patients and results in a particularly aggressive disease course. Identifying the mechanisms that result in antiandrogen resistance continues to be an active area of research. Another detrimental result of persistent inhibition of AR signalling is emergence of tumours bearing some neuroendocrine characteristics, neuroendocrine PCa (NEPC), which may account for up to 15% of mCRPC tumours, while the *de novo* NEPC is extremely rare [12]. Tumours that no longer respond to hormonal therapy are treated with radiation, chemotherapy (platinum compounds in addition to docetaxel), and immunotherapy (NCCN 2018).

Essentially, PCa presents as a spectrum of diseases. The latest World Health Organization classification of PCa recognizes several types and subtypes of this malignancy which exhibit varying molecular, histopathological, and clinical characteristics [13]. Despite this heterogeneity, ADT and AR targeting remains the cornerstone of treatment for the locally advanced PCa, metastatic PCa, and CRPC, and more recently was utilized at the early stages of the disease [8, 14] (NCCN 2018). The subject matter of hormonal therapy in PCa has been extensively reviewed. Here, we are presenting an overview of the topic and latest data, with numerous excellent reviews cited throughout the chapter.

Androgen Receptor

AR Structure and Function

AR (NR3C4, nuclear receptor subfamily 3, group C, gene 4) is a ligand-dependent transcription factor belonging to a family of steroid hormone nuclear receptors that also includes oestrogen (ER) and glucocorticoid (GR) receptors, among others [15]. The AR gene is located within the X chromosome at Xq11-Xq12 and consists of 8 exons, spanning 2757 nucleotides, and 7 introns of varying length. The gene encodes for a 110 KDa protein comprised of 919 amino acid residues. Three major functional domains are recognized in AR (Figure 13.2.3.1a): the N-terminal transcriptional regulation domain (NTD), the DNA-binding domain (DBD) and the C-terminal ligand-binding domain (LBD). DBD and LBD are connected by short hinge region [15, 16].

The NTD is the largest and most variable domain of AR (amino acid residues 1–555). The NTD is a transactivation domain which binds to coactivators of the p160 family and basal transcription factors, TATA-box-binding protein (TBP), and TFIIF [15, 16]. The NTD also interacts with LBD, and this N-to-C-terminal interaction is requisite for maximal AR transcriptional activation function. The AR interacts with chromatin remodelling factors, such as components of the SWI/SNF complex, splicing factors, histone modifying enzymes involved with acetylation and methylation, DNA repair proteins, chaperones, cytoskeletal proteins, signal transduction proteins, as well as the ubiquitin/proteasome pathway [17]. Within the NTD, the region including amino acid residues from 142 to 485, termed activation function 1 (AF-1) is responsible for ligand-independent transcriptional activity of AR and is crucial for maximal AR activation. The NTD is characterized by the presence of variable polyglutamine (CAG) and

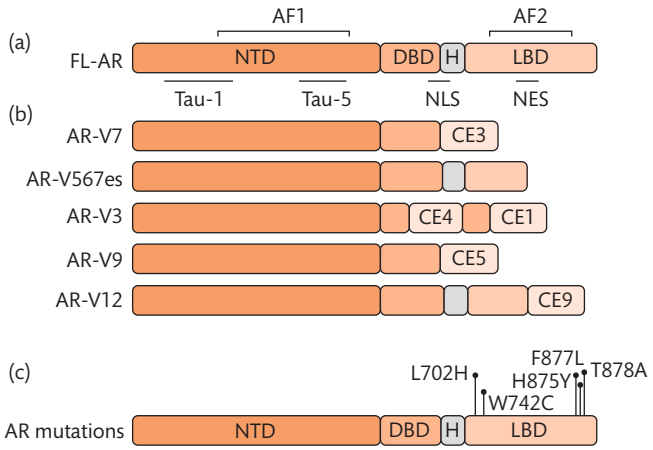

Figure 13.2.3.1 Androgen receptor structure (a), AR splice variants (b), and gain-of-function mutations (C). NTD, N-terminal transcription regulation domain; DBD, DNA-binding domain; H, hinge domain; LDB, C-terminal ligand-binding domain; AF1, activation function 1; AF2, activation function 2; NLS, nuclear localization signal; NES, nuclear export signal; CE1, cryptic exon 1; CE3, cryptic exon 3; CE5, cryptic exon 5; CE9, cryptic exon 9.

polyglycine (GGC) repeats, the lengths of which affect the conformation of the NTD and its interaction with protein partners, consequently impacting transcriptional activity of AR: shorter repeats are associated with higher AR activation, and longer repeats with reduced AR activation [15].

The DBD is a highly conserved cysteine-rich region (residues 556–623), which binds to AR-responsive elements (ARE) in the promoters and enhancers of target genes. Canonical ARE consists of two identical inverted half-sites 5'-AGAACA-3', separated by three nucleotides, and can be bound by AR and other nuclear receptors. The advent of next-generation sequencing and its application to ChIP (ChIP-Seq) greatly expanded the knowledge of the AR cistrome, identifying not only classic and AR-specific selective AREs (5'-GGTTCT-3' or canonical hexamer in direct orientation), but a variety of binding sites with nucleotide changes, half-sites and agonist- and antagonist-liganded AREs [15, 16], revealing the underlying basis of the capacity of AR to initiate diverse specific transcriptional programmes alone or in cooperation.

The LBD (residues 666–919) has the conformation of a three-fold sandwich comprised of eleven α-helices and four β-strands, forming a ligand-binding pocket. This domain also contains the ligand-dependent second activation function (AF2), part of which serves as a 'lid' closing after ligand binding [16].

In the inactive state, AR is sequestered in the cytoplasm in complex with inhibitory heat shock proteins (Hsp90, Hsp70, and p23). Ligand binding elicits conformational changes in AR and dissociation from chaperones, leading in turn to exposure of the nuclear localization signal situated between DBD and the hinge region of the protein. AR is then transported to the nucleus where it undergoes posttranscriptional modifications and dimerization, followed by binding to androgen receptor-responsive elements and coregulators through the zinc-finger of the DBD and AF1/AF2 regions, respectively (Figure 13.2.3.2a). The sum of these events leads to AR initiating a transcriptional programme that mediates a number of biological processes, including cell growth and proliferation, cell cycle progression, protein synthesis, and cell survival. AR-regulated target genes include *KLK3* (encoding PSA), and serum PSA is used in PCa diagnosis and monitoring PCa progression. Dissociation of ligand from the LBD results in the export of AR from the nucleus. In the healthy, non-transformed prostate, AR controls secretion of prostate-specific proteins, regulates lipid metabolism, and normal growth of prostatic epithelium in response to hormone [15, 16].

Androgen Receptor in Progression to CRPC

The molecular underpinnings of prostate tumorigenesis have been better defined in the last decade, as a result of rigorous scientific research and emergence of next-generation sequencing. Detailed analyses of genomic alterations in primary PCa revealed the most frequent genomic aberration—fusion of the AR-regulated TMPRSS2 gene promoter with the coding regions of ETS (E26 transcription specific) oncogene family members, mostly with ERG, which is present in nearly 60% of primary tumours, and also were detected in high-grade PIN cases [18]. These fusions amplify AR signal leading to accelerated growth of prostate epithelium. The ETS-fusion-negative tumours harbour mutually exclusive mutations of *SPOP, FOXA1*, and *IDH1* [18], and form a distinct group of PCa. ETS fusions and SPOP mutation occur early in PCa oncogenesis, followed by alterations of *CDKN1B, MED12, TP53,* and *PTEN*. Additional clinically relevant genes that are mutated in primary PCa, although at lower frequency, include: *ATM, CTNNB1, BRAF, HRAS*, and *AKT1* [18]. Together these genetic aberrations contribute to prostate tumorigenesis through deregulation of cell cycle, DNA repair, cell proliferation, and cell death.

The majority of hormone-sensitive PCa tumours respond well to ADT, but inevitably develop castration resistance, while still remaining AR-dependent [10]. Androgen withdrawal serves as a selective pressure that forces the initiation of numerous adaptive molecular alterations that allow PCa to survive in castrate conditions and to resume growth under control of reactivated AR. The molecular mechanisms of CRPC development include AR gene amplification and AR overexpression, altered expression and function of AR coactivators/corepressors, ligand-independent AR activation, gain-of-function mutations, constitutively active splice variants that lack the LBD, and intratumoral androgen synthesis [19] (Figure 13.2.3.2b). Gain-of-function mutations of the *AR* gene predominantly occur in the LBD (Figure 13.2.3.1c), and result in AR activation by alternative ligands, such as: progesterone, oestrogen, and antiandrogens (T878A, H875Y, W742C, F877L), or by glucocorticoids (H875Y, L702H). As such, *AR* gene mutations present a major clinical challenge [20]. The best described AR splice variant, constitutively, but weakly active AR-V7 (Figure 13.2.3.1b), confers resistance to ADT and is associated with short time to relapse after surgery, faster progression to CRPC and poor prognosis [20], and was recently shown to repress the expression of tumour suppressor genes [21]. AR splice variants AR-V567es, AR-V3, AR-V9, and AR-V12 are also clinically relevant: they are enriched in mCRPC and have been shown to contribute to a resistance to ADT [20]. In addition to AR axis dysregulation, other fundamental pathways are perturbed in CRPC. The most significant abnormalities enriched in CRPC include: hyperactivation of PI3K-AKT-mTOR pathway due to *PTEN* deletion/inactivation and genomic

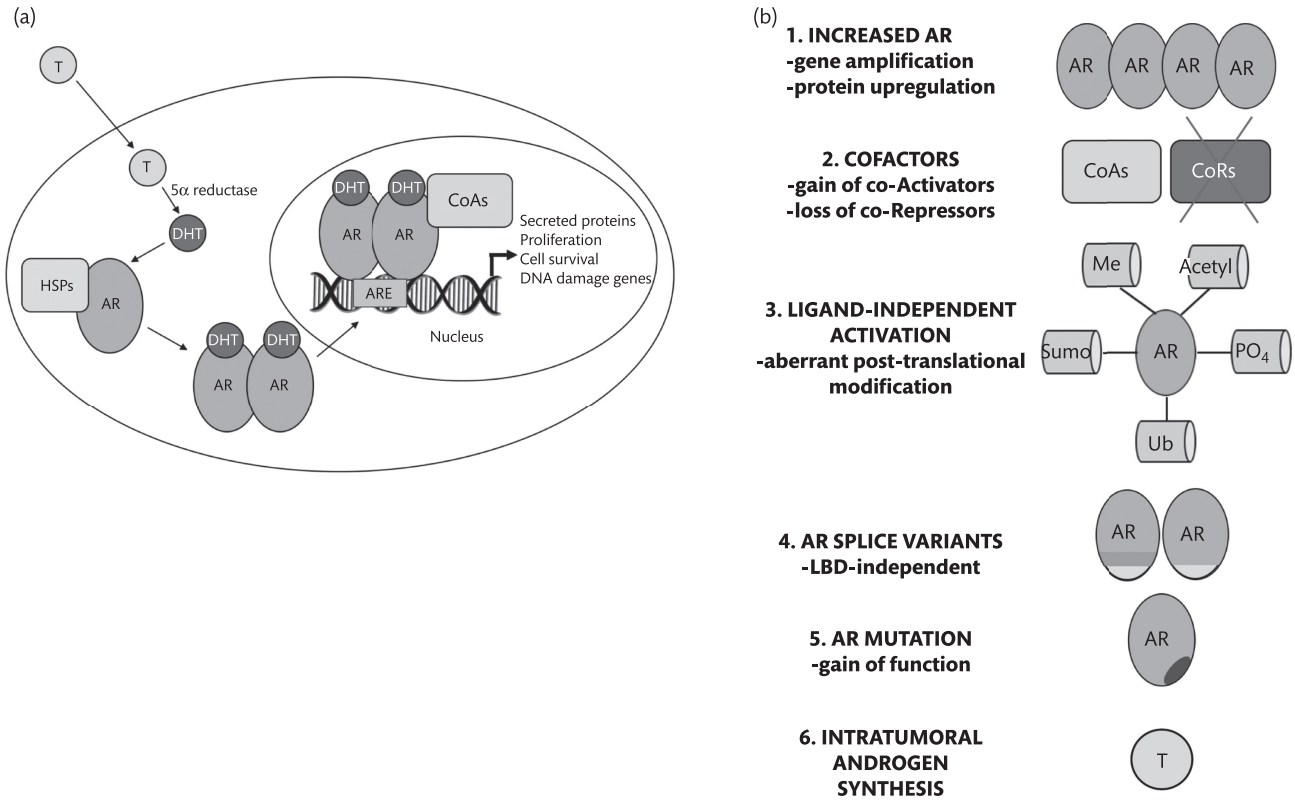

Figure 13.2.3.2 (a) Androgen receptor signalling in prostate cancer cells: testosterone (T) enters prostate cancer cells and is converted to the more potent androgen receptor (AR) ligand dihydrotestosterone (DHT) by 5α reductase. DHT then binds to the ligand-binding domain (LBD) of AR, eliciting conformation changes that release AR from inhibitory heat shock proteins (HSPs), thus permitting nuclear translocation. Once in the nucleus, AR binds to androgen-response elements (AREs) and recruits coregulators (including coactivators; CoAs) to elicit a transcriptional programme that includes genes that encode for secreted proteins, proliferation/cell survival genes, and DNA repair genes. (b) Mechanisms of androgen receptor reactivation in CRPC (castration-resistant prostate cancer). Cartoons indicate the six non-mutually exclusive mechanisms that have been reported to lead to androgen receptor (AR) reactivation in CRPC. Coactivators, CoAs; Corepressors, CoRs; Me, methylation; acetyl, acetylation; sumo, sumoylation; Ub, ubiquitylation; PO_4, phosphorylation; T, testosterone.

aberrations of kinases themselves, mutations of several DNA repair genes (*BRCA1, BRCA2*), deletions (*RB1, CDKN1*) or amplifications (*CDK4*) of cell cycle regulators, and changes in histone modifiers [22]. Collectively, these genomic aberrations constitute the distinct genetic makeup of CRPC, and may provide markers of progression as well as uncover novel nodes of therapeutic intervention.

Deregulated cell proliferation is a hallmark of cancer, and one mechanism of unchecked cell growth is loss of *RB1*. In PCa, deregulation of RB results in unique consequences. Knockdown of *RB1* results in an elevation of *AR* mRNA expression driven by the oncogenic transcription factor E2F1. This elevation of *AR* mRNA corresponds to aberrant heightened AR protein expression, which in turn results in castration-resistant AR function and CRPC *in vivo* [23]. While canonically, it is thought that RB loss results in uncontrolled cell proliferation, in the context of clinical PCa, there is no correlation between RB loss and a hyperproliferative phenotype [24]. Importantly, genomic aberrations (copy number alterations and structural variants) of *RB1* that render the RB protein inactive occur frequently in metastatic CRPC [25]. RB protein expression is heterogenous in PCa, *RB1* deletions are common in aggressive hormone therapy-sensitive PCa and more frequent in CRPC [25]. As such, deregulation of RB is frequent in PCa and results in deranged AR function and CRPC phenotypes.

Hormonal Therapy of Prostate Cancer

Androgen Deprivation

Regulation of steroid hormones: Testosterone (T) plays a central role in normal development of the male reproductive system, including the prostate, secondary sexual characteristics, and sexual behaviour. Levels of circulating T in healthy adult males can range from 2.6 to 9.6 ng/ml. Systemically levels of T are tightly regulated in a pulsatile manner and T biosynthesis is induced when the serum concentration falls below normal levels. T biosynthesis is a multistage process initiated in the hypothalamus, with the production of luteinizing hormone-releasing hormone (LHRH), also known as gonadotropin-releasing hormone (GnRH). GnRH induces the pituitary gland to release luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which in turn activate synthesis of T by Leydig cells in the testes [26]. Increased levels of testosterone lead to inhibition of LH and FSH release through a negative feedback loop mechanism, thus concluding the cycle of androgen regulation (Figure 13.2.3.3a). More than 95% of T is synthesized in the testes, with remaining T produced in the adrenal glands. Consequently, orchiectomy leads to dramatic decrease in circulating testosterone, with concentrations as low as 0.2 ng/ml [27]. In the prostate,

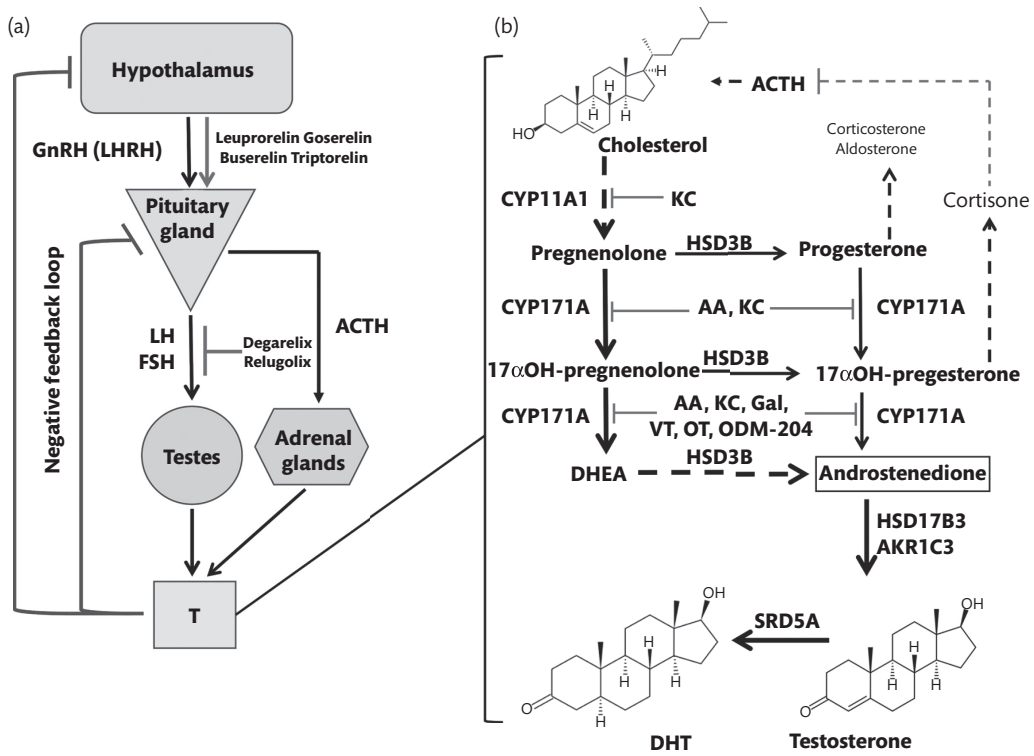

Figure 13.2.3.3 Regulation of testosterone biosynthesis. (a) Systemic regulation of testosterone (T) levels. (b) Scheme of T and dihydrotestosterone (DHT) biosynthesis from cholesterol. GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; FSH, follicle-stimulating hormone; ACTH, adrenocorticotropic hormone. KC, ketoconazole; AA, abiraterone acetate; Gal, galeterone; VT, VT-464; OT, orteronel. Thick arrows represent classical pathway of T biosynthesis, dashed lines depict multistep reactions.

testosterone is converted by 5α-reductase (*SRD5A*) to more potent metabolite, 5α-dihydrotestosterone (DHT), followed by activation of downstream signalling through AR.

Inhibitors of Testosterone Synthesis Through LHRH

Means of systemic testosterone depletion include both agonists and antagonists of GnRH. Agonists bind to and activate pituitary GnRH receptors, initially increasing LH and FSH release resulting in elevated testosterone levels. However, as a result of persisting activation, GnRH receptors become desensitized to the stimulus, which leads to a drop in LH and FSH secretion, effectively reducing androgen synthesis [26]. GnRH agonists are structurally similar to endogenous decapeptide hormone with slight modifications, such as amino acid substitution or alkylation. GnRH agonists currently used in clinic are leuprorelin, goserelin, triptorelin, and buserelin. Although all of the commercially available GnRH agonists were shown to achieve comparable castration levels of plasma testosterone, defined generally as less than 0.5 ng/ml [27], leuprorelin (also known as leuprolide) is the GnRH agonist most often prescribed in the clinic. Leuprolide was approved by the US Food and Drug Administration (FDA) in 1985, and serves as the primary ADT agent for both locally advanced and metastatic PCa (NCCN 2018). When delivered as subcutaneous implant, leuprolide causes a decrease of T to castrate level in 2–4 weeks, which can be maintained for up to 8 months, depending on formulation and treatment needs [28]. Adverse effects of GnRH agonists are due to low androgen levels, and include hot flashes, fatigue, anaemia, and decreased libido. Other detrimental effects, such as bone density loss, metabolic, cognitive, and cardiovascular events, including higher incidence of pulmonary embolism and stroke, were also observed upon treatment with GnRH agonists alone or in combination with antiandrogens. Initial elevation of T levels, so called testosterone flare, was considered a potential risk of driving disease progression, both at early stages and in advanced PCa. However, this view has evolved, as there is no definitive evidence that demonstrate direct consequences of testosterone flare on disease progression [29]. Nevertheless, to alleviate adverse effects of testosterone flare, pretreatment with or concomitant administration of first-generation antiandrogens are approved (NCCN 2018).

GnRH antagonists act as direct GnRH receptor blockers, effectively inhibiting the downstream signalling of the pituitary gland, leading to decreased T release by the testes without the negative effects of testosterone flare. The first GnRH antagonist, abarelix, was approved by FDA in 2004, but despite some beneficial features, was later withdrawn from the clinic in the United States. Currently, degarelix acetate is the only GnRH antagonist approved by FDA for a treatment of advanced PCa. Degarelix is a decapeptide analogue of endogenous GnRH, which was shown to suppress T production with an equal efficacy but more rapidly than leuprorelin, reaching castrate levels of the androgen within as few as 72 hours and maintaining them for up to a year when delivered monthly [30]. The main side effect of degarelix is injection site reaction. Multiple studies to interrogate efficacy and safety of degarelix versus GnRH agonists showed longer progression-free and overall survival in patients treated with the antagonist [30]. There is an ongoing controversy regarding the use of GnRH antagonists versus agonists, and

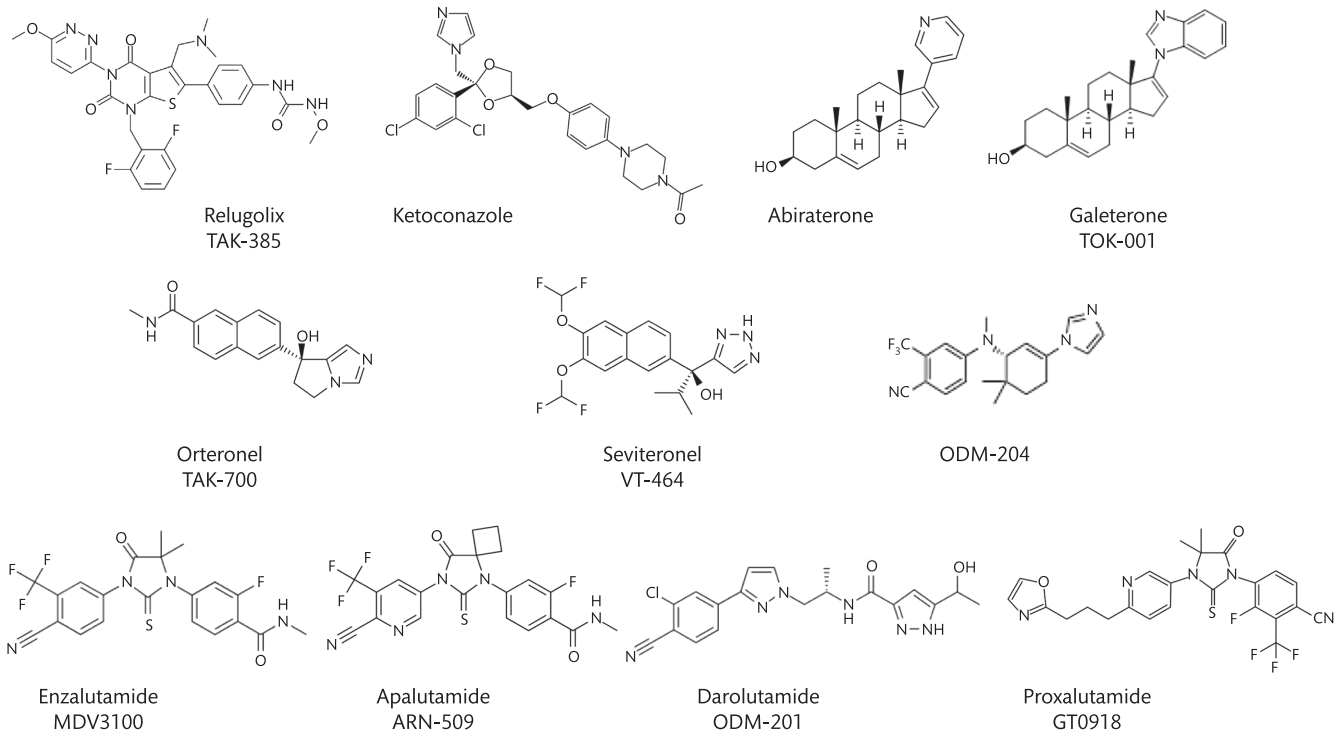

Figure 13.2.3.4 Chemical structure of GnRH antagonist relugolix, CYP17A1 inhibitors, and second-generation AR antagonists.
Taken from original publications and https://pubchem.ncbi.nlm.nih.gov.

degarelix is yet to equal leuprorelin for use in the clinic, but the results of clinical trials, completed and ongoing, indicate its future wider use in all stages of the PCa [31]. The main limiting factor for use of the peptide GnRH antagonists is low solubility and short half-life, mandating frequent injections. To address the disadvantage of peptide-based therapies, development of non-peptide GnRH antagonists is a field of current research effort. One of the non-peptide GnRH antagonists potentially effective in the treatment of PCa, is the oral thienopyridine compound relugolix, TAK-385 [32] (Figure 13.2.3.4). In phase I and II clinical trials, when given as a tablet once daily, relugolix demonstrated an adequate safety profile and achieved castrate T levels as quickly as degarelix, and much faster than leuprorelin (NCT02141659, NCT02135445, NCT02083185). Relugolix is currently in phase III clinical trial in men with advanced PCa, to evaluate retaining of castration in comparison to leuprorelin (NCT03085095). Both GnRH agonists and antagonists curtail gonadal T synthesis without impacting T production by adrenal glands.

Testosterone Biosynthesis

T is synthesized from cholesterol, the common precursor of steroid hormones, in a cascade of reactions mediated by several enzymes [33] (Figure 13.2.3.3b). Mitochondrial CYP11A1, a cholesterol side chain cleavage enzyme, converts cholesterol into pregnenolone in three sequential steps. The remainder of T biosynthesis occurs in the endoplasmic reticulum. 3β-hydroxysteroid dehydrogenase (HSD3B) catalyses the processing of pregnenolone into progesterone, which is crucial for the biosynthesis of all steroid hormones. Cytochrome P450 17α-hydroxylase/17,20-lyase (CYP17A1) possesses dual enzymatic activity, first acting as 17α-hydroxylase and then as 17,20-lyase to mediate conversion of pregnenolone to 17αOH-pregnenolone, and of 17αOH-pregnenolone to dehydroepiandrosterone (DHEA), respectively. 17β-hydroxysteroid dehydrogenase 3 (HSD17B3) mediates final step from androstenedione to testosterone. Once synthesized, T is metabolized into DHT by 5α-reductases [33]. Several small molecules, mostly inhibitors of CYP17A1, were developed and introduced to the clinic to further suppress gonadal T synthesis, which are also capable of inhibiting adrenal and intratumoral androgen synthesis. The problem arising from full inhibition of CYP17A1 is that its 17α-hydroxylase activity is necessary for biosynthesis of corticosteroids, namely cortisol, from 17αOH-progesterone, but not for mineralocorticoids produced downstream of progesterone (Figure 13.2.3.3b). Inhibition of 17α-hydroxylase leads to suppression of cortisol and abrogation of negative feedback loop to regulate pituitary adrenocorticotropic hormone (ACTH), in turn resulting in abnormal activation of steroidogenic pathway and excess of mineralocorticoids. Thus, there is a need for clinically active CYP17A1 inhibitors with strong specificity towards its 17,20-lyase function, which so far was not fulfilled despite several promising candidates briefly described next [34].

Inhibitors of Testosterone Synthesis

Ketoconazole, a synthetic imidazole compound (Figure 13.2.3.4), is a non-specific cytochrome P450 inhibitor approved for a treatment of multiple fungal infections. The inhibitory effects of ketoconazole on steroidogenesis were reported in 1982, leading to off-label use in CRPC patients. Ketoconazole potently inhibits CYP17A1, resulting in a substantial decrease of T levels within 2 to 8 hours, but the effect is short-lived [34, 35]. However, by also inhibiting CYP3A, CYP11A, and CYP24A, ketoconazole impinges on multiple

oxidative reactions catalysed by cytochromes, including potentially adversely modulating drug-drug interactions, although that remains controversial. Ketoconazole was also linked to a significant hepatic toxicity, which caused FDA to issue a safety announcement regarding the use of ketoconazole as an antifungal agent in 2013. In PCa, several studies of ketoconazole as monotherapy showed that, while not prolonging overall survival (OS), ketoconazole demonstrated acceptable toxicity and moderate efficacy in decreasing PSA levels and extending time to PSA progression. It also demonstrated clinical activity in combination with docetaxel [35]. While the newer and more effective agent, abiraterone acetate, has become the leading therapeutic for inhibition of T biosynthesis in mCRPC, ketoconazole is still considered a low-cost option for treatment of patients with non-metastatic CRPC or in cases of mCRPC when standard therapies are not available (NCCN 2018) [35].

Based on the earlier studies with ketoconazole, inhibition of CYP17A1 was identified as a valid approach to inhibit T biosynthesis in PCa treatment. Search for a less toxic alternative led to the development of abiraterone acetate in the mid-1990s. Abiraterone acetate (Figure 13.2.3.4), an oral pregnenolone derivative and irreversible inhibitor of CYP17A1, showed potent downregulation of both 17α-hydroxylase and 17,20-lyase activities in preclinical studies [36]. Treatment with abiraterone acetate suppresses cortisol synthesis and can result in mineralocorticoid excess syndrome (MES), which is minimized by concomitant administration of prednisone. The mechanism of abiraterone acetate function has been well studied. Clinical development of abiraterone acetate progressed rapidly from initial phase I trials in 2008 through phase II studies to a ground-breaking phase III trial, COU-AA-301 (NCT00638690) which demonstrated prolonged OS (4.6 months) with abiraterone acetate versus placebo in post-docetaxel mCRPC patients [37]. The following phase III trial in chemotherapy-naïve mCRPC patients showed similar effects of abiraterone acetate on OS (NCT00887198) [37]. After approval by FDA in 2011, abiraterone acetate was evaluated in combination with ADT in patients with hormone-sensitive metastatic PCa in two large randomized trials, LATITUDE (NCT01715285) and STAMPEDE (NCT00268476), both confirming significant improvement in progression-free survival (PFS) and OS in the ADT/abiraterone arm as compared to ADT alone [38, 39]. Subsequently, hundreds of clinical studies were completed worldwide, with over 100 active and recruiting trials just in the United States currently involving abiraterone, alone or as a complement to a standard ADT, in combination with chemotherapy, radiation, and second-generation antiandrogens at various stages of the disease. In addition to abiraterone-induced mineralocorticoid excess characterized by hypertension, fluid retention, and hypokalaemia [37, 38], and the undesirable side effects of continuous use of corticosteroids, a major limiting factor for abiraterone therapy is primary or acquired resistance. Molecular mechanisms of abiraterone resistance includes upregulation of intratumoral androgen synthesis, AR mutations, AR splice variants (AR-V7 and AR-V3, in particular), and glucocorticoid receptor overexpression, among others [40].

Galeterone (TOK-001) is an oral 17-heteroazole steroid analogue (Figure 13.2.3.4) which was developed as a potent inhibitor of CYP17A1 with a 3-fold selectivity towards 17,20-lyase activity. Subsequently, galeterone was confirmed as an antiproliferative agent for PCa *in vitro* and *in vivo*, and as an antagonist of both wild-type and mutant (T878A) AR [41]. In addition, galeterone prevents nuclear translocation and induces effective degradation of both FL-AR (full-length AR) and AR-V7 splice variant [34, 41]. These preclinical data demonstrating the ability of galeterone to disrupt androgen signalling on multiple levels, without significantly reducing cortisol, were highly encouraging. As a compound structurally similar to DHEA, galeterone was shown to be metabolized by HSD3B to Δ^4-galeterone, which is as effective against steroidogenesis and AR signalling as galeterone *in vitro* and *in vivo*. However, further conversion by SRD5A abrogates AR inhibitory activity of resulting metabolites, which potentially can compromise clinical efficacy of the drug [42]. The FDA granted Investigational New Drug status to galeterone in 2009, leading to clinical phase I and II trials, the ARMOR1 and two-part ARMOR2 trials (NCT00959959, NCT01709734) to assess safety and efficacy of oral galeterone in CRPC patients. Treatment was well tolerated and lead to a more than 50% PSA decline (PSA_{50}) in 70% of patients (combined ARMOR1 and ARMOR2 Part 1) [43]. Data from ARMOR2 Part 2 were presented at the twenty-third EACR Congress: galeterone not only lead to PSA_{50} levels in 75% of M0 and M1 treatment-naïve CRPC patients, but also resulted in measurable PSA decreases in the abiraterone-refractory cohort. More importantly, in 83% of the AR splice variant positive patients, as measured in circulating tumour cells, PSA_{50} levels were achieved, confirming preclinical data on efficacy of galeterone towards truncated AR variants [43]. However, ARMOR3-SV (NCT02438007), a phase III trial initiated in 2015 to compare galeterone with enzalutamide in mCRPC patients expressing AR-V7, was terminated due to a low probability of achieving the primary outcome of radiographic progression-free survival (rPFS) of more than 8 months.

Orteronel (TAK-700) is a non-steroidal imidazole derivative (Figure 13.2.3.4) with 5-fold increased selectivity towards CYP17 17,20-lyase. It has shown potent downregulation of DHEA and TT levels in *in vitro* and *in vivo* preclinical studies without cortisol suppression [34, 44]. Subsequently, in several phase I and phase II clinical trials in metastatic and non-metastatic CRPC, orteronel was well tolerated and demonstrated an effective decrease in TT, DHEA, and PSA levels as monotherapy and in combination with prednisone or docetaxel/prednisone [34, 45]. Orteronel then quickly moved into phase III trials. In the phase III ELM-PC 4 randomized trial (NCT01193244) orteronel was compared to a placebo, both given with prednisone, in chemotherapy-naïve patients [34, 37]. Primary endpoints for this trial were rPFS and OS. The phase III randomized ELM-PC 5 trial (NCT01193257) assessed the same combinations in mCRPC patients progressed after docetaxel, with OS as a primary endpoint [34, 37]. In both trials, orteronel demonstrated acceptable tolerance, significant PSA responses, and improved rPFS as compared to placebo. However, there was no improvement in OS, which led to a decision to unblind phase III studies and terminate further development of orteronel by the manufacturer, causing termination or withdrawal of several trials (clinicaltrials.gov). Despite not meeting the endpoint of OS in the aforementioned studies, orteronel has shown significant improvement in event-free and rPFS (8.5 vs. 2.9 months as compared to placebo) in patients with mCRPC who had stable disease after docetaxel therapy [46]. Currently, two phase III randomized clinical trials are still ongoing: one comparing LHRH agonist/orteronel and LHRH agonist/bicalutamide combinations in patients with newly diagnosed metastatic PCa (NCT01809691) and

another to assess addition of orteronel to dose-escalated radiation therapy in combination with standard ADT (GnRH agonists and antiandrogens prior to RT) in men with high-risk prostate cancer (NCT01546987). The primary outcome measure for both trials is OS. The results of these trials will indicate the feasibility of orteronel for use in both early and advanced PCa.

VT-464 (also marketed as seviteronel) is another novel non-steroidal oral triazole-based (Figure 13.2.3.4) small molecule inhibitor of CYP17A1 17,20-lyase activity. In preclinical studies, VT-464 showed an effective decrease of T concentrations *in vivo* without significant increases in progesterone and ensuing mineralocorticoid overproduction. VT-464 has demonstrated greater inhibition of androgen synthesis in CRPC and enzalutamide-resistant cell models as compared to abiraterone acetate. In addition, more potent inhibition of AR transactivation and decrease of AR-regulated proteins, including PSA, were observed, indicating that VT-464 acts as AR antagonist *in vitro* [34, 47]. Maity *et al.* [48] reported significant reduction of serum DHEA and PSA in mCRPC patient, and, using patient-derived xenograft (PDX) mouse models, demonstrated decreased tumour volume, downregulation of androgens, and inhibition of AR signalling equal or superior to abiraterone acetate. Notably, AR antagonism by VT-464 *in vitro* was demonstrated for full-length T878A AR mutant but not AR-V7, indicating efficacy against ligand-dependent AR functions. VT-464 has been evaluated in several recently completed open label phase I/II clinical trials for safety, tolerability, and efficacy in chemotherapy-naïve CRPC patients (NCT02361086) or previously treated with abiraterone, enzalutamide or chemotherapy (NCT02361086, NCT02012920, NCT02445976). In all studies, VT-464 was given orally once daily in 28-day cycles without steroid coadministration. Primary outcome measures included tolerability or proportion of patients reaching PSA_{50} levels (6 months) and median time to radiographic disease progression (10 months). The results of two latter trials have not yet been published.

ODM-204, novel non-steroidal compound, was synthesized with the purpose of incorporating a cytochrome binding moiety within an antiandrogen (Figure 13.2.3.4), thus enabling dual action against both CYP17A1 and AR. ODM-204 was shown to inhibit CYP17A1 and reduce testosterone *in vitro* with lower efficacy than abiraterone acetate, but as affectively as galeterone. When assessed for AR binging and antagonism, ODM-204 was superior to enzalutamide, the leading second-generation antiandrogen. The antiproliferative effects of ODM-204 were also demonstrated *in vitro* and confirmed *in vivo:* in VCaP xenografts, ODM-204 treatment led to reduction in tumour volume in intact and castrated mice with higher efficiency than abiraterone acetate [49]. On the basis of these promising preclinical studies, a phase I/II multicentre trial was initiated in 2015 to evaluate safety, tolerability, and pharmacokinetics of ODM-204 given in combination with prednisone to patients with metastatic CRPC (NCT02344017). Early results of this study have reported an acceptable safety profile and efficacy in decreasing serum testosterone and PSA levels, but the unsatisfactory pharmacokinetic features of ODM-204 led to a decision to cease further development of this compound [49].

While it is clear that targeting the AR signalling axis has clinical benefit in the management of PCa, the main limitation of ADT is the development of castration resistance. As such, a greater understanding of the mechanisms that lead to therapeutic bypass and means to thwart recurrent PCa are urgently needed.

AR Antagonists

Principle of Action

AR antagonists, or antiandrogens, are small molecules that compete with T and DHT for binding to the androgen receptor. Antiandrogens differ in chemical structure and efficacy, can exert varying side effects, and generally are divided into steroidal and non-steroidal compounds [8]. Steroidal antiandrogens, cyproterone acetate among others, were shown to effectively block binding of endogenous androgens to AR, but with partial agonistic activity paired with significant adverse effects prevented their approval by the FDA. Development of non-steroidal antiandrogens started in the 1960s, and since then efforts have been directed towards development of new non-steroidal antiandrogen therapeutics exhibiting higher affinity/specificity for AR, longer half-life, and fewer side effects [8].

First-Generation Antiandrogens

The first generation of non-steroidal AR antagonists (flutamide, nilutamide, and bicalutamide) bind to the LBD of AR, and thus compete for androgen binding to and activation of AR. Compared to T and DHT, these compounds have low relative affinity for the receptor, but based on preclinical studies and clinical trials, each of the aforementioned first-generation antiandrogens were FDA approved for use in PCa (flutamide, 1989; bicalutamide, 1995; nilutamide, 1996). However, these compounds also demonstrate partial AR agonism, evidenced by the clinical phenomenon of antiandrogen withdrawal response, in which upon discontinuation of use of these antiandrogens, serum PSA levels rise. As will be described next, second-generation antiandrogens have been rigorously developed to better target AR directly [8].

Second-Generation Antiandrogens

Enzalutamide (MDV-3100) is an oral non-steroidal antiandrogen which inhibits AR signalling by blocking the receptor and reducing AR nuclear transport, DNA binding, and recruitment of coactivators (Figure 13.2.3.4). In preclinical studies enzalutamide demonstrated up to 8-fold higher affinity to AR than bicalutamide, and induced tumour regression in mouse models of CRPC [50]. In a phase I/II clinical trial in patients that had received prior chemotherapy or were chem-naïve, enzalutamide was well tolerated, and demonstrated inhibition of DHT binding to AR, significant PSA response (41 weeks), and prolonged time to PSA progression (21 weeks) [51]. These Phase I/II studies were followed by two large, randomized phase III trials: AFFIRM (NCT00974311) [8, 37, 38], in mCRPC patients treated with prior docetaxel, and PREVAIL (NCT01212991) [8, 37, 38], in chemotherapy-naïve mCRPC patients. In both trials, enzalutamide demonstrated improved OS, increased time to PSA progression and rPFS [37, 52]. Based on the outcomes of these trials, enzalutamide was approved by FDA for a treatment of mCRPC patients. Subsequently, two more phase II randomized studies, STRIVE (NCT01664923) and TERRAIN (NCT01288911) in patients with or without metastatic disease showed superiority of enzalutamide over bicalutamide, with an average PFS advantage of 10 months [8, 37]. More recently enzalutamide was also tested as a monotherapy in phase III double-blind, randomized trial in non-metastatic CRPC (nmCRPC) patients, where enzalutamide

demonstrated significant improvements in metastasis-free survival (MFS), PSA progression and time to subsequent therapy (PROSPER, NCT02002924) [53]. In 2018, enzalutamide was approved by the FDA as a treatment for nmCRPC patients. In addition, two active trials are set to evaluate the safety and efficacy of enzalutamide in metastatic hormone-sensitive PCa (mHSPC): in the ARCHES trial, long-term enzalutamide + ADT will be compared to placebo + ADT (NCT02677896), with rPFS as primary outcome at 24 weeks; ENZAMET will measure OS with enzalutamide (with LHRH agonist) as first-line therapy in comparison to conventional non-steroidal antiandrogens (NCT02446405). Preliminary data from the ARCHES study show that enzalutamide + ADT significantly improves rPFS (NR versus 19.4 months on placebo), and PSA response (undetectable in 68.1% patients vs. 17.6% with placebo), although OS data have not been reported to date [54]. Main adverse side effects of enzalutamide treatment are cardiovascular events and seizures. Another major limiting factor for enzalutamide efficacy is the development of resistance, which is based on both AR-dependent and AR-independent molecular mechanisms. AR-dependent mechanisms include AR amplification and overexpression, AR splice variants (AR-V7), activating mutations (T878A, H875Y, F877L), and altered steroidogenesis. Main AR-independent mechanisms are overactivation of the glucocorticoid receptor and the PIK3-AKT pathway, induction of autophagy, EMT and gain of neuroendocrine characteristics [51]. Selected recruiting trials are indicated in **Table 13.2.3.1**.

Apalutamide (ARN-509) is a potent antiandrogen, similar in structure and with similar mechanisms of action to enzalutamide (**Figure 13.2.3.4**), which in preclinical studies showed maximal suppression of tumour growth at lower doses than enzalutamide. Apalutamide also has reduced blood–brain barrier penetrance, which may lead to alleviation of the adverse effects of enzalutamide on central nervous system [55]. In a phase I trial in mCRPC patients, apalutamide was well tolerated and a daily dose of 240 mg was recommended for future studies [8]. A Phase II trial expanded to three cohorts: patients with nmCRPC, and patients with mCRPC with or without prior abiraterone treatment. The primary endpoint in the nmCRPC cohort was a change in PSA levels at 12 weeks, and the secondary endpoint was median time to PSA progression. At 12 weeks, 89% of participants reached PSA_{50}, with median time to PSA progression of 24 months [8]. For the abiraterone-naïve and prior abiraterone mCRPC cohorts, PSA_{50} was achieved in 88% and 22% patients, with median time to PSA progression of 18.2 and 3.7 months, respectively [8].

Results of these studies have become the basis of a pivotal randomized, double-blind, placebo-controlled multicentre phase III trial, SPARTAN (NCT01946204) [56], in nmCRPC patients with continuing ADT. Primary outcome was MFS, while PFS, time to consequent chemotherapy, and OS were among secondary endpoints. Apalutamide showed significant improvement over placebo, with MFS of 40.5 versus 16.2 months. Time to PSA progression was not reached in apalutamide arm and was 3.7 months in the placebo arm. Adverse effects were slightly higher in the apalutamide arm, with the most prevalent being fatigue, rash, and hypertension. There were no grade 3/4 seizures recorded, since the patients with a history or predisposition to seizures were excluded from this study. After one year of additional follow-up, PFS2 (PFS on subsequent treatment from trial randomization) was evaluated and showed that apalutamide continued to be safe and superior to placebo: PFS2 of N/R versus 39.2 months, respectively [57]. Following the outcomes of the SPARTAN trial, apalutamide was approved by the FDA for a treatment on nmCRPC. A phase III randomized, placebo-controlled, double-blind study to determine if the addition of apalutamide to ADT (GnRH agonist or antagonist) improves rPFS or OS for participants with mHSPC (TITAN) is ongoing (NCT02489318). In another active phase III randomized, placebo-controlled, double-blind trial the apalutamide-abiraterone combination will be evaluated in chemotherapy-naïve mCRPC patients (NCT02257736). Selected recruiting trials are indicated in **Table 13.2.3.1**.

Darolutamide (OMD-201) is a non-steroidal antiandrogen structurally distinct from other AR antagonists (**Figure 13.2.3.4**). It was discovered during a compound library screen in AR-HEK293 cells using AR transactivation assay as a readout. In preclinical studies, darolutamide and its active metabolite, keto-darolutamide, demonstrated higher binding affinity to AR as compared to enzalutamide and apalutamide, greater inhibition of AR nuclear translocation, and stronger suppression of cell growth *in vitro* and *in vivo*. In addition, darolutamide blocked the activity of AR mutants, including F877L, which has been implicated in the resistance to enzalutamide and apalutamide. Darolutamide did not increase serum T levels and displayed negligible ability to cross blood–brain barrier [58]. All these features made darolutamide a very promising, more effective, and less toxic, novel AR antagonist for a treatment of PCa. In phase I studies, ARADES (NCT01429064) evaluated safety and bioavailability of darolutamide in mCRPC patients, including chemotherapy- and CYP17i-naïve patients; and ARAFOR (NCT01784757) assessed the efficacy of darolutamide in tablet form in chemotherapy-naïve men with progressive mCRPC [8, 59]. Phase II open label trial to compare darolutamide (1200 mg daily) to ADT (24 weeks of LHRH agonist or antagonist, including leuprolide, goserelin, triptorelin and degarelix) is currently recruiting hormone-naïve PCa patients (NCT02972060). Primary outcome will be PSA response at 24 weeks, defined as ≥80% reduction from the baseline, to demonstrate equal efficacy of darolutamide to standard ADT. A randomized, double-blind phase III trial, ARAMIS (NCT02200614), assessed the efficacy and safety of darolutamide versus placebo in men with high-risk nmCRPC, with MSF as the primary endpoint (up to 72 months), and OS and time to first chemotherapy included as secondary outcomes. Results from the ARAMIS trial showed median MSF of 40.4 in the darolutamide arm versus 18.4 months in the placebo arm; for all secondary endpoints darolutamide also demonstrated significant benefits, with adverse events similar in both cohorts [8, 60]. Another ongoing randomized, double-blind, placebo-controlled Phase III study, ARASENS (NCT02799602), is set to evaluate darolutamide in combination with standard ADT and docetaxel in mHSPC patients. Primary outcome measure is OS (up to 70 months), secondary endpoints are time to CRPC, time to subsequent therapy, and symptomatic skeletal event-free survival, among others. Selected recruiting trials are indicated in **Table 13.2.3.1**.

Proxalutamide (TG0918) is an oral non-steroidal antiandrogen which has shown higher affinity for AR than bicalutamide and enzalutamide, and more potency in blocking AR nuclear translocation and transcriptional activity (**Figure 13.2.3.4**). TG0918

Table 13.2.3.1 Selected recruiting clinical trials of second-generation antiandrogens

Phase	Disease stage	Experimental intervention(s)	Comparator intervention	Primary endpoint	Trial number
Enzalutamide					
Phase II/III	Oligometastatic CRPC	ADT + SBRT + enzalutamide	ADT + enzalutamide	rPFS	NCT02685397
Phase II/III	mCRPC previously treated with docetaxel and features of poor prognosis	ADT + abiraterone **OR** ADT + enzalutamide	ADT + cabazitaxel	CBR	NCT03295565
Phase III	Bone-metastatic CRPC	Radium-223 + enzalutamide	enzalutamide	rPFS	NCT02194842
Phase III	Homologous recombination-deficient CRPC	ADT + rucaparib	ADT+abiraterone **OR** enzalutamide **OR** docetaxel	rPFS	NCT02975934
Phase III	mCRPC	ADT + talazoparib) + enzalutamide	ADT + enzalutamide	rPFS	NCT03395197
Apalutamide					
Phase II	Hormone-naïve locally advanced or metastatic PCa	apalutamide **OR** apalutamide + abiraterone	ADT + abiraterone	PSA ≤ 0.2 ng/ml at 25 weeks	NCT02867020
Phase II	Localized high-risk PCa	neoadjuvant ADT + abiraterone **OR** neoadjuvant ADT + abiraterone + apalutamide	None	pCR or pnCR at prostatectomy	NCT02789878
Phase II	Hormone-naïve primary PCa	neoadjuvant ADT + abiraterone + apalutamide **OR** neoadjuvant ADT + abiraterone **OR** adjuvant ADT + abiraterone + apalutamide	No neoadjuvant or adjuvant therapy	Minimal residual disease and pCR at 2 years	NCT02903368
Phase II	Low risk primary PCa	active surveillance during and after 6 months apalutamide	Active surveillance	Time to definitive local treatment	NCT03088124
Phase II	Very high-risk primary PCa **OR** Hormone-naïve locally advanced or low volume metastatis **OR** Biochemical recurrence after prostatectomy with extrapelvic metastases	ADT + apalutamide **OR** ADT + abiraterone + apalutamide	None	Minimal residual disease and pCR at 2 years	NCT03436654
Phase II	Rising PSA after radical prostatectomy	ADT + bicalutamide followed by salvage RT **OR** ADT + abiraterone + apalutamide followed by salvage RT	None	PSA PFS	NCT03141671
Phase III	High-risk biochemically relapsed PCa	ADT + apalutamide **OR** ADT + abiraterone + apalutamide	ADT	PSA PFS	NCT03009981
Darolutamide					
Phase II	Hormone-naïve PCa (any stage)	Darolutamide	ADT	PSA reduction of ≥ 80% at 24 weeks	NCT02972060
Phase II	mCRPC after prior novel hormonal agent and non-progressive after taxane	Darolutamide	Placebo	rPFS at 12 weeks	NCT02933801

CRPC, castration-resistant prostate cancer; ADT, androgen deprivation therapy; SBRT, stereotactic body radiation therapy; rPFS, radiographic progression-free survival; mCRPC, metastatic castration-resistant prostate cancer; CBR, clinical benefit rate; PCa, prostate cancer; PSA, prostate-specific antigen; pCR, pathologic complete response; pnCR, pathologic near complete response; RT, radiation therapy; PFS, progression-free survival.

also induces downregulation of AR and inhibits proliferation of hormone therapy-sensitive and CRPC cell models *in vitro* and *in vivo* [61]. In an open label phase I/II dose-escalation trial (NCT02826772), GT0918 was given daily at multiple doses for 28 days (up to six cycles planned) to mCRPC patients who progressed after both hormonal and chemotherapy. The drug was well tolerated (at 500 mg dose-limiting toxicity was not achieved) and resulted in stable disease. The phase II/dose extension stage will further evaluate safety, efficacy, and antitumour activity of GT0918 in mCRPC patients [62].

Alternative Approaches

While the clinical data demonstrate that second-generation antiandrogens are likely to improve outcomes for PCa patients, resistance to enzalutamide has been well documented. The same AR activating mutations which result in enzalutamide resistance were

also shown to confer resistance to apalutamide, and AR splice variants diminish efficacy of all LBD-directed drugs in CRPC [20]. With the ultimate goal to maximally inhibit AR signalling axis by targeting wild-type, gain-of-function mutants, and splice variants of AR, multiple alternative approaches are being tested in preclinical and clinical settings.

Considerable efforts have been directed at targeting the NTD domain of AR [63]. One of the most developed compounds is EPI-001, a bisphenol A-derived small molecule antagonist of AR NTD that was identified in a screening of a library of marine sponge extracts for inhibition of both ligand-dependent and ligand-independent AR activation [63]. EPI-001 and its analogues (also called anitens) inhibit protein-protein interactions necessary for AR transcriptional activity by covalently binding to AF1 region of the NTD and blocking transcriptional activity of AR, its splice variants and gain-of-function mutants, and reduce the growth of CRPC xenografts [63]. EPI-001 was also shown to abrogate transcriptional activity of Tau1 and Tau5 domains in reporter-based assays, downregulate endogenous AR expression at the mRNA level and inhibit proliferation in multiple PCa cell lines [63]. Recently it was reported that EPI-001 can induce autophagy along with apoptosis in PCa cell lines, and that addition of autophagy inhibitors enhances antitumour effects of the drug in enzalutamide-resistant LNCaP cells [64]. Despite encouraging preclinical studies, a phase I dose-escalation trial of EPI-506 (prodrug of ralaniten, a.k.a. EPI-002) in mCRPC patients previously treated with abiraterone and/or enzalutamide (NCT02606123) was terminated due to excessive pill burden. EPI-506 was well tolerated but required high doses, which still resulted in minor and short-lived PSA declines. EPI-506 was also readily metabolized into inactive derivatives. Based on data obtained in this study, new aniten molecules EPI-7170 and EPI-7245, with 10–20-fold higher potency and improved metabolic stability were generated. EPI-7170 has shown antiproliferative activity in LNCaP and AR-V7 expressing LNCaP95 cells *in vitro*, and in LNCaP-derived xenografts in castrated mice [65]. IND-selection preclinical studies on the next generation anitens are underway. If successful, the NTD inhibitors might serve as valuable therapeutic agents with the potential to overcome antiandrogen resistance conferred by splice variants, activating mutations, or ligand-independent activation of AR.

Another actively pursued approach to abrogate AR signalling is the development of compounds that induce AR degradation and would be effective against all forms of AR. One example of these, ARV-110, an oral small molecule AR PROTAC (PROteolysis TArgeting Chimera) degrader, which recruits an E3 ubiquitin ligase to AR, followed by AR ubiquitination and proteasomal degradation. Treatment with ARV-110 has demonstrated robust reduction in AR protein levels in a high androgen environment, irrespective of AR mutation status and binding partners, and inhibited proliferation and AR-dependent gene expression in VCaP cells *in vitro* and *in vivo* [66]. The initial results were also confirmed in LNCaP cell line and patient-derived xenografts. In addition, ARV-110 effectively reduced AR-target gene expression in a long-term, castration-resistant and enzalutamide-resistant VCaP tumour model [66]. ARV-110 has completed IND-enabling studies, and a first-in-human phase I clinical trial has been approved by the FDA, and will investigate the safety and tolerability of ARV-110 in mCRPC patients that have progressed after at least two standard therapies (as reported at ASCO GU Symposium, 2019).

To achieve AR degradation, inhibition of AR chaperone proteins is also considered of significant interest. Numerous preclinical studies have demonstrated antitumour activity of heat shock protein (HSP) inhibitors in various cancers, including PCa. For example, HSP90 inhibitors (17-DMAG, onalespib, and ganetespib) have demonstrated potent downregulation of AR signalling and inhibition of tumour growth in multiple AR-dependent and AR-independent PCa models *in vitro, in vivo*, and *ex-vivo* [67]. However, this approach is not specific to AR, and the consequences of degradation of multiple HSP90 client proteins could cause additional toxicity. Furthermore, AR variants are resistant to HSP90 inhibitors, undermining their efficacy in the treatment of CRPC. Two trials (phase 1/2 NCT01685268 and phase II NCT01270880) were carried out to evaluate the efficacy of onalespib (AT13387) and ganetespib (STA-9090) in CRPC patients who were no longer responding to treatment with abiraterone and steroids, or in mCRPC patients previously treated with docetaxel, respectively. Results of the former trial were not reported, and in the latter, ganetespib showed only minimal clinical activity. Four active trials using onalespib and two with ganetespib are currently ongoing, but none is evaluating these drugs in the context of PCa. Unlike HSP90 inhibitors, drugs targeting HSP70, quercetin and VER155008, have demonstrated inhibitory effects on AR-V7 expression and proliferation in the LNCaP95 CRPC model [68]. More recently, development of HSP40/HSP70 inhibitors has identified a small chalcone molecule, C86, active against FL-AR, AR-V7, and GR *in vitro* and *in vivo* [69]. Notably, it was also active against H874Y AR mutant in 22Rv1 cells, suggesting that this drug could abrogate activity of other gain-of-function AR mutants in CRPC. Further research investigating HSP70 and HSP40 inhibitors could yield novel therapeutic agents to help manage progressive disease more effectively.

A novel approach to interfere with aberrant AR signalling was reported by Aboukameel, *et al.* [70]. They used selective inhibitors of nuclear export (SINE compounds) in preclinical studies. The central target was exportin-1 (XPO1), protein controlling nuclear localization of multiple clients, including tumour suppressor proteins, such as p53, RB, BRCA1, and p21, among others. Inhibitors of XPO1 covalently bind to XPO1 cargo-binding pocket, effectively interfering with normal nuclear export of proteins to the cytoplasm. This study revealed that increased expression of XPO1 correlated with higher AR-V7 levels. The silencing of XPO1 by RNAi or with the SINE agents selinexor and eltanexor (KTP-8602) resulted in downregulation of not only AR, AR-V7, and AR-V567es at mRNA and protein level, but also in inhibition of AR coregulators, including FOXA1, Src, and MED1, followed by abrogation of AR transcriptional activity. Eltanexor also suppressed PCa growth and induced apoptosis in AR-V7-expressing 22Rv1 and VCaP cell lines *in vitro* and *in vivo*, and enhanced the efficacy of abiraterone and enzalutamide. Application of SINE compounds to the clinic is underway. A recent phase II trial (NCT02215161) of first-generation drug, selinexor, in mCRPC patients following failure of abiraterone and/or enzalutamide was terminated due to high toxicity of the compound [71]. The second-generation agent, KTP-8602, is in clinical development. An active phase 1/2 trial will assess safety, tolerability, and efficacy of KPT-8602 in patients with several cancers, including mCRPC (NCT02649790). Preliminary results presented at the ASCO GU Symposium [72] showed that the combination of

eltanexor and abiraterone is well tolerated and demonstrates preliminary antitumour activity in patients with mCRPC: out of 21 evaluable patients, 2 exhibited partial response and 15 had stable disease. These data are encouraging, and further investigation of SINE agents is warranted.

Combinatorial Strategies

Based on the fact that the major mechanisms that lead to bypass of both first-line and subsequent AR-directed therapies result in reengagement of the AR signalling axis, it may be worthwhile to develop combinatorial means to either work in concert with ADT/antiandrogens or more fully and durably suppress AR function.

Targeting DNA Repair

The prevalence of DNA repair gene alterations has been determined to be elevated in advanced PCa as compared to primary PCa, and germline DNA repair aberrations have been reported to correspond with poor responses to hormone therapy, but there are conflicting data [73, 74]. Preclinical studies suggested that pharmacologically targeting PARP-1 (poly(ADP)-ribose polymerase-1) has the capacity to delay the onset of CRPC in a xenograft model, and potentially render CRPC tumours responsive to ADT *in vivo* [75]. This was reported as being associated with a decrease in AR residency on chromatin, and subsequently reduced AR transcriptional activity. Multiple PARP inhibitors (PARPi) (olaparib, rucaparib, niraparib, and talazoparib) are in clinical development [76] for PCa management and have been clinically tested in concert with AR-directed therapies. In the TOPARP [77] trial, patients continued an ADT regimen and received olaparib. Responses were enriched for either germline or somatic alterations that may impinge upon DNA repair competency. The ongoing PROFOUND trial (NCT02987543) is comparing olaparib to either abiraterone or enzalutamide in the context of continued ADT, in men with homologous recombination-deficient PCa, with a primary endpoint of PFS, and has the potential yield interesting results. Finally, a trial (NCT01972217) recently presented the 2018 ASCO Annual Meeting demonstrated that in mCRPC patients post-docetaxel therapy that received either olaparib or placebo in combination with abiraterone demonstrated that the combination resulted in an rPFS benefit, irrespective of homologous recombination status.

Immune Checkpoint Inhibitors

The concept of targeting immune checkpoints to activate the immune system to attack tumour cells is also currently under development in combination with AR-directed strategies. A phase II trial combining the anti-PD1 antibody pembrolizumab with enzalutamide demonstrated partial responses or stable disease [78]. The PD-L1 inhibitor atezolizumab is currently undergoing phase III investigation (IMbassador250, NCT03016312) in combination with enzalutamide versus enzalutamide alone in mCRPC patients. While the use of immune checkpoint inhibitors may currently elicit limited responses, it is anticipated that combinations with AR-directed strategies may be clinically useful in the short term.

Cell Cycle-Targeted Therapy

As stated earlier, part of the pro-tumorigenic function of AR is drive tumour cell proliferation. As such, targeting the cell cycle machinery in PCa is a rational approach. Preclinical evidence [79] suggests that combining CDK4/6 inhibition with AR-directed therapy may be a therapeutic strategy that may prove beneficial in

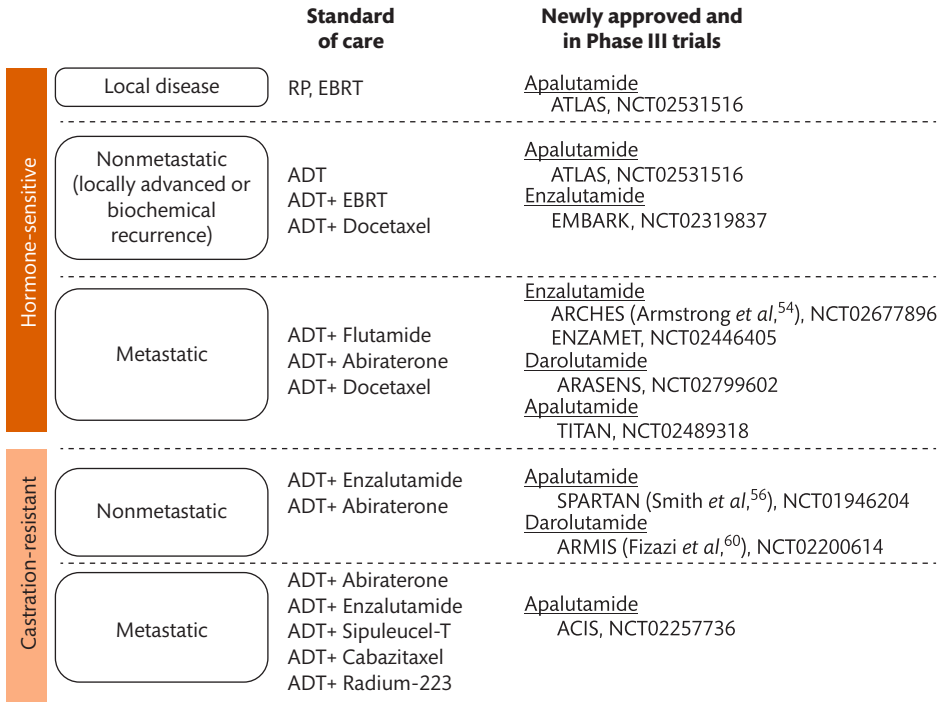

Figure 13.2.3.5 Hormonal therapy of prostate cancer—standard of care and novel approaches.

PCa. This postulate is currently under investigation in a phase Ib/II trial combining the CDK4/6 inhibitor ribociclib with docetaxel in the context of continued ADT, with the primary endpoints of maximally tolerated dose and PFS (NCT02494921). Furthermore, in a single arm phase II trial, the CDK4/6 inhibitor palbociclib is being investigated in the management of mCRPC patients continuing ADT, with the primary outcome being clinical benefit (NCT02905318).

BET Inhibition

As just discussed, AR signalling is aberrantly re-engaged in the transition to CRPC, and developing novel means to thwart castration-associated AR activity is an active category of research in the field of PCa. Bromodomain and extraterminal (BET) protein inhibitors (BETi) have been preclinically demonstrated to impact AR function, including AR-V7 activity [80], and is under clinical investigation (NCT02705469), including in combination with enzalutamide (NCT02711956).

Summary

While AR-directed therapies certainly prolong the lives of men with metastatic PCa, these strategies are not curative. ADT merely stalls disease progression, and serves as an advantageous adjuvant therapy throughout all stages of PCa (Figure 13.2.3.5). Due to tumour heterogeneity, it will be critically important to develop means to identify predictive markers of sensitivity/resistance to hormonal therapy to inform patient selection for the best life-prolonging agents. Furthermore, development of complementary strategies of targeting AR, or identifying therapeutic targets that may synergize with hormonal therapy for PCa remains a critical need.

SECTION 14

Obesity, Dyslipidaemia and other Metabolic Disorders

14.1

Obesity

14.1.1 The Physiology of Bodyweight Regulation

Anthony P. Coll

Introduction

Understanding of the processes that govern body weight is highly relevant to clinical practice as disorders of energy homeostasis cause significant morbidity and mortality. Obesity, defined as excessive storage of energy as fat, is a serious medical and socioeconomic problem, with obese individuals at increased risk of developing a range of cardiovascular, metabolic, musculoskeletal, and malignant disorders [1]. At the other extreme, cachexia is a syndrome of negative energy balance where muscle and fat mass are progressively lost. It affects over a third of all cancer patients and is strongly associated with both reduced tolerance to anticancer therapy and reduced survival times [2].

Mammalian body weight has long been recognized and recorded to be determined by the net result of a number of highly regulated processes. Such regulatory systems have evolved though prehistory, in environments likely to favour highly adaptive systems with the capacity to maintain homeostasis and enable survival through times of food scarcity and extreme physical exertion.

The seeds of our current understanding were sown through the 20th century by many pioneering clinician scientists who noted that a steady body weight is often maintained in the face of marked variation in daily food intake and physical activity. This laid the crucial framework for the more mechanistic detail that was to come. A comprehensive account of this work lies beyond the scope of this chapter (see review by Bray [3]) but several milestone studies are worth highlighting. For example, in what has since become known as 'the Minnesota experiment', Keys *et al.* [4] limited food intake to deplete fat mass in a group of healthy, lean young men and demonstrated a reduction in metabolic rate and physical activity coupled with a marked increase in measures of hunger (**Figure 14.1.1.1**). Conversely, overfeeding of both lean and obese humans resulting in significant weight gain [5, 6] also leads to reduced appetite and increased energy expenditure, thereby opposing the maintenance of the new, heavier body weight and favouring a return to baseline weight.

Compelling evidence for significant heritability of human body weight came from Stunkard's landmark study of identical twins separated after birth and brought up in different families [7]. Adult body mass index, used as a surrogate for fat mass, did not match that of the adoptive family, but had a strong correlation with the identical twin, indicating that genetic influences on body mass index are substantial.

In parallel with these human studies, a series of key observations in rodent models gave additive insights. Kennedy's observed that rats, whether made obese through overfeeding or lean through underfeeding, tended to return to the growth trajectory of *ad libitum* fed controls after removal of the nutritional stress. This helped in formulating the hypothesis that there is a signal generated in proportion to fat mass which regulates body weight [8].

Animal data also highlighted the primacy of certain regions of the central nervous system in body weight homeostasis. For example, dramatic body weight changes evident after ablation of discrete hypothalamic regions, in particular the ventromedial hypothalamus, placed these anatomical sites as crucial 'control nodes', and laid the groundwork for a basic anatomical-behavioural map. Parabiosis experiments surgically connecting the circulations of such a lesioned animal with an intact, lean animal showed that the latter showed reduced food intake and weight gave direct evidence for circulating factor(s) present in the obese animal that influenced appetite and weight (reviewed in [9]).

A further, seminal series of parabiosis experiments by Doug Coleman using severely obese (*ob/ob*) mice and obese diabetic (*db/db*) mice determined that *ob/ob* mice lacked a then-unknown

Figure 14.1.1.1 Photograph of conscientious objectors during starvation experiment.

circulating factor, whereas *db/db* mice produced the factor in excess but were unable to respond to it [10, 11]. Advances in molecular biology and biotechnology over the last 25 years [12] have led to identification of critical mechanisms underpinning many of these physiological observations and have indicated a biological basis for much interindividual difference in body weight.

Control of Long-Term Adipose Mass

Leptin

The discovery in 1994 that the protein product of the *obese (ob)* gene is the adipocyte-derived hormone leptin (the name derives from the Greek *leptos*, or 'thin') transformed study of the endocrinology of body weight regulation [13]. Not only did it herald a change in the view of the adipocyte from being a passive storage receptacle to being a *bona fide* endocrine cell, it also spearheaded re-exploration of how peripheral signals from metabolically relevant tissues communicate with the central nervous system. The identification of the leptin receptor [14] and the description of a mutant leptin receptor in the *db/db* mouse [15] soon followed, thereby defining key components of a regulatory circuit.

Leptin is a 167 amino acid peptide with a molecular weight of 16kD and is structurally related to the family of long-chain helical cytokines. It is produced by adipose tissue and secreted in proportion to total fat mass (Figure 14.1.1.2). Plasma levels show marked sexual dimorphism even allowing for differing fat masses, with leptin concentrations higher in females than in males for any given fat content. Leptin levels fall in response to fasting and reduced body fat stores but the mechanisms behind fasting-induced reduction in leptin, or indeed how the mass of the fat store is signalled to the adipose tissue mass and reflected in appropriate leptin production, remain to be determined. The primary role of the leptin–leptin receptor axis is to communicate a state of severe peripheral energy deficiency to the brain, thereby initiating a counter response. In rodents, falling leptin levels increase appetite, reduce sympathetic tone, suppress the thyroid and reproductive axes, and reduce energy expenditure [16].

Leptin acts via the long form of the leptin receptor (LepRb) although other forms of the receptor exist [17]. LepRb is a type I cytokine receptor of the IL-6 receptor family expressed predominantly in subpopulations of neurons in the hypothalamus, midbrain, and brainstem. Hypothalamic LepRb signalling in the lateral hypothalamic area, ventromedial, dorsomedial, and arcuate nuclei are particularly relevant for energy balance. Leptin binding to LepRb activates the associated JAK2 tyrosine kinase and subsequent tyrosine phosphorylation recruits and activates multiple downstream signalling pathways. Each of these pathways appears to subserve specific aspects of leptin's physiological actions with, for example, phosphorylation of LepRb Tyr1138 and then activation of STAT3 signalling particularly important in the regulation of body weight [18].

The Leptin-Melanocortin Pathway

A model that has held sway for some years holds that leptin's actions on two anatomically distinct subsets of arcuate neurons (POMC neurons and Agouti-related peptide (AgRP)/NPY neuron) play the dominant role in neural control of energy balance [19]. Neurons expressing proopiomelanocortin (POMC) are stimulated by leptin. The POMC pro-peptide is processed post-translationally to produce the melanocortin peptides such as α—and β-MSH, both potent suppressors of food intake (anorexigenic). The second neuronal population is suppressed by leptin and expresses AgRP and NPY. Both peptides stimulate food intake (orexigenic). From the arcuate nucleus, these two populations of neurons project to other brain areas that contain second order neurons expressing neuropeptides involved in energy homeostasis. One site of particular relevance is the paraventricular nucleus which is enriched with melanocortin 4 receptors (MC4R), the cognate receptor for both melanocortin

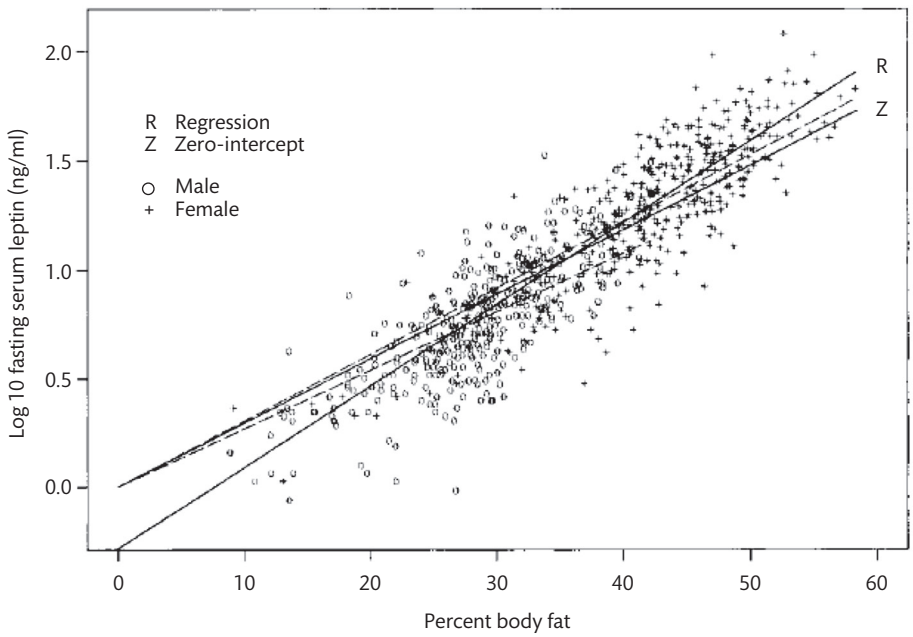

Figure 14.1.1.2 Fasting serum leptin levels plotted on a log scale against percentage body fat for women (+) and men (O). The dashed lines show the mean of the slopes for women (upper line) and men (lower line). The solid lines show two regression lines, one (Z) constrained to go through the origin (0,0), the second (R) where the intercept is estimated from the data.

peptides (agonist) and AgRP (antagonist). As a consequence of this circuitry, when there are suppressed levels of leptin, as in negative energy balance, an increase in orexigenic signals coupled with a decrease in anorexigenic signals strongly favours an increase in appetite and food intake to replenish diminished stores.

The central tenets of this model have held true over several decades of intense scrutiny; leptin's actions on energy balance are primarily, if not wholly, driven by its action within the central nervous system (CNS), and both POMC neurons and central MC4R continue to be active targets for pharmacological manipulation to treat obesity. However, ever more complexity is being revealed within these neural circuits and emerging data indicate that it may be AgRP neurons, rather than POMC neurons, that are the primary site of action for leptin's effects on energy balance [20].

Leptin and Melanocortin Deficiency in Humans

In the 1990s, molecular medicine and the study of patients with severe obesity yielded powerful insights into the fundamental physiological processes that regulate body weight. The first reports of a single gene disorder causing obesity came from detailed biochemical and genetic analysis of a woman with a complex polyendocrine syndrome and severe obesity from childhood, who was discovered to have mutations in both alleles encoding prohormone convertase 1(PC1), rendering her unable to process peptide prohormones such as pro-insulin and POMC [21]. Soon after, two children with severe, early-onset obesity and marked hyperphagia were found to have homozygous mutations in the leptin gene that rendered them totally leptin deficient [22]. Studies using the classic endocrine paradigm of phenotypic analysis first in the absence of hormone and then after replacement therapy defined the clinical phenotype of leptin deficiency and thereby generated key insights into leptin biology in humans. Treatment of congenital leptin deficiency with recombinant leptin significantly reduced hyperphagia, lead to a sustained reduction in fat mass while preserving lean mass weight and had a permissive role in the onset of puberty [23].

Leptin receptor deficiency has also been characterized in humans. Although the clinical phenotype was less severe than in congenital leptin deficiency, affected subjects were hyperphagic, had severe obesity, and also had delayed puberty due to hypogonadotropic hypogonadism. Interestingly, serum leptin levels were within the range predicted by the elevated fat mass and were similar to those seen in equally obese subjects with a normal leptin-receptor gene [24]. However, just as in rodents, the message was clear; reduced activity through the leptin–leptin receptor axis is a powerful signal to the brain to enact responses to reverse what is perceived to be a substantive diminution of energy stores.

Many more reports of humans with obesity due to defects in the neuronal pathways that lie downstream of leptin signalling have since followed [25], including POMC deficiency [26] and MC4R mutations [27, 28] (see Chapter 14.1.6, 'Assessment of Obesity in Children'). These monogenic obesity syndromes have largely validated the central paradigm of a neural control of appetite.

Leptin Therapeutics

Leptin has been successfully used as a therapy in a number of clinical scenarios. The profound effects in congenital leptin deficiency have been well documented [25]. As discussed in Chapter 15.10.2, 'Lipodystrophies and Severe Insulin Resistance', leptin therapy in patients with generalized lipodystrophy who lack leptin due to their deficiency of adipose tissue can also have dramatic

effects on the metabolic sequelae seen in this condition such as hypertriglyceridaemia and poorly controlled diabetes [29]. There have also been promising results for leptin treatment in weight related reproductive disorders such as hypothalamic amenorrhoea. Young women with low leptin levels and low adiposity can have their reproductive function restored with leptin therapy [30].

Leptin is also likely to be a useful adjunctive therapy in preventing weight gain after weight loss. As weight loss is characterized by a relatively leptin deficient state with a range of neurohormonal processes activated to restore the weight that has been lost, leptin supplementation is likely to be helpful in maintaining the weight reduced state [31].

Control of Short-Term Feeding and Satiety

Enteroendocrine Cells

The enteroendocrine cells (EECs) of the gastrointestinal tract play an important role in balancing food intake and energy balance in the short term [32]. Spread throughout the length of the intestine, EECs form a large and interconnected network of functional endocrine tissue that enable direct sensing of ingested nutrients to be coupled with hormonal release and communication with surrounding enteric neurons. Originally classified into distinct 'alphabetical' types based on location, morphology and assumed hormonal production (e.g. cholecystokinin (CCK) from I-cells) the ability to isolate and analyse single cells has revealed a much higher degree of complexity and overlap with many cells type able to produce and cosecrete a range of different peptide hormones.

More than 30 peptide hormones have been identified in the gastrointestinal tract and a full review of all their actions lies beyond the scope of this chapter (see further reading [33, 34]). However, a brief review of the physiology of L cells and the peptides they produce exemplifies how signals from EECs can both have important roles on local gut function and impact upon whole-body physiology [35] (**Figure 14.1.1.3**).

L cells are found throughout the gut but are particularly located in the distal small intestine and the colon. The primary peptides produced are those derived from post-translational processing of the proglucagon precursor molecule (GLP1, GLP2, and oxyntomodulin) and PYY, although most L cells seemingly have plurihormonal capacity [35].

GLP1 (30 amino acids) is a metabolically active gut hormone that has been extensively characterized [33, 34]. It has long been recognized to be a potent incretin hormone, augmenting glucose-stimulated insulin secretion after a meal. This effect on insulin secretion is maintained in many patients with type 2 diabetes mellitus and has led to widespread clinical use of GLP-1 analogues. GLP1 receptors

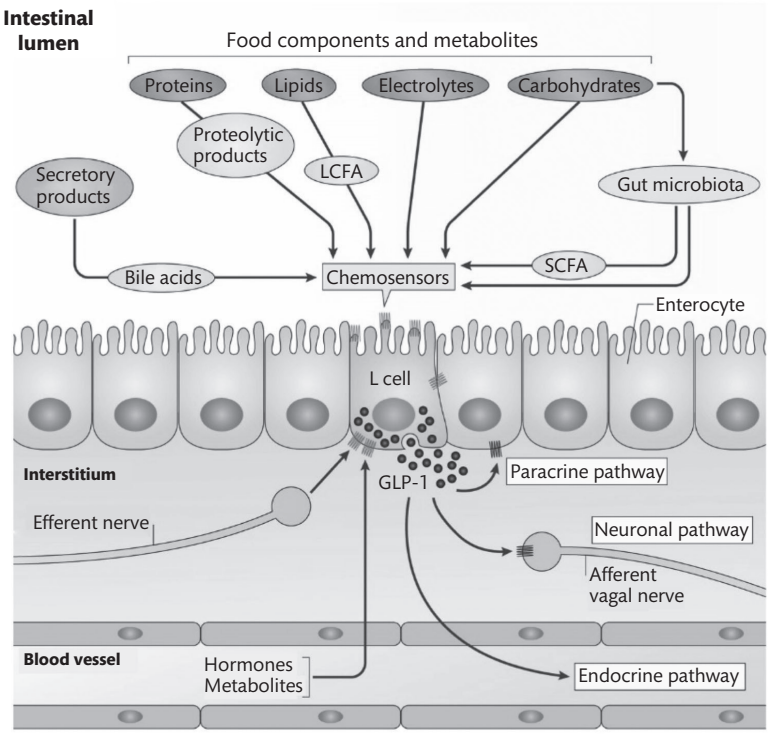

Figure 14.1.1.3 The sensory and secretory function of the L cell. Release of glucagon-like peptide 1 (GLP-1) from L cells is regulated by nutritional, hormonal, and neural signals. Food components and metabolites at the luminal side of the L cell are directly sensed by various G protein-coupled receptors that function as chemosensors and trigger exocytosis of GLP-1-containing granules at the basolateral side of the cell. GLP-1 can act through endocrine, paracrine and neuronal pathways to regulate physiological responses in local and/or remote tissues and cell types. These effects are consistent with the widespread and abundant expression of the GLP-1 receptor. LCFA, long-chain fatty acid; SCFA, short-chain fatty acid.

are found in many regions that regulate feeding and, in addition to its incretin effect, administration of GLP1 can reduce food intake in a dose dependent manner. Intriguingly, GLP1 is also expressed within the nucleus tractus solitarii (NTS) of the brainstem, a relay centre for gut derived signals controlling food intake, and it is likely centrally produced GLP1 also plays a role in energy balance [36].

Glucagon-like peptide-2 (GLP2) is another small (33 amino acid) proglucagon-derived peptide whose plasma levels rise rapidly after eating [35]. It has an important facilitatory role in maintaining gut integrity and performance, being able not only to induce proliferative and pathways in the bowel but also to increase mesenteric blood flow and activate proabsorptive pathways. Recombinant analogues of GLP2 have been successfully used in patients with intestinal failure [37].

Oxyntomodulin, a third peptide product of the proglucagon gene, is composed of the 29 amino acids of glucagon with an 8 amino acid carboxy terminal extension [34]. It is also released from the small intestine after a meal, and is active on GLP1R and glucagon receptors. It reduces gastric motility and improves glucose-dependent insulin secretion. Pharmacological administration reduces energy intake and weight, actions thought to be mediated both indirectly via the vagus nerve and directly in the CNS.

Peptide tyrosine tyrosine (PYY) levels in humans are lowest in the fasting state and rise after food ingestion. PYY 3–36, produced by DPP4-mediated cleavage of the larger peptide PYY 1–36, is the main circulating form and has an anorectic effect via central Y2 receptors within the hypothalamus and brainstem [43].

Therapeutic interest in gut hormones has been further stimulated by the remarkable effects on severe obesity of bariatric surgery [38], discussed in detail in Chapter 14.1.5, 'Metabolic Surgery'. This term encompasses a range of surgical procedures whose purpose is to manipulate the stomach and small intestine to induce weight loss. Common procedures include removal of a portion of the stomach (e.g. sleeve gastrectomy) or the creation of a small stomach pouch with the jejunum pulled up onto this pouch, thereby leaving the stomach and duodenum bypassed (Roux-en-Y procedure). Although there is little doubt that such surgery significantly reduces calorific intake and places the patient in negative energy balance, previous explanations that this was due wholly to restriction of stomach size and/or malabsorption from the modified intestine have more recently undergone a more nuanced review, with effects of these surgeries thought, at least in part, to be mediated through postoperative changes in gut hormones. Clinical trials recapitulating this state through parenteral administration of combinations of peptides to patients with obesity are underway [39].

Gut Microbiota and Body Composition

The human gut contains trillions of microbes existing in symbiosis with their human host [40]. The composition of the gut microbiome varies significantly between and within individuals and can be changed markedly by diet and medication. There are a large number of primary animal studies that suggest the microbiome can produce many bioactive substances potentially affecting energy balance [40]. The significance and true therapeutic potential in humans remain to be fully determined. Many studies to date have been descriptive, lacking the ability to determine if associated changes in microbiota and weight reflect causality. For example, one recent study investigating changes in gut microbiota in obese men after 7 days of amoxicillin or vancomycin found that despite considerably altered microbial composition there was no clinically relevant impact on metabolic health in the subject studies [41].

Methodologies are currently rapidly evolving to permit more rigorous assessment of causality in studies of the relationship between human microbiota and body weight, and it may well be that more focused manipulation of gut flora function will be of therapeutic benefit. One plausible mechanism for such an effect relates to enteroendocrine cells. A number of metabolites generated by colonic gut microbiota through their action on luminal foodstuffs have been implicated as ligands to activate L cells. These include short-chain fatty acids and indole, a product of tryptophan metabolism and a study in humans has shown that an increase in the short-chain fatty acid (SCFA) propionate in the colon can increase PYY and GLP-1 and reduce energy intake [42].

BAT, Thermogenesis, and Energy Expenditure

Mammals have an absolute requirement to maintain their core body temperature. Part of the response to a cold challenge that threatens body temperature is increased sympathetic drive to stimulate brown adipose tissue (BAT) in a process called non-shivering thermogenesis. BAT is composed of specialized adipocytes that break down energy substrate to generate heat in a futile metabolic cycle without generation of adenosine triphosphate (ATP) [34]. This involves expression of uncoupling protein 1 (UCP1), a mitochondrial protein that short-circuits the process of mitochondrial ATP generation. Brown fat has been studied for decades in rodents but its relevance to human metabolism had long been contested and debated [43].

The concept of a highly reactive energy sink through which energy in excess of current requirement (that would otherwise be laid down in fat stores) could be disposed of is not new. At the turn of the twentieth century, Neuman used the word 'luxuskonsumption' to describe the self-observed phenomenon that his weight remained unchanged over a period in which he had noted significant change in dietary intake, including what he considered excess consumption [44].

Work by Rothwell and Stock reporting that rats fed a 'cafeteria diet' appeared to gain less weight than expected due to burning of unaccounted calories in BAT refocused attention on the significance of 'diet-induced thermogenesis' (DIT) [45]. Nevertheless, BAT in humans was considered to be irrelevant outside the neonatal period, and the potential biological purpose of DIT continues to be debated [45].

More recent identification in healthy children and adults of functional BAT in the supraclavicular, neck, perirenal and intercostal regions (Figure 14.1.1.4) has sparked renewed interest in the expenditure side of the energy equation. In particular the notion that targeting pathways innervating and controlling BAT could be an effective and safe way to increase energy expenditure and combat obesity has garnered much attention.

One concept under intense preclinical scrutiny is that adipocytes found in classical white depots that have the ability to express UCP1 to become heat—generating, energy consuming cells may be upregulated as an energy sink [46]. These cells have been viewed as a potential third class of adipocyte sitting between brown and white, thus being named 'beige' or 'brite' ('brown-in-white'). Directing

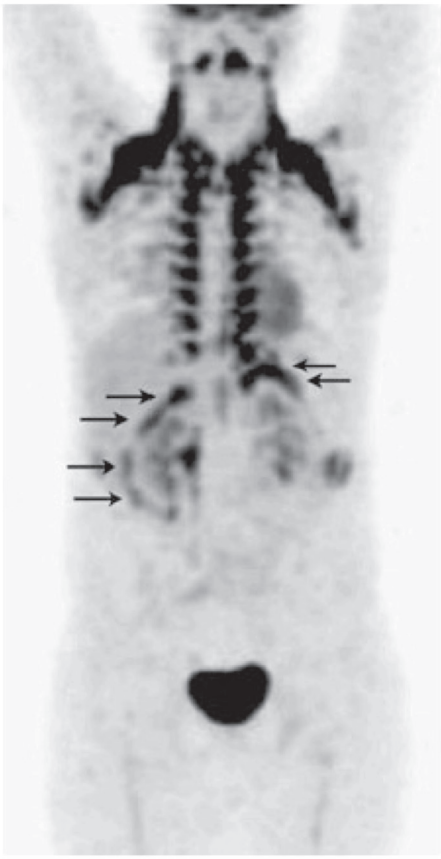

Figure 14.1.1.4 A 13-year-old boy with BAT FDG uptake in the neck, supraclavicular-axillary, paravertebral-intercostal, and mediastinal regions. Arrows indicate uptake around the lateral edge of the kidneys.

such cells into a more energy-consuming role, primarily through augmented sympathetic and adrenergic stimulation, is given the moniker of 'browning'.

Thyroid hormones regulate basal metabolic rate and dysregulation of the thyroid axis leads to marked alterations in energy balance [47]. Increased appetite is also common in hyperthyroidism but the majority of patients with hyperthyroidism exhibit weight loss, indicating that increased caloric intake fails to match the increased energy expenditure. Hypothyroidism, by contrast, is associated with decreased metabolic rate, often causing weight gain despite reduced food intake. Many of these effects have been attributed to direct actions of thyroid hormone on metabolically active tissues such as the liver, fat and muscle but it is now clear that thyroid hormones regulate energy balance and metabolism by acting at the central level, with distinct hypothalamic pathways modulating food intake and regulating thermogenesis in BAT [47].

Outside of thyroid hormone disorders, there are few data to support the concept of a reduced basal metabolic rate (the apocryphal 'slow metabolism') as a cause of severe obesity. However rare variants in kinase suppressor of Ras 2 (KSR2), an intracellular scaffolding protein involved in multiple signalling pathways, seen in individuals with severe, early-onset obesity have been reported to be associated not only with hyperphagia but also with a lower basal metabolic rate compared with subjects with other genetic forms of obesity [48].

Control of Skeletal Muscle Mass

Skeletal muscle is a highly plastic tissue which, throughout life, adapts to external stimuli and internal endocrine signals [46]. Muscle mass and strength peak in early adulthood in both males and females but begin to decline in midlife and fall away more rapidly from the fifth decade onwards [52]. The phenomena of hypertrophy in response to mechanical loading and atrophy on inactivity are well recognized. Muscle mass is also lost directly as a result of a many systemic inflammatory, malignant, and infectious disorders.

A key regulator of muscle mass is myostatin, a member of the TGFβ superfamily [50]. Myostatin strongly inhibits muscle mass development and loss of functional myostatin leads to hypermuscularity in genetically engineered mice or in humans [51] or in cattle such Belgian Blue that are reared for their 'double muscling' [52] (**Figure 14.1.1.5**).

Myostatin is secreted as an inactive peptide that undergoes post-secretion cleavage, forms a C-terminal dimer that then binds to activating type IIB receptor (ActRIIB), which in turn phosphorylates and activates Smad to affect changes in gene transcription. Active myostatin is also negatively regulated by follistatin, which binds directly with the mature dimer and inhibits its ability to bind to receptors. Data from transgenic mouse models indicate that high levels of follistatin can lead to a significant increase in muscle mass, comparable to those seen in myostatin knockout mice [53], and molecules that block signalling through this ActRIIB pathway are currently under active development as agents to treat muscular dystrophies and other disorders involving the loss of functional muscle mass [54].

Fat Cells—How Much and Where?

Adipose tissue is exquisitely adapted to store large amount of energy; however, it is also highly heterogeneous, with fat cells in distinct depots of the body having site-specific roles [55]. Evidence to date, however, indicate that genetically normal, functional fat cells do not harbour a mechanism which is a primary driver of whole-body obesity. What is increasingly clear from human data is that body fat content is primarily determined by neuronal pathways affecting appetitive drive and energy consumption [56, 57]. However, the related but distinct questions of *where* the fat stored and of *how much* can be safely accommodated there are more likely driven by processes autonomous to the peripheral tissues. Indeed, in a recent large genome-wide association study of the genetic architecture of fat distribution, genetic loci implicated were enriched for genes expressed in adipose tissue and for putative regulatory elements in adipocytes [58]. What determines an individual's 'fat mass storage capacity' remains to be fully defined. This has great clinical relevance in societies where overnutrition is commonplace, as excess energy that can no longer be safely stored in adipose depots leads to ectopic deposition of lipids in other tissues such as liver and muscle and the development of adverse metabolic sequelae. The processes

underpinning these adverse consequences have elegantly been explored by O'Rahilly [59].

Cachexia

Cachexia is characterized by involuntary loss of body weight and muscle mass. It is distinct from starvation in that it is not readily reversible by nutritional support alone. It is a major feature of a range of malignant diseases and chronic, non-malignant disorders, with the depletion of skeletal muscle contributing significantly to functional impairment, therapy-related toxicity, and increased mortality [2]. Detailed metabolic studies of cachexia in humans are challenging due to the heavy disease burden borne by many of these patients and much of our current mechanistic understanding of this condition has derived from analysis of animal model systems.

Although the various contributors to the negative energy balance of cachexia likely varies among diseases and individuals, reduction in food intake is an important and often primary driver. A host of different pro-cachectic factors have been implicated including interleukin—6 (IL-6), tumour necrosis factor (TNF) and interferon gamma (IFNg). Working through the CNS these factors are thought to driver further neurohormonal changes, such as activation of the adrenal axis and the sympathetic nervous system, to favour catabolic changes that, in the face of coexisting poor food intake, can be considered aberrant and highly deleterious [60]. However, it is a reflection of the limited understanding of the key mechanisms involved that no effective therapeutic options based on these mechanisms are currently available.

One circulating peptide that has long been associated with a diverse range of cachexia-associated conditions is growth and differentiation factor 15 (GDF15). In humans, serum levels of GDF 15 are a robust biomarker of all-cause mortality and overexpression of GDF15 in animal models robustly suppresses food intake. Recent identification of the receptor for this peptide, expressed in brainstem loci well known to play important roles in energy balance, has reignited interest in this pathway as being potentially amenable to tractable therapies for both cachexia and obesity [61].

Further Reading—Integrating Physiology and Environment

In the face of ever rising obesity, there has been much thoughtful reflection as to why physiological systems that have served us well for millennia now appear to be overwhelmed, leading to a huge increase in obesity. The physiology of the overfed state and the evidence to date for the existence of a regulatory system that could defend against excessive fat mass expansion is expertly review by Ravussin and colleagues [62]. At the population level Speakman's article on the evolutionary genetics of human obesity makes a compelling case against the 'thrifty genotype' hypothesis (the evolutionary advantage of ingesting excess calories in times of plenty to enable survival in times of famine). He argues that genes predisposing to obesity are neutral and have been drifting over evolutionary time, with the more recent food abundance and release from predation combining to explain current trends in body weight [63]. Finally, readers concerned to understand why health-harming behaviours such as continued overeating in the presence of metabolic disease are so hard to change are directed to an excellent article by Marteau and colleagues on the automatic processing associated with human disease [64].

14.1.2 Obesity as a Public Health Problem

Adrian Bauman

Public Health Approaches to Obesity

Obesity has been recognized as a disease by the American Heart Association, posing both challenges and opportunities [1]. This formalizes a definition (e.g. body mass index (BMI) ≥30), empowers health services to plan approaches to obesity management, and allows clinical therapy to be institutionalized. However, it is also a 'public health' or population-wide problem. The public health problem is illustrated by the rapidity of the increase in the prevalence of obesity, such that it is described as an epidemic, or more accurately as a pandemic (because it is globally pervasive). A public health approach posits that obesity has resulted from changes to human culture and technology that have led in turn to decreased total physical activity (energy expended) and increased food consumed (energy intake) especially in industrialized and rapidly developing nations.

Figure 14.1.2.1 depicts a public health approach to obesity, showing the stages in its classification as a 'population or public health problem' (left hand box), and the need for parallel clinical and population strategies to address the problem. Public health (primary prevention) aims to avoid the long-term morbidity, mortality, and healthcare costs attributable to obesity.

A Brief History of Public Health Thinking About Obesity

Bray (1995) [2] reviewed obesity-related medical writings from antiquity to the present, especially over the past three centuries; he noted clinical tomes with titles such as the 1727 *'Discourse Concerning the Causes and Effects of Corpulency Together with the Method for its Prevention and Cure'* but concluded that the upswing in obesity writings occurred around 1940, when it became more frequent in the medical literature.

The earliest papers that described *obesity as a public health problem* date to the 1950s, well before the oft-reported increases in adult obesity since the 1980s. For example, *Life Magazine* (1954) featured a special issue on obesity, describing it as a 'health crisis' affecting 20–30% of adult Americans over 'the desirable weight', and a 50% increased risk of mortality [3, 4]; these were curiously accurate estimates, considering the lack of any public health surveillance or epidemiological studies available at that time. The solutions proposed included reduced calorie intake, and prophetically, fewer meals consumed outside of the home [3]. By 1968, Huenemann reported that obesity was a problem among adolescents too, with obesity rates between 10% and 15% (although variously defined). She also described childhood obesity as persisting into adult life, and being associated with cardio-metabolic risk [5].

Obesity continued to be described as a public health issue during the 1970s and as 'the second greatest public health problem after tobacco' [6], antedating the subsequent 'obesity epidemic'. Epidemiological risks were characterized in the 1980s, also predating the recognition by public health agencies that obesity was

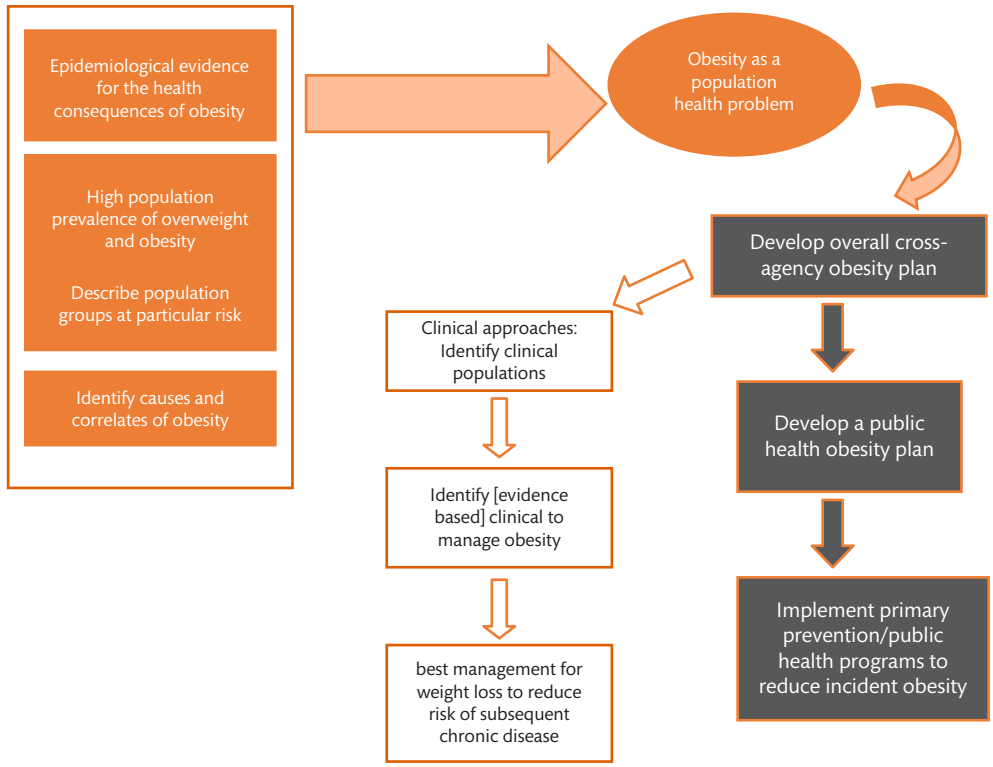

Figure 14.1.2.1 Stages in clinical and public health approaches to the problem of obesity.

a problem [7]. This illustrates the delays commonly observed between problem definition and public health policy response.

Prevalence and Trends in Obesity

Epidemiological studies of overweight and obesity can be characterized as (i) studies of trends in the prevalence of obesity; (ii) studies of the correlates and causes of obesity in populations; and (iii) aetiological studies of the health consequences of obesity.

The rapidly increasing rates of obesity, especially in high- and middle-income countries, have occurred since around 1980. For epidemiological and surveillance purposes, studies standardize assessment through the unitless metric, BMI, derived as weight (kg) divided by height in metres squared. Levels of BMI over 25 are classified as overweight and BMI values over 30 as obese. Obesity increases have mesmerized policymakers, the mass media, and the general public, although solutions are challenging and complex to implement.

In high-income countries, overweight and obesity may affect half to two-thirds of the adult population, and a quarter of adolescents [8]. Globally, objectively measured obesity among adults has increased between 1975 and 2016, with the highest current rates in Polynesian/Melanesian Pacific Island countries, in some middle Eastern nations, and in the USA [8]. Self-reported data on obesity trends adapted and updated from an OECD report are shown in Figure 14.1.2.2. For high-income countries such as the USA, the UK, and Australia, increases started in the 1980s, with obesity rates reaching between 20–30% of adults within two decades. Overall obesity rates have started to plateau in European countries, but seem to be still increasing in the USA [8]. Several countries in Europe (such as the Netherlands and France) and high-income countries in Asia (Japan, South Korea) showed a delayed pattern, with obesity increases not occurring until the mid-1990s or later. Other global patterns [8] show later onset in middle-income and rapidly developing countries in the twenty-first century, notably countries with large populations that are showing rapid industrialization and urbanization, such as China and India, who now report huge absolute numbers of overweight and obese adults.

Global childhood and adolescent obesity rates have increased from <1% in 1975 to around 6% of in 2016 [8]. There has been a concomitant global decline in underweight children. For children in Western Europe and the UK, a clear flattening off in prevalence has occurred, assessed through objectively measured weight in population surveillance systems. Nonetheless, as with adults, even if a plateau in obesity occurs, it still poses a long-term public health challenge in the form of future non-communicable disease risk. By contrast, in many middle-income countries, obesity rates are continuing to increase, and prevention efforts are urgently needed.

Obesity rates vary between and within countries. In high-income countries, the risk of obesity was originally higher among affluent adults and children, but is now 2–3 times more likely in the most socially disadvantaged groups; by contrast, in rapidly industrializing countries, such as China and India, the reverse pattern may still occur, obesity being more prevalent among the economically booming and wealthier middle classes [9]. Obesity in high-income countries varies by other demographic characteristics, with rates higher in rural than urban adults, and higher rates in specific population subgroups, such as indigenous populations in Australia, New Zealand, and North America. These demographic patterns, and the delineation of at-risk subgroups may be quite different in low- and

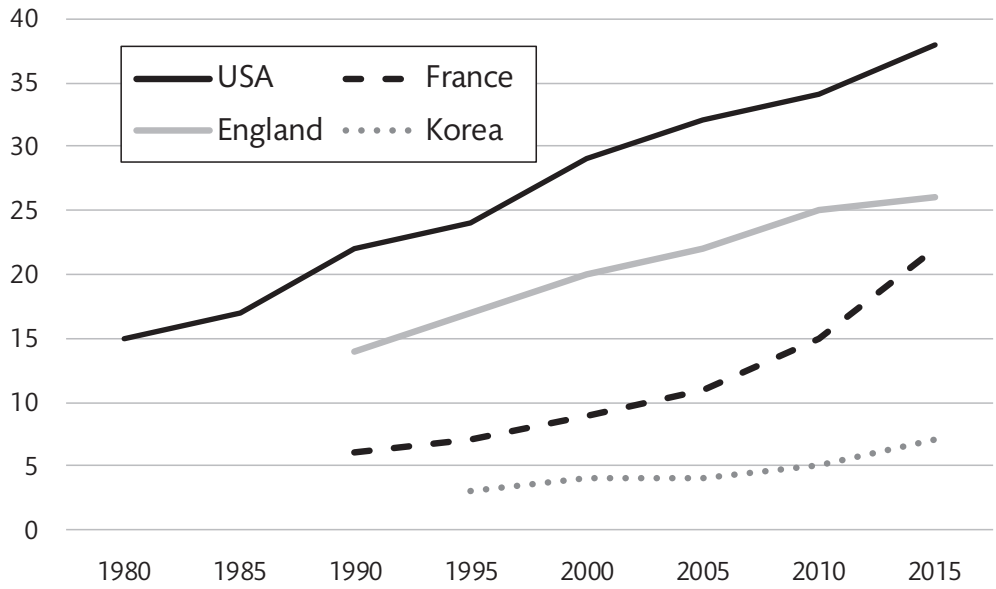

Figure 14.1.2.2 Trends in adult obesity rates selected countries.
Data derived from OECD (2013), Education at a Glance 2013: OECD Indicators, OECD Publishing. http://dx.doi.org/10.1787/eag-2013-en

middle-income countries. In some countries, obesity rates are higher among women (such as in Africa), but this pattern is not universal.

Other correlates that are relevant to policy relate to the social and physical environments in which people live. Those who have ready access to inexpensive unhealthy foods are more likely to be obese than those with access to healthier food and physical activity choices in their local environments [10]. Social and cultural groups where obesity was or has become normative also show an increased likelihood of being overweight or obese. These environmental factors are mutable, but may interact with individual genetic propensity for obesity, through increasing focus on epigenetic mechanisms.

Health Risks and Costs of Obesity

The health risks of overweight and obesity are based on a combination of basic science (mechanistic evidence), clinical observations and trials, and long-term prospective epidemiological studies. These risks are reviewed in Chapter 14.1.3, 'Medical Complications of Obesity', but selected elements of the evidence base are of public health significance and will be discussed further.

The proportion of chronic disease attributable to obesity varies among countries and across epidemiological studies. This variation is contributed to by different methods for estimating attributable risk. Reported estimates for all-cause mortality ranged from 5% to 15%, up to 8% for all-cancer incidence, 7% to 44% for cardiovascular disease (CVD) incidence, and 3% to 83% for incident diabetes.

Some epidemiological studies noted the lack of increased cardiovascular risk for overweight adults, and sometimes even for grade 1 obesity. This has become known as the 'obesity paradox'. In a meta-analysis, Flegal (2013) observed that there was a slight decrease in all cause and cardiovascular deaths among the overweight and grade 1 obese [11, 12]. More recent large studies have challenged this view. A meta-analysis of 239 cohorts (10.6 million adults, from across the world, followed for ~13.7 years) has provided contrary evidence and has suggested that there is a continuous increased risk across all levels of overweight and obesity, with risk increasing at the usual established overweight level (BMI≥ 25) [13]. A similar fine-grained analysis of CVD incidence and mortality reached a similar conclusion, namely that all levels of overweight and obesity conferred increased risk [14].

An area of consistent evidence is the relationship between obesity and type 2 diabetes. Meta-analytic evidence from epidemiological cohorts suggests a 7–8-fold increase in risk of diabetes incidence among obese adults, and a threefold increase in risk among those who are overweight. The distribution of obesity appears to influence risk, with abdominal (central) obesity being a marker of greater risk, even among people with apparently healthy BMI levels. The population attributable fraction or obesity and diabetes is large, with up to 40–50% of diabetes potentially preventable if obesity were eliminated from the population [11]. In the large Swedish SOS trial, improvements in diabetes control occurred with weight loss when it occurred at any initial level of BMI, indicating the metabolic benefits occur across the spectrum of obesity [15].

Obesity is associated consistently with diabetes risk, but not all obese people develop diabetes. An expert consensus statement concluded that some of the risk is mediated through inflammatory biomarkers, and other metabolic factors that regulate glycaemic control and insulin resistance [16]. Further, being 'metabolically healthy' despite being obese does lower non-communicable disease (NCD) and mortality risk, irrespective of which definition of metabolic health is used. This may be further attenuated if the person is physically active, which may offset diabetes risk [17].

Another area of concern is the risk of maternal obesity or excessive weight gain in pregnancy, which may lead to adverse pregnancy-related and postnatal outcomes, as well as influencing the NCD risk in their offspring [18]. This is a public health problem, since effective interventions are seldom generalized and delivered to

the whole target population. This requires strategies beyond enrolling volunteer overweight pregnant women into lifestyle trials.

Although recent evidence suggests that increases in health risk occur across all levels of increased BMI or adiposity, the risks increase markedly for grade 2 and 3 obesity (BMI levels > 35 and >40 respectively). At these higher ends of the obesity spectrum, clinical therapy is essential, including pharmacological and surgical approaches. For the much large proportion who are overweight, upstream prevention approaches are essential to prevent incident obesity, prevent additional weight gain in those already overweight, and the challenge of weight loss, where possible, at the population level.

Furthermore, since obesity tracks across the lifespan, high BMI levels in adolescence may lead to chronic disease risk decades later. However, the media-fuelled alarmist concept that children may have shorter life expectancies than their parents [19] is probably an overstatement, as management continues to improve. Obese people are kept alive for longer, and the once-anticipated ever-increasing linear projections in obesity are unlikely in high-income countries. Nonetheless, this is not cause for public health complacency, especially in middle-income countries, where obesity prevalence is rapidly escalating, and globally, as the absolute numbers at risk of chronic disease still pose dire challenges for future healthcare spending.

Many studies have examined the *direct costs* (healthcare) of overweight and obesity, and the *indirect costs* (IC) (lost productivity, absenteeism, premature morbidity, and mortality) or both. The parameters vary substantially across studies, but are always impressively high as a total dollar value, or as a proportion of health costs or national GDP [20] and consistent increases in most countries are seen. Typically, studies report that between 3% and 10% of healthcare costs, or between 0.7 and 2.8% of total GDP is attributable to obesity [21]. Another method involves estimation of the proportion of costs attributable to obesity-related non-communicable disease and musculoskeletal disease. Around 15–30% of such disease costs may be due to obesity and overweight [22].

Population Level Causes of Obesity

It is unlikely that the rapid increases in obesity are wholly attributable to individual-level biological changes or genetic factors alone, and equally improbable that very similar patterns of increase coincided with the subsequent economic development in low- to middle-income countries. Furthermore, the reverse trend, seen when a country rapidly becomes less affluent and obesity decreases in a short time period, as was demonstrated in Cuba in the 1990s [23]. This does not preclude epigenetic contributions to obesity, but does point to a more complex web of metabolic, behavioural, environmental, cultural, and socioeconomic influences. These were summarized in the Foresight model prepared for the UK Department of Health [24]. This report identified groups of interrelated areas in the food system and the physical activity system that contributed directly or indirectly to the 'obesogenic environment' and to obesity. This systems map identified thematic groupings of likely causal factors [24]. These included:

- Individual-level factors can contribute, including individual physiology, responses to thermogenesis, response to early life exposures, and individual potential for epigenetic phenomena to upregulate obesity-related metabolism
- Dietary behaviours that exist within a food system. These are composed of food production choices and food distribution systems that influence patterns of food consumption; additionally, geographic and cultural factors related to food availability and choices; societal and individual norms related to food preferences, convenience, and choice; food marketing and distribution of low-cost energy-dense and nutrient-poor foods to the majority of the population
- Physical activity-related behaviours within a 'physical activity system', influencing active recreation, exercise, and sport; urban environments and transport systems that influence active travel and active commuting; influences on activity at workplaces and in domestic settings.

While genetic factors, individual-level choices, and metabolic factors may be amenable to clinical and individual-level interventions, the broader social, environmental, and societal level contributors to 'obesogenesis' provide a mandate for population-wide preventive interventions. Even if genetic factors are only expressed in adverse 'obesogenic' environments, then programmes, policies, and strategies to address these macro-level determinants are needed to address obesity in the immediate future.

Public Health Solutions

There is broad awareness of the extent and seriousness of the obesity problem, but it is very challenging to develop and implement feasible public health solutions at the population scale. The principles of public health solutions to obesity can be drawn from previous public health 'success areas', such as tobacco control and HIV prevention in many high-income countries. These have been distilled into the 'lessons for obesity' shown **Box 14.1.2.1**. They epitomize the components of a likely effective community-wide approach to obesity prevention. Note that some solutions lie outside the health sector, and that 'evidence-based action' requires public health actions across the inter-related obesogenic 'system' in society.

Fox (2013) suggested key obesity-relevant policy actions for the USA, namely increasing the availability of healthy foods (and reducing 'food deserts'); taxing unhealthy foods or subsidizing healthy foods (especially for disadvantaged groups) [25]. One target is sugar-sweetened beverages (SSBs), which include carbonated and other high-sugar, mass-produced and heavily marketed beverages, it is widely accepted that taxation of SSBs appear effective in reducing population SSB consumption, but may be politicised and not implemented through subtle food industry lobbying and influences on governmental views. Physical activity-relevant policies include improving public transport systems and the provision of places to be active, including sports fields, walking paths (sidewalks), and low-cost exercise facilities. The evidence base is mixed, but this public health approach describes 'best bets' in a comprehensive suite of obesity prevention policies [26].

For children and adolescents, obesity prevention strategies have been described by World Health Organization (WHO), starting with prenatal influences and preventing excess maternal weight

Box 14.1.2.1 Six lessons from tobacco: elements of successful public health relevant to obesity

1. Need to consider the social and environmental determinants [of obesity], which includes working outside the health sector, with a range of Government departments, non-Government agencies, and the private sector
2. Need sustained public education, and consistently disseminated obesity mass media and social media campaigns, and coordinated advocacy (especially against unhealthy food marketing)
3. Have a clear cross-agency (cross-sectoral) mandate, clearly identified leadership, sustained policy support and resources, and an implemented multiyear (national) obesity prevention plan
4. Implementing regulatory policies and taxation as appropriate (for SSBs or across a broader range of unhealthy foods) and policies that change the (food and physical activity related) environments and the social environment (social norms) that support obesity
5. Have the flexibility to implement actions, based on best available public health evidence (not waiting for controlled trial and meta-analytic evidence syntheses to precede public health actions)
6. Integrate health sector and health professional advice into the overall obesity prevention strategy

Data derived from Bonfiglioli, C.M.F., Allman-Farinelli, M.A., King, L., Bauman, A.E., 2008. Mapping solutions to obesity: Lessons from the Human Genome Project. *Australian and New Zealand Journal of Public Health* 32, 546–8; Capewell, S., Lloyd-Williams, F., 2018. The role of the food industry in health: Lessons from tobacco? *British Medical Bulletin* 125, 131–43; Heymann, E.P., Goldsmith, D., 2011. The battle against obesity: Lessons from tobacco. *The Lancet* 378, 2069.

gain in pregnancy. Subsequently, breastfeeding should be encouraged at least to 6 months of age [27]. Strategies for childhood obesity include restricting marketing of unhealthy foods and beverages, ideally through legislated action. Taxes on SSBs are recommended as an evidence-based approach to reducing consumption at the population level [27]. Front of pack food labelling is also recommended. School environments should prioritize healthier canteen food, restrict vending machines, and encourage physical activity within and outside of the school.

Integrating Clinical and Population Approaches

In summary, there is a clear place for clinical treatment of obesity, but given its population prevalence, upstream preventive efforts are also required. The latter are expensive, require formulation in a policy environment, and may pose challenges to implement. Ongoing advocacy for obesity prevention efforts, for the implementation of existing national obesity plans, and for ongoing surveillance to document success are essential ingredients. The biggest task for public health is to integrate efforts across Government and non-Government agencies, beyond the health sector alone.

14.1.3 Medical Complications of Obesity

Friedrich C. Jassil and Rachel L. Batterham

Introduction

Obesity is a chronic progressive condition associated with multiple diseases and reduced life expectancy (Figure 14.1.3.1). Countries such as the United States and Canada, as well as several professional health bodies including the World Health Organization and the World Obesity Federation, have recognized obesity as a disease, on the basis that the pathogenesis of obesity fits the epidemiological model of a disease process. In this chapter, the latest epidemiological and clinical studies describing the associations and suggested links between obesity and its medical complications are summarized, and current understanding of potential underlying mechanisms are briefly described.

Candidate Mechanisms Linking Obesity and its Medical Complications

A large number of mechanisms have been proposed to account for the link between obesity and metabolic sequelae, but how these interact in humans, and which mechanisms play the dominant role, remains uncertain. Important themes in current understanding include inflammatory consequences of adipose tissue overload, and differences among different adipose depots.

Adipocytes play a crucial role metabolically, storing excess caloric intake in the form of highly energy-dense triglycerides. They also produce a panoply of factors that act in a paracrine, autocrine, and endocrine manner, impacting upon a multitude of physiological functions including energy and glucose homeostasis, reproduction, and immune responses [1]. Following periods of energy surplus, adipocytes expand in size and number to accommodate excess lipid storage. Hypertrophic adipocytes resulting from unhealthy increase in size produce pro-inflammatory adipokines and cytokines such as tumour necrosis factor-alpha (TNF-α) and interleukin-6 (IL-6), with concomitant downregulation of the anti-inflammatory protein adiponectin. Ultimately, these changes lead to chronic systemic low-grade inflammation which is associated with adverse clinical manifestations such as atherosclerosis, insulin resistance and hyperinsulinaemia [2]. It has been shown that individuals with obesity, particularly abdominal (central) obesity, exhibit greater levels of pro-inflammatory biomarkers compared to normal-weight counterparts [3]. Conversely, achieving at least 10% weight loss is beneficial in improving the obesity-associated unfavourable inflammatory markers.

Differences among different adipose depots are also believed to play an important role in obesity-related disease. In the face of continued positive energy balance, it is postulated that when subcutaneous adipose tissue reaches its maximal capacity to expand, excess substrate is redirected and accumulates as lipid in visceral depots, leading to abdominal obesity, and is also accumulated ectopically, in extra-adipose sites in organs such as the liver, muscles, pancreas, and heart [4]. Excess ectopic lipid leads to cell lipotoxicity and lipoapoptosis and impairment of the respective organ function. For instance, excess lipid accumulation in the liver results in non-alcoholic fatty liver disease (NAFLD) and non-alcoholic steatohepatitis (NASH), in muscle leads to insulin resistance, in the pancreas is associated with β-cell failure, and in the heart is linked to cardiomyopathy [5].

Health Complications of Obesity

Type 2 Diabetes Mellitus

Being obese is associated with a sevenfold increase in the relative risk (RR) of developing T2D [6]. More worryingly, over the last few decades, the rise in prevalence of childhood obesity has been accompanied by a growing trend of incident T2D in youth, dispelling the notion of T2D as an adult-onset disease. For every ten years of living with obesity, there is a 7% higher chance of developing T2D for both men and women [7]. Importantly, adiposity gained during young adulthood has been linked to a greater RR of T2D incidence than if the same level of adiposity was gained during middle age [8].

The ability of weight loss interventions to ameliorate T2D provides further evidence for a causal role of obesity in mediating T2D. In the Diabetes Remission Clinical Trial (DiRECT), weight loss induced by lifestyle measures was associated with reversal to a non-diabetic state in a weight dependent manner. Of those achieving ≥15 kg weight loss at 12 months' follow-up, 86%

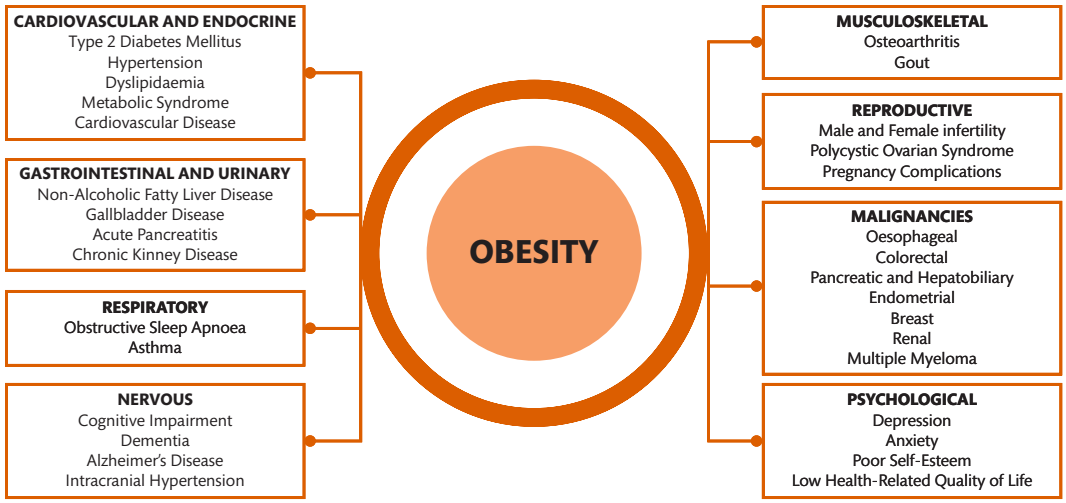

Figure 14.1.3.1 Health complications of obesity.

were able to achieve a glycated haemoglobin (HbA1c) <6.5% and stop all of their T2D medication compared to only 7% in those who were able to maintain 0–5 kg weight loss [9]. Similarly, following bariatric surgery, T2D remission has been shown to be dependent upon the magnitude of weight loss achieved post-surgery. Indeed, mechanistic studies undertaken in animals and humans have demonstrated that weight loss induced via lifestyle interventions or surgical means leads to restoration of the first-phase insulin response, possibly owing to reversal of intrapancreatic fat accumulation, which is suggested to drive β-cell dysfunction and de-differentiation [10].

Hypertension

Obesity also plays a key role in the pathogenesis of hypertension. According to data from the Third National Health and Nutrition Examination Survey (NHANES III), the prevalence of hypertension in men and women with Body Mass Index (BMI) ≥30 kgm^{-2} was 41.9% and 37.8%, respectively, compared to 14.9% and 15.2% in people with BMI ≤25 kgm^{-2} [11]. Also, data from the Johns Hopkins Precursors Study further revealed that obesity in early adulthood conferred a threefold risk of developing hypertension later in life even after adjustment for potential confounders [12]. It is known that blood pressure control is more difficult to achieve in hypertensive patients with obesity while weight loss resulting in better control. Furthermore, obesity is also a common cause of treatment-resistant hypertension. These highlight the importance of weight loss as an adjunct therapeutic approach in managing hypertension.

Dyslipidaemia

As discussed in more detail in Chapters 15.13.4, 'Diabetic Dyslipidaemia' and 14.2 'Lipoprotein Metabolism and Dyslipidaemia', many individuals with obesity have deranged lipid metabolism that manifests clinically as fasting and postprandial lipemia with elevated triglyceride, reduced high-density lipoprotein (HDL) cholesterol and slightly increased or normal level of low-density lipoprotein (LDL) cholesterol. Data from the NHANES III revealed a direct relationship between increased BMI and dyslipidaemia in adult (11). Similarly, in youth aged 12–19 years, 42.9% of those with BMI exceeding the 95th percentile were reported to have at least one abnormal lipid level [13]. In obesity, enhanced free fatty acid influx to the liver, brought about by insulin resistance, leads to continuous hepatic hypersecretion of very low-density lipoprotein (VLDL) particles. Once this triglyceride-rich lipoprotein is released into the circulation, it undergoes a sequence of lipoprotein changes through enzymatic actions leading to a reduction in circulating levels of antisclerotic HDL cholesterol and production of the atherogenic remnant of small dense LDL with consequent hypertriglyceridemia. Increased circulating small dense LDL can trigger the pro-inflammatory response that eventually promotes the development of atherosclerosis. Conversely, reduced HDL cholesterol levels impair the reverse cholesterol transport, a mechanism that serves as a protection against atherosclerosis [14].

Metabolic Syndrome

Metabolic syndrome (MetS) is a clinical condition diagnosed based on the simultaneous clustering of at least three of the following risk factors: abdominal obesity, raised triglycerides, reduced HDL cholesterol, elevated blood pressure, and raised fasting plasma glucose. This constellation of metabolic abnormalities are primarily mediated by insulin resistance. In the long-term, MetS increases the risk of T2D and cardiovascular disease (CVD) [15].

In a Multi-Ethnic Study of Atherosclerosis (MESA) involving 2748 adult men and women, of 1362 subjects with obesity without MetS at baseline, 44% developed MetS within 2 years. Further analyses have shown that greater obesity severity and duration were both associated with higher odds of incident MetS [16]. Indeed, growing evidence from prospective studies suggests that metabolically healthy obesity is a transient state before transitioning to a metabolically unhealthy phenotype, mainly driven by an increase in general and abdominal adiposity. Medical weight loss that leads to reduction in waist circumference has been shown to improve all components of metabolic abnormalities of MetS. Importantly, a recent systematic review and meta-analysis has concluded that children with overweight or obesity from birth to 6 years of age have a higher risk of developing MetS later in life [17].

Cardiovascular Disease

Obesity is a well-known independent risk factor for CVD. Obesity also increases CVD risk secondarily through worsening of other weight-related comorbidities including T2D, hypertension, dyslipidaemia, MetS, and NAFLD. Together, obesity and its comorbidities adversely affect the cardiovascular system, impacting upon cardiac structure, function and haemodynamics [18]. The higher incidence of coronary artery disease in people with obesity has been reported to be strongly associated with endothelial dysfunction and systemic inflammation [19]. Worryingly, robust evidence from epidemiological and post-mortem studies in children with obesity has shown that the atherogenic process begins in early childhood [20]. A meta-analysis of prospective studies including more than two million adults from Western and Eastern populations has demonstrated that relative to normal-weight individuals, the RR for ischaemic stroke and haemorrhagic stroke were 1.64 and 1.24, respectively, in individuals with obesity [21]. Also, data from the Framingham Heart Study showed that after adjustment for other established risk factors, obesity was associated with 5% and 7% increased risk of heart failure in men and women, respectively [22]. Moreover, in another report from the same study cohort, every one unit of increment in BMI was independently associated with 4% increased risk of atrial fibrillation observed in both genders [23]. Also, obesity doubled the risk of developing venous thromboembolism due to its hypercoagulability and pro-inflammatory state, and impaired fibrinolysis [24].

Cancer

Another major adverse health consequence of obesity is cancer. Recent reports from both the United States and United Kingdom populations revealed that overweight and obesity is now one of the leading causes of cancer, second only to tobacco smoking. Obesity is linked to many cancer types with strong evidence observed for oesophageal, colorectal, pancreatic, and hepatobiliary, endometrial (in premenopausal women), breast (in postmenopausal women) and renal cancers, in addition to multiple myeloma [25]. Many mechanisms and mediators have been proposed to underlie increased obesity-related risk of cancer development and progression, including insulin resistance with compensatory hyperinsulinaemia; pro-inflammatory changes in adipose secretome including upregulation of leptin and cytokines and downregulation of adiponectin; changes in sex hormones; increased circulating plasminogen activator inhibitor-1 and vascular endothelial growth factor; and changes in gut microbiota [26]. Importantly, obesity may impact upon cancer survival as well as quality of life, cancer progression, and recurrence, metastasis, treatment efficacy, and adverse treatment effects.

Non-Alcoholic Fatty Liver Disease

Excess adiposity is the major risk factor for NAFLD, characterized by intrahepatic triglyceride (IHTG) content of more than 5%. A subset of patients with obesity-induced NAFLD progress to NASH, a more aggressive form of fatty liver characterized by steatosis, inflammation and/or fibrosis which may further progress to cirrhosis and hepatocellular carcinoma (HCC). Worryingly, accumulating evidence has shown that HCC can develop in patients with NAFLD in the absence of cirrhosis [27]. In a pathophysiological study undertaken in subjects with obesity, 5% weight gain was associated with 20% increase in *de novo* intrahepatic of fatty acid synthesis from carbohydrates, hence increasing the IHTG content. In contrast, the rate of β-oxidation, a mechanism for removing IHTG, decreased substantially [28]. Both of these processes were mediated by impairment in insulin sensitivity as a result of weight gain. Although the export of IHTG from the liver was upregulated through higher production of triglyceride-rich VLDL particles following weight gain, this process was unable to adequately compensate for the increased IHTG production rate [28].

Gallbladder Disease

Obesity is one of the predisposing non-genetic risk factors for gallbladder disease, particularly gallstones. Analysis of data from published prospective studies revealed that for every five unit increase in BMI, the RR for gallbladder disease was 1.63 [29]. Hypersecretion of hepatic cholesterol is known to be one of the metabolic abnormalities occurring in obesity. Increased biliary cholesterol secretion leads to supersaturation of bile, resulting in formation of cholesterol gallstones [30]. Due to the increased prevalence of gallstones among people with obesity, the incidence of developing acute pancreatitis is thus higher. Unfortunately, if people with obesity do develop acute pancreatitis, its severity tends to be greater.

Chronic Kidney Disease

There is an association between obesity and renal impairment, even in the absence of the predisposing comorbidities such as T2D and hypertension. An analysis undertaken in more than 600 000 adults with normal renal function found that after a mean follow-up period of 6.8 years, participants with obesity exhibited 28% increased risk for new-onset reduced estimated glomerular filtration rate and 51% increased risk for albuminuria [31]. Obesity causes upregulation of the renal tubular sodium reabsorption, and this leads to renal vasodilation and glomerular hyperfiltration that act as feedback mechanisms to maintain sodium balance. Together, these haemodynamic changes result in glomerular hypertension, glomerulomegaly and glomerulosclerosis that eventually lead to a progressive loss of kidney function [32]. Weight loss intervention, especially bariatric surgery, have been shown to prevent further decline in renal function through normalization of glomerular filtration rate and reduction in albuminuria and proteinuria.

Reproductive Health and Pregnancy Outcomes

Obesity affects a significant number of women of childbearing age and has a substantial negative impact on overall reproductive health. It is well documented that obesity contributes to primary and secondary infertility and exacerbates many aspects of the polycystic ovarian syndrome phenotype [33]. Women with obesity are more likely to experience anovulation brought about by dysregulation of the hypothalamic–pituitary–ovarian axis and high circulating leptin levels. Furthermore, obesity also appears to affect oocyte development and quality, embryo implantation and endometrial receptiveness [33, 34]. As compared to pregnancy in normal weight, the risk of adverse maternal and fetal outcomes such as miscarriage, gestational diabetes, pregnancy-induced hypertension, prematurity, abnormal fetal growth and congenital anomalies are increased in obesity [33, 35]. Obesity also negatively impacts upon the male reproductive potential, primarily due to impaired spermatogenesis and sexual

dysfunction. Data from a meta-analysis provide clear evidence that men with obesity are more likely to exhibit poor semen quality such as oligospermia or azoospermia and increased proportion of sperm with DNA damage, abnormal morphology, and low mitochondrial membrane potential, compared to normal-weight men [36]. Furthermore, it has become evident that both maternal and paternal obesity are associated with adverse health consequences of the offspring such as increased risk of obesity, T2D, and CVD in later life, mediated by epigenetic alterations in sperm and *in utero* [35, 37].

Weight reduction increases the chances of pregnancy from natural conception and improves ovulation, menstrual cycles regulation, and an overall improvement in pregnancy outcomes with higher live birth rates. Similarly, in men with obesity, weight loss has been shown to be effective in reversing infertility by improving semen parameters and reproductive hormonal profile.

Osteoarthritis

Obesity is a recognized modifiable risk factor for osteoarthritis (OA). Every five unit increase in BMI is associated with 35% and 11% increased risk for knee and hip OA, respectively [38, 39]. In a large population-based cohort study of 1 764 061 subjects followed-up for a median of 4 years, the incidence rate of OA was reported to be higher in subjects with obesity compared to subjects with normal weight with the knee joint being greatly affected followed by the hand and hip [40]. OA in obesity was initially thought to be solely caused by biomechanical overload of the weight-bearing joints due to excessive body mass but new evidence is emerging that suggests increased expression of pro-inflammatory cytokines and adipokines (particularly leptin) and obesity-related dyslipidaemia may play a pivotal role. This explains why OA of non-weight-bearing joints such as those in the hand is also common among individuals with obesity [41]. The relationship between obesity and OA also appears to be bidirectional. OA leads to reduced mobility often contributing to further weight gain and a vicious cycle of increasing weight and worsening OA. Weight loss is a mainstay of treatment for OA, even a 5% weight reduction will promote improvement in physical disability. Importantly, patients with obesity who underwent joint replacement surgery for the treatment of severe or end-stage OA reported experiencing poorer post-surgery outcomes compared to patients without obesity.

Gout

Obesity increases the burden of gout. Data from the NHANES has shown the relationship between body weight and prevalence of gout appears to be dose-dependent and continues to persist even after adjustment for comorbidities and serum uric acid level [42]. It is postulated that obesity-associated insulin resistance and high leptin production promote hyperuricemia by inhibiting the renal excretion of uric acid. Furthermore, associated comorbidities such as elevated triglycerides and blood pressure increase plasma uric acid concentration [43]. In contrast, weight loss among patients with overweight and obesity diagnosed with gout has been shown to provide a beneficial effect in lowering uric acid level.

Obstructive Sleep Apnoea

Obesity is widely acknowledged as a major risk factor for obstructive sleep apnoea (OSA). Indeed, the incidence of OSA in adults, children, and adolescents parallels obesity prevalence. Individuals with obesity, particularly those with regional obesity, have a greater neck circumference due to parapharyngeal fat deposition resulting in greater collapsibility of the pharyngeal airway during sleep. Furthermore, intra-abdominal fat accumulation in obesity decreases lung volumes which further exacerbates OSA. Elevated circulating leptin levels and pro-inflammatory cytokines may also play a role in the pathogenesis of obesity-related OSA given their influence upon respiratory drive and neuromuscular control of the upper airways [44]. Interestingly, OSA also contributes to further weight gain as sleep disruption leads to altered energy expenditure, appetite hormones, and eating pattern.

Asthma

Obesity is recognized as an important risk factor for asthma in both children and adults. In fact, the prevalence and incidence of asthma are highly correlated with the magnitude of obesity. Obesity is associated with poor asthma control, frequent hospitalization, and decreased response to treatment. The mechanism by which obesity causes asthma is still not well understood, but genetic susceptibility, changes in lungs mechanics, airway inflammation, cardiometabolic abnormalities and diet and lifestyle have been suggested to be key contenders [45]. Indeed, weight loss via both non-surgical and surgical means lead to overall improvement in asthma control.

Cognitive Impairment and Dementia

Growing evidence supports the link between obesity and cognitive dysfunction encompassing poor executive function and short-term memory and increased risk of dementia, particularly Alzheimer's disease. The recent finding based on data from over 1.3 million adults from different regions indicates that high midlife BMI was directly associated with greater risk of dementia in later life [46]. Chronic inflammation, neurodegeneration, vascular disease, and metabolic alteration are among the potential mechanisms proposed to explain the link between obesity and cognitive decline [47].

Intracranial Hypertension

Intracranial hypertension is characterized by raised intracranial pressure that typically seen in women with obesity and of reproductive age [48]. Headaches, visual loss, pulsatile tinnitus, dizziness, and back and neck pain are among the common reported symptoms. The mechanism by which obesity causes intracranial hypertension is still unknown [48]. However, preliminary findings have suggested the beneficial effect of weight loss surgery in improving the associated symptoms and a reduction in intracranial pressure.

Psychological Comorbidities

From a psychological point of view, children and adolescent with obesity are more likely to develop depression, anxiety, lower self-esteem, and poor health-related quality of life compared with peers of healthy-weight. This is in part, due to weight-related stigma, teasing and bullying which can have a serious impact upon their mental health [49]. Adults with obesity report perceived discrimination in various settings such as work-related, healthcare-related,

and day-to-day interpersonal settings. Such weight-related stigmatization may negatively affect psychological well-being. It is therefore not surprising that people with obesity were 32% more likely to develop depression compared to their normal-weight counterparts [50].

Conclusion

Excess accumulation of adipose tissue leads to an adverse metabolic and inflammatory state that drives several disease processes, which, coupled with biomechanical effects of excess weight and obesity-associated stigma, lead to a multitude of comorbidities and premature death. A deeper understanding of how obesity contributes to such a myriad of health complications is therefore imperative and will pave the way for development of evidence-based therapeutic interventions. Importantly, the growing body of evidence that obesity-related health complications are present in young people with obesity highlights the need for more effective and robust prevention and therapeutic strategies that should be implemented as early as feasible.

14.1.4 Dietary and Medical Management of Obesity

John P. Wilding and Jonathan Z.M. Lim

Introduction

Overweight and obese individuals have excess adiposity due to complex interactions among genetic, developmental, physiological, environmental, and psychological factors. Fat distribution, especially increased intraabdominal (visceral fat) may be as important as overall obesity in increasing risk of coronary artery disease, type 2 diabetes, and certain reproductive and gastrointestinal cancers. While scientists debate exactly how much visceral fat is too much, cross sectional data shows that weight gain and visceral fat increment of over twofold in men and over threefold in women between the ages of 25 and 65 years contributes to the increased risk of metabolic complications [1]. Mechanical complications include joint pain and arthritis, sleep apnoea, and higher obstetric risk. The psychosocial effects of obesity include an increased risk of mood disorders and the effects of stigmatization. The impact on health is so significant that several worldwide organizations including the American Medical Association and the World Obesity Federation have identified obesity as a disease [2, 3]. We discuss the evidence behind successful weight management strategies including dietary approaches, the role of physical activity and effective use of behaviour modification, and show how they can be supported by the use of pharmacotherapy.

Energy Balance and Energy Requirements

Imbalance between energy derived from intake of food and expenditure of energy to maintain body physiology and perform physical work account for changes in the body's energy stores, primarily composed of fat tissue. Factors contributing to energy imbalance include genetic predisposition, maternal obesity, environmental, and cultural influences. Weight gain is associated with an increase in energy expenditure, due to an associated increase in the metabolically active component of the body (i.e. fat-free mass). Conversely, weight loss leads to a decrease in energy expenditure, which may partly explain why weight loss tends to plateau in the context of ongoing dietary restriction. Manipulation of dietary quantity or composition may alter overall energy intake and/or energy expenditure with a corresponding change in fat-free mass and subsequently alter the energy stores of the body [4].

Up to 60–70% of an individual's total daily energy expenditure is accounted for by the resting energy expenditure (REE) required to maintain normal body physiology. REE varies according to age, sex, pubertal growth, ethnicity, pregnancy, lactation, and physical activity. The British Nutrition Foundation has established the average estimated dietary reference values according to age groups, based on the average healthy population in the United Kingdom [5] (Table 14.1.4.1).

Estimated Energy Requirement = REE × Physical Activity Level (PAL)

The Physical Activity Level (PAL) is estimated using a list of the physical activities undertaken within a 24-hour period. PAL is determined based upon the impact of basal activity on energy expenditure (a factor of 1.1) and the sum of all activities (sum of Δ PAL). A third of obese individuals (BMI > 30 kg/m^2) would fit into a description of an inactive person, defined as overall PAL of less than 1.4. Estimated values of PAL are listed in Table 14.1.4.2.

Overall, physical activity levels in the United Kingdom are low; the amount of time spent on any physical activity is on average 6.5 hours for men and 5.5 hours for women per week [6]. One in five individuals in UK spend less than 30 minutes undertaking moderate physical activity per week. Thirteen per cent (13%) of all UK men and women report being sedentary for longer than eight and a half hours per day [6]. The American College of Sports Medicine (ACSM) and the World Obesity Federation recommended that 150–250 min/week of moderate to vigorous physical activity with an energy equivalent of 1200–2000 kcal/week prevents a weight gain of greater than 3% [7, 8].

Table 14.1.4.1 UK Energy requirements based on the average energy required for people with a healthy weight who are moderately active. British Nutrition Foundation (2016)

	Males		Females	
Age (years)	MJ/d	Kcal	MJ/d	kcal
19–24	11.6	2772	9.1	2175
25–34	11.5	2749	9.1	2175
35–44	11.0	2629	8.8	2103
45–54	10.8	2581	8.8	2103
55–64	10.8	2581	8.7	2079
65–74	9.8	2342	7.7	1912
75+	9.6	2294	8.7	1840

Dietary Interventions

Reducing energy intake below the requirement for weight maintenance leads, by definition, to weight loss. The most commonly recommended diets advise reduction of energy intake by about 500–600 kcal from estimated daily requirements and tend to recommend reduction in dietary fat [9]. There is controversy as to whether low-fat or low-carbohydrate diets are superior for weight loss. The positive energy balance due to increased intake of refined carbohydrate [10] is hypothesized to be a consequence of insulin-driven shift in fat partitioning towards storage and away from oxidation by metabolically active tissues such as heart, muscle, and liver. The POUNDS Lost trial [11] included over 800 obese participants who were placed on similar recommended energy restriction with either a low-carbohydrate or low-fat diet over 8 years. Prescribing very low carbohydrate diets appears to offer short-term benefit for weight loss [12], although the mechanisms are uncertain. Such diets may suppress appetite by promoting a rise in circulating ketones and may also be higher in protein which increases satiety, decreases overall energy intake, and increases energy expenditure [13].

Very-low-calorie diets (VLCD) restrict energy to 800 kcal/day or less. Low-calorie diets (LCD) have a deficit of between 800 and 1200 kcal/day. Anderson and colleagues [14] analysed 29 long-term observational studies using VLCDs compared to hypocaloric balanced diet. Negative deficit in energy was observed to produce rapid weight loss of between 15% and 25% of initial body weight within 3 to 6 months of treatment with VLCD or LCD diet and may maintain 8–9% one year after treatment [14]. Greater weight loss of up to 10–16% initial body weight was observed with VLCD, although it was not sustainable and gradual weight regain occurred within 2 years [15]. Additionally, during the weight loss maintenance phase, dietary adherence with meal replacements and prolonged refeeding phase improved overall weight loss maintenance by 3–5% at 12 months [16]. The recommendation for close medical supervision in VLCD and LCD arises from health concerns over theoretical loss of lean tissue mass, and higher incidence of gallstones [17].

Intermittent energy restriction entails a combination of regular food consumption alternating with days of caloric restriction, such as seen in the 5:2 diet. There is a suggestion that this could be as effective as continuous energy restriction, but data is limited by low sample size and lack of long-term follow-up [18]. Reducing calorie intake across different diets often is a result of secondary behaviour change with imposed dietary restrictions, which alter habitual eating habits. Over time weight regain mainly occurs due to dietary non-adherence, but also in part, explained by the individual finding

Table 14.1.4.2 Examples of low to intense physical activity. MET (metabolic equivalent) is the ratio of activity metabolic rate to resting metabolic rate. One MET is expressed as 1 kcal/kg/hour

Low intensity physical activity (approx. 1.4–2.0 METs) Light activity without exertion of pulse rate or breathing	Moderate intensity physical activity (approx. 3–6 METs) Moderate effort with acceleration of pulse rate	Heavy intensity physical activity (approx. >6 METs) Heavy intense effort accompanied by rapid pulse rate and breathing
• Sitting on couch • Hospital stay in bed • Office-based job at desk • Short-distance stroll	• Domestic and household chores • Washing and drying clothes • Cleaning within the house • Gardening • Carrying light loads • Recreation sport (swimming, bicycling at regular pace) • Physical work in agriculture or construction	• Continuous running • Climbing or hiking up a hill • Fast-paced cycling • Fast-paced swimming • Competitive athletic sports (e.g. tennis, badminton, hockey, basketball) • Carrying heaving loads (>30 kg)

alternative ways to satisfy their food cravings within the context of diet restriction.

Lean *et al.* [19] conducted a cluster-randomized trial in Scottish and North East England primary care centres in people with type 2 diabetes using total meal replacement (825–853 kcal/d) for 3–5 months, stepped food re-introduction (2–8 weeks) and structured dietary support and compared this to best practice care guidelines. After 12 months, 36 participants (24%) in the intervention group achieved >15% weight loss compared to none in the control group, and the importance of this was substantiated by the 68 participants (46%) who showed remission from type 2 diabetes. The 2-year results showed sustained remissions at 24 months for more than a third of patients with type 2 diabetes [20].

The Role of Physical Activity

Evidence from randomized controlled trials (RCTs) has demonstrated that structured exercise programmes ranging from 1000 to 4000 kcal/week energy expenditure without energy restriction is associated with reductions in visceral and abdominal adiposity [21]. A positive relationship between the amount of exercise (energy expenditure) and reduction in the components of abdominal obesity (waist circumference, visceral adipose tissue, and abdominal subcutaneous abdominal tissue) is observed across several studies varying in exercise-induced energy expenditure [22]. Overall there appears to be beneficial effects of aerobic exercise on blood glucose and insulin measures in obese individuals, which is more pronounced in those with impaired glucose tolerance and type 2 diabetes [23].

Behavioural Elements and Modification

Overweight and obese participants enrolled into intensive behavioural programmes typically achieve weight losses of between 8% and 10% [24]. The Australian Bureau of Statistics projected that the daily intake of an 'average person' comprises of one-third discretionary foods [25] deemed as nutrient poor and/or with high levels of sugar sweetened beverages. Behaviour modification for weight management is the core intervention for the treatment of obesity. Commonly applied strategies include establishing baseline dietary patterns [26] to facilitate realistic weight loss goals and becoming educated about the nutrients required and reducing energy dense foods and/or reducing portion sizes. Clinicians must be mindful of patients' or parents' attitude towards receiving information. Integrating motivational interview during the consultation encourages positivity and promotes self-reflection which is particularly useful to challenge the stigma associated with being overweight. The element of success in behavioural therapy is associated with lower levels of depression and disinhibition [27].

Weight Maintenance

While it is difficult to lose weight, maintaining weight loss is even more challenging. The energy deficit triggers a decrease in energy expenditure, a rise in hunger signals and reduction of satiety hormones, causing increased hunger and food intake. Formerly obese individuals are more likely to have low REE values after adjusting for fat-free mass, leading to the hypothesis that calorie restriction may only be sustained in a small proportion of overweight or obese individuals. Human studies on effects of hypocaloric diets on REE, demonstrated that REE could be significantly reduced by 10–15%. Furthermore, altered REE was sustained up to 2 months after achieving the new energy balance [28]. We are yet to understand how these effects change in the long-term or whether or not they are sustained.

The National Weight Control Registry (NWCR) consists of over 10 000 participants in the United States of people who have lost at least 30 lbs (13.6 kg) and maintained the weight loss for at least 1 year [29]. Over the 10-year longitudinal follow-up key, predictors of success include food intake modification, increased physical activity [30], regular portion meals including daily breakfast and decrease in leisure-time activity (watching less than 10 hours of TV per week). NWCR consists of 2886 participants, of which 78% women, reported mean weight loss of 23.8 kg (95% CI = 23.2, 24.4) at 5 years and 23.1 kg (95% CI = 22.3, 23.9) at 10 years [29]. However, it is important not to generalize these results to the overweight and obese population as this is not representative of a random sample. Maintainers of long-term weight loss were more likely to adhere with the recommended calorie restriction, reported lower fat content in diet and cultivated exercise strategies to maintain high levels of physical activity (~1 h/d). Low mood, depression and disinhibition influenced the likelihood of obese participants to comfort eat and significantly impacted upon their self-confidence [31].

Lifestyle Changes to Support Weight Management in Prediabetes and Type 2 Diabetes

The US Diabetes Prevention Programme studied the effects of intensive lifestyle intervention in over 3200 participants with impaired glucose tolerance. Intensive lifestyle intervention included 150 minutes of moderately-intense physical activity per week with an energy restriction of 1200–1500 kcals per day [32]. Furthermore, the lifestyle group received up to 16 behavioural modification sessions over 24 weeks. After an average of 2.8 years' follow-up, participants in the lifestyle group lost significantly more weight than the metformin and placebo groups (lifestyle = –5.6 kg; metformin = –2.1 kg; placebo = –0.01 kg). The incidence of diabetes was 58% lower in the lifestyle group, and 31% lower with metformin when compared to placebo. Similar intensive lifestyle intervention studies conducted in Finland, China, and India have largely supported these findings [33–35], and many countries, including the United Kingdom, have implemented programmes to support lifestyle changes in people at high risk of developing diabetes.

The Look AHEAD (Action for Health in Diabetes) is the largest RCT focused on intensive lifestyle changes through energy restriction (1200–1800 kcal/d), behaviour modification and increased physical activity (energy consumption) in 5145 overweight and obese individuals with type 2 diabetes [36] over a median follow-up of 9.6 years. Interestingly only 830 participants achieved ≥10% weight loss after one year, of those, 324 participants (39%) managed to maintain this weight loss after 8 years. Key predictors of successful maintenance of weight loss at 1, 4, and 8 years for participants include greater number of behavioural sessions attended, number of meal replacements used, and weekly minutes spent on physical activity [37].

Diet and lifestyle interventions are considered core components in management of obesity, however they may not effect meaningful long-term weight change [38]. As most patients may find it difficult to maintain lifestyle changes in the long-term, typically showing reduced rate of weight loss, weight plateau, and thereafter weight regain, it is worth considering the prospect of combining other strategies to support weight loss and weight maintenance, including the use of pharmacotherapy.

Pharmacotherapy for Obesity

Despite the option of bariatric surgery, it is not an appropriate intervention for most people with obesity due to high costs, limited availability, and risk of perioperative and long-term complications. Antiobesity pharmacotherapy is licensed only for patients with BMI ≥30 kg/m² or BMI ≥27 kg/m² in the presence of metabolic risk factors like diabetes. Used as an adjunct to lifestyle intervention, pharmacotherapy use as a treatment modality could serve a useful tool to help achieve greater weight loss and promote long-term weight maintenance.

There has been longstanding research interest in development of drugs to promote long-term weight loss. Theoretical approaches include inhibition of food intake centrally, either by inhibiting appetite stimulatory pathways, or enhancing satiety signals (some of which may originate in the GI tract), inhibiting absorption of food, and/or increasing energy expenditure. Despite recent advances, there remains concern of the long-term use of drugs to treat obesity, and many apparently good concepts were eventually found to be ineffective or to have significant adverse effects. Early attempts included use of amphetamine and its derivatives and mitochondrial uncoupling agents such as dinitrophenol, which is highly toxic. Fenfluramine/dexfenfluramine broadly target 5HT receptors, leading to concerns over cardiac valvulopathy. Rimonabant, a cannabinoid receptor antagonist, was withdrawn in Europe and never marketed in the United States, due to risk of increased suicidal ideation and low mood. These examples of antiobesity pharmacotherapy serve to remind us of the need for robust, long-term data on safety of all antiobesity agents [39].

Currently only four drugs (phentermine/topiramate, naltrexone/bupropion, orlistat and liraglutide) are US FDA-approved for use in chronic weight management; only orlistat, naltrexone/bupropion and liraglutide are approved in Europe. Four other centrally acting agents are limited to short-term use. Further advances in our understanding of appetite regulatory hormones and complex neurobiology interactions have led to much interest but much pessimism remains on the use of long-term pharmacotherapy to treat obesity.

Pancreatic Lipase Inhibitors

Orlistat

Orlistat is an intestinal lipase inhibitor chemically synthesized from lipstatin, a natural product isolated from the fungus *Streptomyces toxytricini.* It covalently binds to pancreatic lipase enzyme inhibiting absorption of approximately 30% of dietary fat. The prescribed dose is 120 mg three times daily with meals. In a multicentre randomized controlled trial, the orlistat group on average lost more than placebo group (10.2% [10.3 kg] vs. 6.1% [6.1 kg]); a weight loss difference of 3.9 kg at the end of 1 year [40]. Participants who continued with orlistat for a second year regained only half as much weight as compared to those crossed over to placebo arm. The XENDOS trial, a 4-year double-blind prospective study on orlistat use plus lifestyle changes found a reduced incidence of diabetes (6.2%) for participants taking orlistat, compared to placebo (9%) at 4 years [41]. Mean weight loss after 4 years was also significantly greater with orlistat (5.8 vs. 3.0 kg). Steatorrhoea, abdominal cramps, and flatulence limit its acceptability to many patients. Reduced absorption of fat-soluble vitamins was observed in clinical trials, but participants were asymptomatic and severe deficiencies do not develop.

Centrally Acting Antiobesity Drugs

Phentermine

Phentermine hydrochloride is an amphetamine-derived appetite suppressant, approved for short-term (up to 3 months) use by the FDA since 1977. It acts on the central nervous system to decrease hunger [42]. Phentermine monotherapy (30 mg daily) remains the most commonly prescribed therapy by US bariatric physicians. It

is a controlled drug available only on prescription for short-term (3 months) use in Europe. The attrition rates in controlled trials and presentation of data for study completers only led to scarcity of long-term data. Among the completers, commonest side effects were transient insomnia, irritability, and anxiety. Clinical use has not been associated with phentermine cravings, withdrawal, or abuse leading to psychological or physical impairment. Clinicians should not use phentermine in patients with coronary artery disease, stroke, arrhythmias, congestive cardiac failure, and uncontrolled hypertension [43].

Phentermine/Topiramate

The combination of low dose, controlled-release phentermine and topiramate (7.5/46 mg or 15/92 mg) are FDA-approved as an adjunct to hypocaloric diet. The effects of weight loss observed from use of topiramate as an anticonvulsant promoted its potential as a weight-loss agent. Combined with phentermine, clinical data demonstrates impact on reduced appetite, proposed to stem from centrally driven neurotransmitter pathways causing appetite suppression and improved satiety. Phentermine/topiramate 15/92mg ER use was associated with mean weight loss of 9.3% from baseline at 56 weeks [44]. Greater proportions of participants on the PHEN/TPM CR achieved clinically significant weight loss of 5% (79% vs. 30% in placebo) and 10% (53.9% vs. 11.5%) and 15% (31.9% vs. 6.6%) [45]. Although lowering doses of both drugs helps minimize adverse effects compared to doses needed for weight loss as monotherapy, adverse effects of dizziness, paraesthesiae, and dry mouth are common. This combination was not approved in Europe due to concerns over teratogenicity with topiramate, and ongoing concerns over the cardiac and neuropsychiatric safety of phentermine.

Lorcaserin

Lorcaserin is a selective $5HT2_C$ receptor agonist, promoting hypophagia and improved satiety. Activity at other serotonin receptors, including the 2B heart valve receptors, is minimal. Lorcaserin 10 mg twice daily is FDA-approved for chronic weight management adult obesity (BMI ≥ 30 kg/m² or ≥ 27 kg/m² in the presence of ≥ 1 weight-related comorbidity). Its combination with lifestyle intervention for obese, non-diabetic patients, 47.5% achieved ≥ 5% weight loss vs. 20.3% with placebo [46]. In a pooled-analysis of lorcaserin-treated obese participants, week 12 early responders from the BLOOM and BLOSSOM studies were observed to demonstrate better weight loss (10.8% weight loss of initial baseline weight at week 52) as compared to 2.7% for week 12 non-responders [46, 47]. Despite previous controversy around association of fenfluramine/dexfenfluramine with cardiac valvulopathy [48], no reports of valvulopathy were demonstrated with lorcaserin use. The 5-year post-marketing cardiovascular outcome trial provided reassurance to clinicians that long-term use of lorcaserin was not associated with any major cardiovascular events [49].

Naltrexone SR/Bupropion SR

Bupropion is a weak inhibitor of dopamine and norepinephrine reuptake. Naltrexone, an opioid antagonist has minimum effect on weight loss on its own, but naltrexone is thought to block the inhibitory effects of opioid receptors at the hypothalamic proopiomelanocortin (POMC) neurons, stimulating α-melanocyte stimulating hormone (α-MSH) release. α-MSH initiates a cascade, leading to reduced food intake. Forty-nine percent of participants treated with naltrexone/bupropion achieved 5% weight loss at 1 year, while 25% achieved 10% weight loss [50]. Mean reduction in body weight was −1.3% in placebo, −6.1% in naltrexone 32 mg plus bupropion group, and −5.0% in the naltrexone 16 mg plus bupropion group at 56 weeks [51, 52]. Despite the label containing a warning of suicidal ideation, an FDA requirement for antidepressants, clinical use have not demonstrated any serious concerns of increased depression or suicidality as compared to placebo [51, 52]. Most common adverse effects include nausea, constipation, diarrhoea, and headache. Approximately 1 in 4 patients discontinued naltrexone/bupropion as a result [52]. Its use is contraindicated in uncontrolled hypertension, opioid dependence, and pregnancy.

Liraglutide

Glucagon-like peptide (GLP)-1, released from intestinal L cells following a consumption of a meal, circulates naturally as $GLP\text{-}1_{7\text{-}36\ amide}$. Up to 50–70% of insulin response to a meal is due to the incretin effect, which denotes the much greater insulin secretion noted on oral glucose challenge compared to a parenteral isoglycaemic glucose administration. Among other therapeutic benefits, GLP-1 inhibits glucagon secretion from alpha cells, reduces gastric emptying and improves satiety, all of which improve glycaemia.

GLP-1 is also synthesized by neurones in the nucleus tractus solitarius (NTS) of the caudal brainstem. The NTS projects to hypothalamic and hindbrain neurones expressing GLP-1 receptors. In animal studies, intracerebroventricular GLP-1 inhibits food intake, while peripheral administration leads to increased uptake and activity within the mid and hindbrain areas involved in feeding regulation [53]. GLP-1 receptors are thus accessible both to GLP-1 as gut hormone peripherally and GLP-1 as neurotransmitter centrally, potentially explaining its appetite-suppressant satiety-inducing effects. Effects of GLP-1 are shown in **Figure 14.1.4.1**.

Liraglutide is a GLP-1 receptor agonist consisting of a polypeptide backbone structure derived from human GLP-1, following modification of the sequence of amino acids and addition of fatty acid chain to protect against rapid degradation by native dipeptidyl peptidase-4. The biochemical change renders liraglutide more effective as a GLP-1 agonist with higher affinity for albumin binding compared to its native predecessor. From 2014, liraglutide has been approved for use in chronic weight management by the FDA and EMA at a dose of 3.0 mg [54].

In SCALE obesity and prediabetes [55], 3731 patients with BMI >30 kg/m² or BMI >27 kg/m² with comorbidities were randomized into liraglutide 3.0 mg or placebo with diet, exercise, and lifestyle modification (54, 55). Intervention group demonstrated a weight loss of 8.4 kg +/− 7.3 kg; as compared to placebo (2.8 kg +/− 6.5 kg; P <0.001). Lorcaserin was withdrawn in early 2020 after concerns about increased cancer risk. Up to two-thirds (63.2%) of patients reported weight loss ≥5%, as compared to the 27.1% in placebo group; and 33.1% and 10.6%, respectively, reported weight loss ≥10% [55]. Liraglutide 3.0 mg used as an adjunct to diet and exercise, showed maintenance of the weight loss [54] (81.4% maintained the ≥5% run-in weight loss) as compared to participants on placebo (48.9%)

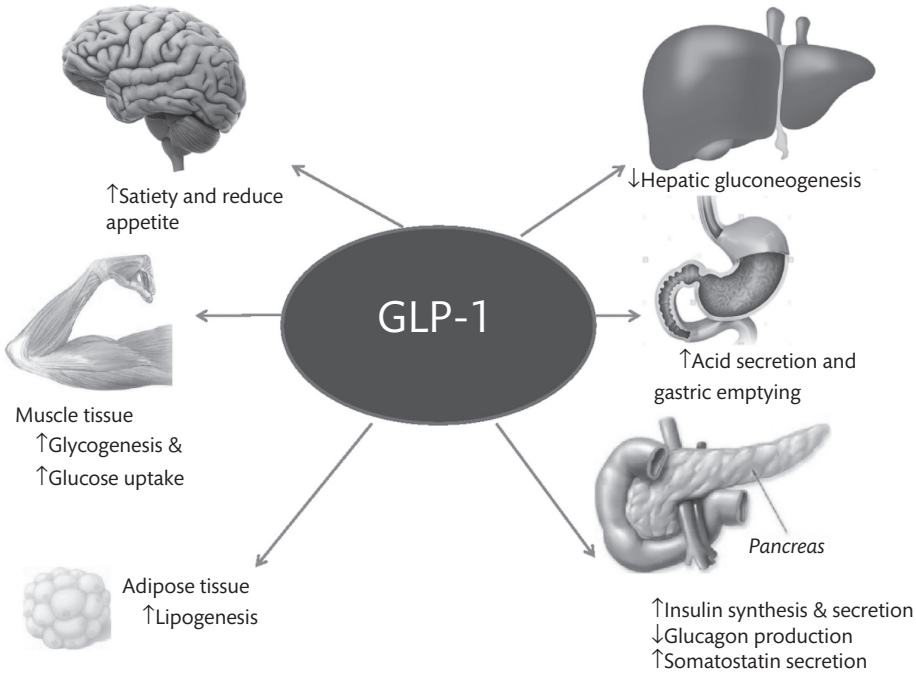

Figure 14.1.4.1 Summary of effects of GLP-1.

[54] over 56 weeks. Predominantly, participants report a mixture of gastrointestinal adverse effects of nausea, stomach cramps, flatus, diarrhoea, constipation, and fatigue. Despite these adverse effects, attrition rate associated with liraglutide 3.0 mg use is similar to that of phentermine/topiramate and naltrexone/bupropion, but slightly higher compared to lorcaserin and orlistat [56]. Reassuringly, post-hoc analysis did not demonstrate any firm association between liraglutide and pancreatitis [57].

Future Medical Therapies in Chronic Weight Management

Semaglutide is another GLP-1 receptor agonist for which phase II trial [58] results demonstrate that 83% of participants on the highest dose tested (0.4 mg once daily), attained ≥5% weight loss and 65% achieved ≥10% weight loss. The most common reported adverse event was dose-dependent nausea, similar to that of other GLP-1 agonists. Phase 3 trials using a weekly dosing regimen, including a large cardiovascular outcomes trial, are ongoing.

Another potential antiobesity agent in development is setmelanotide, a high potency melanocortin-4 receptor (MCR4) agonist, that is effective in obese individuals with pro-opiomelanocortin (POMC) deficiency [59]. This rare genetic disorder usually results from heterozygous defects within the MC4 receptor, which drives hyperphagia in infancy and lifelong severe obesity. Setmelanotide has also entered phase III trials for use in leptin receptor deficiency and Bardet-Biedl syndrome. Leptin replacement therapy (metreleptin, Myalept) is approved only for use in one extreme form of monogenic obesity, namely congenital leptin deficiency (CLD) [60].

Conclusion

Cumulative epidemiological, observational, and randomized clinical trial evidence has demonstrated that maintenance of moderate energy deficit of 500–600 kcal/d leads to 3–5% sustainable weight loss. In principle, lifestyle interventions in the form of dieting and/or exercise are the core tool in tipping energy balance towards a net deficit; use of meal replacements with a robust behavioural support package may result in greater weight loss, but longer-term maintenance remains difficult. Unsurprisingly, the key predictors of success in weight loss and weight maintenance are dietary adherence, maintenance of an increased energy expenditure through physical activity, and frequent attendance and participation in individual or group behavioural sessions. Given that many people find it difficult to maintain these crucial lifestyle changes, due to physiological responses to weight loss, including increased hunger and lower energy expenditure, physicians now have the option to consider the benefits and risks of introducing adjunct pharmacotherapy to induce and further support maintenance of weight loss. As our understanding of the complex neurobiology and role of different neurohormonal or enteroendocrine classes of antiobesity medications evolve, shared decision making with patients leading to individualized and personalized care would help bridge the gap of managing obesity. Pharmacotherapy use requires further long-term

data to support efficacy and more importantly patient safety. Future therapies may include new drug combinations designed to maintain efficacy while considering tolerability and safety of potential long-term adverse effects.

14.1.5 Metabolic Surgery

Francesco Rubino, Vivian Anastasiou, Luca Ferraro, Dalal Qanaq, and Ghassan Chamseddine

Introduction

Type 2 Diabetes currently affects more than 400 million people worldwide and this number is increasing rapidly. Despite constantly evolving drugs many patients with type 2 diabetes develop micro and macrovascular complications that increase risk of further illness and mortality. In the USA, only about half of the patients with type 2 diabetes achieve recommended levels of HbA_{1c}, and less than 20% achieved combined targets for HbA1c, low-density lipoprotein (LDL) cholesterol, and blood pressure [1]. Developing novel and more effective strategies to understand and treat diabetes is therefore an important priority for medical research.

Recently, 56 medical organizations worldwide have approved guidelines from the 2nd Diabetes Surgery Summit (DSS-II) that recommend consideration of bariatric/metabolic surgery as a standard treatment option for patients with obese type II diabetes [2, 3]. This conclusion is based on both biological and clinical evidence. In fact, in addition to positive effects from weight reduction, studies in both animals and humans have shown that gastrointestinal operations can induce weight-independent effects on glucoregulatory physiology [4, 5]. Furthermore, several randomized clinical trials have shown that surgery achieves better glycaemic control than lifestyle and available pharmaceutical interventions [6], even including long-lasting remission of hyperglycaemia.

Although the exact mechanisms of action of surgery remain unclear, the study of metabolic surgery provides the most compelling evidence so far in support of a critical role of the gastrointestinal system in glucose homeostasis. Further elucidation of the mechanisms of action of surgery and the role of the gut in metabolic regulation may provide clues about the cause of the disease and help identify novel targets for prevention and therapy of diabetes and obesity. To capitalize on the opportunities provided by surgery, however, will require a shift in mindsets across the broad spectrum of care and research, and addressing of misperceptions and misconceptions that still impede appropriate use of this effective therapeutic strategy. This chapter reviews biological, clinical, and economic evidence supporting a surgical approach to type 2 diabetes and discusses current evidence-based indications.

Surgical Treatment of Diabetes: The History So Far

In 1925, a report in *The Lancet* [7] described sudden normalization of glycaemia in a patient with diabetes undergoing a gastrointestinal operation to treat a peptic ulcer. Similar clinical observations documenting dramatic improvement or resolution of diabetes after gastrectomies for ulcer or cancer were reported in ensuing decades and became more common after the advent of bariatric or weight-loss surgery in the mid-1950s. During the 1980s and 1990s, resolution of diabetes was reported after various types of bariatric surgery procedures, including in a landmark report by Pories and coworkers documenting more than 80% resolution of hyperglycaemia in a series of 120 patients undergoing Roux-en-Y Gastric bypass surgery [8].

Experiments in rats conducted in the early 2000s investigated whether a modified form of gastric bypass surgery could directly influence glucose homeostasis. These experiments documented that manipulation of the anatomy of the gastrointestinal tract, similar to those imposed by bariatric surgery procedures, can exert weight-independent effects on glucose homeostasis [5].

Subsequent mechanistic studies in both animal models and humans corroborated these findings, implicating various mechanisms of gastrointestinal (GI) physiology, including changes in gut hormones, bile acids, microbiota, and nutrient sensing signals. Surgical teams from around the world started to use standard bariatric procedures and novel operations in mildly obese and non-obese humans with type 2 diabetes, documenting efficacy of surgery in patients with body mass index (BMI) levels above and below the traditional BMI 35 threshold for indication to traditional bariatric surgery. On the back of these studies, a multidisciplinary group of leading clinicians and scientists convened at the first Diabetes Surgery Summit (DSS-1) in 2007 recognized the biological and clinical rationale for repurposing conventional bariatric operations as a treatment for type 2 diabetes, a practice referred to as 'metabolic surgery', thereby establishing an agenda for research priorities. The DSS-1 inspired further mechanistic studies and randomized clinical trials that now provide the evidence supporting a role of surgery in diabetes. In September 2015, the introduction of surgery into standard care for type 2 diabetes was formally recommended by the participants of the second Diabetes Surgery Summit—DSS-2 [2]. Clinical guidelines established through the DSS-2 are now endorsed by over 56 organizations from worldwide and are consistent with other clinical guidelines for diabetes including NICE guidance, ADA Standards of Care and a recent ADA-EASD consensus algorithm for the treatment of hyperglycaemia [3].

Biological Rationale for Surgical Treatment of Type 2 Diabetes

Studies in humans and rodents show that various gastrointestinal (GI) procedures, and especially gastric bypass or sleeve gastrectomy cause dramatic changes in circulating levels of various gut hormones, including suppression of ghrelin [9], a hunger-inducing hormone of hormones and elevation of glucagon-like peptide-1 (GLP-1) and peptide YY (PYY), which can explain at least in part increased insulin production and decreased appetite. See Figure 14.1.5.1.

Studies show that Roux-en-Y gastric bypass (RYGB) and sleeve gastrectomy can also increase total circulating levels of bile acids as well as change bile acids composition [10], an effect that may contribute to the insulin-sensitizing effects of these operations. In fact, in addition to their role in facilitating digestion, bile acids are re-absorbed into the bloodstream and act as metabolic regulators by signalling through receptors in the nucleus (FXR receptor) or membrane (TGR-5 receptor) of cells of various organs and tissues and participating in the regulation of gut hormones, lipid metabolism, inflammation, and insulin sensitivity [11].

Gastric bypass surgery and duodenal-jejunal bypass (DJB), a stomach-sparing experimental form of metabolic surgery have also been shown to influence intestinal glucose transport and intestinal glucose metabolism in rodents and pigs, thus contributing to the systemic glucose-lowering effects of these procedures [12, 13]. Experiments in rodents also showed that DJB, an experimental,

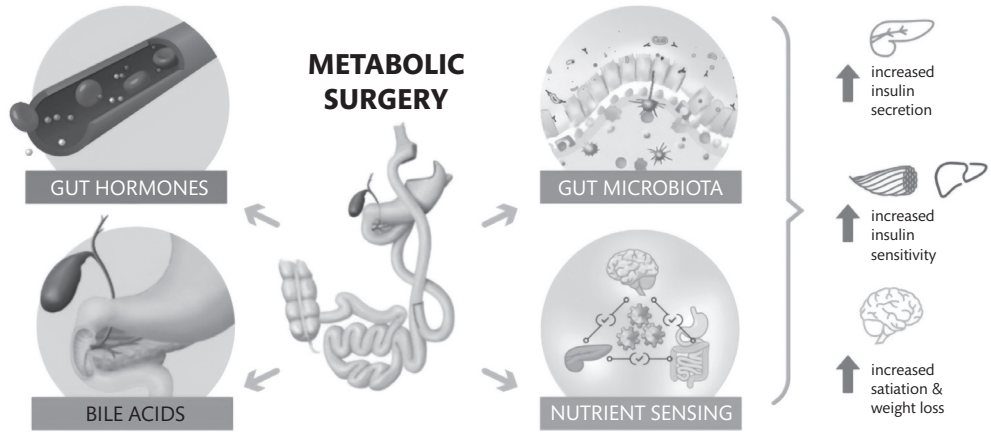

Figure 14.1.5.1 Metabolic surgery changes various mechanisms of GI physiology involved in metabolic regulation. Given its role in metabolic regulation, the GI tract constitutes a clinically and biologically meaningful target for the management of type 2 diabetes.

stomach-sparing form of gastric bypass surgery, enhances nutrient sensing mechanism that signal via the vagus nerve to the brainstem and to the liver to suppress hepatic glucose output [14].

GI surgery alters intestinal nutrient exposure and the acidity of the gut, which in turn can influence the local microbe population. In fact, experiments in humans and rodents have showed that bariatric/metabolic surgery can cause significant changes in gut microbiota. In one experimental study, bacteria extracted from gastric bypass-treated mice were transferred to non-operated, germ-free mice on a high fat diet, causing the recipients to gain less weight compared to matched animals that received similar transplants from sham-operated controls.

Other mechanisms have also been hypothesized. For example, it has been hypothesized that surgery may reduce putative nutrient-stimulated anti-incretin signals from the gut that are responsible for dysregulation of insulin sensitivity and/or secretion [15]. In aggregate, studies to date do not identify the exact mechanism responsible for diabetes remission, however, they provide evidence of a complex and critical role of the gastrointestinal tract in metabolic regulation. On the back of this evidence, in 2016 the DSS-2 recognized the gastrointestinal tract as a legitimate target for antidiabetes interventions.

Clinical Rationale for Surgical Treatment of Type 2 Diabetes

Various gastrointestinal operations originally developed as weight-loss intervention ('bariatric surgery'), can cause dramatic improvement of Type 2 Diabetes and even complete remission of hyperglycaemia, without need for ongoing medical therapy [6]. Remission of diabetes is a durable phenomenon after surgery. While recidivism of diabetes is possible, studies show that the disease recurs in a small subset of patients who have undergone RYGB, after a median disease-free period of 8.3 years [16]. Taking into account the 'legacy effect' of intensive control of diabetes on cardiovascular complications [17], even patients who experience diabetes recurrence after metabolic surgery are likely to attain long-lasting cardiovascular benefits. Although randomized studies with hard endpoints are needed, well matched case-controlled studies show that metabolic surgery diminishes cardiovascular (CV) risk as well as CV events such as myocardial infarction and stroke, cancer and overall mortality [6, 18–21].

Several clinical observations in these studies support the notion that both diabetes and CV effects of surgery are not merely a consequence of weight loss. In fact, diabetes remission appears soon after surgery, well before weight loss occurs. Furthermore, glucose homeostasis is better regulated after metabolic surgery compared to similar weight reduction obtained after changing lifestyle alone [6, 18–20]. Improvement of diabetes, but also amelioration of hard cardiovascular outcomes is not proportional to the amount of weight lost after surgery. Moreover, experimental operations or devices that partially reproduce the anatomy of bariatric/metabolic surgery induce diabetes remission with little or no weight reduction, uncoupling the weight loss effects from effects on glucose regulation. Moreover, uncommon complications of bariatric surgery such as hyperinsulinemia and hypoglycaemia, which typically occur years after surgery, suggest long-lasting enhancement of beta cell function and/or mass postoperatively. This is not an effect achievable by weight reduction alone. In addition, metabolic surgery achieves comparable diabetes remission rates in patients with BMI <30 kg/m^2 and BMI ≥ 35 kg/m^2 preoperatively [22]. Evidence of weight-independent effects on glucose homeostasis after gastrointestinal bypass operations and the role of the GI tract in glucose metabolism provide a rationale to considering a surgical approach to treat type 2 diabetes, even in patients who are only mildly obese [23]. Accordingly, the term 'metabolic' surgery has been coined in recent years to indicate a surgical approach intentionally aimed at treating type 2 diabetes and metabolic disease.

Clinical Outcomes of Metabolic Surgery

Over several decades, clinical practice and research have shown that bariatric/metabolic surgery is an effective and safe procedure for treatment of severe obesity and related diseases. Surgery results in major and sustained weight reduction, as well as improvement of glycaemic and lipid control, cardiovascular risk, and reduced incidence of microangiopathy complications, heart attacks, strokes, cancer, and death compared to patients of similar BMI who do not

undergo surgery [6, 18–21]. Nine long-term observational studies have shown major reduction in overall mortality among subjects with severe obesity undergoing bariatric/metabolic surgery [6, 20, 24, 25], with a remarkable 92% reduction of diabetes-specific related deaths [25].

Furthermore, 12 randomized clinical trials comparing surgical vs. non-surgical diabetes treatments have been recently reported. A DSS-II meta-analysis of such trials (level 1A evidence) revealed remarkable consistency in the results [2, 6] and showed that surgery outperforms conventional diabetes therapies (lifestyle + medications) in important clinical outcomes. In fact, surgically treated patients achieve better glycaemic control and diabetes remission, increased high-density lipoprotein (HDL) and lower triacylglycerol levels, and better quality of life while also dramatically reducing overall drug utilization. Furthermore, these benefits were associated with a low rate of complications and non-surgical related deaths during a follow-up period of 5 years, representing unanimous level 1a evidence. Moreover, great improvements in LDL levels and hypertension were found, although these outcomes were not as profound or consistent as the results for diabetes and its comorbidities, even for the patients with a preoperative BMI <35 kg/m² [2, 6, 26].

Safety of Metabolic Surgery

The development of minimally invasive laparoscopic approaches as the gold standard for the surgical treatment of morbid obesity has dramatically improved safety of bariatric surgery, with a ten-fold decrease in surgical mortality compared to equivalent open-surgery operations [27]. Furthermore, recent evidence has assessed bariatric/metabolic perioperative mortality to be as far lower than other routinely performed operations in general surgery. Mortality rates peribariatric/metabolic surgery are in fact similar to those of operations such as laparoscopic cholecystectomy or hysterectomy, and complication rates are even lower than those observed after other types of major general surgery procedures [28]. Although laparoscopic RYGB is a complex and technically challenging procedure, which requires adequate surgical skills and training, it has a perioperative 3.4% complication rate, which is less than that for laparoscopic operations such as hysterectomy, cholecystectomy, or appendectomy, as reported by a recent US National Registry [28]. Most common long-term complications of bariatric/metabolic surgery are summarized in Table 14.1.5.1. Among these, the most common is iron deficiency. Patients who undergo bariatric/metabolic procedures are usually on lifelong oral iron supplementation and might require repeated iron infusion in cases of severely lowered iron levels or related anaemia. There is also a risk for metabolic bone disease, osteoporosis, and fracture especially after malabsorption-inducing procedures. Moreover, some studies suggested that bariatric/metabolic surgery is associated with an increased relative risk of some unpredictable long-term outcomes, such as suicide, alcohol abuse and accidental injuries [6], although definitive evidence of a causal link to bariatric surgery is not available. These potential adverse events must be carefully weighed against the numerous potential benefits in terms of weight loss, resolution of comorbidities, and reduction of medication intake. Despite risks of long-term complications, all nine existing published series of long-term overall mortality have reported that death rates are reduced in patients who have undergone bariatric/metabolic procedures compared to non-surgical controls [6], [29, 24, 25]. Additionally, the AHRQ (Agency for Healthcare Research and Quality) review considered most of the surgical complications after bariatric surgery minor and not requiring complex management in most of the cases [30].

Table 14.1.5.1 Most common long-term complications of bariatric/metabolic surgeries, including Roux-en-Y Gastric Bypass (RYGB), vertical sleeve gastrectomy (VSG), laparoscopic adjustable gastric banding (LAGB), and biliopancreatic diversion (BPD) [6, 31–42]

	Most common with: (type of procedure)
Surgical complications	
Internal hernia/small bowel occlusion	RYGB and BPD
Stricture	RYGB, VSG
Band slippage/erosion	LAGB
Marginal ulcers	RYGB (rare report with BPD)
G-E Reflux/Barret oesophagus	VSG
Re-operation	All
Nutritional/metabolic complications	
Iron deficiency	All (++ RYGB, VSG)
Vitamin B_{12} deficiency	RYGB, VSG, BPD
Vitamin D deficiency	All
Vitamin A deficiency	BPD, RYGB
Anaemia	All (++ BPD, RYGB, VSG)
Post-prandial hypoglycaemia	RYGB, VSG, (BPD?)
Hypocalcaemia	++RYGB, (VSG, BPD)
Osteoporosis and fracture risk	All (++ BPD, RYGB)
Copper deficiency	BPD, RYGB
Zinc deficiency	All, (++ BPD, RYGB, LAGB)
Thiamine (B_1) deficiency (rare development of Wernicke encephalopathy)	BPD, VSG, RYGB

Data derived from Schauer, P.R., *et al.*, Clinical Outcomes of Metabolic Surgery: Efficacy of Glycemic Control, Weight Loss, and Remission of Diabetes. *Diabetes Care*, 2016. 39(6): p. 902–11.

Standard and Novel Procedures in Metabolic Surgery

Bariatric/metabolic procedures most commonly performed worldwide are RYGB, vertical sleeve gastrectomy (VSG), laparoscopic adjustable gastric banding (LAGB) and biliopancreatic diversion (BPD) (Figure 14.1.5.2). The efficacy on weight loss and diabetes remission is ordered as follows: BPD>RYGB>VSG>LAGB, whereas the inverse is true for safety. VSG has currently overtaken RYGB in many countries, due to a fairly simple learning curve, however, RYGB is considered to be the gold standard operation for resolution of metabolic diseases and diabetes by most surgeons. Nowadays several bariatric/metabolic operations are under development, including: (1) Proximal intestinal bypass procedures for type 2

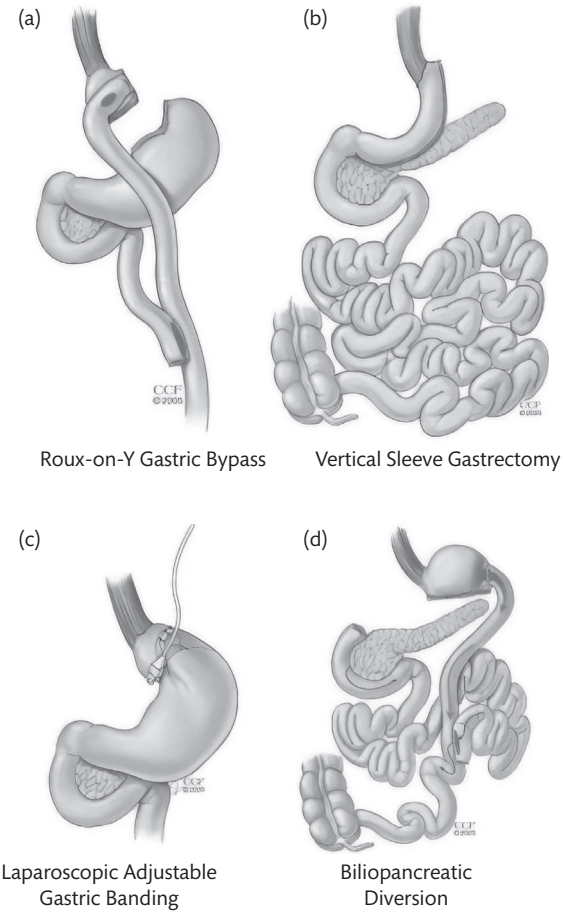

Figure 14.1.5.2 Bariatric/Metabolic Procedures most commonly performed: Roux-en-Y gastric bypass (RYGB): the stomach is divided, and a small proximal pouch is created. (a) A gastro-jejunal anastomosis is created. The remnant stomach, duodenum, and proximal jejunum are excluded from the transit of nutrients. Bile and biliopancreatic juices are diverted; (b) laparoscopic adjustable gastric banding (LAGB): an inflatable band is placed around the upper part of the stomach. The band adjusted by injecting saline into a subcutaneous port.; (c) vertical sleeve gastrectomy (VSG): a vertical gastric resection is performed along the smaller curvature using staples, leaving behind a 'sleeve-shaped' stomach, without rerouting the intestine; biliopancreatic diversion (BPD): the stomach is resected horizontally—classic BPD, or vertically—'BPD-duodenal switch'. The duodenum, jejunum, and part of the ileum are bypassed. Nutrients and biliopancreatic juice mix only within the distal 50–100 cm of the ileum—this segment is dubbed 'common channel'.

Reproduced with permission from Rubino, F., *et al.*, Metabolic Surgery in the Treatment Algorithm for Type 2 Diabetes: A Joint Statement by International Diabetes Organizations. Diabetes Care, 2016. 39(6): pp. 861–77; and from Cummings, D.E. and R.V. Cohen, Bariatric/Metabolic Surgery to Treat Type 2 Diabetes in Patients with a BMI <35 kg/m². *Diabetes Care*, 2016. 39(6): pp. 924–33.

diabetes (e.g. DJB surgery, endoscopically implanted endoluminal sleeves and endoscopic duodenal mucosal resurfacing); (2) Ileal interposition surgery to increase the secretion of L-cell peptide from the distal gut; (3) Endoscopic reduction of gastric volume for weight loss (e.g. new-generation gastric balloons, gastric plication, and gastric electrical stimulation). Most of these approaches are currently used primarily in clinical trials.

Cost-Effectiveness of Metabolic Surgery

All of the studies investigating economic aspects of bariatric/metabolic surgery have reported surgery for obesity or diabetes to be cost-effective with a mean price of $5000–10 000 per quality-adjusted-life-year (QALY). This figure is far below the average threshold of $50 000/QALY used to determine coverage by healthcare insurance [43, 44]. Additionally, bariatric/metabolic surgery seems more cost-effective than medication for glycaemic and lipid control, that are reported to have $41 384/QALY and $51 889/QALY, respectively [45]. The time to achieve return-on-investment differs significantly among studies. However, the total cost after bariatric/metabolic surgery seems to be compensated throughout time avoiding further expenditure for hospitalizations, medications, and complications related to the progression of the disease. Thus, insurance companies should be able to recoup the cost of surgery over time and, prospectively, the whole insurance coverage for bariatric/metabolic surgery may decrease the entire cost of the private healthcare system. It is reasonable to contemplate that the public healthcare system, such as the UK National Health Service (NHS), would experience similar benefits.

Current Indications for Surgical Treatment of Type 2 Diabetes

Historical international guidelines for bariatric surgery have limited indications to only patients with BMI ≥35 kg/m², based on a 1991 National Institutes of Health (NIH) consensus statement [30]. Such weight-centric criterion for surgery was not originally based on evidence of clinical or biological efficacy and is particularly inadequate to identify patients with greatest potential benefits from surgery when control of diabetes is the primary concern.

A recent meta-analysis has compared 94 579 surgical patients with type 2 diabetes, showing similar rates of disease remission (71% vs. 72% respectively) among patients with baseline BMI either lower or greater than 35 kg/m² [46]. Similar outcomes have been reported by a meta-analysis of 11 randomized clinical trials, in which no differences were found in the remission rate of diabetes among the six randomized clinical trials with preoperative BMI ≥35 kg/m², when compared with the five randomized clinical trials in which mean baseline BMI of the study cohorts was <35 kg/m² [22].

Randomized clinical trials to identify the correct indications for surgical treatment of diabetes was initially supported by the first Diabetes Surgery Summit in 2007 [47, 48]. In 2015 a multidisciplinary and international group of diabetes scholars, representing leading diabetes organizations reviewed available evidence for the 2nd Diabetes Surgery Summit and developed new guidelines that recognize metabolic surgery as standard of care option for type 2 diabetes. These guidelines recommend that metabolic surgery be considered for treating diabetes in patients with a BMI >30 kg/m² or BMI >27.5 kg/m² for Asian individuals. These guidelines (Figure 14.1.5.3) have been ratified by 56 organizations from around the world up to the present time including diabetes and surgical societies [2, 49].

14.1.6 Assessment of Obesity in Children

I. Sadaf Farooqi

Introduction

Obesity is defined by excess body fat. In adults, internationally accepted criteria rely on body mass index (BMI; weight in kg/height in metres²) to define overweight (BMI≥25 kg/m²), obesity (BMI≥30 kg/m²) and severe obesity (BMI≥40 kg/m²). However, in children, body composition changes with age, and differs by gender, and longitudinal data permitting prediction of the impact

of different weight trajectories in childhood and adolescence, is lacking. The US Centers for Disease Control (https://www.cdc.gov/) recommend use of gender-specific charts accounting for the change in BMI with age: children are diagnosed as overweight if the BMI is >85th percentile but <95th percentile and obese if the BMI is >95th percentile for age and gender. BMI data for children under 2 years of age is lacking; in this age group, a child is considered obese if the weight for recumbent length is >97.7th percentile. Extreme obesity is defined as a BMI >120% of the 95th percentile or >35 kg/m^2.

Using these definitions, the prevalence of childhood obesity has been shown to be increasing worldwide driven by inexpensive, easily available, energy-rich, highly palatable foods which promote increased energy intake, and factors which contribute to a decrease in energy expenditure such as sedentary lifestyles (television watching) and reduced physical activity at school and in leisure time. However, within a given environment, there is considerable variation in body weight and fat mass among individuals, with some children much more likely to gain weight than others [1, 2]. This variability is influenced by complex interactions between environmental and biological (genetic, developmental, and behavioural) factors [3]. As well as an increase in the mean BMI in many populations, the proportion of children at the upper end of the distribution, those with severe obesity, has also increased. Physicians thus need a systematic approach to the assessment of severe childhood-onset obesity.

Clinical Assessment

The assessment of severely obese children should include appropriate screening for potentially treatable endocrine and neurological conditions. Testing for underlying genetic conditions should also be considered, so that appropriate genetic counselling and, in some cases, specific treatment can be instituted. In most patients, specific endocrine and neurological (tumours) causes can be excluded by a careful clinical history, examination and investigations focusing on associated clinical features (**Box 14.1.6.1**). A short history of rapid weight gain may be a key clue in such cases. Obese children should also be assessed for the potential complications of severe obesity such as sleep apnoea, impaired glucose tolerance/type 2 diabetes, fatty liver disease, and hypertension as well as valgus/varus skeletal deformities and orthopaedic problems (see Chapter 14.1.3 'Medical Complications of Obesity').

Medical History

A specific weight history should be taken to establish the age of onset of obesity (photographs can be helpful), as obesity that begins in early childhood is more likely to be driven by a strong genetic component. Previous treatment for obesity and the amount of weight lost, regular diet inside and outside the home, and levels of physical activity should be noted. A careful history should be taken to identify hyperphagia, and associated food-seeking behaviours such as searching for/stealing food, waking at night to find food, or eating food others leave behind. Such behaviours can be distressing for families and may not be volunteered to healthcare professionals, particularly if parents fear they will be blamed for causing their child's obesity. A sensitive approach to history taking is an important aspect of the assessment of severe childhood-onset obesity. Hyperphagia and impaired satiety typically occur as a result of disruption of hypothalamic pathways involved in the regulation of energy balance. Pica, the eating of non-food items, is rare but can be indicative of disruption of neural circuits in the hypothalamus and amygdala. Specific genetic causes of this have not been defined to date. A clear history of hyperphagia should prompt genetic investigation, and neurological causes should be excluded where the history is short.

Developmental history is also important as several obesity disorders are associated with speech and language delay. Sometimes severely obese children are slow to walk for mechanical reasons; this seldom represents true motor delay, although muscle weakness in children with mutations in thyroid hormone receptor alpha (who are often overweight) is recognized [4]. Vision and hearing should be assessed as some genetic syndromes are associated with retinal dystrophy and hearing loss (as follows). A behavioural history is important as autistic behaviour, hyperactivity, and/or aggression are features of a subgroup of genetic disorders. Anxiety, mood disorders, and self-harm are also common in obese adolescents and should be tactfully considered. A general history should seek features suggestive of hypothalamic dysfunction (sleep disturbance, temperature dysregulation, abnormal thirst), delayed pubertal development, and frequent infections. A family history to identify potential consanguineous relationships, other family members with severe childhood obesity (some of whom may have had bariatric surgery) and the ethnic and geographical origin of family members should be noted.

Box 14.1.6.1 Features in the clinical history suggesting genetic and/or other causes for severe obesity

Age of onset—use growth charts and family photographs. Early onset (<5 years of age) suggests a genetic cause and warrants investigation.

Duration of obesity—short history suggests endocrine or central cause.

Hyperphagia—often denied, but sympathetic approach needed. Ask specific questions, such as waking at night to eat, demanding food very soon after a meal suggest hyperphagia. If severe, especially in children, suggests a genetic cause for obesity and warrants investigation.

Past history of damage to the CNS (infection, trauma, haemorrhage, radiation therapy, seizures) suggests hypothalamic obesity with or without growth hormone deficiency or hypothyroidism. Morning headaches, vomiting, visual disturbance, and excessive urination or drinking also suggests that the obesity may be caused by a tumour or mass in the hypothalamus.

Dry skin, constipation, intolerance to cold, or fatigue can suggest hypothyroidism. Mood disturbance and central obesity may suggest Cushing's syndrome. Frequent infections, cholestatic jaundice, hypoglycaemia, and fatigue may suggest ACTH deficiency due to POMC/PCSK1 mutations.

Developmental delay—check milestones, educational history, behavioural disorders. Consider craniopharyngioma or structural causes (often relatively short history) and genetic causes.

Visual impairment and deafness can suggest genetic causes.

Onset and tempo of pubertal development—onset can be early or delayed in children and adolescents. Primary hypogonadotropic hypogonadism or hypogenitalism associated with some genetic disorders.

Family history—consanguineous relationships, other children affected, family photographs useful. Severity may differ due to environmental effects and as yet unidentified genetic modifiers.

Treatment with certain drugs or medications e.g. glucocorticoids, oral contraceptives, antidepressants, and antipsychotics.

Medical Examination

Height should be measured using a stadiometer and weight measured in light clothing with shoes off. Waist circumference is taken as the mid-point between the lower rib margin and the iliac crest. Skinfold thickness has limited value and its measurement is uncomfortable for patients. An examination of the skin is important, however: thin, atrophic skin is a feature of excess corticosteroids; acanthosis nigricans (pigmented 'velvety' skin creases, especially in the axillae) suggests insulin resistance. Assessment for hypogonadism and any dysmorphic features is important.

Clinicians should use laboratory testing to evaluate obese patients who may be at high risk for cardiovascular disease and type 2 diabetes. Investigations to consider are fasting plasma glucose or 2-h postprandial glucose levels and serum lipid levels. Thyroid-stimulating hormone (TSH) may be helpful in excluding hypothyroidism. Other tests to consider depend on clinical assessment and include liver imaging for hepatic steatosis, polysomnography for patients with possible sleep apnoea; and head CT or MRI when pituitary or hypothalamic disorders are suspected. The use of these tests has recently been reviewed as part of US and European guidelines for the assessment of childhood obesity [5]. Genetic testing is now recognized as an important part of the assessment of severe childhood obesity [5]. The measurement of serum leptin is not recommended routinely, but should be undertaken in very young patients with severe obesity, as congenital leptin deficiency is a potentially treatable disorder.

Genetic Obesity Syndromes–An Overview

Genetic studies focusing on severe childhood obesity have led to the identification of several genes in which rare, highly penetrant variants cause obesity (Figure 14.1.6.1). While individually these disorders are rare, cumulatively at least 10% of children with severe obesity have rare chromosomal abnormalities and/or highly penetrant genetic mutations that drive their obesity [6]. This figure is likely to increase with wider access to genetic testing in clinical practice and adherence to clinical guidelines recommending that children with severe obesity before the age of 5 years and hyperphagia should be tested [5]. Some genetic obesity syndromes are associated with learning difficulties and developmental delay which mean they often come to medical attention at a young age. However, there is a large and increasing group of genetic disorders where severe obesity itself is the presenting feature [7, 8].

Obesity With Developmental Delay

Prader–Willi Syndrome

Prader–Willi syndrome (PWS) is one of the most prevalent genetic obesity syndromes affecting approximately 1 in 25 000 people [9]. Classical clinical features include hypotonia and failure to thrive in infancy, learning difficulties, short stature, the development of hyperphagia and severe obesity in childhood and hypogonadotropic hypogonadism [10]. Children with PWS have reduced lean body mass and increased fat mass, abnormalities which resemble those

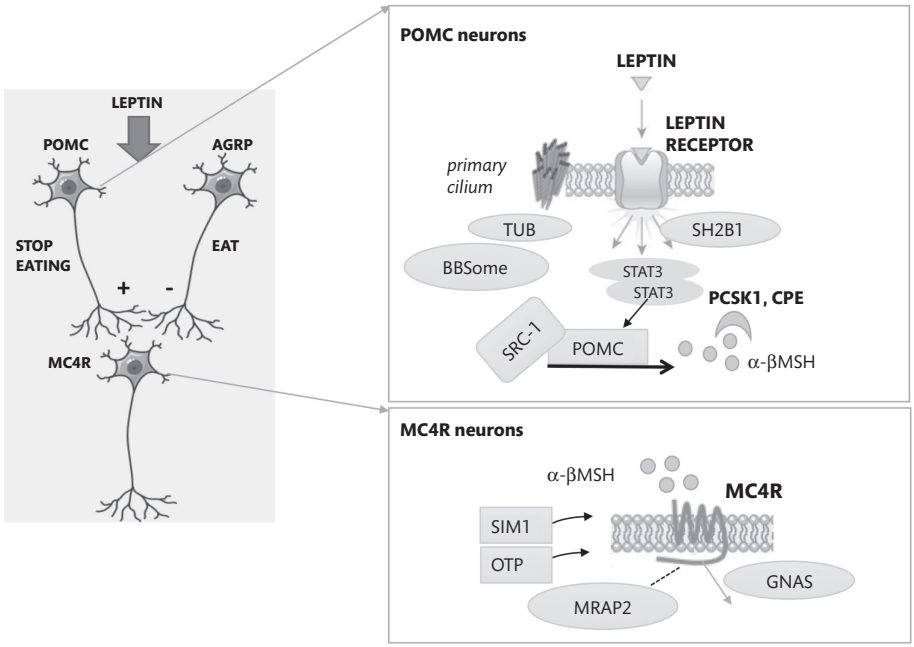

Figure 14.1.6.1 Mutations in multiple components of the leptin-melanocortin pathway are associated with severe childhood obesity. The adipose tissue-derived hormone leptin crosses the blood-brain barrier to activate/inhibit primary neurons expressing pro-opiomelanocortin (POMC) or agouti-related peptide (AGRP) which express the leptin receptor on their cell surface. POMC is post-translationally processed to yield POMC peptides, alpha and beta-MSH which are agonists at the melanocortin 4 receptor (MC4R) expressed on second order neurons; POMC stimulates MC4R signalling (+) while AGRP is a MC4R antagonist (–). In orange are genes affected by mutations associated with severe childhood obesity; all disrupt the development of, or signalling by, neurons in this circuit that reduce food intake. As a result, these obesity syndromes are characterized by hyperphagia, an increased drive to eat.

seen in growth hormone (GH) deficiency. GH treatment in children, adolescents, and adults decreases body fat and increases linear growth, muscle mass, fat oxidation and energy expenditure and as a result is often now commenced at a young age [11].

PWS is caused by sporadic deletion of a critical segment on the paternally inherited copy of chromosome 15q11.2-q12 or loss of the entire paternal chromosome 15 with 2 maternal copies (uniparental maternal disomy). Chromosomal abnormalities can be identified by a karyotype analysis or by the detection of differences in DNA methylation of the parental alleles. Chromosomal deletions that cause PWS vary in size and so disrupt a number of genes and non-coding ribonucleic acids (RNAs). The minimal genetic lesion associated with severe hyperphagia and obesity in PWS contains a cluster of non-coding small nucleolar RNAs (snoRNAs)—the SNORD116 gene cluster [12, 13]. A recent transcriptomic study of post-mortem hypothalamic tissue from PWS patients versus age- and BMI-matched controls [14] found that genes downregulated in PWS were involved in neurogenesis, neurotransmitter release, and synaptic function. Expression of brain-derived neurotrophic factor (BDNF), a major regulator of neuronal development and maturation, was found to be reduced in the hypothalamus of PWS patients. However, plasma BDNF levels were not reduced in people with PWS versus age-matched obese controls. In line with these findings, several imaging studies have identified structural abnormalities such as reduced cortical grey matter volume and abnormal gyrification in PWS patients [15]. This transcriptomic study confirmed findings from a previous histopathological study of the PWS hypothalamus which found a significantly reduced number of oxytocin neurons [16] in PWS patients. As low levels of oxytocin in the hypothalamus could contribute to some of the behavioural difficulties seen in patients as well as to the hyperphagia, clinical trials of intranasal oxytocin administration in PWS are being conducted [17]. Plasma ghrelin levels are markedly elevated in children and adults with PWS although the physiological relevance of this finding is unknown [18].

BDNF and TrkB Deficiency

A small number of children with hyperphagia, obesity, impaired short-term memory, hyperactivity, moderate to severe learning difficulties and impaired nociception who have mutations or chromosomal deletions that disrupt BDNF or its tyrosine kinase receptor tropomyosin-related kinase B (TrkB) [19, 20] have been reported. Given the severe developmental phenotype of these patients, it is not surprising that mutations often arise *de novo* and as such should be considered where both parents are of normal weight and IQ.

Albright's Hereditary Osteodystrophy

Albright's hereditary osteodystrophy (AHO) is characterized by short stature, obesity, skeletal defects, and impaired olfaction due to mutations in *GNAS1*, the gene encoding $G\alpha_s$ protein which mediates signalling by multiple G-protein coupled receptors (GPCRs). Imprinting at this locus results in a variable clinical phenotype in patients who carry loss-of-function mutations in *GNAS1*. *GNAS1* is imprinted in a tissue-specific manner, being expressed primarily from the maternal allele in some tissues and bi-allelically in other tissues; thus multihormone resistance occurs only when $G\alpha_s$ mutations are inherited maternally [21]. As a result, maternal transmission of *GNAS1* mutations leads to the classical AHO phenotype with resistance to several hormones (e.g. parathyroid hormone) that activate $G\alpha_s$ in their target tissues (pseudohypoparathyroidism type IA), while paternal transmission leads only to AHO (pseudo pseudohypoparathyroidism). To date, a diagnosis of AHO is generally only considered when the classical clinical features are present. Clinical series of patients with features of AHO often include a large number of patients with deletions or frameshift mutations [22]. However, recent studies in large cohorts of children with severe obesity have shown that some patients with *GNAS1* mutations present with obesity without some of the classical features of AHO including short stature (although learning difficulties are present in over 60%) [23]. Molecular studies of these variants, which are often missense mutations that impair signalling by some but not all $G\alpha_s$-coupled GPCRs, suggest that the spectrum of clinical phenotypes associated with *GNAS1* mutations may in part be explained by the molecular consequences of specific mutations. In view of this heterogeneity, this genetic disorder should be considered in all patients with severe obesity and developmental delay even in the absence of the classical clinical features of AHO.

SIM1 Deficiency

Chromosomal deletions and heterozygous loss-of-function mutations that disrupt single-minded 1 (SIM1) result in severe dominantly inherited obesity [24]. SIM1 is a basic helix-loop-helix transcription factor involved in the development and function of the paraventricular nucleus (PVN) of the hypothalamus and may be involved in mediating melanocortin and oxytocin signalling. Prevalent features in SIM1 deficient patients are speech and language delay and neurobehavioural abnormalities including autistic type behaviours. Patients are hyperphagic with evidence of autonomic dysfunction (characterized by low systolic blood pressure). As the hyperphagia of *sim1* haplo-insufficient mice is partly ameliorated by the central administration of oxytocin [25, 26], a neurotransmitter involved in the modulation of emotion and social interaction, impaired oxytocinergic signalling is one possible mechanism implicated in the obesity and behavioural phenotype seen in SIM1 deficiency. A small number of patients have been reported with heterozygous mutations in Orthopedia (Otp) [26], a gene that interacts with SIM1 to regulate the differentiation of neurons in the PVN. These patients also exhibit speech and language delay, autistic type behaviours, and anxiety.

Ciliary Disorders

Bardet-Biedl syndrome (BBS) is a rare autosomal recessive disease characterized by obesity, learning disability, dysmorphic extremities (syndactyly, brachydactyly or polydactyly), retinal dystrophy or pigmentary retinopathy, hypogonadism, and structural abnormalities of the kidney or functional renal impairment [27]. BBS is a genetically heterogeneous disorder caused by mutations in at least 16 genes with mutations in more than one gene sometimes required for complete expression of the phenotype (tri-allelic inheritance). These genes all affect proteins localized to the basal body of the primary cilium. While hypothalamic neurons express cilia, their precise function is unknown. Other recessive disorders of ciliary function include Alström syndrome (retinal dystrophy, severe insulin resistance, deafness) and *TUB* mutations [28]. The presence of cilia on leptin-responsive neurons involved in energy balance and animal data suggesting that their disruption causes obesity suggest

that there is a link between ciliary function, leptin signalling and energy homeostasis that remains to be explored [29]. Rare homozygous/compound heterozygous mutations in *ADCY3* (encoding adenylate cyclase 3) have also been identified in children with severe obesity [30] with some evidence that this gene is localized to the cilium [31].

Obesity Without Developmental Delay

Neural circuits within the hypothalamus regulate energy balance in response to peripheral nutrient-related cues [32, 33]. Leptin-responsive Agouti-related protein (Agrp)-expressing neurons in the arcuate nucleus of the hypothalamus are activated during fasting/caloric deficit to drive an increase in food intake, while in the nutritionally replete/fed state, Pro-opiomelanocortin (Pomc) neurons are activated to reduce food intake [34, 35]. Loss-of-function mutations that disrupt the function of these neural circuits result in severe obesity, demonstrating their pivotal role in human energy homeostasis [2, 36].

Leptin and Leptin Receptor Deficiency

Homozygous mutations in the genes encoding leptin and the leptin receptor cause recessively inherited severe obesity [37]. Leptin receptor mutations have been found in some non-consanguineous families, where both parents are unrelated but carry rare heterozygous variants [8]. Patients exhibit rapid weight gain in the first few months of life resulting in severe obesity by age 2 years (mean body mass index standard deviation score (BMI SDS): +5.8–7.8). Early development is usually normal. The most notable feature is intense hyperphagia with food-seeking behaviour and aggressive behaviour when food is denied. Children with leptin deficiency have impaired T cell-mediated immunity [38] consistent with high rates of childhood infection and of mortality from infection [39]. In those that survive, obesity continues into adult life with hepatic steatosis [40], hyperinsulinemia and type 2 diabetes [41]. Leptin and leptin receptor deficiency are associated with hypothalamic hypothyroidism and hypogonadotropic hypogonadism but there is some evidence for the delayed but spontaneous onset of menses in some leptin and leptin receptor deficient adults. Leptin and leptin receptor deficient children have normal linear growth in childhood and normal IGF-1 concentrations but final adult height is usually reduced due to the absence of a pubertal growth spurt.

Although leptin deficiency is very rare, it is treatable with daily subcutaneous injections of recombinant leptin [38] which is currently available to patients on a named patient basis in a small number of centres around the world. The major effect of leptin treatment is on food intake, with normalization of hyperphagia and enhanced satiety [38, 42]. Importantly, leptin also has permissive effects on the development of puberty and if given in early childhood permits appropriate linear growth. A recent trial of Setmelanotide, a MC4R agonist, which would be predicted to improve signalling downstream of LEPR, suggests that patients with loss-of-function leptin receptor mutations may potentially be treated [43].

Serum leptin is a useful test in patients with severe early-onset obesity as an undetectable concentration is highly suggestive of congenital leptin deficiency. Very rare mutations in the *LEP* gene that result in a bio-inactive form of the hormone but appropriate leptin concentrations have also been reported, however [44]. Serum leptin concentrations are appropriate for the degree of obesity in leptin receptor deficient patients; elevated serum leptin is not necessarily a predictor of leptin receptor deficiency [8]. However, a subset of *LEPR* mutations resulting in abnormal cleavage of the extracellular domain of LEPR, which acts as a leptin binding protein, are associated with markedly elevated leptin concentrations [45].

Pro-Opiomelanocortin (POMC) Deficiency

Children who have homozygous or compound heterozygous mutations in the *POMC* gene present in neonatal life with adrenal crisis due to adrenocorticotrophic hormone (ACTH) deficiency and require long-term corticosteroid replacement [46]. Such children have pale skin and white Caucasians often have red hair due to the lack of melanocortin signalling at melanocortin 1 receptors in the skin. Children from different ethnic backgrounds may present with a less obvious pigmentary phenotype. POMC deficiency results in hyperphagia and early-onset obesity due to loss of melanocortin signalling at the melanocortin 4 receptor, MC4R. In a clinical trial, Setmelanotide led to dramatic weight loss in patients with complete POMC deficiency [47]. Heterozygous mutations affecting POMC-derived peptides are more prevalent [48]; trials in these patient groups are currently taking place.

PC1/3 (PCSK1) Deficiency

Proprotein Convertase Subtilisin/Kexin type 1 2 (PCSK1) is expressed in neuroendocrine tissues and acts to cleave prohormones including pro-opiomelanocortin (POMC), pro-thyrotropin-releasing hormone (TRH), proinsulin, proglucagon, and pro-gonadotrophin-releasing hormone (GnRH) to release biologically active peptides. Compound heterozygous or homozygous mutations in *PCSK1*, which encodes PC1/3, cause small bowel enteropathy and patients may present in neonatal life or early infancy with persistent diarrhoea requiring parenteral feeding. Other important clinical features include hypoglycaemia and neuroendocrine effects (including diabetes insipidus) due to a failure to process a number of prohormones. Hyperphagia and severe obesity tend to become apparent by 2–3 years of age [49]. Measurement of the ratio of immature proinsulin to mature insulin is a useful diagnostic test for this disorder and potentially for homozygous mutations in Carboxypeptidase E, which have been reported in one adult female with overlapping clinical features [50].

MC4R Deficiency

Heterozygous loss of function mutations in *MC4R* represent the most common genetic form of obesity and assessment of the sequence of the MC4R is increasingly seen as a necessary part of the clinical evaluation of the severely obese child [7]. The prevalence of pathogenic *MC4R* mutations ranges from 0.5% to 2.5% of people with a BMI >30 kg/m^2 in UK and European populations to 5% in patients with severe childhood obesity [7, 51]. Over 300 different heterozygous mutation in MC4R have been identified to date (https://www.mc4r.org.uk). Codominance, with modulation of expressivity and penetrance of the phenotype, is the most appropriate descriptor for the mode of inheritance. Homozygous mutations in *MC4R* have been identified in children from consanguineous families.

The clinical features of MC4R deficiency include hyperphagia in early childhood and accelerated linear growth, which may be

a consequence of disproportionate early hyperinsulinemia [52]. Reduced sympathetic nervous system activity in MC4R-deficient patients is likely to explain the lower prevalence of hypertension and lower systolic and diastolic blood pressures seen in adults [53]. Thus, leptin-melanocortin signalling appears to play an important role in the regulation of blood pressure and its coupling to changes in weight. Several studies have shown that adolescents and adults with heterozygous *MC4R* mutations respond to Roux-en-Y-bypass surgery [54]. Moreover, the GLP-1 agonist, Liraglutide, can also be effective at inducing weight loss in some patients with MC4R deficiency [55]. As most patients are heterozygotes with one functional allele intact, it is possible that small molecule MC4R agonists [56] or pharmacological chaperones which improve receptor trafficking to the cell surface might be appropriate treatments for this disorder in the future.

SH2B1 Deficiency

Severe obesity without developmental delay is associated with a significantly increased burden of rare, typically singleton copy number variants (deletions/duplications) [57]. Deletion of a 220-kb segment of 16p11.2 is associated with highly penetrant familial severe early-onset obesity and severe insulin resistance [6]. This deletion includes a small number of genes, one of which is *SH2B1*, known to be involved in leptin, insulin, and BDNF signalling. These patients gain weight in the first years of life, with hyperphagia and fasting plasma insulin concentrations that are disproportionately elevated compared to age- and obesity-matched controls. Loss-of-function mutations in the *SH2B1* gene have been reported in association with early-onset obesity, severe insulin resistance, and behavioural abnormalities including aggressive behaviour [58, 59].

KSR2 Deficiency

To date, most of the genetic obesity syndromes are characterized by hyperphagia as a major driver of the obesity. Heterozygous mutations in *KSR2* (Kinase Suppressor of Ras2) are associated with increased food-seeking behaviour in childhood and low basal metabolic rate (BMR) in the presence of normal thyroid function [60]. Clinical reports suggested that some carriers of *KSR2* mutations experienced marked weight loss in childhood when prescribed the antidiabetic drug metformin (for severe insulin resistance) although the cellular mechanisms underlying these effects have not been fully explored to date.

Rare Genetic Variants That Contribute to Severe Childhood Obesity

There is increasing evidence that rare genetic variants that do not follow Mendelian patterns of inheritance may also contribute to severe obesity in some patients. The class 3 semaphorins (SEMA3A-G) direct the development of gonadotropin-releasing hormone (GnRH) neurons into the hypothalamus [61, 62] and rare variants that disrupt SEMA3 signalling are associated with hypogonadotropic hypogonadism [62, 63]. In a recent study, rare loss-of-function variants in the genes encoding SEMA3 ligands, receptors and coreceptors were found to be enriched in severely obese cases compared to healthy controls [64]. These variants altered the function of these proteins through multiple molecular mechanisms which led to aberrant development of hypothalamic melanocortin circuits that modulate energy homeostasis. However, variants were not fully penetrant and did not segregate with severe obesity in families demonstrating non-Mendelian inheritance.

There are parallels in this emerging pattern of genetic association with hypogonadotropic hypogonadism, where incomplete penetrance and variable expressivity within and across families has been observed [65]. As the number of genes implicated in hypogonadotropic hypogonadism has increased, it has become clear that oligogenic inheritance (i.e. more than one gene mutated in the same individual) can in part explain these observations. Indeed, some of the obese adolescents with rare variants in these genes had hypogonadotropic hypogonadism. Additionally, rare heterozygous loss-of-function variants in *SEMA3C* and *SEMA3D* have been associated with Hirschsprung's disease [66], a disorder characterized by failure of development of parasympathetic ganglion cells in the large intestine. Several obese patients carrying these variants had severe medication-resistant constipation in childhood with multiple hospital admissions, suggesting that these variants contribute to the spectrum of phenotypes seen.

Another example of rare variants that do not follow Mendelian inheritance but seem to contribute to a distinct clinical phenotype which includes severe obesity, involves Steroid receptor coactivator (SRC)-1, which belongs to a family of coactivators (SRC-1, -2, and -3) that regulate gene expression downstream of nuclear hormone receptors and other transcription factors. SRC-1 is abundantly expressed in neurons in the arcuate nucleus of the hypothalamus which respond to leptin. In a recent study, SRC-1 was shown to modulate leptin's ability to suppress appetite by stimulating POMC expression by interacting with phosphorylated STAT3 [67]. Rare heterozygous variants in *SRC-1* identified in severe childhood-onset obesity impaired this signalling pathway in cells, where they had a dominant negative effect. In this study, a mouse model of a human loss-of-function variant developed obesity indicating the physiological relevance of this mechanism.

Another gene in which rare variants have been found in severely obese patients and where strong biological data supports their physiological relevance is *MRAP2* (Melanocortin Receptor Accessory Protein 2), a chaperone that alters expression of MC4R [68]. Collectively, these studies indicate some of the challenges associated with establishing the contribution of rare genetic variants to clinical phenotypes. However, such mechanistic studies can lead to new understanding and can pave the way for mechanism-based approaches to therapy for patients.

Conclusions

The diagnosis of a genetic obesity syndrome can provide information that has diagnostic value for the family to whom genetic counselling can be provided. There is particular value in a genetic diagnosis in severe obesity which, unlike other clinical disorders, may not be recognized as a medical condition by some healthcare professionals and educators. A genetic diagnosis can help children and their families deal with the social stigma that comes with severe obesity and where severe obesity has been considered a reason to invoke parental neglect, the making of a genetic diagnosis can prevent

children from being taken into care. A genetic diagnosis can inform management (many such patients are relatively refractory to weight loss through changes in diet and exercise) and can inform clinical decision making regarding the use of bariatric surgery. Importantly, some genetic obesity syndromes are now treatable.

14.1.7 Management of Obesity in Children and Young People

Billy White and Russell M. Viner

Introduction

The role of medical practitioners assessing children and young people (CYP) with obesity is not limited to managing endocrine causes, comorbidities, and complications of obesity. These are relatively rare in childhood, whereas the wider medical, psychological, and social needs of those with obesity can be significant and often unmet. Medical professionals thus need to consider the holistic needs of those with obesity, including managing cardiovascular risk and the full range of obesity-related complications.

Body mass index (BMI, kg/m^2) is the best measure of adiposity for routine clinical use and should be calculated for all children and plotted on appropriate national or international (e.g. International Obesity Task Force) BMI growth charts. Country-specific BMI thresholds are based on normative population data, with 95th or 98th centiles of data obtained prior to the recent obesity epidemic commonly used as thresholds. There is less consensus on definition of severe obesity, but 120% of the 95th centile and a standard deviation score of 3.33 are two proposed BMI-based thresholds.

Obesity-related complications include type 2 diabetes, dyslipidaemia, hypertension, polycystic ovary syndrome, sleep apnoea, non-alcohol fatty liver disease and some cancers, including endometrial, liver, oesophageal adenocarcinoma, colorectal carcinoma, renal carcinoma and breast cancer. The metabolic syndrome, which is variably defined but encompasses central obesity, insulin resistance, dyslipidaemia, and hypertension, plays an important role in several of these, which are discussed in more detail in Chapter 14.1.3, 'Medical Complications of Obesity'.

Assessing Cardiometabolic Risk in Obesity

Early identification and modification of cardiovascular risk factors can reduce later morbidity and mortality and should be a key component of obesity management. Ischaemic heart disease (IHD) is very rare in children whereas IHD risk-factors (hypertension, dyslipidaemia, and type 2 diabetes) are common, particularly in those with severe obesity. In the Bogolusa Heart Study 84%, 59%, and 18% had 1, 2, or 3 of dyslipidaemia, hypertension, and hyperinsulinaemia [1]. Unlike adults, there are no good risk-predictor tools available that predict overall cardiovascular risk based on BMI, blood pressure, glycaemia, and lipids (e.g. qrisk2 in adults). Obesity-related IHD risk is associated with, but not fully explained by, mass of excess adipose tissue. Distribution of fat should be noted, with central adiposity conferring greater IHD risk however measurement of waist circumference is not recommended in children due to limited normative data.

IHD risk-factors frequently cluster in families and history of IHD and IHD risk-factors should be ascertained from first- and second-degree relatives. Early familial IHD and IHD risk-factors increase risk in the child, with doubling of risk where there is IHD affecting first-degree males under 55 years and females under 65.

There is no international consensus on screening for IHD risk-factors. The US 2011 Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents recommends the most proactive screening schedule [2] whereas the UK National Institute for Health and Care Excellence recommends 'consideration' of comorbidity screening but does not suggest which children should be screened nor how.

Hypertension

Hypertension in childhood increases risk of both hypertension and IHD in adult life. Those with severe obesity >99th centile are fourfold more likely than normal-weight children to have hypertension [3]. There are insufficient data to directly stratify cardiovascular disease (CVD) risk by absolute BP in childhood and statistical cut-offs based on normative data of 50 000 CYP are currently recommended [4]. The 95th centile for age and height, or adult hypertension threshold of 135/80 (whichever is lowest) on three separate occasions is used to define stage 1 hypertension, with readings 5 mm greater than the 95th centile defined as stage 2 hypertension. Readings between the 90th and 95th centiles are defined as high-normal.

US guidelines recommend blood pressure measurement at all clinical encounters [5]. Clinic blood pressure measurement is usually performed by the automated oscillometry method; this imputes systolic and diastolic blood pressure based on mean arterial pressure. It can be used to screen for, but not diagnose, hypertension. Oscillatory monitors read higher than manual auscultatory and cannot be used to compare to normative data which has been obtained by the auscultatory method. Therefore, BP measurement should be undertaken after 3–5-minute rest using the correct cuff size (often not available in primary care) and ideally the auscultatory method. It should be repeated three times and the average of last two measurements used. Both arms should be used at the first visit, with the higher value used as reference.

Ambulatory 24-hour blood pressure monitoring provides better real-life monitoring, higher reproducibility, and higher correlation with end-organ damage. American Academy of Pediatrics (AAP) but not European guidelines recommend ambulatory blood pressure monitoring (ABPM) to confirm diagnosis of hypertension, screen for hypertension in high-risk groups who may be normotensive in clinic (masked hypertension) or those with high blood pressure in clinic who are likely normotensive (white coat hypertension) [6]. Home blood pressure monitoring is controversial for diagnosis, but can be used for ongoing monitoring.

Hypertension in those with obesity is more likely to be primary than secondary to another condition, especially in older children. Major guidelines thus recommend only limited screening for rare causes of hypertension. Differentiation between primary and secondary causes of hypertension can usually be achieved by history and examination. All CYP with hypertension should have renal ultrasound, urine microscopy, full blood count and U+E measurement to rule out secondary renal causes, echocardiography (not electrocardiogram (ECG)) and quantification of albuminuria to screen for end-organ damage together with lipid and glucose measurement for concurrent risk stratification.

Dyslipidaemia

Fasting determination provides the best assessment of the lipid profile, particularly for triglyceride concentration, however non-fasting measurement is acceptable, pragmatic, and provides similar readings to fasted levels for total cholesterol and subfractions. Fasting lipid concentrations should be checked at least once where raised non-fasting triglyceride is found, and twice prior to initiation of pharmacotherapy. Low-density lipoprotein (LDL) levels are usually

calculated from total and non-LDL cholesterol values rather than direct assay. Non-high-density lipoprotein (non-HDL) cholesterol concentration is the best single predictor of atherosclerosis, with low levels protective against CVD. LDL above 4.9 mmol/L, or 4.1 mmol/L where there is either family history of hypercholesterolaemia and/or a strong early familial CVD risk, should prompt suspicion of familial hypercholesterolaemia.

Secondary causes of dyslipidaemia should also be considered including liver disease, nephrotic syndrome, pregnancy, drugs (e.g. isotretinoin) and hypothyroidism. Lipid management in CYP is controversial given limited long-term safety data for statins and should be supervised by experts. The pathophysiology and management of dyslipidaemia is discussed in further detail in Chapter 14.2.1, 'Lipoprotein Metabolism' and Chapter 14.2.2, 'Genetic Forms of Dyslipidaemia'.

Insulin Resistance

Puberty and excess adiposity can both cause insulin resistance, which is intimately associated with type 2 diabetes, fatty liver disease, and polycystic ovarian syndrome. It is however practically hard to quantify, and normative data are insufficient [7]. Measures such as fasting insulin concentration and HOMA-IR should not be routinely measured to assess insulin resistance. Acanthosis nigricans is suggestive of insulin resistance but not pathognomonic, and its absence rules out neither insulin resistance nor diabetes.

Type 2 Diabetes

Type 2 diabetes risk is increased by maternal diabetes in pregnancy (gestational or type 2), high-risk ethnicity (e.g. Asian, Latino, African) and first/second-degree family history [8]. Based on this, the American Diabetes Association recommends screening where a child is overweight (BMI >85th centile) with one of these risk factors or signs of insulin resistance [9]. The International Society for Paediatric and Adolescent Diabetes (ISPAD) recommends consideration of type 2 diabetes in those with comorbidities associated with diabetes, particularly obesity, non-alcohol fatty liver disease, elevated triglycerides, and elevated blood pressure.

Type 2 diabetes is best screened for using the oral glucose tolerance test (OGTT) or HbA_{1c}. While each of these methods measure different aspects of glucose control, HbA_{1c} is most closely correlated with diabetes-related complications, is pragmatic in that it can be performed at the time of seeing the patient, and is cheaper than OGTT. An HbA_{1c} of 6–6.4% (38.8–46.4 mmol/mol) is defined as 'pre-diabetes' and >=6.5% as diabetes. The term 'pre-diabetes' is controversial but can be less confusing to patients than the terms impaired glucose tolerance or impaired fasting glucose. Effective diabetes control is considered imperative for minimizing cardiovascular health and any young person diagnosed with type 2 diabetes should be managed by an expert.

Optimizing Weight and Cardiometabolic Health

Diet, physical activity, and physical inactivity influence adiposity and cardiometabolic health yet there is significant interindividual variation [10]. Changes in lifestyle may not correlate with changes in weight and health and weight alone should not be used as a marker of successful lifestyle change.

The conscious behaviour of any individual has a limited influence on bodyweight, with genes, environment, and social psychology all having a greater impact [11]. Weight loss success has often inappropriately been attributed to 'will power', motivation and education but this oversimplifies a complex construct [10]. Homeostatic mechanisms antagonise weight loss through changes in appetite, muscle efficiency and basal metabolic rate [12].

Weight loss targets of 6–8% in adults have been shown to improve health; there are no similar data in children. Weight-loss targets in children vary between national guidelines ranging from no recommended weight loss (Australia) to stratified targets based on BMI centile (USA) and some guidelines avoiding targets altogether. This variation reflects lack of evidence. Cessation of weight gain with ongoing vertical growth will cause reduction in adiposity.

Unrealistic weight-loss targets can put undue pressure on individuals and damage patient-provider relationships. Some are able to lose clinically significant amounts of weight though lifestyle change, yet it is not clear why these individuals are able to lose weight while many are not. An inability to achieve weight control does not necessarily indicate lack of adherence to recommended lifestyle changes. A step-wise approach should be considered to optimise weight and cardiovascular health once comorbidities have been assessed and managed, featuring (1) lifestyle optimisation, (2) drug therapy, and (3) bariatric surgery.

Lifestyle

A. Physical activity: Physical activity improves cardiometabolic fitness, reduces IHD risk, and should be promoted regardless of effect on weight. There is strong evidence that increased moderate-vigorous physical activity is associated with lower blood pressure, BMI, and increased fitness, as well as lowered total and LDL cholesterol, and triglyceride concentrations and insulin resistance, with increased HDL cholesterol. Conversely, there is no evidence for harm associated with increased physical activity. Daily physical activity should be recommended for all, including walking as a pragmatic form of exercise, with 60 minutes a day recommended by most major guidelines.

Back, hip, knee, and ankle pain can limit exercise; this is frequently caused by deconditioning due to inactivity and should lead to assessment and rehabilitation by physiotherapists. Rarely, obesity can cause sciatica, slipped upper femoral epiphysis, or bowed legs (Blount disease). These need effective identification and management.

Breathlessness is common during exercise. This is caused largely by lack of fitness and a supervised fitness training with an exercise professional may be needed to improve capacity to exercise. Exercise-induced asthma and inadequate asthma control can be difficult to differentiate with poor fitness and should be considered as a cause of exercise intolerance.

B. Diet: In the controlled laboratory environment, total caloric intake reduction has the greatest impact on weight. Different approaches exist to reduce overall caloric intake including portion control, reduction of energy-dense foods and macronutrient balance but there is little clear evidence (including insufficient evidence to guide the low-carbohydrate versus low-fat diet debate) [2]. The evidence that does exist is summarised in Box 14.1.7.1. The role of a diet history is unclear. Recall is often poor and the use of food diaries to monitor intake can promote behaviour change and aid discussions with health professionals.

Box 14.1.7.1 Dietary interventions for which some evidence of benefit exists

Strongest evidence

- Limit fat to 30%, saturated fat to 7–10% of total calories, and cholesterol to 300 mg/day (lowers total—and LDL—cholesterol, obesity, and insulin resistance)
- Consume fat-free milk
- Consume plant-based foods (low-calorie sources of nutrients including vitamins and fibre). Increasing access to fruit and vegetables has been shown to increase their intake

Moderate evidence

- Reduce sugar-sweetened beverages (reduces obesity)
- Increase dietary fibre (intake is inversely associated with energy density and increased body fat, and positively associated with nutrient density)
- DASH (Dietary Approaches to Stop Hypertension; a promising approach to improve nutrition and decrease cardiovascular risk)
- Reduce simple carbohydrates (associated with decreased weight and triglyceride concentration)

C. Lifestyle interventions: Evidence-based group lifestyle interventions can support behaviour change [13]. They are mostly community-based and have been trialled largely in children rather than adolescents and in academic centres. These studies are usually of short duration (<6 months) and the long-term evidence for these interventions is non-existent. Group lifestyle interventions are not widely available, with limited funding by either insurance or state-funded health systems. Some adult commercial programmes, such as Weight Watchers and Slimming World, allow adolescents to enrol with an accompanying adult and are more widely available. Some find the regular supervision and education that these programmes offer to be a helpful way of controlling weight, however, many families do not wish to take part in such interventions.

There is strong evidence for smoking avoidance (and cessation) in improving health. There is less evidence on how to effectively prevent smoking initiation or support cessation.

Pharmacotherapy

Use of weight-loss medications in CYP is rare [14]. Only the lipase-inhibitor orlistat is licenced for CYP in the EU. Within clinical trials it can result in modest BMI loss and is recommended in the UK for use in those over 12 years of age with severe obesity. Outside research trials, few tolerate the side-effects associated with fat ingestion (abdominal pain, urgency, nausea, incontinence) and the vast majority do not request a second prescription. It can be used as a feedback tool to identify fat intake in those willing to cut energy consumption by reducing fat intake.

Metformin is used off-licence, largely by endocrinologists and gynaecologists in those with insulin resistance and/or polycystic ovarian syndrome [15]. A mean change of 1.42 kg/m² was detected in a meta-analysis of small studies. It is a first line drug for those with polycystic ovary syndrome (PCOS) and can improve menstrual irregularity. Its role in diabetes prevention is less clear and it should not routinely be used for this indication.

The newest generation of weight control medications have all been licenced for other indications prior to being used for weight-reduction. Their weight beneficial effects have led to subsequent licencing for weight control, namely the GLP-1 agonist liraglutide and the combinations of naltrexone/bupropion and phentermine/topiramate. They have not been licenced to date for CYP.

Bariatric Surgery

Bariatric surgery is the only current evidence-based intervention that results in large magnitudes of weight loss (mean weight loss 13.5 kg/m² at 1 year) [16]. Furthermore, bariatric surgery appears to fundamentally change gut physiology to reduce appetite, increase satiety, and enable weight loss with concurrent control of comorbidities such as type 2 diabetes, hypertension and obstructive sleep apnoea (OSA). Bariatric surgery improves many of these comorbidities prior to significant weight loss suggesting that both the physiological changes achieved by surgery and the acute calorie reduction that it allows ameliorate these comorbidities. Physiological changes include increased and faster incretin production after food ingestion (including GLP-1) and changes in gut microbiota, vagal tone, and bile acid circulation.

Three main procedures have been used in adolescents: the adjustable gastric band (AGB), sleeve gastrectomy (SG) and gastric bypass (GB). All three result in a smaller functioning stomach. In the AGB, a silicon inflatable band is placed around the stomach and inflated via a subcutaneous port. In the SG, the greater curvature is removed to reduce stomach size by up to 80%. In the GB, the stomach is divided to form a 30 ml functioning stomach which is connected directly to the jejunum. The distal end of the 'defunctioned' proximal gut (known as the Roux limb) is anastomosed to the jejunum distally to the stomach-jejunum anastomosis to allow bile acids and stomach products to re-join the functioning gut.

These procedures have not been compared in head to head trials in this age group. Only the AGB has undergone a randomized control trial which showed greater weight loss and improved CV health compared to a group lifestyle intervention. Multiple cohort studies have published outcome data for the three procedures, with greatest weight loss at one year seen in those undergoing GB and least loss after AGB. Two high quality cohorts have published outcome data for the SG and GB at 3–5 years with outcomes similar to those seen in adults and between the two procedures [17].

Weight loss is greatest in the first 6 months and plateaus after 1–2 years with a normal distribution of weight change after surgery which includes total weight gain. The evidence underpinning selection of patients for surgery is very limited. Risk alleles including FTO appear to influence outcome but are not routinely used to select patients or match patients with procedure. There is minimal evidence for psycho-social predictors of BMI outcomes with higher levels of loss of control eating and family conflict conferring worse outcomes in one study [18]. Cessation of weight gain, appropriate attendance at appointments, prior engagement with a lifestyle intervention, appropriate mental health support, and good social support are common selection criteria by clinical teams.

Most national guidelines limit surgery to those with near completion of growth due to theoretical concerns about bone density loss after surgery. BMI thresholds of 40 kg/m², or 35 kg/m² with obesity-related comorbidities are common with the largest cohorts routinely operating on young people from around 12 years of age.

The AGB is the easiest procedure to perform however long-term risk of spontaneous gastric perforation, need for ongoing adjustment of band pressure and lesser weight loss compared to other procedures mean it is now rarely advocated. Choice of procedure

between the SG and GB is controversial with the SG increasingly being seen as the procedure of choice in this age group, given it is a less invasive and quicker procedure than the GB and has lower risk of micronutrient deficiency and stenosis. Both the SG and GB are deemed safe, with no surgery-related mortality reported in adolescents. Complications include strictures requiring endoscopic dilatation, symptomatic gallstones requiring cholecystectomy and vitamin deficiencies (particularly fat-soluble vitamins).

Weight loss after surgery can result in excess skin which can be both physically and emotionally distressing. Funding for removal of excess skin (apronectomy) is usually more limited than bariatric surgery, both in insurance- and state-funded health systems and plastic surgery itself can be associated with greater risk than bariatric surgery.

Mental health outcomes have been less widely reported than those of physical health with limited data beyond anxiety and depressive disorders [18]. Both appear to follow a similar trajectory to weight with improvement in the first 6 months and subsequent plateauing and some deterioration thereafter. Many patients believe that weight loss will dramatically improve their lives: weight loss can have significant improvement in quality of life, with greatest improvement in physical functioning domains. However, evidence for improvements in other domains is less clear and many need ongoing mental health support after surgery, particularly those whose weight loss is less than they wished.

Optimizing Other Aspects of Health Related to Obesity

Health professionals often inappropriately focus on weight loss to control obesity-related poor health while avoiding effective treatments. While weight loss can make many of these conditions better, it is often difficult to achieve, and poor health can further exacerbate this. Obesity-related poor health should be proactively medically managed concurrently with lifestyle change.

Polycystic Ovarian Syndrome

Diagnosis of polycystic ovary syndrome relies on the combination of clinical hyperandrogenism (hirsutism, severe acne), menstrual irregularity, and polycystic ovaries. Use of these criteria in adolescence is controversial as these features are frequently part of normal puberty [19]. Some recommend use of the adult Rotterdam criteria but this may lead to overdiagnosis and inappropriate worry related to future infertility. Other causes of androgen excess should be considered where there is severe hyperandrogenism or menstrual dysfunction, including congenital adrenal hyperplasia or steroid excess.

Treatment is largely symptomatic, focusing on control of clinical hyperandrogenism and menstrual dysfunction. Lifestyle change and weight loss can improve insulin resistance and menstrual irregularity (see next). Hormonal contraceptives are recommended first line treatments for cutaneous symptoms (acne, hirsutism) with careful consideration of venous thrombotic risk (combined oestrogen/progestogen contraceptives and obesity cumulatively increase risk factors for venous thromboembolism (VTE)). Improvement is usually slow, with acne not improving for at least 1 month and hirsutism for around 6 months. Metformin is additionally recommended where there are signs of metabolic syndrome. Hirsutism control can be challenging and treatments include topical ornithine decarboxylase inhibitors (Vaniqa), spironolactone, antiandrogens, and laser treatment.

Non-Alcohol Fatty Liver Disease (NAFLD)

NAFLD is usually asymptomatic and classic clinical features of liver disease are rare. Accumulation of fat in the liver (steatosis) can in some result in the progressive spectrum of fibrosis, cirrhosis, and hepatocellular carcinoma, collectively known as non-alcohol steatohepatitis (NASH). This is not directly correlated to volume of steatosis and presence of fibrosis is the best predictor of liver-related morbidity and mortality. There are limited treatment options with the exception of liver transplant in those with end stage disease which is rare in childhood.

Screening in childhood is problematic given inadequately validated screening tools and very low prevalence of those who would benefit from liver transplant. Liver ultrasound and liver enzymes have both been advocated as first line screening tools, yet both have significant issues with sensitivity. Ultrasound does not detect fibrosis or inflammation but can identify steatosis and may identify signs of significant fat-related liver disease such as nodularity or splenomegaly and other causes of deranged liver function tests. Accepted tools in adult practice (elastography using fibroscan and MRI) have not yet been validated in CYP and fibrosis markers such as ELF (enhanced fibrosis score) again have limited evidence base. Only liver biopsy can reliably differentiate between steatosis, hepatosteatosis, and fibrosis.

NAFLD is highly correlated with insulin resistance and metabolic syndrome and European guidelines suggest screening only this group [20]. In the UK, NICE additionally recommends screening in those with type 2 diabetes [21]. Those from Hispanic backgrounds have the highest risk with black ethnicity being protective [22].

The discovery of either steatosis or raised liver enzymes, either incidentally or by screening, should lead to comprehensive evaluation of secondary causes rather than assumed NAFLD, including hepatitis B and C, excess alcohol consumption, autoimmunity, Wilson, and a1-antitripysin [20].

Sleep

There is increasing evidence that inadequate or poor-quality sleep can both cause and complicate obesity, sometimes contributing to enuresis, learning problems, headaches, inattention, daytime somnolence, preference for high-calorie foods, exercise avoidance, ventricular dysfunction, and/or hypertension [23]. Obesity and adeno-tonsillar hypertrophy are the major risk factors for OSA, particularly in adolescence and with increasing adiposity [24]. Snoring is increasingly considered to be a negative predictor of good health. Some patients with OSA have the typical features of snoring with difficulty breathing and apnoeas, but many do not, making diagnosis difficult. Severe OSA can exist without snoring and a high degree of clinical suspicion is needed including consideration of both day and night symptoms, physical signs, and attention to comorbidities. Factors increasing the likelihood of OSA are shown in Box 14.1.7.2.

Inpatient polysomnography is the gold-standard investigation for the diagnosis of OSA. Overnight ambulatory saturation monitoring is poor at excluding OSA (low negative predictor value) [25]. Where OSA is suspected or diagnosed, treatments include

Box 14.1.7.2 Clinical factors indicating increased probability of obstructive sleep apnoea

Night symptoms: snoring, apnoea, difficulty breathing, enuresis

Day symptoms: morning headache, difficulty in rousing, inattention, poor behaviour, somnolence, mouth breathing (including dry mouth)

Comorbidities: sinusitis, poorly controlled asthma

Signs: anterior neck adiposity, airway abnormalities (e.g. trisomy 21, craniofacial anomalies), mouth breathing, adeno-tonsillar hypertrophy

Box 14.1.7.3 Commonly used drugs that promote weight gain

Mental health: amitriptyline, sertraline, paroxetine, haloperidol, risperidone, olanzapine, quetiapine, lithium

Diabetes: insulin, gliclazide, pioglitazone

Anticonvulsants: sodium valproate, carbamazepine, gabapentin

Steroid hormones: prednisolone, high dose inhaled steroids, some combined contraceptives

Cardiac: β-blockers

adeno-tonsillectomy, weight loss (including bariatric surgery), treatment of airway disease, and nocturnal ventilation. Secondary sequalae such as left ventricular hypertrophy should be excluded by echocardiogram where OSA is severe.

Mental Health

Effective mental health support can be critical in weight control, for example binge eating or affective disorders. Mood disturbances are more common in obesity and may be associated with obesity-related inflammation. Conversely, pharmacotherapy for mental health problems can cause weight gain, particularly if involving older generation antipsychotics.

Rapid weight gain is more likely to be caused by adverse mental health than by a medical cause, especially where normal growth is maintained. Symptoms suggestive of medical causes of obesity including nausea and headaches are also common in mental health and can render diagnosis difficult.

Obtaining a mental health history can be challenging. It should usually be undertaken in part with the young person alone. Obtaining effective mental health support can also be difficult, with families often not wanting to engage with mental health professionals, while mental health resources are often insufficient to support those who do wish to. Use of validated questionnaires can help bypass the often-stringent triage processes employed by many mental health services.

Binge eating disorders are relatively rare and hard to diagnose. Questionnaires such as the Eating Disorder Diagnostic Scale (EDDS) or the Eating Disorder Examination Questionnaire (EDE-Q) can help identify key features of a binge eating disorder, including eating large volumes of food with loss of control, associated guilt, and compensatory behaviours such as purging, diuretic use, fasting, and excessive exercise. Depressive and anxiety disorders can also drive excessive eating and can be screened using the Strengths and Difficulties Questionnaire (SDQ) and Revised Child Anxiety and Depression Scale (RCADS) questionnaire. Referral to specialist mental health services should be initiated where any questionnaires suggest a disorder.

Low self-esteem and confidence and lack of motivation to engage in behaviour change are common. Support for this is more challenging and may not require weight-specific interventions. Generic interventions such as the Duke of Edinburgh award, cadets, or dramatic arts can be effective at promoting confidence, socialisation, and behaviour change. Medical conditions reducing self-esteem should be proactively addressed, such as acne and gynaecomastia. Apparent small penis can be distressing for boys practically and psychologically, and should be differentiated from true micropenis and hypogonadism.

Low self-esteem and mental health disorders can limit exercise, particularly if exercise involved changing clothes in public (such as school PE classes), reduced clothing (such as swimming) or mixing with very fit people (such as going to the gym). Strategies to minimise these barriers should be considered including private changing facilities, single sex swimming sessions, or encouraging exercises that require minimal adaptations, such as walking.

Drugs

Certain drugs are weight-promoting and avoidance of these drugs, their replacement with weight-neutral or even weight-sparing drugs, or other treatment options should be considered. Common weight-promoting drugs are shown in Box 14.1.7.3

Activities of Daily Living

The ability to undertake activities of daily living should be checked in those with severe obesity. This includes the ability to reach and tie shoelaces in those BMI over 40 kg/m^2. Many cannot adequately toilet or wash in standard facilities nor comfortably sit/sleep in standard chairs and beds. This information will not usually be proactively shared by families. Many will be sitting/sleeping in broken chairs/beds which will be exacerbating any existing musculoskeletal and sleep abnormalities and specialist beds and chairs can be accessed by occupational therapists. Home assessments and adaptations by occupational therapists should be initiated.

14.1.8 Planning Obesity Care Pathways

Nicholas Finer

Introduction

The prevalence of obesity, its protean and relapsing nature, and the need for multidisciplinary involvement in effective care makes planning and organizing care pathways particularly challenging. Public health perspectives have tended to focus on prevention, or short-term interventions, rather than applying chronic care models to obesity which fall under the umbrella of disease management. Despite many authoritative national and international reports, systematic reviews, official recommendations, and guidelines [1–5] the need for people with overweight and obesity to receive medical care remains largely unmet. This chapter considers, mainly from an English perspective, how clinical care pathways for the management of obesity have been developed, and how they could, and should, be implemented, as well as some of the barriers to success. The development of pathways in the United Kingdom has differed from that in the USA [6], being viewed as a way of achieving a continuum of care across care settings rather than as a framework for balancing costs and quality [7].

Obesity as a Chronic Disease

Obesity is a disease of multifactorial origin driven by innate biological factors (genetic predisposition, a physiology favouring energy accumulation and protecting against weight loss), societal influences on food supply (composition, cost, availability, hedonic power) and energy expenditure (declining physical activity at work and at home), psychological factors (beliefs, executive function) and their interactions. Societal changes over the past 40 years have driven the obesity pandemic, with human physiology now maladapted to the environment. The mechanism of weight gain can be considered straightforward (sustained positive energy balance), but unless care pathways address the complex causal network management is likely to be ineffective. Since obesity is a chronic disease, increasingly starting in childhood, a life-course approach is needed [8] and long-term, even lifelong, weight management is likely required [9–11]. Effective treatment of obesity should aim to improve health and wellbeing, rather than simply aiming for weight loss; Comprehensive care of people with obesity also needs to focus on ensuring that the many complications of obesity are diagnosed and

appropriately managed. The components of comprehensive care may include behavioural, nutritional, and physical activity advice and support, as well as pharmacological and surgical interventions. However little high-quality evidence exists on how to combine, either simultaneously or sequentially, interventions or on how to personalize treatment to the individual patient.

Obesity Care Pathways

With this background there is both a clear rationale, and need, to establish obesity care pathways. An (integrated) clinical pathway is a multidisciplinary management tool based on evidence-based best practice for a specific group of patients to aid the coordination and delivery of high-quality care [12]. A pathway will embed guidelines, protocols, and locally agreed patient centred care into everyday use for the individual patient. The pathway will define the roles of professionals involved in patient care. For obesity this will include physicians, dietitians, nurse specialists, surgeons, physiotherapists, exercise specialists, psychologists, and even psychiatrists. Clinical pathways aim to standardize treatment regimens, but record variations from planned care aiming to improve outcomes and allow continual service improvement through evaluation and audit [13]. There is increasing high level evidence evaluating the efficacy (or otherwise) of care pathways [14], but much of this evidence comes from outcomes of trials of pathways focused on relatively predictable trajectories of care where efficacy in supporting proactive care management ensured that relevant clinical interventions and/or assessments were deployed in a timely manner [15]. Clinical care pathways are thus not synonymous with guidelines, which are often more generalized and do not detail the individual patient journey. Since a comprehensive clinical care pathway for the patient with obesity is likely to span levels of care from primary to specialist and involve multiple specialities (from both medical and healthcare professionals), they are most likely to be developed within comprehensive healthcare systems (e.g. the UK National Health Service).

The 5As framework, originally developed as a model for smoking cessation [16] has been adapted by the Canadian Obesity Network to form a model of initiating discussion and behaviour change based upon the principles of motivational interviewing [17, 18]. This considers a process characterized as Ask, Assess, Advise, Agree and Assist (or Arrange) (Figure 14.1.8.1). The impact of using this approach was evaluated in primary care in a 'before and after' study and showed that implementing the 5As of Obesity Management resulted in a twofold increase in the initiation of obesity management (from 19 to 39%), and a significant increase in perceived follow-up/coordination efforts [19]. Thematic network analysis of a subsequent study involving 24 chronic disease teams in Alberta, Canada concluded that the 5As Team intervention had multiple impacts on providers and teams to improve obesity management, as well as provider confidence and capability, both preconditions for developing effective patient interventions [20].

Care Pathway Development in England

In England, there are many examples of obesity care pathways, although many are confined to bariatric surgery for severe obesity. The most overarching is that developed by the National Institute for Health and Care Excellence (NICE) [21]. An overarching design principle was developed for adults within the National Health Service in which pathways are organized under a 4-tiered model (Figure 14.1.8.2) [22, 23]. Tier 1 addresses whole population prevention activity, focusing on primary prevention and includes health promotion, where primary prevention is preventing the onset of a disease. Tier 2 consists of community weight management services, that should include lifestyle advice on diet and physical activity and focus on secondary prevention of conditions associated with overweight and obesity through encouraging behaviour change, where

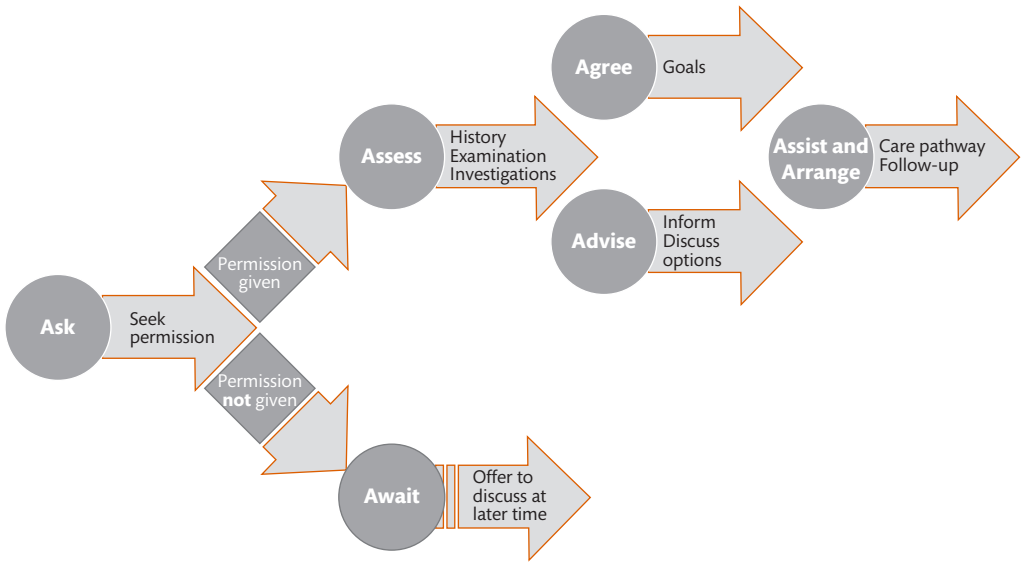

Figure 14.1.8.1 The five 'A's as a template for obesity care. In this modified schema, a sixth A—'Await' reflects that not all patients will at the point of assessment wish to proceed down the care pathway.

secondary prevention is preventing progression of early disease. The intention is that both these tiers are funded, organized, and provided by public health experts and from the public healthcare budget. Specialist, medicalized, services are represented by Tiers 3 and 4, commissioned and funded from the health service budget. Tier 3 services are specialist multidisciplinary obesity and weight management services. Access for patients would be through specialist referral routes and engagement, with Tier 3 services a requirement for consideration for surgical services. For people with obesity, this is an example of tertiary prevention, where activities prevent complications from established disease. Tier 4 services include bariatric surgery, but also care for those with genetic or complex disorders.

A practical example of an overall adult weight management obesity pathway and service model is that given in a 2017 report from Public Health England to the East of England Clinical Senate Assembly (one of twelve similar bodies across England established to provide independent, strategic advice and guidance to commissioners and other stakeholders to assist them in healthcare planning for the populations they represent) (Figure 14.1.8.3) [24]. This pathway diverges considerably from current guidelines, including those developed by NICE. This may reflect the economic tool used to estimate the return on investment for weight management services. This calculated that for Tier 2 interventions producing an average weight loss of 2.5 kg in 74% of patients completing a 12-month programme, an upfront cost of £50 per patient enrolled would yield a healthcare saving of £36 per annum over 5 years [25, 26]. The report also highlights the gap between public health perceptions of obesity and its reality as a chronic disease, with a conclusion stating that 'The challenge (of obesity) is not to find new medicines or provide more surgery to patients. It is the population that requires treatment rather than individuals' [24]. From this viewpoint it is not surprising that there are barriers in developing, funding, and

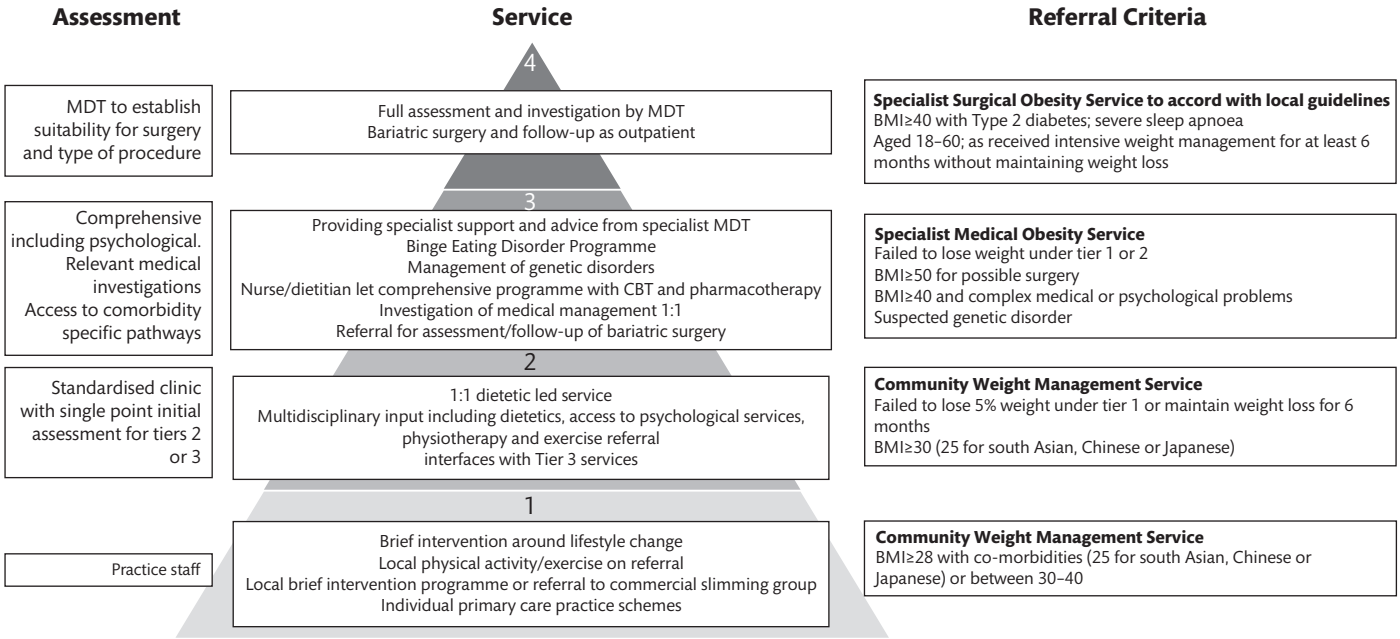

Figure 14.1.8.3 An example from the east of England of delivery of tiered obesity services. MDT, multidisciplinary team.

implementing care pathways which by their very definition address individual health needs. Further evidence for such a bias and for underinvestment in obesity care was reported by the recent UK All Party Parliamentary Group on Obesity, who found, following a freedom of information request, that only 52% of local authorities commission Tier 1 services and 82% Tier 2, while 57% of NHS clinical commissioning groups commission Tier 3 services [27].

Recommendations for care pathways for those with severe obesity requiring Tier 3 and 4 services are better developed. Using a National Institute of Health Care Excellence (NICE)-accredited process, a Guidance Development Group representing and endorsed by a wide range of professional stakeholders met to establish the evidence base for best practice in Tier 2 or Tier 3 weight management services, including all interventions provided as a precursor to Tier 4, bariatric surgery. It also issued guidance for the structure and working of weight assessment and management clinics (WAMC) to provide specialist support for primary care physicians in the management of complex patients, including a pathway into bariatric surgery for suitable patients [28].

The resulting report recognized that the guidance was aspirational, and that although the final consensus was tailored to the English NHS, the basic principles should be applicable to every healthcare setting. A key element of the report was recognition that, since the facilities and resources for obesity treatment (especially specialist Tiers 3 and 4) were so poorly developed, capacity building would be required to develop such clinics. The potential overlap with diabetes clinics and sleep medicine clinics meant that some of the infrastructure necessary for WAMCs already existed and potentially could be 're-labelled'. Depending on the availability of bariatric surgical units and the preference of commissioners, WAMCs could be located either in primary or secondary care and work as a hub and spoke arrangement with the surgery service. If colocated, the whole team would in effect work together as one clinic with local arrangements for patient flow through the system for non-surgical and surgical patients (Figure 14.1.8.4). A regional WAMC would also work as a hub and spoke with different referring practices. The report also highlighted the need for hospitals to have a designated 'obesity champion' (along the lines, for example, of a lead clinician for malnutrition) as had first been proposed in a report from the Royal College of Physicians [29].

A subsequent paper updated the evidence base and expanded recommendations to include more detailed guidance on commissioning care pathways for weight assessment and management in adults and children with severe obesity [30]. It represented the views of 22 organizations including nine royal colleges, with the intention of providing a template for developing obesity services within primary and secondary care, for staffing infrastructure, and for referral practices.

Examples of Obesity Care Pathways

There are several examples in England of excellence in the development and provision of obesity care pathways within primary care. These include the Aintree LOSS scheme [31], Rotherham Institute for Obesity (RIO) services [22] and obesity services in Fakenham [32].

Aintree LOSS

Aintree LOSS is a community-based, Tier 3, multidisciplinary weight management programme for patients living in Liverpool with severe and complex obesity (a body mass index >40 kg/m² or >35 kg/m² with one or more comorbidities), focusing on a flexible and individualized service with follow-up for up to 2 years. The team initially consisted of general practitioners, a physician with a special interest in obesity, dieticians, and physiotherapists but was

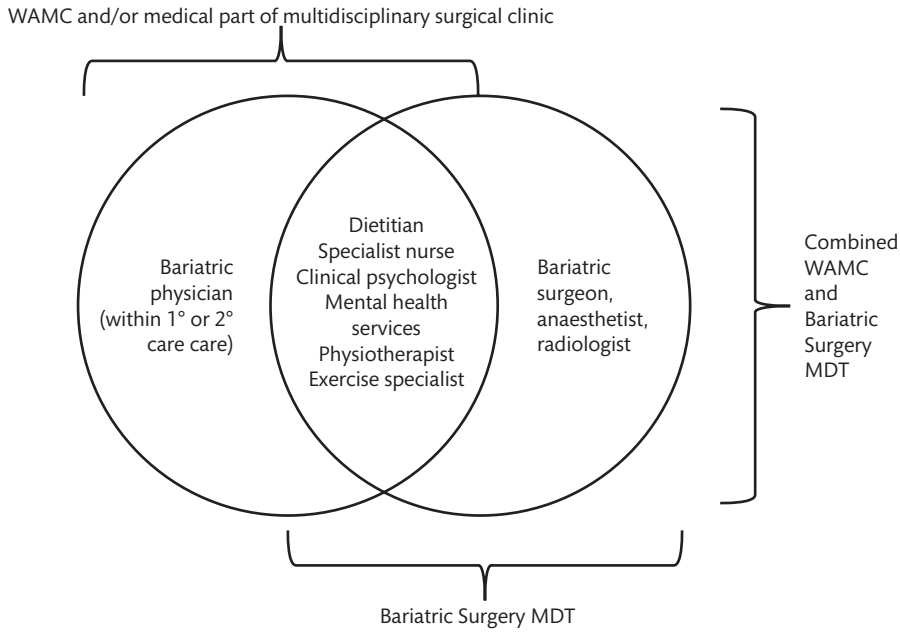

Figure 14.1.8.4 The role of the multidisciplinary team in weight management assessment clinics. MDT, multidisciplinary team; WAMC, weight management assessment clinic.

Copyright © 2016, Springer [28].

later expanded to include psychologists and occupational therapists. Interventions are delivered at locations across Liverpool, including a hospital clinic, general practice surgeries, community centres, and a sports centre. Following referral, the patient is contacted by telephone and booked to their preferred site. Initial assessment conducted by a GP with a special interest in obesity includes full medical history, examination, and blood tests. A personalized management plan is agreed upon from a pick list of dietetics, physiotherapy, and occupational therapy as well as group sessions (joint physiotherapy and dietetics and hydrotherapy). Individual reviews take place every 1–3 months depending on the intensity of intervention required. Contact with leisure services via swimming and aquafit session referral is also included. In appropriate cases, bariatric education is provided in a group setting, and there are monthly multidisciplinary team meetings to assess suitability for bariatric surgery onward referral. Evaluation of 2472 patients referred to the service between October 2009 and 2013 found a mean body mass index of 45.6 kg/m² at baseline with most patients coming from areas in the most deprived decile nationally. Of 2315 appropriate referrals, 1249 (55.1%) attended >2 visits; mean final weight loss was 3.50 ± 8.55 kg, and 24.1% achieved ≥5% weight loss. Of patients attending, 754 (33.3%) attended for over 6 months; mean final weight loss was 4.94 ± 10 kg, and 34% achieved 5% weight loss [31].

Rotherham Institute for Obesity

In 2008 NHS Rotherham agreed to make £3.5m available to fund their NHS obesity strategy, based upon the four-tier model, for a 3-year pilot period. Reshape Rotherham provided Tier 2 service for adults between 2009 and 2014 overseen by the local dietetics department, while for children this was delivered by Places for People leisure. Patients could self-refer to these services or be referred by an appropriate healthcare professional after an assessment of motivation. For those who did not meet their healthy weight targets, or for those considered to be more at risk of the cardiometabolic consequences associated with obesity, referral was into Tier 3 specialist services delivered by the Rotherham Institute for Obesity (RIO). After 2014 the integrated framework of services was referred to as Weigh Up Rotherham, and it had a single point of access. Although there are no peer-reviewed published outcome data, RIO has been regarded as a model care pathway [33], reporting a full analysis of data for 2010 and 2011 of 49% of 3325 referrals completing the 6-month intervention. 72% achieved a ≥5% and 18.6% a ≥10% weight loss. Despite this, in 2017 funding for the service was withdrawn.

Fakenham

In Fakenham, a rural area in the east of England, a Tier 3 service aimed to deliver evidence-based interventions including medical assessment, motivational interviewing to support behaviour change, dietary and activity advice, psychological therapies, drug therapy with orlistat, medically supervised meal replacement diets and assessment for suitability for bariatric surgery using the NHS East of England criteria (aged 18–60 years, BMI ≥40 kg/m², with either diabetes or severe obstructive sleep apnoea, and having undergone a 6-month intensive weight-loss programme). The service aimed to facilitate weight loss by implementing progressive and sustainable lifestyle changes, based on individually agreed goals over a 1-year programme. This was delivered by individual monthly appointments with obesity specialist nurses. Participants were considered for pharmacotherapy, low energy liquid diets, or bariatric surgery if clinically appropriate. Psychological therapies offered included cognitive behaviour therapy, neurolinguistic programming, emotional freedom therapy, clinical hypnosis, solution focused therapy, transactional analysis, psychodynamic therapy, and cognitive analytical therapy (Figure 14.1.8.5) [32]. An evaluation of the service

using the National Observatory Standard Evaluation Framework [34, 35] followed a cohort of 230 patients (out of 367 referrals) sequentially enrolled over a 1-year period from August 2011. Of these, 213 entered a 1-year programme, and 17 a more intensive 6-month programme; two-thirds had a BMI above 40 kg/m². The service identified additional pathology in 48 patients: hypothyroidism, hypercholesterolaemia, abnormal liver function, diabetes mellitus, obstructive sleep apnoea, and hypertension. More than half completed their programmes and attended at 1 year. In these 117 'completers', weight losses >5% were 34.2, 53.8, 65.8, and 72.6% at 3, 6, 9, and 12 months. The mean percentage weight loss at 1 year was −6.4% (SD 6.1) in those with weights recorded, and −8% (SD 6.0) in 'completers'. There were significant improvements in quality of life measures.

Conclusions

The generic process for developing and managing care pathways is well established, but has been poorly developed for comprehensive care of people with obesity. National guidelines and systematic literature reviews have been generated and, in some cases (particularly for more severe obesity) translated into advice for commissioning integrated pathways of care, but these have hardly been implemented. This may reflect prejudice of healthcare providers against obesity as a disease worth treating, underestimation of the clinical and economic benefits of effective obesity care, or the complexities of designing pathways for its management.

14.2

Lipoprotein Metabolism and Dyslipidaemia

14.2.1 Lipoprotein Metabolism

Bo Angelin and Paolo Parini

Introduction

Lipids are a heterogeneous group of substances with a myriad of structural and regulatory functions. Phospholipids and cholesterol are essential components of cell membranes, and cholesterol is also the precursor of steroid hormones, bile acids, and, in the skin, of vitamin D. Some fatty acids serve as precursors of bioactive compounds such as prostaglandins, thromboxanes, and leukotrienes; several lipids may also serve as signalling molecules in their own right. Furthermore, lipid complexes are necessary for the transport of lipid-soluble vitamins, and may have a protective role in the defence against toxins and infectious agents. From an overall perspective, however, the bulk function of plasma lipid metabolism relates to exchange of fats as energy substrates.

Plasma Lipids and Energy Transport

Fat as triglyceride is the major form of energy storage in the body [1]: about 12–15 kg of triglycerides (corresponding to ~500 000 kJ) are stored as an energy depot in the adipose tissue. Fat supplies 60–70% of cellular energy consumption, with a considerable portion of that formed through *de novo* synthesis from carbohydrate (lipogenesis) in the liver. Plasma lipids such as triglycerides and non-esterified fatty acids (NEFA) are quantitatively the most important system of energy exchange among organs (**Figure 14.2.1.1**). Each day, 6000–9000 kJ are transported in the circulation in triglycerides, and almost the same amount in NEFA. The transport of lipids is regulated very efficiently, and integrated with carbohydrate metabolism. Through the hormonal and metabolic control of enzymes (lipases) catalysing the uptake of fat in various organs and the mobilization of fat from adipose depots, energy from fat can be distributed and channelled in response to rapidly fluctuating demands. Although many hormones influence the activity of these enzymes, the predominant regulation is through insulin and catecholamines.

The inflow of dietary lipids into the circulation as chylomicron triglycerides corresponds to about 100 g/day. Another 20–50 g is secreted in very low-density lipoprotein (VLDL) triglycerides by the liver. The plasma pool of triglycerides is small, but since the elimination process normally is far from saturated, large amounts of triglycerides can be assimilated without more than a twofold to threefold rise in plasma concentration after a fat-rich meal.

Triglycerides routed to metabolically active tissues, such as skeletal muscle and heart, are rapidly utilized for oxidation. In the adipose tissue, fatty acids and monoglycerides are re-esterified to triglycerides for storage, and later mobilized rapidly on demand by lipases including hormone-sensitive lipase. The fractional uptake of free fatty acids from the circulation is relatively constant, so that the distribution to different tissues mainly follows that of blood flow. Roughly, one-third of NEFA is taken up by the liver and one-third by muscular tissue. The energy reaching the liver in this way exceeds demand, and a major fraction of fatty acids is re-esterified, returning to the circulation in VLDL triglycerides. Thus, NEFA and VLDL contribute to an energy cycle mainly between adipose tissue and the liver (**Figure 14.2.1.1**).

After food intake, when plasma concentration of insulin is high and those of catecholamines low to normal, lipoprotein lipase activity in adipose tissue is high at the same time as fatty acid mobilization is reduced. Thus, lipids are channelled to adipose tissue storage. Any surplus of carbohydrate energy can be utilized in

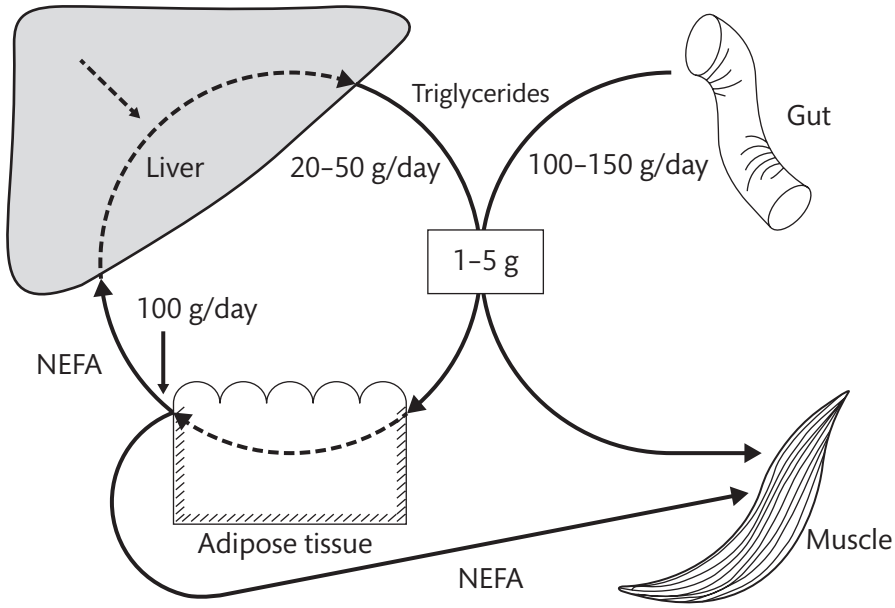

Figure 14.2.1.1 Schematic representation of the exchange of lipids between different organs.

hepatic *de novo* lipogenesis (DNL) which through VLDL transport can be redistributed to adipose tissue.

In response to starvation or stress, with low insulin and increased catecholamine levels, the lipid flux is redistributed to ensure appropriate energy delivery to metabolically active tissues, particularly heart and skeletal muscle. Lipoprotein lipase in adipose tissue is reduced, whereas it is increased in heart and muscle. Simultaneously, NEFA are mobilised from the adipose tissue, and the amount taken up by the liver can be recirculated in VLDL triglycerides. At a very high inflow of NEFA to the liver, as occurs after prolonged fasting, the surplus will be converted into ketone bodies that can be preferentially utilized in cellular metabolism.

Plasma Lipoproteins and Apolipoproteins

The requirement for transport of lipids in plasma poses a basic biophysical challenge arising from the insolubility of most lipids in water: virtually all plasma lipids thus have to be solubilized by association with specific proteins. NEFA are bound to albumin with a molar ration of 2:1, while more complex lipids are transported in hydrophilic lipoproteins [2]. These are spherical emulsion particles, in which unipolar lipids—mainly triglycerides and cholesteryl esters—are covered by a polar phospholipid membrane harbouring free cholesterol and proteins called apolipoproteins. These apolipoproteins maintain the structure of the lipoproteins, and may also serve as ligands for specific receptors or as enzyme activators. Triglycerides, cholesteryl esters, free cholesterol, and phospholipids are the main lipids present in lipoproteins, which also carries many other water-insoluble endogenous or exogenous substances.

Lipoproteins are generally classified on the basis of their hydrate density [3] or electrophoretic mobility (Table 14.2.1.1). Such classifications are obviously operational, and it is important to recognize that lipoproteins represent populations of constantly interchanging particles. Differences in density is commonly used to separate lipoproteins by ultracentrifugation. The density of lipoprotein particles is inversely related to their size, reflecting the relative amount of non-polar low-density core lipid and high-density surface protein. The two largest classes of lipoproteins thus contain mainly triglycerides: the chylomicrons (containing apoB-48) which are secreted from the intestine, and the VLDL (containing apoB-100) which are secreted from the liver. The smaller lipoprotein classes, intermediate density lipoproteins (IDL), low-density lipoproteins (LDL) and high-density lipoproteins (HDL_2 and HDL_3), mainly have cholesteryl esters in their cores, and represent products formed during the processing of the triglyceride-rich chylomicrons and VLDL. High-density lipoprotein (HDL) can also be produced by the liver and small intestine, and in their nascent form can be

Table 14.2.1.1 Normally occurring human plasma lipoproteins

Lipo-protein	Density (g/mL)	Electro-phoretic mobility	Diameter (nm)	Particle composition (weight %)				Major apolipo-proteins
				Trigly-ceride	Chole-sterol	Phos-pholipid	Protein	
Chylo-micron	0.93	Origin	80–1200	85–95	2–5	3–8	1–2	B-48, A-I, A-II, A-IV, (C, E)
VLDL IDL LDL	0.93–1.006 1.006–1.019 1.019–1.063	Pre-β β β	30–80 23–35 18–25	50 20 11	22 38 47	19 23 22	8 19 21	B-100, A-I, C, E B-100, C, E B-100
HDL_2 HDL_3	1.063–1.125 1.125–1.21	α α	9–12 5–9	6 6	22 15	30 23	41 55	A-I, A-II, C, E A-I, A-II, C, E

seen as bilayered discs on electron microscopy. The hydrolysis of triglyceride-rich lipoproteins also contributes to the formation of mature HDL particles in circulation. Lipoprotein(a) [Lp(a)] is larger but denser than LDL and exhibits slow pre-β mobility on electrophoresis. Essentially, Lp(a) consists of an LDL particle with apo(a) bound to the apoB-100 molecule.

A large number of apolipoproteins have been identified (Table 14.2.1.2). Several of the smaller ones (apoAs, apoCs, and apoE) belong to the same gene family [4]. They contain characteristic α-helical structures, which give them detergent-like properties. Like free cholesterol, these molecules can readily exchange between lipoprotein particles and with other lipid surfaces, whereas phospholipids and non-polar core lipids require specific transfer proteins for exchange. ApoB exists in two forms: apoB-100 is found mainly in VLDLs and LDLs, whereas apoB-48 is found only in chylomicrons [5]. Apo B-48 represents the amino-terminal half (48%) of apo B-100, and the synthesis of both proteins emerges from one gene. In the intestine, but not in the liver, a stop codon is introduced into the mRNA after transcription of the apo B gene (posttranscriptional editing), resulting in the formation of the truncated apo B-48 protein [6]. Thus, in humans—but not in rodents—triglyceride-rich lipoproteins containing apo B-48 and apo B-100 can be identified as being of intestinal and hepatic origin, respectively. Apo B-100, but not apo B-48, contains the ligand-binding site for the LDL receptor. Despite this the half-life in circulation of the apo B-48 containing particles is much shorter than that of the apo B-100 containing particles because the former can load a higher amount of apoE on their surface. Apo E is a strong ligand for the LDL receptor, which is also known as the apoB/apo E receptor, and for other receptors.

Table 14.2.1.2 Human apolipoproteins

Apolipoprotein	Molecular weight (kDa)*	Function/related to	Chromosome location
A-I	29	LCAT cofactor	11
A-II	9		1

M	25	HDL metabolism	6
Apo (a)	280–800		6

* From amino acid composition.
** Same gene, posttranscriptional editing of mRNA.

The genes of all the common apolipoproteins have been cloned, and there is evidence of a considerable number of genetic polymorphisms, some of which may result in altered functional properties of the protein. One important example is genetic variation at the apoE locus, where the presence of three variant alleles results in six major phenotypes of the apoE protein (E2/2, E2/3, E2/4, E3/3, E3/4, and E4/4). ApoE2 has lower binding affinity to the lipoprotein receptors, and individuals carrying this isoform have a slower clearance of chylomicron and VLDL remnants.

Apo (a) differs from the other apolipoproteins: it has a plasminogen-like structure, with a variable number of so-called kringle IV repeats [7]. Apo (a) is linked to apo B-100 by a disulphide bond, changing the properties of the LDL particle. There is a pronounced, genetically determined size variation based on the number of repeats, and there is an inverse correlation between plasma level and apo (a) isoform size. How elevated Lp(a) levels contribute to an increased risk for cardiovascular disease is still not understood, but mechanisms related to decreased plasmin formation as well as increased endothelial cell permeability and inflammation or oxidation have been discussed [7].

During their metabolism, lipoproteins may be modified by a number of mechanisms. Among those are oxidation, glycation, carbamoylation, and enzymatic degradation [8]. Such changes may occur in the circulation, but they are probably of particular importance when lipoproteins become retained within the subintimal layer of the vessel wall [9, 10]. Such modifications, most notably mild oxidation, stimulate the uptake of lipoproteins in tissue macrophages by so-called scavenger receptors leading to an uncontrolled expansion of cellular cholesteryl ester content. The result is the formation of foam cells, initiating the development of early atherosclerotic plaques. Changes in the lipid composition, particularly triglyceride enrichment of LDL, make the lipoprotein particles more susceptible to oxidation which may explain the increased propensity of atherosclerosis in conditions such as diabetes, insulin resistance, and obesity. Modified lipoproteins and crystals of cholesterol precipitated in the atherogenic plaque activates the inflammasome in macrophages and initiates inflammatory responses, which in turn accelerate atherogenesis [11].

Lipoprotein Receptors

The delivery of lipoprotein lipids to various tissues in the body is regulated by specific receptors and enzymes that interact with the individual apolipoproteins. The *LDL receptor* is a cell surface receptor present on all cells, capable of binding and internalizing lipoproteins containing apo B-100 or apo E [12]. It belongs to a gene family containing ligand-binding 40-amino acid cysteine-rich repeats, growth factor repeats, and spacer sequences that show homology with the epidermal growth factor precursor. The LDL receptor is synthesized in the endoplasmic reticulum and transported to the Golgi apparatus for glycosylation. After transport to the cell surface, the receptors cluster in specific regions rich in clathrin, the so-called coated pits. In these receptor-enriched regions, internalization of the LDL receptor (with or without bound LDL) takes place continuously through endocytosis. Whereas LDL is degraded in the lysosomal compartment, the receptors are recycled to the cell surface several times. The

expression of the LDL receptor is closely entrained to cellular demand for cholesterol.

Among other members of this gene family are the **LDL receptor-related proteins (LRPs)**, the **VLDL receptors**, and **megalin** [13]. LRP-1 is a large structure that is mainly expressed in the liver and seems to be involved in the binding and uptake of chylomicron remnants through apoE, but it can also bind several non-lipoprotein ligands. A number of *scavenger receptors* with a wide spectrum of ligand-binding properties are expressed on macrophages, and some of these are probably involved in the uptake of atherogenic lipoproteins to form foam cells in the arterial wall. *Scavenger receptor type B class 1 (SCARB1)* is a receptor highly expressed in the liver and adrenal, and seems to be involved in reverse cholesterol transport [14].

Enzymes and Transfer Proteins

Three enzymes have a major role in plasma lipoprotein lipid transport: lipoprotein lipase, hepatic lipase, and lecithin:cholesterol acyl transferase. The first two belong to a large gene family also including pancreatic lipase [15]. Cholesteryl ester transfer protein and phospholipid transfer protein are required to promote the exchange of core lipids between lipoprotein particles during their metabolism in plasma [16].

Lipoprotein lipase (LPL) is synthesized in the endoplasmic reticulum (ER) of adipocytes and muscle cells. In the ER of these cells a chaperone protein called lipase maturation factor 1 (LMF1) is responsible for LPL assembly and folding. Another protein called GPIHBP1 (GPI-anchored endothelial cell protein) binds LPL in the interstitial space and shuttles it across endothelial cells to its site of action in the capillary lumen [17] where it is tethered to the luminal surface of the capillary endothelium via heparan sulphate proteoglycans [15]. This enzyme, which is active as a dimer, hydrolyses triglyceride in the lipoprotein core, converting it into fatty acids and monoglycerides. APOC2 and APOA5 are cofactors for the enzymatic reaction [18]. The activity of LPL is regulated by nutritional demand via hormonal control. Enzyme activity is increased in adipose tissue during carbohydrate feeding and reduced during fasting; the regulation is reverse in skeletal muscle and heart. Loss of function mutations of all these genes (LPL, LMF1, GPIHBP1, APOA5, and APOC2) cause a rare monogenic dyslipidaemia characterized by very high levels of circulating triglyceride (see Chapter 14.2.2).

Hepatic lipase is synthesized in hepatocytes, secreted and bound to proteoglycans on the capillary endothelium of the liver. It is also present on endothelial cells in the adrenals and gonads. This enzyme has a broad activity and is believed to be involved in the metabolism of HDL and IDL [19]. Thus, by hydrolysing triglycerides and phospholipids in HDL_2, hepatic lipase is thought to promote its conversion to HDL_3. The enzyme activity is stimulated by thyroid hormone, insulin, and androgens, and decreased by oestrogen and glucocorticoids.

Lecithin: cholesterol acyl transferase (LCAT) is synthesized in the liver [20]. It binds to HDL, and catalyses the conversion of lecithin and free cholesterol to lysolecithin and cholesteryl esters; apo A-I and also apo A-IV act as cofactors for the enzyme. Through the action of LCAT, free cholesterol on the surface of nascent HDL is converted to more lipophilic esters, leading to expansion of the HDL particle.

Cholesteryl ester transfer protein (CETP) is predominantly synthesized in the liver and intestine, but also in adipocytes and the spleen [16]. It mediates transfer of cholesteryl esters from HDL and LDL to VLDL and chylomicrons, and the reciprocal exchange of triglycerides.

Phospholipid transfer protein (PLTP) is a member of the same gene family as CETP [16]. It mediates the transfer of phospholipids from triglyceride-rich lipoproteins to nascent HDL during lipoprotein lipase-mediated lipolysis.

Lipoprotein Metabolism

Lipoproteins serve three main functions: (1) transport of exogenous dietary lipids from the gut to peripheral tissues and the liver, carried out by chylomicrons and their remnant particles; (2) transport of endogenous lipids (triglyceride and cholesterol) from the liver to peripheral tissues, by the VLDL-IDL-LDL-pathway; and (3) reverse cholesterol transport from peripheral tissues to the liver, where HDL plays a central role (Figure 14.2.1.2). Apo B-100 and apo B-48 thus

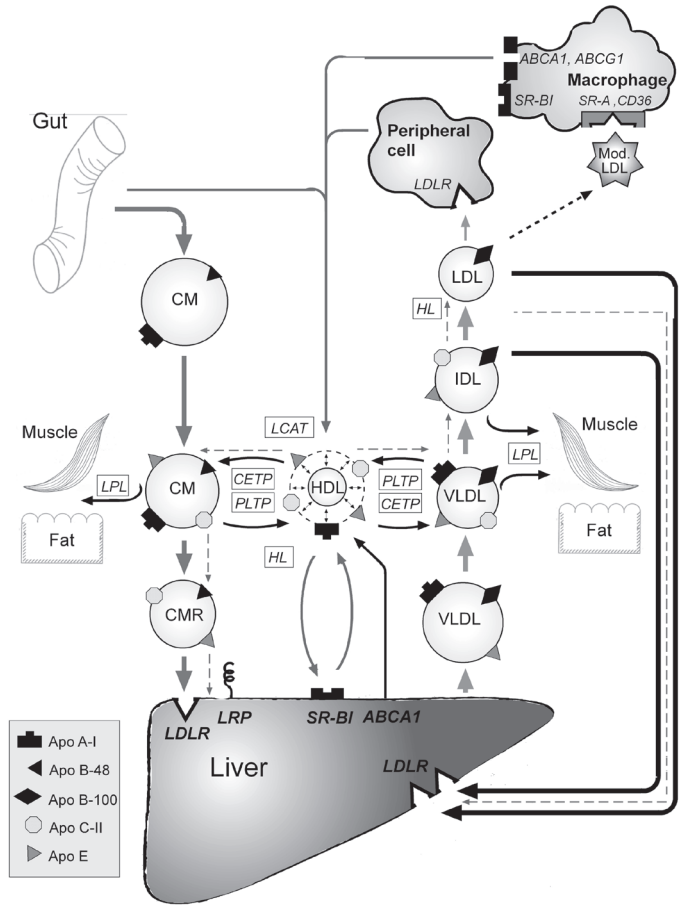

Figure 14.2.1.2 Simplified scheme of normal lipoprotein metabolism in humans. CM, chylomicrons; CMR, chylomicron remnants; VLDL, very low-density lipoprotein; IDL intermediate density lipoprotein; LDL, low-density lipoprotein; HDL, high-density lipoprotein; LPL, lipoprotein lipase; HL, hepatic lipase; CETP, cholesteryl ester transfer protein; PLTP, phospholipid transfer protein; LCAT, lecitin:cholesterol acyl transferase; ABC-1, ATP-binding cassette transporter 1; LDLR, LDL receptor; LRP, LDL receptor-related protein; SR-B1; scavenger receptor class B type 1; SR-A, scavenger receptor class A.

constitute the transport chains for chylomicron–chylomicron remnants (exogenous) and VLDL-IDL-LDL (endogenous), respectively, whereas apo A-I is closely related to reverse cholesterol transport.

Exogenous Lipid Transport

Ingested triglycerides (100–150 g/day) are hydrolysed by pancreatic lipase and almost completely absorbed in the upper small intestine [21, 22]. The solubilizing actions of biliary bile acids are vital in this process. Cholesterol of both biliary (600–800 mg/day) and dietary (300–400 mg/day) origin is absorbed to a much lesser degree (30–50%). Due to the presence of active influx via the Niemann-Pick C1-like 1 protein (NPC1L1) and active efflux promoted by the ATP-binding cassette transporters G5 and G8 (ABCG5/G8), enterocytes absorb unesterified cholesterol at a faster net rate than plant sterols. Intracellular fatty acid binding proteins facilitate fatty acid uptake in the enterocytes. After re-esterification, triglycerides are incorporated into the very large chylomicrons together with esterified cholesterol produced by the enzyme acyl CoA: cholesterol acyl transferase-2 (ACAT-2), encoded by the sterol O-acyltransferase 2 (*SOAT2*) gene; this core is surrounded by a monolayer of phospholipids, free cholesterol, and APOB48. APOB48 is partially lipidated during its translocation across the membrane of the ER, whereafter it fuses with the bulk of lipids. The fully lipidated particles are transported to the Golgi apparatus, whence they are transported to the basolateral plasma membrane and secreted into the extracellular space. Chylomicrons pass into the intestinal lacteals and enter the circulation via the thoracic duct. In addition to apo B-48, nascent chylomicrons contain apo A-I, A-II, and A-IV that have been synthesized in the enterocytes. Upon exchange with HDL in lymph and blood, chylomicrons rapidly acquire apo Cs and apo E.

In the circulation, chylomicrons are trapped on the capillary walls of adipose tissue and muscle, probably involving a complex interaction between the lipoprotein, lipoprotein lipase, and endothelial proteoglycans. Apo C-II is an obligate activator of lipoprotein lipase that attacks the triglyceride core of the chylomicron, resulting in intravascular hydrolysis of triglycerides liberating NEFA and glycerol. Most of the NEFA are taken up by adipose or muscular tissue, but some are also transported with albumin to the liver and fuelling the increased VLDL secretion that occurs in later phases of the postprandial period [23]. In the peripheral tissues, NEFA are either re-esterified to depot triglyceride or oxidized for energy production. The whole process of lipolysis is very efficient and only takes about 10–15 minutes in normal individuals.

The excess surface lipids and apolipoproteins resulting from lipase-induced reduction of the chylomicron core volume are transferred to HDL. APOB48, together with APOE, remains on a much smaller particle containing esterified cholesterol and small amounts of triglyceride in its core. The liver rapidly clears this **chylomicron remnant** via APOE-recognizing receptors on the surface of the hepatocytes [24]. Chylomicron remnants bind with high affinity to the LDL receptor in the liver, but there is ample evidence that other lipoprotein receptors including LRP-1, and surface heparan sulphate proteoglycans are also involved in the hepatic uptake. Normally, remnants have a very short half-life, which is why such particles are normally absent in plasma from fasting individuals, except those carrying the APOE2 phenotype. After endocytosis, released fatty acids and cholesterol can be used in VLDL assembly, or can be stored as triglycerides and cholesteryl esters. Cholesterol can also be excreted into the bile as free cholesterol or after conversion to bile acids.

Endogenous Lipoprotein Transport

VLDLs are similar to chylomicrons in structure and composition, but are much smaller and contain relatively less triglyceride (Table 14.2.1.1). The assembly of VLDL in the liver is essentially analogous to that of chylomicrons in the intestine. Each VLDL particle contains a single molecule of apo B-100 which is synthesized on ribosomes attached to the ER and lipidated cotranslationally. Increases of triglyceride secretion in VLDL determines increases in particle volume. Hormones such as oestrogens and growth hormone, and nutrients such as alcohol and excess carbohydrate stimulate VLDL triglyceride synthesis, whereas insulin retards secretion of VLDL. Fully lipidated VLDL are transported to the Golgi, where glycosylation occurs before trafficking and release into the space of Disse. Nascent VLDLs contain some apo A-I, apo A-II, apo E and apo Cs, and their exchange with HDL probably occurs very rapidly when in plasma. While VLDLs of varying size are released from the liver, it is still not clear whether LDL-like particles may be secreted directly.

In the circulation, VLDLs are subject to lipolysis by lipoprotein lipase, and in the postprandial state there is competition between VLDLs and chylomicrons for the lipoprotein lipase. The estimated half-life of VLDLs is considerably longer than that of chylomicrons, 1–2 hours. A major difference from the exogenous pathway is that the resulting VLDL 'remnants', referred to as IDLs, can have alternative fates. More than half, presumably those enriched in APOE(24), undergo rapid endocytosis in the liver, whereas the remaining fraction is metabolized further via hepatic lipase and transfer of lipids and apolipoproteins to HDL. The final products of this processing of circulating IDL are mature LDLs, only carrying the apo B-100 protein. The continued presence of apo C-III on IDL particles inhibits a rapid removal by the LDL receptor and leads to the formation of denser LDL particles that are very poor in triglycerides, also known as small-dense LDL [25]. Recently, the composition of LDL in respect to their phospholipid content (phosphocholine vs. sphingomyelin) and in respect of their lipid core content (triglycerides vs. esterified cholesterol) determines the susceptibility of these particles to aggregate to each other, a process that promote their atherogenic potential [26].

The half-life of LDL is 2–3 days in normal humans, which explains why the number of LDL particles is much larger than that of VLDLs. Their prolonged residence in the circulation also explains why these particles may be the major site of modification (e.g. oxidation, glycation, and carbamylation). Although passive uptake of LDL (proportional to plasma concentration) takes place in all tissues, the predominant route for elimination of LDL is endocytosis by the LDL receptor in the liver [27].

While all cells contain the enzymatic machinery to synthesize cholesterol from acetate, receptor-mediated endocytosis of LDL appears to be the preferred pathway for acquiring the cholesterol necessary for maintaining cellular homeostasis in peripheral cells. By uptake of LDLs, the cells are also supplied with tocopherols, which are present in these lipoproteins. The number of LDL receptors is increased during cell division and under other circumstances when the demand for cholesterol is increased. High numbers of LDL receptors are expressed on steroidogenic cells, and also in some

tumour cells [27]. The absolute mass of LDL receptor is greatest in the liver, and at least 50% of LDL catabolism occurs in this organ [27]. The great importance of the expression of LDL receptors in normal lipoprotein metabolism is evident from the phenotype observed in patients with familial hypercholesterolemia, where the LDL receptor is functionally deficient.

Each cell has the capacity to regulate its cholesterol balance by sensing its cellular membrane cholesterol level [28]. This influences the activity of transcription factors which are bind sterol responsive elements (SREs) in the promoter regions of the LDL receptor gene. Such SREs are also present in the genes coding for two major enzymes regulating cellular cholesterol synthesis, 3-hydroxy-3-methylglutaryl (HMG) CoA reductase and HMG Co A synthase, and of the posttranscriptional modulator of the LDL receptor, proprotein convertase subtilisin/kexin type 9 (PCSK9). The transcription factors, the so-called SRE-binding proteins (SREBPs), and are normally attached to the cellular membrane, but undergo controlled proteolytic cleavage by specific enzymes which are activated when sterols are depleted from the membrane. The resulting SREBP fragment then migrates into the nucleus and activates gene transcription of the LDL receptor, cholesterol-synthesizing enzymes, and PCSK9. In addition, the enzymatic activity of HMG-CoA reductase is regulated by sterol-induced degradation of the enzyme. PCSK9 acts by increasing the degradation of the LDL receptor during its cell cycle (Figure 14.2.1.3), adding to the complexity of the regulation of cellular cholesterol uptake [29]. Of particular interest, genetic variation in PCSK9 expression is important for variation in LDL cholesterol levels and incidence of coronary heart disease [30]. Emerging evidence suggests moreover that several hormones influence hepatic LDL receptor number through modulation of PCSK9. LDL receptor cycling is also influenced by cellular proteins including LDLRAPs and IDOL, in which genetic variants may also be important.

HDL Metabolism and Reverse Cholesterol Transport

HDL denotes a heterogeneous, metabolically active lipoprotein fraction, in which the particles are continuously remodelled, changing their composition accordingly [16]. The two major classes of HDL, HDL_2, and HDL_3, differ in their density and their protein content (Table 14.2.1.1). By serving as an apolipoprotein reservoir which provides enzyme cofactors and lipid transfer factors, HDL may stimulate both the exogenous and endogenous lipid transport pathways (Figure 14.2.1.2).

Apo A-I is the common structural element of HDL particles. There are HDL particles that contain both apo A-I and apo A-II, and particles with only apo A-I. Whereas apo A-I is synthesized both in the intestine and the liver, apo A-II is made exclusively in the liver. A major part of the apolipoproteins and phospholipids that eventually contribute to plasma HDL originates from chylomicrons and VLDL secreted into the circulation. The transmembrane transporter ABCA1 secretes phospholipids and free cholesterol to poorly lipidated apo A-I to form a nascent HDL (pre β1-HDL) (Figure 14.2.1.4). The liver seems to contribute more than the intestine to this process [31]. The various lipid and protein components of HDL have different pathways of metabolism, resulting in considerably differing turnover rates. The catabolic half-life of plasma apo A-I and apo A-II in normal humans averages 4–5 days; cholesteryl esters may turn over 10–40 times more rapidly.

Overall, there is a cycle of enlargement of HDL from influx of lipids, apolipoproteins, and LCAT activity, followed by cholesterol

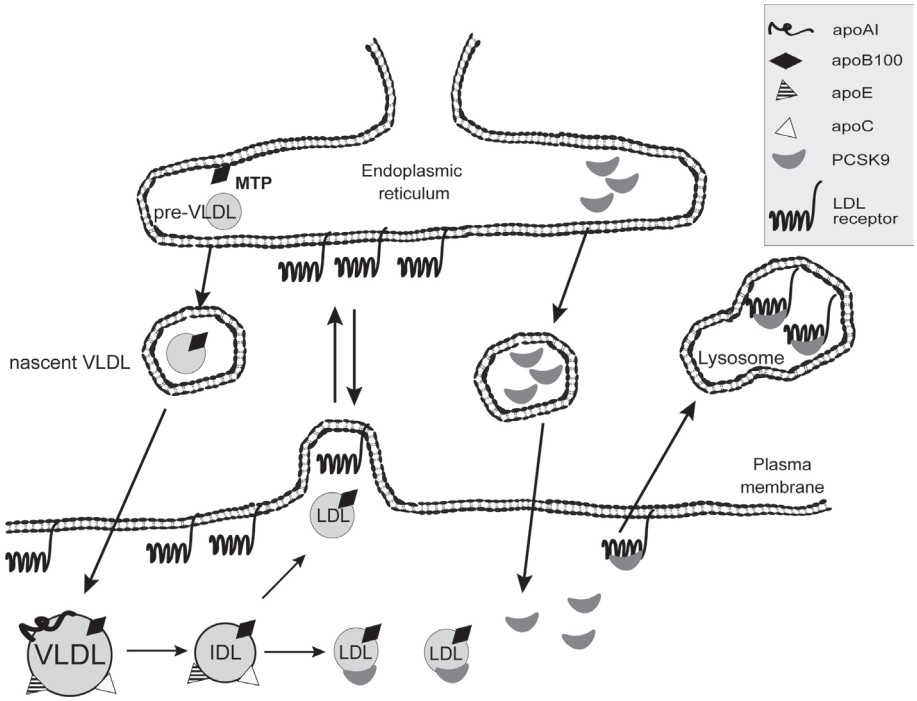

Figure 14.2.1.3 Secretion of VLDL and interaction between PCSK9 and LDL receptor. PCSK9 is transported from endoplasmic reticulum to cell surface via COP II (coat protein complex II) vesicles. Circulating PCSK9 prevents the normal recirculation of LDL receptors to the cell surface reducing their numbers at cell.

ester—triglyceride exchange and then shrinkage of HDL and loss of lipid and protein following hepatic lipase activity [16]. The cholesterol esters formed in HDLs following LCAT action can be transferred to triglyceride-rich lipoproteins by CETP, they may be transferred to cells by selective uptake without degradation of the HDL particle, and they may be catabolized with intact HDL.

HDL is currently believed to be active in the removal of cholesterol from peripheral tissues, promoting transport of cholesterol to the liver, the only organ that excretes significant amounts of cholesterol from the body. Cellular cholesterol removal occurs by several mechanisms, relying upon different HDL subclasses that play specific roles in distinct mechanisms, namely (a) aqueous diffusion (which involves unknown transporters) to mature HDL; (b) SR-BI-mediated efflux to mature HDL; (c) ABCG1-mediated efflux to mature HDL and preβ-HDL; and (d) ABCA1-mediated efflux to apoAI, preβ-HDL and small HDL particles [32–35] (Figure 14.2.1.4).

In humans ABCA1 is of major importance, as evident from the lack of HDL in patients with homozygous ABCA1 deficiency (Tangier disease). HDL can transport cholesterol directly to the liver, probably by the interaction of apo A-I with SCARB1, the human homologue of SR-BI [25], but also via exchange of core triglycerides in the triglyceride-rich lipoproteins for core cholesterol esters in HDL. By such mechanisms, cholesterol elimination from peripheral tissues may occur also utilizing the exogenous and endogenous pathways (Figures 14.2.1.2 and 14.2.1.4).

Cholesterol Elimination

The liver has a central role in maintaining body cholesterol homeostasis [36, 37]. Several pathways may deliver cholesterol to this organ, as discussed (Figure 14.2.1.5): chylomicron remnants, IDL and LDL, and via HDL. In addition, cholesterol can be synthesized de novo in the liver, a process under tight transcriptional and posttranscriptional feedback control. Hepatic cholesterol may be stored as cholesterol esters, incorporated in secreted VLDLs, or excreted in the bile, either directly or after conversion to bile acids.

Cholesterol esterification is catalysed by the microsomal enzyme ACAT. In humans, two genes exist, *SOAT1* and *SOAT2,* encoding two different enzymes: ACAT1 and ACAT2, respectively. While ACAT1 is present in most tissues, ACAT2 appears to be specific to hepatocytes and enterocytes, and has been proposed to be the enzyme responsible for synthesizing cholesterol esters destined for VLDL secretion [38].

While minor amounts of cholesterol are converted into steroid hormones (50 mg/day) or lost through skin exfoliation (80 mg/day), faecal excretion is the major pathway for net excretion of cholesterol from the body. This process takes place either by direct secretion of free cholesterol in the bile, or by conversion of cholesterol to bile acids (Figure 14.2.1.5). Bile acids additionally promote hepatic secretion of cholesterol by stimulation of bile flow. Simultaneously, bile acids also contribute to cholesterol input by facilitating cholesterol absorption in the small intestine. A non-biliary route for cholesterol elimination from the body has also been described, named transintestinal cholesterol excretion (TICE) (Figure 14.2.1.4). TICE is responsible for direct transport of cholesterol from blood across the enterocytes into the intestinal lumen [39] and its relevance for humans is under debate [40].

Whereas only 30–50% of the cholesterol present in the intestinal lumen is absorbed, bile acids are almost completely reabsorbed via passive diffusion along the small intestine and via active transport in the distal ileum. The latter process is critically reliant on a sodium-dependent ileal bile acid transporter (IBAT) [41]. After reabsorption, bile acids are returned to the liver via the portal vein, and subsequently resecreted into the bile. By this efficient recycling, the preponderance of bile acids is conserved within the enterohepatic region, and only about 300–500 mg are lost in the faeces each day.

The capacity to synthesize bile acids from cholesterol is a unique property of the hepatocytes. In a normal adult human, about 300–500 mg of bile acids are produced daily, to compensate for faecal loss [36, 37]. In humans, the first and rate-limiting step in bile acid synthesis is the conversion of cholesterol into 7α-hydroxycholesterol, a reaction catalysed by the microsomal enzyme cholesterol 7α-hydroxylase [42]. This enzyme is mainly regulated by the flux of bile acids in the enterohepatic circulation, sensed through the bile acid-binding nuclear receptor farnesoid X-receptor (FXR) [43] which is expressed both in the ileum and in the liver. Details of this regulation are still under study, but it appears as if humans have a low

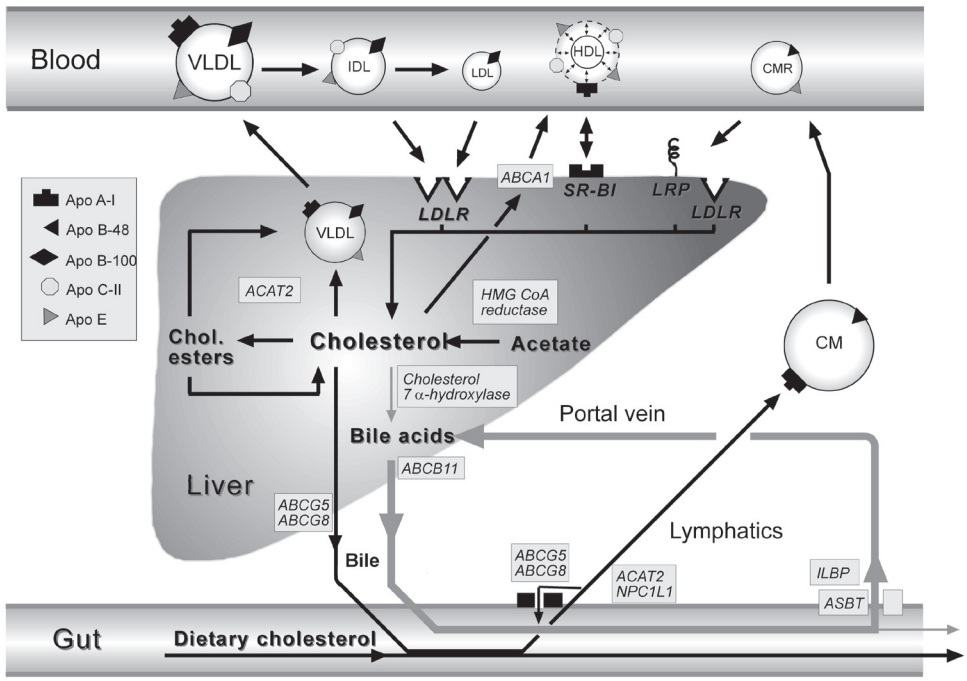

Figure 14.2.1.5 Schematic representation of hepatic cholesterol metabolism and the enterohepatic circulation. basal capacity for bile acid synthesis compared to most other species. Instead they show marked stimulation following interruption of the enterohepatic circuit (e.g. by ileal resection or treatment with bile acid binding resins), resulting in marked adaptive responses mediated via the SREBP-system: both HMG-CoA reductase activity and LDL receptor expression being stimulated [44]. This is the rationale for therapy with resins, and particularly explains the pronounced effects when such drugs are administered together with inhibitors of cholesterol synthesis. Inhibition of intestinal absorption and biliary reabsorption of cholesterol by ezetimibe, which block both NPC1L1 in the intestine and in the liver, does not affect the synthesis of bile acid in humans [45].

Stressors of Lipoprotein Metabolism Across the Lifespan

As discussed in Chapter 14.2.2, many severe monogenic disorders of lipoprotein metabolism are now known. Common genetic variants may also produce dyslipidaemia; however, this commonly only becomes overt in the presence of physiological or other stressors. Disturbances of lipoprotein metabolism thus represent excellent examples of interaction between genetic background and environmental influence. Selected conditions and circumstances in which clinically significant perturbation of lipoprotein metabolism may occur across the lifespan are discussed next.

Insulin has an antilipolytic effect on adipose tissue, inhibits VLDL release from the liver, and is necessary for lipoprotein lipase function. Thus, in insulin deficiency, as in newly diagnosed or severely undertreated type 1 diabetes, the absence of insulin increases NEFA and VLDL triglyceride levels, and fasting chylomicrons are frequently present, resulting in massive hypertriglyceridaemia [46]. HDL levels are reduced due to the inefficient triglyceride clearance. When type 1 diabetes is well controlled with insulin, in contrast, lipoprotein abnormalities are minimal, and if hyperlipidaemia remains it may reflect a coexisting (often primary) disorder of lipoprotein metabolism. In type 2 diabetes, insulin resistance is probably the main factor driving dyslipidaemia characterized by elevated VLDL, small-dense LDL, and low HDL [47]. Metabolic dyslipidaemia is discussed further in Chapter 15.13.4, 'Diabetic Dyslipidaemia'.

Hypercaloric intake enhances production of VLDL triglyceride [48], and, particularly together with insulin resistance, this may produce hypertriglyceridaemia. Increased VLDL triglyceride production also appears to be a major mechanism for the hyperlipoproteinaemia sometimes caused by **alcohol** consumption [49]. If VLDL clearance mechanisms (such as lipoprotein lipase) are intact and able to compensate for this increased production, enhanced flux through the VLDL pathway may explain the increase in HDL concentration seen after moderate alcohol intake. Stimulation of VLDL catabolism may also explain the positive influence of **physical exercise** in elevating plasma HDL cholesterol.

Thyroid hormone stimulates expression of hepatic LDL receptors [50]. Whereas LDL levels are low in hyperthyroidism, increased lipolysis and triglyceride production may lead to hypertriglyceridaemia. Raised LDL cholesterol is a frequent finding in hypothyroidism, where hypertriglyceridaemia and increased Lp(a) are also common findings. *Growth hormone* seems to be essential for the normal expression of hepatic LDL receptors [51], and also stimulates VLDL triglyceride flux. Replacement therapy

in growth hormone deficient subjects normalizes the elevated LDL cholesterol levels and increases HDL cholesterol; interestingly Lp(a) is also increased by growth hormone treatment.

Plasma LDL cholesterol concentration typically increases with **ageing** [52], apparently due to a reduced capacity for LDL clearance, reflecting diminished expression of hepatic LDL receptors. It has been suggested that these may at least partly relate to a relative deficiency of growth hormone with ageing.

Gender differences in plasma lipoproteins appear at puberty [53]. In comparison to males of similar age, females have lower VLDL and LDL levels and higher HDL_2 levels. Although gender-related differences in plasma lipoproteins are contributed to by differences in diet, alcohol, and smoking habits, the direct action of sex hormones on plasma lipoprotein metabolism is likely to be the dominant explanation. By the sixth decade of age, the gender differences in plasma lipoproteins change: women present increased LDL levels, associated with a decrease in LDL particle size. This relatively marked increase in LDL cholesterol levels, observed after menopause, is probably related to loss of oestrogen stimulation of LDL receptors. A fall in HDL cholesterol, due to a reduction of both HDL_2 and HDL_3 is also observed in menopausal women underlining the importance that oestrogen has for apo A-I metabolism [54]. Lp(a) levels are also influenced by oestrogen.

Understanding of the role of disturbances in lipoprotein metabolism in the development and progression of coronary heart disease is constantly becoming deeper. Because dyslipidaemias are the consequence of interactions between genetic background and environmental influences, therapeutic strategies should not only try to target contributory genetic defects, but should also consider hormonal and nutritional status. Therefore, a pharmacological approach needs to be individualized and associated with appropriate hormonal substitution, if relevant, and with changes in lifestyle by modification of diet, increased physical activity, and discontinuation of smoking and overconsumption of alcohol.

14.2.2 Genetic Forms of Dyslipidaemia

Stefano Romeo, Bo Angelin, and Paolo Parini

Introduction

Disturbances of blood lipids are frequent and may contribute to premature atherosclerosis and its complications, including coronary heart disease, angina pectoris, stroke, and claudication [1]. Some forms of dyslipidaemia are also linked to pancreatitis, lipid deposition in skin and tendons, and corneal arcus. Dyslipidaemias may be 'primary' and genetic, in which severe dyslipidaemia is the inevitable result of an underlying genetic mutation, and these will be the main focus of this chapter. For many dyslipidaemias, however, a genetic predisposition interacts with exacerbating nutritional, pharmacological, or disease factors, for example in conditions such as diabetes, insulin resistance, hypothyroidism, hypopituitarism, hypo/hypercortisolism, chronic kidney disease, and polycystic ovary syndrome. Suggested investigations helpful in screening for secondary dyslipidaemia are shown in Box 14.2.2.1.

Pathogenic Aspects of Genetic Dyslipidaemias

Highly penetrant genetic dyslipidaemias are often severe and relatively easy to recognize. However, the most common heterozygous forms of genetic dyslipidaemias may go unrecognized for many years until experienced doctors identify them. If left untreated, genetic dyslipidaemias may lead to reduced lifespan or poor quality of life, depending on the severity of the phenotype. Since the body is generally exposed to such negative effects from birth, it is important to recognize genetic dyslipidaemias early in life, in order to initiate preventive treatment.

The study of genetic dyslipidaemias has yielded critical insights into the physiology and pathophysiology of human lipoprotein metabolism, also allowing identification of metabolic networks and endo-phenotypes that are common with chronic non-communicable diseases. Considering the vast number of proteins involved in lipid metabolism, it is not surprising that a relatively large number of monogenic diseases have been identified (Box 14.2.2.2). With the development of modern sequencing technology, we are rapidly approaching a more detailed understanding of interindividual variation. Accurate molecular diagnoses and targeted therapies are becoming a reality in an increasing proportion of patients with genetic dyslipidaemias.

Classification of lipoprotein disorders has historically been based on serum lipoprotein distribution, assessed by electrophoresis as originally outlined by Fredrickson in 1965 (Box 14.2.2.3) [2]. Currently, the classification of dyslipidaemias is based on the descriptions of more specific phenotypes (Box 14.2.2.4). These genetic forms of dyslipidaemias will be the focus of the rest of this chapter.

Box 14.2.2.2 Terminology in genetics

Homozygous: Harbouring the same mutation in both maternal and paternal gene copies.

Compound heterozygous: Harbouring two different mutations, one in the maternal and one in the paternal gene copy.

Double heterozygous: Harbouring two different heterozygous mutations in two different genes (e.g. a mutation in the LDL-receptor and a mutation in the APOB gene)

(Autosomal) Recessive: Disease become manifest in the presence of mutations in both maternally and the paternally inherited copies of a gene. Affected individuals can be homozygous, compound heterozygous, or double heterozygous.

(Autosomal) Dominant: The disease become manifest in the presence of only one mutation, usually in either the maternal or paternal gene copy.

Familial Hypercholesterolaemia

Heterozygous Familial Hypercholesterolaemia (FH)

Familial hypercholesterolaemia (FH) is an autosomal codominant disease caused by mutations in the genes encoding the LDL-receptor (LDLR), apolipoprotein B (APOB) or proprotein convertase subtilisin/kexin type 9 (PCSK9). While mutations in the LDLR or APOB causing loss-of-function determine FH, those in PCSK9 cause gain-of-function. Described as early as in the 1930s, FH is the most common monogenic disorder of lipid metabolism with a prevalence of ~1/250 in most populations [3]. Some regions are known to have clusters with a higher incidence of FH, due to population isolation permitting expansion of rare mutations—the so-called founder effect—as in the French Canadians and Boers in South Africa, for example. The most striking feature of individuals with FH is elevated levels of LDL-C (usually > 5 mmol/L) resulting in 10–15-fold increased risk in cardiovascular disease. If untreated, heterozygous FH carriers have an estimated 10–15 years shorter expected lifespan.

Diagnosis

Clinical diagnosis of FH is based on a dominant pattern of inheritance in the family pedigree. Total cholesterol levels are ≥8 mmol/L (≥6 mmol/L in children), triglyceride, and HDL-cholesterol levels are generally unremarkable. Scores to evaluate the probability of FH based on clinical criteria have been developed, and although far from perfect may be useful for decisions about family screening. The most commonly used is the Dutch Lipid Clinic Network (DLCN) score (Box 14.2.2.5) [3]; others are the Simon Broome and the Make Early Diagnosis to Prevent Early Deaths (MEDPED) diagnostic criteria. Among the clinical signs of cholesterol accumulation, spheroidal xanthomata of the extensor tendons of the hands, elbows, knees, or the Achilles tendons are a strong support for the diagnosis of FH (Figure 14.2.2.1). Arcus senilis (a white circle of cholesterol deposit in the outer edge of the iris appearing before the age of 40) or xanthelasmata (a demarcated yellowish area of cholesterol under the skin around the eyelids) are also common but are not pathognomonic for FH (Figure 14.2.2.1).

Lifestyle Intervention and Assessing the Risk

It is recommended that FH patients adhere to a healthy lifestyle and diet [3]. It is imperative that smokers quit smoking, and are referred to a specialized tobacco unit/programme when necessary. Advice to children and young adults not to start smoking is very important. Individuals with this condition generally do not achieve clinically relevant reduction of cholesterol in response to dietary intervention or weight loss alone. The absence of reduction of LDL-C after changing lifestyle indeed increases the suspicion of FH. The cardiovascular risk in FH patients cannot be inferred by using the traditional scores (e.g. Framingham risk score); these individuals are at high risk for cardiovascular disease and should be treated to reduce LDL-C levels early in life.

Treatment

LDL-cholesterol is the primary target of therapy and the reduction in both cardiovascular and total mortality is proportional to the degree of LDL-cholesterol reduction [3]. Treatment in FH should be started during teenage years with a goal of 3.5 mmol/L. In FH adults, the LDL-C to achieve should be 2.5 mmol/L while in individuals with additional risk factors for cardiovascular disease (diabetes mellitus, hypertension, smoking, obesity, insulin resistance) or in secondary prevention LDL-C levels should be maintained below 1.8 mmol/L. All untreated individuals with FH above age 40 should be considered to be at very high cardiovascular risk, as they have been exposed to elevated LDL-cholesterol levels since birth.

Statins are the first line treatment because they reduce circulating LDL-C by increasing removal of LDL particles through upregulation of hepatic LDLRs. Treatment with the maximal dose of a potent statin should ideally be used: either atorvastatin 80 mg or rosuvastatin 40 mg daily (or pitavastatin 4 mg/daily). Alternative statins are simvastatin or pravastatin. Simvastatin 80 mg should not be used because it is associated with elevated risk of myositis and

Figure 14.2.2.1 Characteristic clinical signs in a 40-year-old male patient with heterozygous FH (left to right): *Arcus senilis*; xanthomas on flexor tendons; xanthoma on Achilles tendon.

rhabdomyolysis. Statins are generally well tolerated [4, 5]. The most severe statin side effect is rhabdomyolysis occurring in approximately 1 of every 100 000 prescriptions. The major symptom of this is severe pain in large proximal muscles not explained by fever or severe physical exercise. The risk of rhabdomyolysis increases when a statin is combined with some drugs, including gemfibrozil, antifungals, macrolides, calcium channel blockers, protease inhibitors, and cyclosporin. Transient increases in liver enzymes occur in 0.5–2% of patients taking statins but are not clinically relevant. Routine monitoring of creatine kinase or transaminases is not recommended, and an increase of up to threefold the reference levels of these enzymes should not generally contraindicate continued treatment. Statin therapy is associated with a modest increase in the risk of new-onset diabetes mellitus (ca. 1/1000 patient-years). The risk is significantly higher in patients with metabolic syndrome or prediabetes. Statins do not adversely affect cognitive function.

Second-line treatment, in addition or alone, is with ezetimibe (10 mg daily), which achieves an average further reduction of 20% by reducing uptake of cholesterol from the intestine. Bile acid binding resins such as colesevelam (up to 3750 mg a day) generally further effectively reduce LDL-C. Treatment with the recently available inhibitors of PCSK9, such as the subcutaneous injection of monoclonal antibodies alirocumab (75–150 mg every two weeks) or evolocumab (140 mg every 2 weeks), can reduce LDL-C up to 70%, opening up the possibility to reach even the very stringent treatment goals for LDL-C in heterozygous FH [6, 7].

Cascade Screening in Families with FH

Considering the high risk for premature cardiovascular disease, the dominant pattern of inheritance and the well-established positive effects from lipid-lowering therapy, it is reasonable to offer first-degree relatives of patients with a diagnosis of heterozygous FH screening for this disorder [3]. This can be achieved through screening of lipid levels (Box 14.2.2.1), and/or through DNA analysis. There is ample evidence for clinical benefit from such procedures, and a number of programmes have implemented them, with offspring of known carriers actively sought through their healthcare providers. Although this may be relatively straightforward in a family with established hypercholesterolaemia and a known disease-causing mutation in the LDLR, APOB, or PCSK9, there are some caveats that should be considered when engaging in such an approach [8, 9]. First of all, the spectrum of mutations in the LDLR is large, with thousands of different mutations described, complicating genetic screening in families where the primary defect has not yet been identified. Furthermore, a remaining fraction of patients with clinical FH may have mutations in additional genes yet to be implicated in FH. In addition, there are relatively frequent disease-modifying mutations in other genes (such as variants of

apolipoprotein E (APOE) or loss-of-function mutations in PCSK9) which prevent the hypercholesterolaemic phenotype being expressed in carriers of known FH-causing mutations, thus leading to underestimation of their potential to transmit the trait. Increased availability of next generation sequencing techniques will make diagnosis more exact but will also require a more profound understanding from managing physicians.

Homozygous FH

Individuals homozygous, or compound heterozygous, for mutations in FH-causing genes generally present with a much more severe phenotype [10]. The prevalence of this disorder is approximately 1 in 500 000–1 000 000 except for in isolated ethnic groups, particularly when intermarriage between cousins is frequent. In the classical form, these individuals generally have LDL-C levels > 9 mmol/L and may present with cardiovascular disease even before the age of 10. Xanthomata are present at an early age, and frequently are the reason for clinical presentation. Double heterozygous FH (i.e. FH caused by heterozygosity for disease-causing mutations in two different genes; **Box 14.2.2.2**) has an intermediate phenotype. In addition to marked tendon xanthomas, planar cutaneous xanthomata are a distinct sign of these more severe forms (**Figure 14.2.2.2**). FH homozygotes with no residual LDLR expression are essentially resistant to treatments aimed at increasing LDLR function, whereas some lipid-lowering can be achieved in those with some remaining function. The most efficient treatment available today is removal of plasma LDL by selective LDL-apheresis, generally at weekly intervals [10]. Inhibition of hepatic very low-density lipoprotein (VLDL) secretion by oral treatment with lomitapide (10–40 mg a day) or subcutaneous injection of mipomersen (200 mg/ml per week) also has effect and may reduce the frequency of LDL-apheresis therapy. A side effect of such treatment is development of fatty liver disease, which needs to be monitored. For resistant cases of homozygous FH, more drastic treatments such as liver transplantation has been tried, and initial attempts at gene therapy have been undertaken, with modest success to date.

Autosomal Recessive Hypercholesterolaemia (ARH)

In rare cases, a phenotype similar to homozygous FH but with a recessive inheritance, with early extensive xanthomata but with normal parental LDL levels may be observed (**Figure 14.2.2.3**). This is likely to be due to homozygosity for mutations in the LDLR adapter protein-1 (*LDLRAP1*) gene, which influences recycling of the LDLR, leading to marked LDL-C elevations and premature cardiovascular disease [11, 12]. These patients generally respond well to treatment with statins in combination with ezetimibe, which may even produce evidence of regression of manifest atherosclerosis.

Sitosterolaemia

Another very rare form of recessive dyslipidaemia is sitosterolaemia, where large xanthomata accumulate due to the deposition of plant sterols such as sitosterol and campesterol. This is generally due to homozygous or compound heterozygous mutations in the ABCG5 and ABCG8 genes, which code for an intestinal and hepatic transmembrane transporter complex responsible for the elimination of plant sterols and cholesterol [13]. The patients have very high levels of sitosterol and campesterol, while plasma LDL-C may or

Autosomal recessive hypercholesterolaemia: normalization of plasma LDL-cholesterol by ezetimibe in combination with statin treatment. *J Intern Med*. 2004; 256: 406–12. Copyright © 2004, John Wiley and Sons. (Ref 10)

may not be elevated. In these cases, plant sterols are a major component of the xanthomata. Patients with sitosterolaemia show extreme phenotypic heterogeneity, ranging from almost asymptomatic individuals to those with severe hypercholesterolaemia leading to accelerated atherosclerosis and premature cardiac death. Haematologic manifestations include haemolytic anaemia with stomatocytosis, macrothrombocytopaenia, splenomegaly, and abnormal bleeding. The therapy includes dietary restriction of both cholesterol and plant sterols and the use of ezetimibe, an intestinal sterol absorption inhibitor. Vegetable oils, wheat germs, nuts, seeds, avocado, shortening, margarine, and chocolate should be restricted. If present, hypercholesterolaemia in these patients is extremely responsive to low cholesterol diet and bile acid sequestrants.

Cerebrotendinous Xanthomatosis (CTX)

In this very rare recessive disease, the underlying molecular defect is in the sterol 27-hydroxylase (*CYP27A1*) gene, resulting in an inability to synthesize normal bile acids from cholesterol [14]. Loss of feedback inhibition of bile acid synthesis results in a very high hepatic production of bile acids and cholestanol. The increased bile acid synthesis leads to increased *LDLR* expression. Hence, patients with CTX generally have low levels of LDL-C. Characteristic clinical manifestations of CTX include chronic diarrhoea, bilateral cataracts, tendon xanthomas, and neurologic dysfunction. CTX is associated with abnormally high levels of cholestanol in the blood and accumulation of cholestanol and cholesterol in the brain, tendon xanthomas, and bile. There is marked variability in signs and symptoms, severity, and age of onset between patients. CTX is progressive and potentially debilitating or fatal, particularly with respect to neurologic presentations that can include intellectual disability, autism, behavioural and psychiatric problems, and dementia. Chenodeoxycholic acid treatment helps to restore normal bile acid synthesis and reduces the levels of cholestanol. Since chenodeoxycholic acid also appears to be generally effective in preventing adverse clinical manifestations of CTX from occurring or progressing if administered early enough, an early diagnosis is of great importance.

Elevated Lp(a)

Lipoprotein Lp(a) is an LDL-like particle where the plasminogen-like APO(a) is covalently linked to the structural APOB molecule. Studies using genetic variations whose primary effect is to increase circulating Lp(a) levels have shown that elevated Lp(a) increases the risk for cardiovascular disease independently of LDL-C or non-HDL-C levels and of the presence of other cardiovascular risk factors [15]. The level of Lp(a) is strongly influenced by a genetically determined size variation, with an inverse relation between the plasma level and isoform size. Individuals with FH tend to have higher Lp(a) than predicted by their APO(a) genotype, and the

degree of Lp(a) increase predicts risk in this condition. Clinically, elevated levels of Lp(a) should also be suspected in the context of progressive and recurrent myocardial infarction despite effective statin therapy. The role of Lp(a) in the pathogenesis of cardiovascular disease seems to be due to its atherogenic and prothrombotic properties and the European Atherosclerosis Society has suggested that the desirable level of Lp(a) is less than 125 nmol/L (50 mg/dl) [15]. There is no effective treatment to reduce Lp(a), although sex hormones and thyroid hormone are known to decrease its concentration. Traditional lipid-lowering therapies (e.g. statins, fibrates, and ezetimibe) have no or very minor effects on Lp(a). Treatment with niacin, lipoprotein apheresis, or PCSK9-inhibitors can decrease Lp(a) levels. Niacin and PCSK9-inhibition decrease the Lp(a) levels approximately 30%, whereas lipoprotein apheresis decreases them by 25–40% [16]. Since these treatments also have a positive effect on plasma lipid profiles; it has been difficult to discern the specific effects due to Lp(a) lowering.

Familial Chylomicronaemia Syndrome (FCS)

FCS, previously referred to as type I hyperlipoproteinemia according to Fredrickson's classification, is a recessive disorder characterized by high circulating levels of triglycerides, typically above 10 mmol/L, in the absence of secondary causes [17, 18]. This disease results from reduced catabolism of chylomicrons. Clinically, patients may have abdominal pain and recurrent pancreatitis that may be associated with eruptive xanthomata, hepatomegaly, and lipemia retinalis. Moreover, the hypertriglyceridemia is usually resistant to treatment with fibrates. The prevalence of this disease is low at ~1/1 000 000, except in isolated populations or in those in which consanguineous marriage is prevalent. The most common genetic defects responsible for FCS are loss-of-function mutations in lipoprotein lipase (LPL), APOC2, apolipoprotein A5 (APOA5), lipase maturating factor 1 (LMF1) and glycosylphosphatidylinositol anchored high-density lipoprotein binding protein 1 (GPIHBP1) genes [19]. Double heterozygotes for mutations in pairs of these genes generally have a milder phenotype and respond to fibrate treatment. There are no specific drugs to treat FCS, but promising therapies are currently under investigation, including inhibition of APOC3 and of angiopoietin like-3 (ANGPTL3). Also gene therapy for LPL deficiency has been tested but it is not currently available for a lack efficacy. FCS generally responds well to a diet with a fat content of 15–20 g per day (10–15% of total daily energy intake). The diet should meet recommendations for essential fatty acids: alpha-linolenic acid and linoleic acid. Complex carbohydrate foods should be preferred while limiting simple and refined carbohydrates. Supplementation with fat-soluble vitamins, minerals, and medium-chain triglyceride oil, is given as needed. Recommended foods include vegetables, whole grains, legumes, lean protein foods, fruits in limited amounts, and fat-free milk products without added sugars. Foods to avoid include alcohol and products high in sugar.

Familial Hypertriglyceridaemia (FHTG)

Apparently autosomal dominant elevated triglyceride concentration due to increased VLDL (type IV hyperlipoproteinaemia), is relatively common and is probably mechanistically heterogeneous, being attributable to various underlying molecular defects [17, 20]. It may be associated with the presence of chylomicrons in the fasting state (type V hyperlipoproteinaemia). Although the risk of cardiovascular disease is probably increased, it is not as marked as for increased LDL levels [20, 21]. Eruptive xanthomas may occur, and at very high triglyceride levels there is an enhanced risk of pancreatitis. Overproduction of VLDL-triglycerides is frequent, and there are links to enhanced cholesterol and bile acid production in some cases [22]. Optimizing weight, low caloric intake, and exercise are important, and a family history of early cardiovascular disease strengthens the introduction of drug therapy, with statins or fibrate drugs as first choice.

Familial Combined Hyperlipidaemia (FCHL)

This clustering of hyperlipidaemia of varying hyperlipidaemic phenotypes (elevated VLDL, LDL or their combination) with apparent autosomal dominant inheritance was first described in 1973 [23, 24], and still remains a pathogenic mystery, lacking solid diagnostic markers. The pattern is common (perhaps 1%), and it is clearly linked to an increased risk for early cardiovascular risk [14], being seen in at least 10% of individuals with myocardial infarction before the age of 60. The lipid phenotype appears to be more clearly expressed with increasing age, and there is a large overlap with abdominal obesity, insulin resistance, hypertension, and type 2 diabetes. 'FCHL' is most probably due to a combination of several genetic variants and aggravated by lifestyle influences [25]. In carefully selected patients, overproduction of APOB-containing lipoproteins and deficient lipolysis seem to be involved [26–28]. Importantly, the presence of a combined lipid phenotype in a patient with a family history of mixed hyperlipidaemia and early vascular disease, particularly in combination with high APOB levels, could motivate active screening in first-degree relatives. In addition to lifestyle adjustment, treatment with statins and/or fibrates generally has very good effect.

Type III Dyslipoproteinaemia

This is a very rare form of highly atherogenic dyslipidaemia which is also important to identify in general practice, since its treatment frequently is very successful. It is generally caused by the combination of two abnormalities: homozygosity for the APOE2/2 genotype (which is present in ~1% of the population), and overproduction of lipoproteins such as seen in FCHL or type 2 diabetes [29, 30]. Hypothyroidism in a subject with the APOE2/2 genotype frequently results in a type III lipoprotein pattern. It should be recognized that subjects with the APOE2/2 genotype generally have low lipoprotein levels, but when subject to an increased lipoprotein flux they accumulate chylomicron and VLDL remnants due to the reduced interaction of these with hepatic LDLRs. This results in elevated cholesterol and triglyceride levels, generally in the range of 8–10 mmol/L; LDL-cholesterol (and APOB) is generally low. The remnant particles make the plasma opalescent, and the uptake of those so-called beta-VLDL in macrophages results in a very typical (almost pathognomic)

lipid deposition in the palmar creases as well as tuberous xanthomata, particularly of the elbows and knees. This is probably also the reason for the high propensity to develop atherosclerotic deposits, often most pronounced in peripheral arteries. Following treatment with drugs such as fibrates or statins, there is generally a very marked response, not only in plasma lipids but also both in xanthomas and arteriopathy. Clinically, it is also of note that type III hyperlipidaemia carries a high risk of atherosclerosis despite generally having a low APOB level and a low APOB/APOA1 ratio.

Familial Hypobetalipoproteinaemia (FHBL) and Abetalipoproteinaemia (ABL)

These are disorders belonging to the same spectrum, characterized by low production of lipoproteins [13, 31]. HBL can occur in homozygous or heterozygous form, and is caused by mutations in APOB, generally leading to truncation of the protein and deficient or decreased secretion of chylomicrons and VLDL, respectively. While the heterozygotes have low LDL, they generally have normal fat absorption and seem to have a normal or even increased life span. The homozygotes have fat malabsorption that results in failure to thrive and deficiency of fat-soluble vitamins. In ABL, there is generally a homozygote or compound heterozygote mutation in microsomal triglyceride transfer protein (MTTP) which gives essentially a similar phenotype. Both conditions also predispose to fatty liver disease due to the retention of VLDL, with progressive fibrosis and risk of developing hepatocellular carcinoma. Treatment is generally based on dietary treatment with vitamin substitution and medium chain length triglyceride/MCT).

Chylomicron Retention Disease (CMRD)

Also known as Anderson's disease, CMRD is a very rare autosomal recessive disease characterized by lipid malabsorption due to mutations in the SAR1B gene, a protein involved in intracellular trafficking and chylomicron assembly [13, 32]. This causes the chylomicrons and VLDL synthesized in the small intestine and liver to be retained in the respective cells of origin, resulting in fat malabsorption and failure to thrive. Following a fatty meal, there is no postprandial chylomicron secretion, and a 'fatty gut' can be seen in intestinal biopsies. Treatment is similar to that in FHBL and ABL, and the clinical course seems somewhat milder.

Low LDL Levels

Loss-of-function mutations in the *PCSK9* gene are associated with low LDL-C levels and have been shown to protect against cardiovascular disease in several populations [33]. The APOE2/2 variant is also linked to lower LDL levels, and in both situations this probably reflects increased clearance of LDL from the circulation. Subjects with heterozygous FHBL, which may be as frequent as 0.1% in the population, generally have extreme low LDL levels, probably due to the combination of deficient production and increased clearance of APOB [13]. The risk for development of fatty liver is increased and carriers of these sequence variations have higher risk of hepatocellular carcinoma [34].

Familial Combined Hypolipidaemia

This is a condition characterized by very low/undetectable levels of all lipoprotein species, caused by mutations in the angiopoietin like protein 3 (ANGPTL3) gene [35]. This gene encodes a protein which inhibits the activity of LPL explaining the very low levels of circulating triglycerides; the mechanisms resulting in the reductions in HDL-C and LDL-C are incompletely understood. Individuals with this condition have been shown to be more sensitive to insulin, and are probably protected from cardiovascular disease and type 2 diabetes. These findings have stimulated the development of treatment of hyperlipidaemic conditions by administration of antibodies or antisense oligonucleotides targeting ANGPTL3.

Hypoalphalipoproteinaemia (Low HDL)

Low HDL-cholesterol (<1 mmol/L for males, <1.3 mmol/L for females) is relatively common, and has been associated with an enhanced risk for cardiovascular disease. In most cases, this finding probably reflects inefficient lipid transport as seen in the 'metabolic syndrome', with slow VLDL-clearance, moderate triglyceride increase, abdominal obesity, and insulin resistance [36]. This should serve as an indicator for interventions to promote metabolic health, including lifestyle changes. There is no clearly beneficial pharmacological treatment directed at HDL levels, although oestrogen substitution after menopause probably works at least partly via this pathway. There are some rare monogenic disorders that may cause substantial lowering of HDL-C.

Tangier Disease

This is a classical recessive dyslipidaemia which is caused by mutations in the *ABCA1* gene [37]. Clinically, there is relatively modest evidence for an increased risk of cardiovascular disease, despite substantial lipid deposition in macrophages, seen as hypersplenism and large, orange-coloured tonsils. The lack of functional *ABCA1* results in deficient uptake of cholesterol from peripheral cells, and APOA1 protein is rapidly lost from the circulation.

Lecithin–Cholesterol Acyltransferase (LCAT) Deficiency

This is a recessive disorder in which esterification of cholesterol and its transfer from HDL to VLDL and chylomicrons are absent, leading to very low levels of esterified cholesterol in plasma, and accumulation of small discoid HDL_3 particles [37]. Clinically, the most relevant finding is gradual deterioration of kidney function which frequently leads to end stage kidney disease which may require dialysis and kidney transplantation. There is also a high frequency of early cataract formation, particularly seen in so-called fish-eye disease. The evidence for an increased risk of cardiovascular disease is so far not fully convincing.

APOA1 Deficiency

Although there are structural variants in APOA1 that seem to result in deficient reverse cholesterol transport and early cardiovascular

disease, they are relatively rare [37]. Most of those described are inherited as a dominant trait.

Hyperalphalipoproteinaemia (High HDL)

Based on epidemiological evidence of an inverse correlation between HDL-C and cardiovascular risk, there was for a long time a conviction that genetic variants resulting in high HDL or APOA1 levels would be beneficial, a concept supported by reports of a reduced frequency of atherosclerosis in Japanese families with cholesterol ester transfer protein (CETP) deficiency. However, essentially negative results from trials of treatment with CETP inhibitors, together with accumulating genetic evidence of a more complex risk pattern, have led to a more balanced view. The mechanism responsible for the HDL-C elevation (e.g. through a reduced flux of cholesterol removal or by an increased production of APOA1) is probably more important for the development of atherosclerosis than changes in static HDL-C concentration, and explains observations of a U-shaped risk curve for HDL-C [38].

Cholesterol Ester Transfer Protein (CETP) Deficiency

CETP transfers and exchanges cholesteryl esters and triglycerides between HDL and triglyceride-rich lipoproteins. Homozygous carriers, identified mainly in Japan, show 3 to 6-fold elevated HDL-C levels, with concomitant high levels of APOAI, APOAII, APOCIII and APOE [39]. The levels of LDL-C and APOB are usually slightly reduced. The HDL particles in CETP-deficient patients are very large, rich in cholesterol esters, and poor in triglycerides. The increase in HDL-C is accounted for by a rise of HDL_2, whereas HDL_3-C is normal.

Scavenger Receptor Class B Type I (SCARB1) Mutations

SCARB1 mediates delivery of HDL-C to the liver and steroidogenic organs. Families with a missense mutation (P297S) in this gene have been identified [40]. The carriers have increased HDL-C and a reduced capacity for efflux of cholesterol from macrophages, but the carotid artery intima-media thickness was similar in carriers and non-carriers. Platelets from carriers had an increased content of unesterified cholesterol and were functionally impaired. In carriers, adrenal steroidogenesis was attenuated, as evidenced by decreased urinary excretion of corticosteroids metabolites, decreased response to corticotropin stimulation, and in some cases symptoms of diminished adrenal function.

Concluding Remarks

Atherosclerosis is a chronic process started by accumulation of cholesterol in the subintimal space of arteries. The inflammatory component is driven by cholesterol crystals and sustained by some fatty acids present in triglycerides and reduced by HDL particles. Hence, dyslipidaemia represents a highly important risk factor for cardiovascular disease by driving the atherosclerosis process. The phenotypes of the different dyslipidaemias are the consequence of an interplay between genetic and environmental influences. Abnormalities of lipid metabolism are also commonly due to or precipitated by underlying endocrine diseases. The molecular understanding of how lipid metabolism is regulated has resulted in an explosive development of diagnostic tools for individual diagnosis and in the rapid emergence of effective and specific treatment options. The knowledge that the degree of lifetime exposure to cholesterol carried in LDL particles (and remnant particles) in circulation determines the occurrence of clinical relevant cardiovascular disease dictates an early diagnosis and prevention in order to lead to large positive health effects. Hence, the continuous dissemination of new knowledge to practising physicians is a pillar of prevention strategies. Nevertheless, the recognition of characteristic physical signs in patient care, and the value of obtaining a relevant family history in patients with primary dyslipidaemia will continue to be of major importance also in the future.

Other Metabolic Disorders

14.3.1 Hyperinsulinaemic Hypoglycaemia

Khalid Hussain and Sonya Galcheva

Introduction

Hyperinsulinaemic hypoglycaemia (HH) is a condition in which insulin secretion from the pancreatic β-cells is dysregulated so that insulin continues to be secreted even in the presence of hypoglycaemia [1]. HH is a major cause of persistent and recurrent hypoglycaemia in neonates and children. In HH, plasma glucose levels provide the main source of fuel for the brain as the main alternative substrates (ketone bodies) are suppressed by hyperinsulinaemia. It is this biochemical milieu (hyperinsulinaemic hypoketotic hypoglycaemia) which increases the risk of brain injury (leading to neurological sequelae such as developmental delay, cerebral palsy and epilepsy) in children with HH. In order to prevent or reduce the extent of hypoglycaemic brain injury the diagnosis of HH should be made as soon as possible and appropriate treatment started early [2].

HH can be secondary to various factors such as maternal diabetes, intrauterine growth retardation (IUGR) and perinatal asphyxia, in which case it is usually self-limiting, or congenital due to defects in genetic pathways regulating insulin secretion from pancreatic β-cells [3]. The congenital forms of HH can be classified histologically into diffuse and focal forms. The presurgical differentiation of these two subtypes is important for management [4].

Classification of HH Subtypes

Table 14.3.1.1 lists all the different causes of HH.

Transient HH

Transient HH occurs in at-risk neonates, caused by neonatal factors (prematurity, IUGR, large size for gestational age, perinatal stress and birth asphyxia, erythroblastosis fetalis and Rh isoimmunization) or maternal factors (diabetes mellitus (gestational or type 1)), medication use (sulphonylureas) or intravenous glucose infusions during labour) [5]. In some at-risk infants HH can be prolonged and require treatment with diazoxide to maintain euglycaemia until β-cell insulin secretion is normalized within several weeks or months [6].

The physiological and genetic mechanisms underlying transient HH are not known but could relate to failure of postnatal metabolic adaptation, depletion of hepatic glycogen stores, abnormal gluconeogenesis, transient alteration in the β-cell insulin secretion and/or increased insulin sensitivity, or a combination of these [7].

Monogenic Forms of Congenital Hyperinsulinism (CHI)

Monogenic CHI is relatively rare (incidence 1:40 000–50 000 in the general population) but in some populations the incidence can be as high as 1:2500 due to increased consanguinity [5]. These monogenic forms of CHI are caused by defects in key genes involved in regulation of β-cell insulin secretion. Mutations in at least 14 different

Table 14.3.1.1 Causes of hyperinsulinaemic hypoglycaemia

Causes of Transient HH	
Neonatal factors	Prematurity, IUGR, large for gestational age (LGA) infants, perinatal stress/birth asphyxia, Rhesus isoimmunization
Maternal factors	Diabetes mellitus (gestational or type 1) Medication use (sulphonylureas) Intravenous glucose infusion during labour
Monogenic forms of HH	
Mutations in genes encoding channels or ion transporters	K_{ATP} channel: *ABCC8* or *KCNJ11* Lactate transporter: *SLC16A1* Calcium channel: *CACNA1D*
Mutations in genes involved in regulation of insulin secretion	*GLUD1, GCK, HK1, HADH, UCP2, PGM1, PMM2*
Mutations in genes encoding transcription factors	*HNF1A, HNF4A, FOXA2*
Syndromic causes of HH	
Prenatal or postnatal overgrowth syndromes	Beckwith–Wiedemann, Sotos, Simpson–Golabi–Behmel, Perlman syndrome
Chromosomal abnormality syndromes	Trisomy 13, Mosaic Turner syndrome
Postnatal growth failure syndromes	Kabuki syndrome, Costello syndrome
Contiguous gene deletion including ABCC8	Usher syndrome
Syndromes with abnormal calcium homoeostasis	Timothy syndrome
Other syndromes	Congenital central hypoventilation syndrome (Ondine's curse), Donohue syndrome (Insulin resistance syndrome*), Poland syndrome, CHARGE syndrome
Metabolic causes of HH	
Congenital disorders of glycosylation	CDG Ia, CDG Ib, CDG Id
Tyrosinemia type 1	
Miscellaneous causes of HH	
Postprandial HH	Dumping syndrome, insulin receptor gene mutation*, non-insulinoma pancreatogenous hypoglycaemia, insulin autoimmune syndrome
Other causes	Insulinoma, Factitious hypoglycaemia, Drug-induced

IUGR, Intrauterine growth retardation; LGA, Large for gestational age; GDH, Glutamate dehydrogenase; GCK, Glucokinase; HK1, Hexokinase 1; HADH, Hydroxyacyl-CoA dehydrogenase; HNF1α, Hepatocyte nuclear factor 1α; HNF4α, Hepatocyte nuclear factor 4α; Kir6.2, inward rectifier potassium channel 6.2; MCT1, Monocarboxylate transporter 1; SLC16A1, solute carrier family 16, member 1; SUR1, Sulfonylurea receptor 1; UCP2, Mitochondrial uncoupling protein 2; CDG, Congenital disorder of glycosylation; PGM1, Phosphoglucomutase 1; PMM2, Phosphomannomutase 2; CACNA1D Calcium voltage-gated channel subunit alpha1 D; FOXA2, Forkhead Box A2. * In extreme insulin resistance

genes have been described to date leading to non-physiological insulin hypersecretion [4]. Monogenic CHI can broadly be classified into types due to (a) defects in genes regulating channel and ion transporter proteins; (b) gain and loss-of-function of genes encoding enzymes involved in regulating insulin secretion; and (c) transcription factor defects. These subtypes of HH will be described briefly.

Defects in Genes Regulating Channel and Ion Transport Proteins

K_{ATP} channel: *ABCC8* and *KCNJ11* mutations

Insulin secretion from pancreatic β-cell is mainly under the control adenosine triphosphate (ATP)-sensitive potassium (K_{ATP}) channels located in the pancreatic β-cell membrane. These channels play a key role in glucose homeostasis by entraining the electrical excitability of the β-cell membrane to glucose metabolism, and thus to subsequent insulin secretion [3].

The major monogenic causes of CHI are defects in *ABCC8* and *KCNJ11* genes, encoding the SUR1 and Kir6.2 proteins of the K_{ATP} channel, respectively [5, 8]. Homozygous or compound heterozygous inactivating mutations cause the most severe forms of CHI, which are typically unresponsive to diazoxide treatment, often requiring pancreatectomy to control hypoglycaemia [8]. These mutations lead to defects in K_{ATP} channel biogenesis and turnover, defects in channel trafficking from the endoplasmic reticulum and Golgi apparatus to the plasma membrane, and/or alteration of channel regulation by nucleotides or open-state frequency [5].

Dominant inactivating mutations of *ABCC8* or *KCNJ11* usually cause a milder phenotype of CHI with a later age at presentation than the recessive condition. However, medically unresponsive dominant forms have also been reported [9]. A single, paternally inherited K_{ATP} channel mutation with a concomitant postzygotic loss of the maternal 11p15.1-11p15.5 chromosomal region, encoding the K_{ATP} channel and tumour suppressor genes, usually results in a focal adenomatous hyperplasia [10].

Lactate Transporter and Calcium Channel Defects

The *SLC16A1* gene encodes the monocarboxylate transporter 1 (MCT1), which transports monocarboxylates such as pyruvate and lactate into cells. In normal physiological conditions, pancreatic β-cells have low MCT1 expression, so intracellular pyruvate and lactate concentrations are too low to induce insulin secretion. However, dominantly inherited promoter-activating mutations in *SLC16A* lead to increased β-cell MCT1 expression, resulting in pyruvate uptake and metabolism by cells, driving increased ATP

production and thus insulin exocytosis [11]. CHI caused by these mutations is known as exercise-induced hyperinsulinism (EIHI). Affected individuals (older children and adolescents) become hypoglycaemic within 30–45 min after active anaerobic exercise due to pyruvate accumulation [12].

CACNA1D gene encodes the α-subunit of the main L-type calcium voltage-gated channel that has a key role in insulin secretion from the pancreatic β-cell. A gain-of-function mutation in this gene (p.G403D) has been reported to cause diazoxide-responsive HH in a macrosomic neonate [13].

Defects in Key Enzymes Involved in Controlling Insulin Secretion

Activating mutations in the enzymes glutamate dehydrogenase (GDH), CCK, and Hexokinase 1.

The *GLUD1* gene encodes the mitochondrial matrix enzyme glutamate dehydrogenase (GDH). It catalyses reversible oxidation of glutamate to α-ketoglutarate and ammonia. De novo or dominantly inherited missense mutations in *GLUD1* result in gain of enzyme function by reducing its sensitivity to allosteric inhibition by guanosine triphosphate (GTP). This allows activation of insulin secretion by the amino acid leucine. These heterozygous activating mutations cause a protein (leucine)-sensitive form of CHI—hyperinsulinism/hyperammonaemia syndrome (HI/HA), characterized by inappropriate pancreatic insulin secretion and excessive ammonia production. This form of HH is associated with asymptomatic hyperammonaemia and postprandial hypoglycaemia after protein/leucine-rich meals [1, 4, 14].

GCK is a glycolytic enzyme that functions as a glucose sensor in the pancreatic β-cell, regulating the glucose-stimulated insulin secretion [15]. Heterozygous activating mutations in the *GCK* gene lead to an increased glucose affinity of the enzyme, resulting in an increased ATP:ADP ratio in the β-cells, closure of the K_{ATP} channel and inappropriate insulin secretion at low glucose concentrations. Patients often have a dominant family history of hypoglycaemia, with variable severity of symptoms within families [16].

The *HK1* gene encodes the glucose-phosphorylating enzyme hexokinase1 (HK1), which catalyses the first step of the glucose metabolism to glucose-6-phosphate. The absence of HK1 prevents normal β-cells from secreting insulin at the time of hypoglycaemia. Recently a dominantly inherited form of diazoxide-responsive HH has been reported, linked to a gain-of-function mutation in the *HK1* locus [17]. Patients present with mild hypoglycaemia in infancy after prolonged fasting or following a glucose load.

Loss-of-Function Mutations in the Enzymes HADH, UCP2, PGM1, PMM2

HADH is a mitochondrial enzyme that catalyses the NAD^+ dependent dehydrogenation of 3-hydroxyacyl-CoA to 3-ketoacyl-CoA in the β-oxidation of fatty acids [18]. It is highly expressed in pancreatic β-cells. Recessively inherited mutations in the *HADH* gene lead to HH [19]. In HADH deficiency there is a loss of the inhibitory protein-protein interaction between GDH and HADH, which causes overstimulation of GDH, an increase in cellular ATP and upregulated insulin secretion [18]. Unlike in HI/HA syndrome, activation of GDH in HADH deficiency is largely limited to the pancreatic β-cells, so the enzyme deficiency does not lead to hyperammonaemia. The clinical presentation is heterogeneous varying from mild fasting or protein/leucine-induced late-onset hypoglycaemia to severe neonatal hypoglycaemia. Some patients have abnormal acylcarnitine metabolites (raised plasma 3-hydroxybutyrylcarnitine and urinary 3-hydroxyglutarate levels) [3].

The *UCP2* gene encodes a mitochondrial carrier protein largely expressed in pancreatic α- and β-cells. This gene plays a role in protection against oxidative stress during fatty acid metabolism and has been implicated in negative regulation of glucose-stimulated insulin secretion [20]. UCP2 loss-of-function heterozygous mutations have been reported in children with congenital HH, however, another study has shown that variants in *UCP2* may be not a monogenic cause of CHI [21].

Phosphoglucomutase 1 (PGM1) catalyses reversible interconversion of glucose-6-phosphate and glucose-1-phosphate and is essential for glycogen formation, glycogenolysis, and protein glycosylation. PGM1 activity within the pancreatic islets modulates glucose-stimulated insulin secretion. Affected children have both fasting ketotic hypoglycaemia and symptomatic postprandial hypoketotic HH due to a defect in SUR1 glycosylation and exaggerated glucose-stimulated insulin secretion [22].

Phosphomannomutase 2 (PMM2) gene encodes for a key enzyme in glycosylation, and deglycosylation in the pancreatic β-cells has been shown to alter insulin secretion. A recessive mutation in the promoter region of the *PMM2* gene (c.-167G.T) causes a newly described form of CHI, associated with the development of congenital polycystic kidney disease [23].

Transcription Factor Defects

Mutations in *HNF4/1α* and *FOXA2* Genes

HNF4α gene encodes the transcription factor hepatocyte nuclear factor 4α (HNF4α), which belongs to the nuclear hormone receptor superfamily and controls the expression of genes involved in the glucose-stimulated insulin secretion. Heterozygous *HNF4α* mutations have been reported to cause mild transient or persistent congenital HH. Mutations in *HNF4α* cause maturity-onset diabetes of the young 1 (MODY1), and such patients are thus at increased risk of diabetes in later life, and commonly have a family history of diabetes [24]. The *HNF1α* gene encodes a transcription factor, which enhance expression of liver and pancreatic specific genes. Heterozygous, loss-of-function mutations in this gene cause *HNF1α* CHI. Patients present with mild macrosomia at birth and usually develop MODY3 in later life [25]. Two cases of a mutation in *FOXA2* with hypopituitarism, hyperinsulinism and endoderm-derived organ abnormalities have been reported [26, 27]. However, the direct link between HH and the mutation in *FOXA2* has not been proven yet.

Syndromes and Metabolic Causes Associated with HH

Many syndromes have been reported to feature HH either in the neonatal period or at a later age [28]. The most common syndrome associated with HH in childhood is Beckwith–Wiedemann

syndrome (BWS) [29]. Almost half of the patients with BWS develop hypoglycaemia but in most of these children, HH is transient and resolves spontaneously in a few days. However fewer than 5% of the children have HH beyond the neonatal period. In rare cases there is no response to medical therapy and near-total pancreatectomy may be required. Kabuki syndrome is the second most common syndromic form of HH. It is caused by inactivating mutations in two genes: autosomal recessive mutations in *KMT2D* (70–75% of cases) and X-linked mutations in *KDM6A*, which account for 1–9% of cases [30]. Up to 70% of children with Kabuki syndrome have HH and most of these are diazoxide-responsive. Congenital disorders of glycosylation (CDG) are metabolic multisystem diseases caused by defects in the biosynthesis or transfer of lipid-linked oligosaccharides to the nascent protein chain [31].

Postprandial HH (PPHH)

Postprandial hyperinsulinaemic hypoglycaemia (PPHH) occurs within a few hours of food consumption due to inappropriate insulin secretion in response to a meal. It is rare in childhood and the oral glucose tolerance test (OGTT) and mixed-meal tolerance (MMT) test are used for its diagnosis. The most common cause of PPHH in children is '*dumping syndrome*' after gastroesophageal surgery (Nissen's fundoplication). In these patients the secretion of glucagon-like peptide-1 (GLP-1) after ingestion of hyperosmolar carbohydrate-containing solutions is exaggerated, contributing to an inappropriate insulin release and consequent hypoglycaemia within 1 to 4 hours [32]. Another rare cause of PPHH is extreme insulin resistance caused by insulin receptor (*INSR*) gene mutations [33]. PPHH occurs a few hours after meal ingestion and may be related to decreased insulin clearance.

As discussed in more detail in Chapter 14.3.2, 'Autoimmune Hypoglycaemia', PPHH can also be caused by **insulin autoimmune syndrome**, an autoimmune condition characterized by the presence of high levels of insulin autoantibodies in patients who have not previously been exposed to exogenous insulin [34].

Insulinoma

Insulinoma is a rare neuroendocrine tumour, which causes fasting or postprandial HH in older children and adolescents. It can occur either in isolation, or may be a part of the familial dominant syndrome, multiple endocrine neoplasia type 1 (MEN1), so the family history is an important clue to the diagnosis of familial cases [35]. The diagnosis of insulinoma is confirmed by histological examination of the excised pancreatic tissue, showing well-demarcated nodules of endocrine tissue without hyperplasia of the exocrine components.

Munchausen by Proxy Syndrome

Factitious HH is an important consideration in cases with no clear explanation for hypoglycaemic episodes. It is caused by covert exogenous administration of insulin or oral antidiabetic drugs (sulphonylureas). In some cases, this has led to misdiagnosis and consequent pancreatectomy [1].

Histological Subtypes of HH

There are two main histological subtypes of congenital HH, namely diffuse and focal. The diffuse form affects all pancreatic β-cells with variable involvement of the islets. It features enlarged hyperfunctioning cells with very abundant cytoplasm and nuclei that are 3–4 times larger than normal [4, 36]. The most common genetic causes of diffuse HH are recessive and dominant mutations in *ABCC8* and *KCNJ11* genes, as well as all the other genes described earlier. This form of HH accounts for 60–70% of all diagnosed cases.

Focal HH is associated with small (*c.* 2–10 mm diameter) and poorly delineated areas of the pancreas. Lesions consist of large endocrine cells with a large cytoplasm and dispersed abnormal nuclei of irregular and angular shape. The area of abnormal pancreatic development is multilobular and can have satellites in nearby pancreatic tissue that necessitate intraoperative margins analysis to ensure complete excision and avoid recurrence [4, 37].

Focal disease is sporadic and has a distinctive genetic aetiology involving two independent events—inheritance of a paternal mutation in *ABCC8* or *KCNJ11* genes and somatic loss of the maternal 11p allele (11p15.1-15.5) involving the *ABCC8* and *KCNJ11* region within the focal lesion [38]. This paternal uniparental isodisomy unmasks the paternally inherited K_{ATP} channel mutation, which leads to β-cell proliferation due to the altered expression of a number of imprinted genes (maternally expressed tumour suppressor genes *H19* and *CDKN1C* and paternally expressed growth factor IGF2). This accounts for almost 30–40% of all congenital HH cases.

Clinical Presentation

HH most commonly presents with recurrent and persistent hypoglycaemia, which can be fasting or precipitated by the ingestion of protein meals or strenuous physical exercise. The most severe forms of HH typically present in the neonatal period whereas in older children the clinical presentation may be more subtle. Affected newborns may be macrosomic due to fetal hyperinsulinaemia, with hepatomegaly and hypertrophic cardiomyopathy. The clinical manifestations vary between patients, ranging from mild non-specific symptoms (such as poor feeding in the neonatal period) to severe, medically unresponsive symptoms such as apnoea, seizures or even coma [1, 3, 4].

Diagnosis of HH

The diagnosis of HH should be made as soon as possible and appropriate treatment started early to avoid hypoglycaemic brain injury. The diagnosis of HH relies on the combination of clinical findings and biochemical markers consistent with inappropriate insulin secretion at the time of hypoglycaemia.

The medical history should focus on the presence of maternal risk factors, eventful delivery, birth weight, and gestational age, family history of diabetes mellitus or infantile seizures and unexplained infant deaths, parental consanguinity, the time and clinical characteristics of the hypoglycaemic episode, and its relationship to the most recent meal or exercise. On physical examination, there might be evidence of macrosomia or IUGR, syndromic features, hepatomegaly, and cardiomegaly [39].

Laboratory (blood and urine) findings are informative and diagnostic if a 'critical sample' has been taken at the time of hypoglycaemia (usually with a BG level below 3.0 mmol/L) before treatment. When hypoglycaemic samples are not available, a controlled fast should be performed under strict monitoring conditions to induce hypoglycaemia. CHI is the only condition in which hypoglycaemia can persist despite the continuous administration of glucose. The maintenance of normoglycaemia with an intravenous glucose infusion rate higher than 8 mg/kg/min is a powerful diagnostic criterion for HH [39].

Inappropriate insulin secretion at the time of hypoglycaemia, whether spontaneous or provoked, is pathologic and consistent with the presence of HH. Since insulin secretion is pulsatile and since it is rapidly cleared by hepatic metabolism serum insulin levels may be falsely low and there is no correlation between the severity of hypoglycaemia and serum insulin levels. At the same time, the C-peptide concentration, reflecting endogenous insulin secretion, is almost always elevated during hypoglycaemia and its measurement could be more helpful for the diagnosis of dysregulated insulin secretion compared to insulin measurement. In addition, inappropriately low or suppressed serum ketone (predominately 3-β-hydroxybutyrate) and fatty acid concentrations during hypoglycaemia and absence of ketonuria are highly suggestive of HH. Increased serum ammonia concentrations in a patient suspected to have CHI suggest HI/HA syndrome, while increased plasma hydroxybutyrylcarnitine and urinary 3-hydroxyglutarate may indicate *HADH* deficiency.

In some settings, specific stimulation tests can be performed to confirm the diagnosis of HH. A positive glycaemic response of more than 1.5 mmol/L, following a glucagon bolus at the time of hypoglycaemia, is confirmatory of HH [39]. Improvement in hypoglycaemia after a subcutaneous dose of octreotide is also supportive evidence of HH.

Some types of HH may be demonstrated by provocation tests. In patients with HI/HA syndrome, having both fasting and protein-induced hypoglycaemic episodes, a protein/leucine load test will be required for the diagnosis [14]. Patients with EIHI will require a formal exercise test and/or a pyruvate load to demonstrate hypoglycaemia [12]. Patients with a history of PPHH should undergo an MMT test, which is superior to OGTT.

Currently genetic testing is a well-established method to define the best approach to treatment of CHI. Finding two pathogenic variants (homozygous or compound heterozygous mutations in *ABCC8* and *KCNJ11*) is usually diagnostic of medically unresponsive diffuse disease. Patients with a single recessive pathogenic variant on the paternal allele of *ABCC8* and *KCNJ11* genes or without identified mutations potentially have curable focal disease and require further imaging to localize the lesion(s) precisely [3, 4].

Management of Congenital HH

Management of HH can be very challenging. Patients should ideally be managed in centres of excellence with the necessary experience and expertise, as they will require multidisciplinary care. Patients with HH require frequent blood glucose monitoring and often need a central venous catheter to deliver concentrated glucose infusions. The key aims in meticulous management are to maintain normoglycaemia (blood glucose levels >3.5mmol/L), to encourage oral feeding, to assess the response to medical therapy, and to decide if urgent genetic testing is indicated, undertaking pancreatic imaging with 18F-DOPA PET/CT if required and surgical intervention again if required [1, 39]. The management cascade and medications used are shown in Figure 14.3.1.1 and Table 14.3.1.2.

Surgery in HH

The type of surgical procedure will depend on the underlying histology of the HH. Before the patient undergoes any type of surgery it will be important to know the underlying histological basis of the HH. Patients with autosomal recessive mutations in *ABCC8/KCNJ11* will have histologically diffuse disease. However, those with a paternal ABCC8/KCNJ11 mutation are likely to have focal disease and will need imaging with 18F-DOPA PET/CT to localize the focal lesion(s).

Focal Lesions

Focal forms of CHI can be completely cured with partial pancreatectomy or limited lesionectomy with a complete excision of the lesion or enucleation of the tumour confirmed by intraoperative biopsies. In large focal lesions in the pancreatic head or neck, especially when they are close to the common bile or pancreatic duct, open laparotomy with a resection and Roux-en-Y pancreaticojejunostomy is performed. Fluorine-18-L-dihydroxyphenylalanine positron emission tomography (18F-DOPA PET/CT) is the current gold standard technique for precise preoperative localization of focal lesions [40]. As a result, the extent of the pancreatic surgical resection can be guided and children with focal HH can be cured by limited surgery. This technique is based on the ability of the β-cells to uptake L-dihydroxyphenylalanine (L-DOPA) and to convert it to dopamine by the enzyme DOPA decarboxylase. The positron emitting tracer 18F-DOPA is an analogue of DOPA and the former can be used to detect lesions of hyperfunctional β-cells visualized as bright areas over a darker background [40].

Diffuse Forms

Children with diffuse forms of medically unresponsive HH requires near-total pancreatectomy (removal of 95–98% of the pancreas) leaving a small amount of pancreatic tissue around the duodenum and the common bile duct [41]. The immediate post-surgical outcome is unpredictable—from persistent hypoglycaemia to insulin-requiring diabetes and exocrine pancreatic insufficiency. Postoperatively some children still have episodes of hypoglycaemia and further postoperative therapy with medications and/or frequent feedings is required or re-operation may be performed [42]. Near-total pancreatomy is also associated with a high incidence of

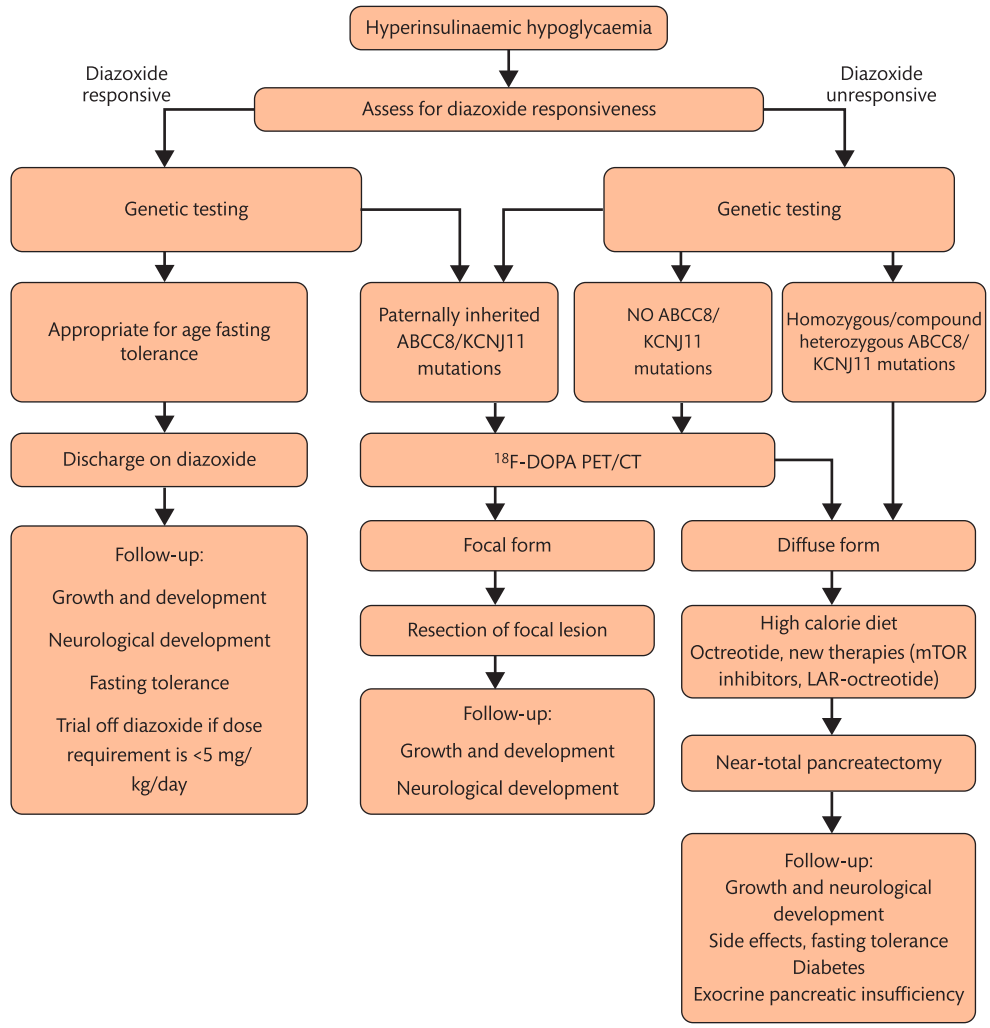

Figure 14.3.1.1 Diagnostic and management algorithm in patients with hyperinsulinaemic hypoglycaemia.

Table 14.3.1.2 Drugs used in the management of hyperinsulinaemic hypoglycaemia

Drug	Dose	Mechanism of action	Side effects
Older conventional medications			
Diazoxide	5–20 mg/kg/day in 3 oral doses	K_{ATP} channel agonist	**Common:** fluid retention, hypertrichosis, loss of appetite. **Rare:** cardiac failure, hyperuricemia, leukopenia, eosinophilia, paradoxical hypoglycaemia, pulmonary hypertension
Chlorothiazide	7–10 mg/kg/day in 2 oral doses	Synergistic effects with diazoxide	Hyponatraemia, hypokalaemia
Nifedipide	0.25–2.5 mg/kg/day in 2–3 oral doses	Calcium channel blocker	Hypotension
Glucagon	0.02 mg/kg s.c/i.m. bolus or 1–10 µg/ kg/h of s.c/i.v. infusion	Induces glycogenolysis/ gluconeogenesis	Nausea, vomiting, skin rash, rebound hypoglycaemia (at higher doses)
Octreotide	5–35 µg/kg/day, divided in 3–4 s.c. doses or continuous s.c. infusion	Somatostatin analogue; reduces insulin biosynthesis and secretion	**Acute:** nausea, abdominal distension, hepatitis, long QT, tachyphylaxis, necrotizing enterocolitis. **Long term:** decreased intestinal motility, bile sludge, cholelithiasis, pituitary suppression
Newer medications			
Lanreotide/ LAR-octreotide	Total dose of octreotide as above *or* 15–60 mg given 4 weekly as i.m./deep s.c. injection	Long-acting somatostatin analogues	Similar to daily multiple injection octreotide; long-term follow-up not reported
Rapamycin (Sirolimus)	Initially 0.5 mg/m^2/day in 1–2 oral doses, then titrated to blood levels of 5–15 ng/ml	mTOR inhibitor; inhibits β-cell proliferation and insulin secretion	Mucositis, immunosuppression, hyperlipidaemia, transient elevation of liver enzymes, thrombocytosis, impaired immune response to Bacillus Calmette–Guérin (BCG) vaccine

diabetes mellitus and exocrine pancreatic insufficiency as the risk for these complications increases with age.

Conclusion

Infants and children with HH should be diagnosed as soon as possible and treatment commenced early. HH remains a challenging condition for paediatric endocrinologists and it is recommended that children with congenital HH should be referred to centres of excellence if possible. Although there have been significant advances in understanding the genetic basis of HH, in imaging and in medical therapy there are still a large number of (diazoxide-responsive) children in whom no genetic aetiology is identified. The diffuse form of the disease remains a challenge as some children will not respond to any of the current treatments and therefore new treatment options are required in these patients. New and readily available imaging techniques (as ^{18}F-DOPA is available in only scattered centres) are required for children suspected of having focal HH.

14.3.2 Autoimmune Hypoglycaemia

Phillip Gorden and Noemi Malandrino

Introduction

Two rare causes of hypoglycaemia have an autoimmune aetiology. The first, insulin autoimmune syndrome, also known as Hirata disease, is characterized by hyperinsulinaemic hypoglycaemia and a high titre of antibodies against endogenous insulin in the absence of both pancreatic islet disease and prior exposure to exogenous insulin [1]. The second condition, type B insulin resistance, presents with extreme insulin resistance, and hyperglycaemia and/or hypoglycaemia, due to autoantibodies against the insulin receptor [2].

Both disorders are mediated by antibodies to self-antigens. This is distinct from antibodies against exogenous recombinant human insulin, which are commonly detected in patients with insulin-treated diabetes, but which, except in rare cases of labile glycaemic control, do not have clinical significance. Differentiating non-self-antigen-induced antibodies from autoantibodies is difficult in patients treated with exogenous insulin, making the biochemical diagnosis of insulin autoimmune syndrome problematic. The risk of overdiagnosis of pathogenic antibodies is illustrated by the low prevalence of insulin resistance in patients who received animal-derived insulins and developed high titres of insulin-binding antibodies [3, 4].

This chapter reviews the clinical characteristics, pathophysiology, diagnosis, and management of autoimmune hypoglycaemia syndromes. Additionally, the complexity of diagnosis of insulin autoimmune syndrome in patients treated with exogenous insulin and showing positive insulin antibodies is discussed, together with the challenges in discrimination of those antibodies with clinically significant effects on insulin kinetics.

Insulin Autoimmune Syndrome

Clinical Characteristics in Asian Populations

The insulin autoimmune syndrome was first described in Japan by Hirata in 1970 [5]. Most of the cases have been reported in Asia, including at least 380 cases in Japan and more than 70 cases in China [5, 6]. In Japan, the insulin autoimmune syndrome is the third leading cause of spontaneous hypoglycaemia, after insulinoma and extrapancreatic neoplasms [1]. The peak age of onset is 60–69 years [1]. A similar age of onset has been described in male Chinese patients, while the disease most commonly occurs at 30–39 years in Chinese females [6]. The reasons for this sex difference in Chinese patients are not fully understood. Males and females are equally affected, except for the age groups 20–29 and 30–39 in Japanese and Chinese patients, where a higher percentage of females (75–85%) is reported [6].

Asian patients show a high prevalence of the Cw4/B62/DR4 allelic combination [1]. Most of the DR4-positive patients are DRB1*0406 positive, although some patients are DRB1*0403 or DRB1*0407

positive. The DRB1*0406 allele shows the highest risk for susceptibility to the insulin autoimmune syndrome and seems to mediate the presentation of insulin peptides to T cells [5].

In about 42% of Japanese patients, prior exposure to medications containing sulfhydryl groups has been reported, including methimazole, alpha-mercaptopropionyl glycine, glutathione, gold thioglucose, captopril, penicillamine, and alpha lipoic acid [5]. Sulfhydryl compounds may cleave the disulphide bonds linking the A and B-chains of insulin, allowing the interaction between antigen-presenting cells and insulin-derived peptides and the activation of self-insulin T-helper cells. Non-sulfhydryl compounds have also been associated with insulin autoimmune syndrome, including aceglatone, steroids, interferon-alpha and non-steroidal anti-inflammatory drugs [5].

Clinical Characteristics in Non-Asian Populations

A smaller number of patients with the insulin autoimmune syndrome has been reported in non-Asian countries [7]. The disease in these populations develops more frequently in individuals over 40 years of age, with similar prevalence in males and females [7]. While the DRB1*0406 allele is 10–20 times more common in Asian patients, in non-Asian patients the insulin autoimmune syndrome is more frequently associated with the DRB1*0403 allele. The different prevalence of DRB1*04 alleles in these populations may account for the higher frequency of insulin autoimmune syndrome in Asia, given the higher risk associated with DRB1*0406 [8].

In non-Asian patients, frequent association of insulin autoimmune syndrome is noted with rheumatologic diseases, including systemic lupus erythematosus, rheumatoid arthritis and systemic sclerosis, or with haematologic diseases, including benign monoclonal gammopathy and multiple myeloma. Patients may have positive antinuclear antibodies, antidouble-stranded DNA and rheumatoid factor, and an abnormal blood count, urine and serum protein electrophoresis and bone marrow examination [7].

As for Asian patients, exposure to various medications before development of the disease has been reported, including captopril, penicillamine, pyritinol, carbimazole, and methimazole, imipenem, propylthiouracil, hydralazine, procainamide, isoniazid, penicillin G, and alpha lipoic acid. However, the relationship between sulfhydryl-containing medications and the occurrence of the syndrome is not as clear as in Japanese patients [7].

Pathophysiology and Mechanism of Hypoglycaemia

Hypoglycaemic episodes in the insulin autoimmune syndrome are caused by the production of antibodies against endogenous insulin in patients with no exposure to exogenous insulin. Hypoglycaemia most often occurs in the postprandial state, although fasting hypoglycaemia and hypoglycaemia exacerbated by exercise have been described. Paradoxically, hyperglycaemia may occur immediately following a meal or oral glucose challenge, and may explain the elevated glycated haemoglobin seen in some patients, despite hypoglycaemic episodes [7].

Both hyper and hypoglycaemia are thought to be related to the binding of endogenous insulin by antibodies, resulting in physiologically inappropriate levels of bioavailable insulin. After a meal or oral glucose load, insulin is secreted in response to rising blood glucose. In the insulin autoimmune syndrome, the binding of secreted insulin to the antibodies reduces insulin availability to receptors in the liver and peripheral tissues, which may result in hyperglycaemia and further insulin release. As the blood glucose concentration decreases and insulin secretion declines, the antibody-bound insulin is released, resulting in inappropriately high free insulin concentrations and hypoglycaemia (see Figure 14.3.2.1) [7].

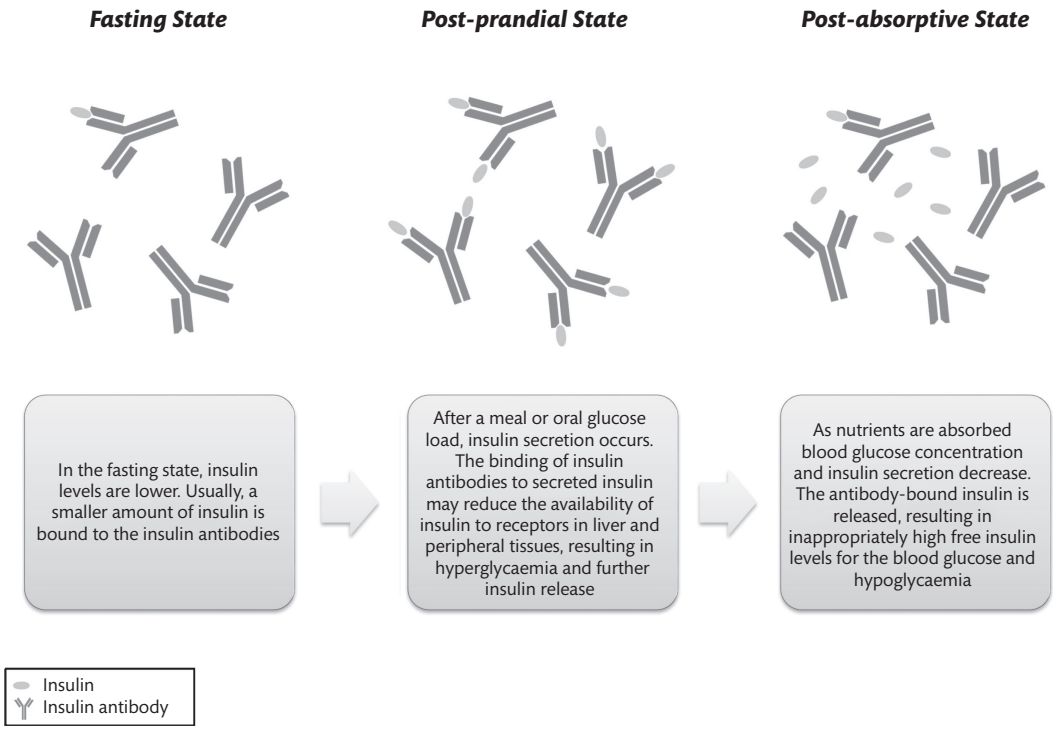

Figure 14.3.2.1 Mechanism of hypoglycaemia in the insulin autoimmune syndrome.

In the insulin autoimmune syndrome, insulin levels may be markedly elevated, due to interference of endogenous autoantibodies with the insulin immunoassay. In this situation the insulin assay is unreliable. Alternatively, the insulin values may be low depending on the specific immunoassay technique. Thus, in these situations the insulin immunoassay may be misleading and the most accurate technique to determine the presence of an insulin-binding protein, such as an antibody is polyethylene glycol or gel filtration chromatography [9]. Insulin autoantibodies may sometimes interfere with C-peptide and proinsulin immunoassays, leading to erroneously elevated concentrations of these hormones too [7].

Most insulin antibodies are immunoglobulin G (IgG) with various ratios of kappa to lambda light chains. However, other immunoglobulin classes have also been reported. Based on affinity curves for binding to human insulin and the presence of solitary light chains, insulin antibodies are classified as monoclonal or polyclonal. The clonality has been related to the type of amino acid at position 74 of the HLA-DR4 beta 1 chain. Most of the Asian patients develop polyclonal IgG insulin antibodies with two classes of insulin-binding sites: high affinity/low capacity and low affinity/high capacity. In contrast, non-Asian patients show a higher prevalence of monoclonal low affinity/high capacity antibodies [7]. High affinity/low capacity antibodies seem to be frequently associated with hyperglycaemia and insulin resistance, whereas low affinity/high capacity antibodies are more likely to induce hypoglycaemia due to the dissociation of insulin from the insulin-antibody complex [10].

Insulin antibodies can be measured by assessing binding by serum of ^{125}I-labelled insulin, by enzyme-linked immunosorbent assay, or indirectly by determining recovery of immunoreactive insulin after polyethylene glycol precipitation of plasma [7]. Radioligand binding assays are also used to assess the clonality and affinity of insulin antibodies. After incubation of a fixed concentration of serum insulin antibody with a fixed amount of ^{125}I-insulin and increasing concentrations of unlabelled insulin, Scatchard analysis is performed by plotting the bound/free versus bound insulin concentration, and binding capacities and affinities of antibodies are determined. While Scatchard analysis has been frequently used, its interpretation is problematic in the context of polyclonal antibodies [4].

Complexity in the Diagnosis of Insulin Autoimmune Syndrome in Patients Treated with Exogenous Insulin and with Positive Insulin Antibodies

Patients with diabetes treated with recombinant human insulin or insulin analogues commonly develop antibodies against exogenous insulin, which are polyclonal IgGs with a wide range of affinities and capacities [4, 11]. In patients with type 1 diabetes autoantibodies may be present prior to the development of hyperglycaemia. These autoantibodies are markers of the immune process and do not have biologic significance. Episodes of insulin resistance and/or severe hypoglycaemia have been described in patients with positive insulin antibodies and treated with exogenous animal-derived insulin [3, 4]. With the introduction of recombinant human insulin, the incidence and severity of immunological response to insulin treatment has significantly decreased. While the low titres of antibodies induced by recombinant human insulin do not usually affect glycaemic control or interfere with therapy, insulin-treated patients with high levels of insulin antibodies have rarely developed hyperglycaemic and/or hypoglycaemic episodes [4, 11, 12]. These patients most commonly have type 1 diabetes, and the poor glycaemic control is attributed to circulating antibodies against exogenous insulin [11, 12]. In a few cases, coexistence of insulin autoimmune syndrome has been proposed as the cause of hypoglycaemia [11, 13]. An additional uncommon condition proposed as a possible cause of insulin resistance and/or hypoglycaemia in type 1 diabetes is subcutaneous insulin resistance, defined according to three criteria: (1) resistance to the action of subcutaneous insulin, with normal sensitivity to intravenous insulin; (2) lack of increased circulating insulin after the administration of subcutaneous insulin; (3) increased degradation of insulin in the subcutaneous tissue. The existence of this condition is highly questionable and difficult to document [14].

Patients with type 1 diabetes treated with exogenous insulin may present with unstable glycaemic control, hypoglycaemia, and insulin antibodies. However, the role of the antibodies in causing hypoglycaemia is not always clear. Thus, several factors may affect blood glucose stability in these patients. The type and dose of insulin, and the site and technique of injection can affect the rate of insulin absorption. Slower absorption of insulin may be associated with longer time to peak and longer duration of the effect, resulting in initial hyperglycaemia, followed by hypoglycaemia a few hours after a meal. Alterations at the injection site (e.g. lipohypertrophy), and factors influencing the subcutaneous blood flow, including exercise, massage at the injection site and temperature, may also affect insulin absorption. Finally, psychosocial factors and poor compliance to insulin treatment may be associated with decreased glycaemic control [15–17]. Identification and correction of these factors is extremely important and often results in significantly improved glycaemic control. Therefore, administration of antibody-depleting therapies in individuals treated with exogenous insulin and with positive insulin antibodies should be considered with extreme caution and after careful consideration of alternative factors associated with poor glycaemic control. Furthermore, in those cases where the coexistence of insulin autoimmune syndrome is suspected, it is difficult to distinguish antibodies induced by exogenous insulin from autoantibodies. As discussed earlier, Scatchard analysis may be used to study the affinity and binding capacity of antibodies, to determine their possible role in the development of insulin resistance and/or hypoglycaemic events [4, 11]. In addition, a gel filtration chromatography method coupled to *ex vivo* insulin binding/exchange has been developed to improve identification of insulin autoantibodies that are likely to alter insulin pharmacokinetics and pharmacodynamics (see Figure 14.3.2.2) [18].

Type B Insulin Resistance

Clinical Characteristics

Type B insulin resistance is a rare disease, although the exact prevalence is unknown. The largest cohort includes 48 patients followed at the National Institutes of Health (NIH). The typical patient is a middle-aged African-American woman (~85% of patients). In the NIH cohort, the average age of onset is 41 years in women, and 57 years in men, although the disease can occur in children and the elderly [7, 19].

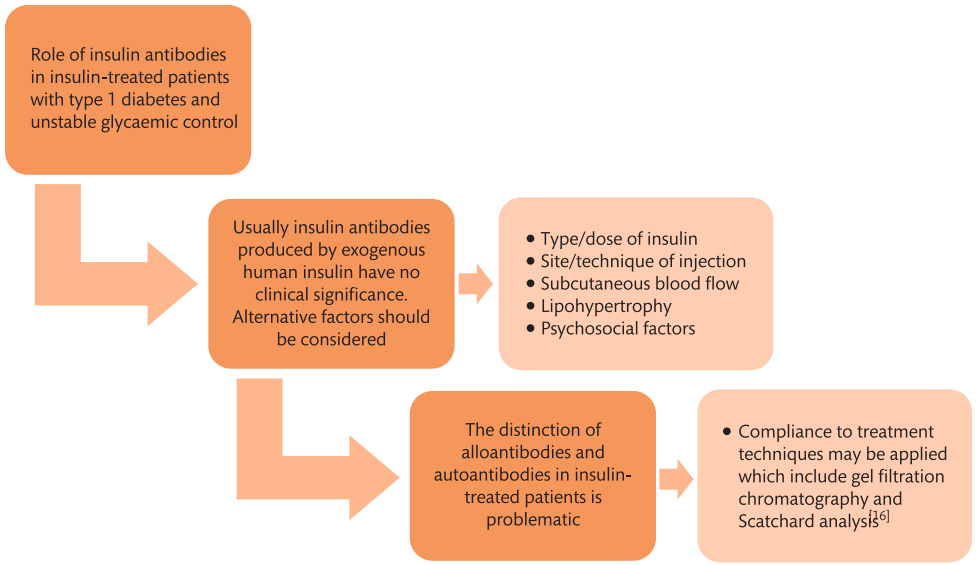

Figure 14.3.2.2 Factors affecting the stability of glycaemic control in type 1 diabetes.

Most patients present with extreme insulin resistance, relatively acute onset of moderate to severe hyperglycaemia and profound glycosuria, polyuria, and weight loss. Endogenous insulin levels are elevated prior to administration of exogenous insulin. Some patients may develop a hyperglycaemic phase followed by hypoglycaemia, or hypoglycaemia alone. The hypoglycaemia may develop in the fasting or postprandial state. Several patients presenting with hypoglycaemia show higher body mass index (BMI) than those with hyperglycaemia. In a subgroup of the NIH cohort, 62% of the hyperglycaemic patients had a BMI <25 kg/m² and 19% had a BMI >30 kg/m², whereas 33% of the hypoglycaemic patients had a BMI <25 kg/m² and 67% had a BMI >30 kg/m² [19].

In type B insulin resistance, acanthosis nigricans is a striking clinical feature. While it most commonly affects the axillae, groin, and neck, patients with type B insulin resistance may show more diffuse anatomical extent involving the periocular, perioral, and labial regions. Some patients also develop acanthosis on the trunk, buttocks, lips, and vulva [19]. Polycystic ovarian enlargement and hyperandrogenism are commonly seen in premenopausal women. Reduction in testosterone levels occurs when the autoantibody syndrome remits [7, 19].

Low fasting triglycerides and high plasma concentrations of the fat cell-derived protein adiponectin are additional biochemical characteristics associated with this disease. These may help distinguish type B insulin resistance from other syndromes of insulin resistance, which are typically associated with high fasting triglycerides and hypoadiponectinemia. Of note, low triglycerides and high adiponectin levels are also observed in patients with insulin-receptor mutations, therefore these metabolic characteristics appear to be a unique feature of insulin-receptor dysfunction as opposed to non-receptor-mediated insulin resistance [20]. In addition, in type B insulin resistance, the reduction of insulin-receptor autoantibodies and the resolution of insulin resistance result in normalization of adiponectin levels [7].

Type B insulin resistance is frequently associated with systemic lupus erythematous and/or other autoimmune diseases [19]. The metabolic derangements of type B insulin resistance usually appear after the onset of the underlying systemic autoimmune disease. Type B insulin resistance may also develop as a paraneoplastic manifestation of conditions such as multiple myeloma and Hodgkin's disease [19]. Proteinuria has been reported in ~50% of the patients. Despite uncontrolled hyperglycaemia, proteinuria appears to be related to different forms of lupus nephritis, such as mesangial and proliferative lupus nephritis, rather than diabetic nephropathy [7, 19]. Haematologic abnormalities, including leucopoenia, thrombocytopenia, and anaemia, may also be related to the underlying autoimmune disease [19].

Pathophysiology and Mechanism of Hypoglycaemia

Type B insulin resistance is caused by circulating autoantibodies against the insulin receptor which are primarily polyclonal IgGs. Patients may present with either insulin resistance or hypoglycaemia. These dual effects are related to the partial agonist activity of the receptor autoantibodies. These autoantibodies can in fact mimic insulin action in cell cultures, by causing autophosphorylation of the insulin receptor and stimulation of 2-deoxyglucose uptake or glucose oxidation, which in turn result in hypoglycaemia. On the other hand, extended exposure of the cell cultures to the autoantibodies induces increased insulin-receptor degradation, decreased number of cell-surface receptors and insulin resistance. Similarly, when administered acutely to fasting rats, the autoantibodies induce hypoglycaemia in a dose-dependent manner, whereas chronic administration of the receptor autoantibodies to fed rats results in persistent hyperglycaemia and insulin resistance. The partial agonist activity of the receptor autoantibodies is consistent with the observation that low antibody titres are associated with hypoglycaemia and high antibody titres are associated with hyperglycaemia (see Figure 14.3.2.3). A fall in the autoantibody titre is observed in some patients shifting from the insulin resistant to the hypoglycaemic state [7, 19].

Receptor autoantibodies appear to be specific for the insulin receptor in its native conformation, as binding does not occur with denatured receptors. Additionally, the autoantibodies bind

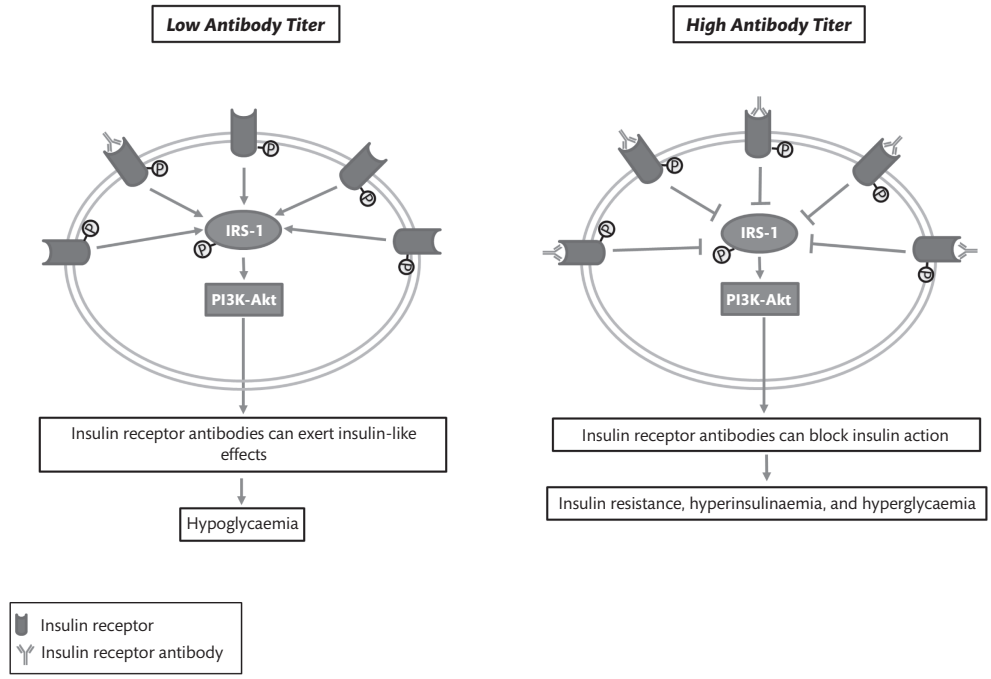

Figure 14.3.2.3 Partial agonist activity of the insulin-receptor antibodies in type B insulin resistance.

to a region of the insulin receptor in the carboxy terminal half of the alpha subunit, which is different from the domain containing the insulin-binding site in the amino terminus of the alpha subunit. Therefore, it has been suggested that, without binding to the same site as insulin, the receptor antibodies can inhibit insulin binding to the receptor through alternative mechanisms including allosteric inhibition, steric hindrance, or misalignment of the insulin-binding site. Furthermore, the binding of the autoantibodies to the insulin receptor may interfere with the receptor-mediated insulin degradation, leading to the hyperinsulinaemia [19].

To date, assays for the measurement of the autoantibodies to the insulin receptor are available only in research laboratories. The immunoprecipitation assay, which is the most sensitive and specific method, measures the ability of patients' sera to immunoprecipitate recombinant human insulin receptors [21]. Additional assays include those based on inhibition of ^{125}I-labelled insulin binding or the stimulation of glucose oxidation/lipogenesis in cells incubated with patients' sera [7].

In patients affected by type B insulin resistance, circulating insulin antibodies may be detected in addition to the insulin-receptor antibodies. Although a few cases have been reported in patients with no history of prior exposure to exogenous insulin, insulin antibody production is most commonly related to the administration of insulin [22–24].

Clinical Comparison Between Insulin Autoimmune Syndrome and Type B Insulin Resistance

The insulin autoimmune syndrome and type B insulin resistance can both present with hypoglycaemia during fasting and/or after a meal. Clinical and biochemical characteristics may help differentiate between the two syndromes (see Table 14.3.2.1). The insulin autoimmune syndrome occurs frequently between ages 40 and 80 years, equally affecting men and women. Additionally, most non-Asian patients are Caucasian. Type B insulin resistance typically occurs in African-American women between ages 40 and 50 years, though it is also seen in other ethnic groups.

In the insulin autoimmune syndrome, hypoglycaemia may develop during the fasting state and/or more commonly during the postprandial state. Hyperglycaemia may occur immediately after a meal because binding of insulin to the autoantibodies reduces insulin availability to the peripheral tissues. In type B insulin resistance, most patients present with severe hyperglycaemia. Some patients may develop hypoglycaemia after a period of hyperglycaemia, or present only with severe fasting hypoglycaemia.

Acanthosis nigricans and signs of hyperandrogenism may develop in type B insulin resistance, but not in the insulin autoimmune syndrome. While both types of autoimmune hypoglycaemia may be associated with rheumatologic or haematologic diseases, the insulin autoimmune syndrome is also associated with exposure to medications, especially sulfhydryl-containing compounds. In these cases, the hypoglycaemia often resolves with medication cessation.

In the insulin autoimmune syndrome, insulin, C-peptide, and proinsulin concentrations determined by immunoassay may be unreliable, and although values returned are usually extremely high, most of the insulin is bound to antibody and not bioavailable. In the type B syndrome, insulin values are usually high in the basal state and even more exaggerated after glucose. A remarkable feature of the type B syndrome is an extremely high insulin/C-peptide ratio, due to impaired receptor-mediated insulin degradation and unaffected non-receptor-mediated C-peptide degradation.

Table 14.3.2.1 Clinical features in patients with insulin autoimmune syndrome and type B insulin resistance

Feature	Insulin autoimmune syndrome (Asians)	Insulin autoimmune syndrome (non-Asians)	Type B insulin resistance
Type of hypoglycaemia	Reactive (most common) and/or fasting	Reactive (most common) and/or fasting	Fasting; reactive uncommon
Hyperglycaemia	Common	Variable	Common
Insulin level	Very high*	Very high*	High
C-Peptide level	Very high*	Variable*	High
Proinsulin	Very high*	Variable*	High
Sex	Men and women	Men and women	Mostly women
Age of highest incidence (yrs)	40–80	40–80	40–50
Race	–	Mostly Caucasian	Mostly African-American
Acanthosis nigricans	Rare	Rare	Usually severe
Hyperandrogenism	No	No	Common
Associated Rheumatologic disease	Less common	Common	Common
Associated Haematologic disease	No	Uncommon	Common
Medication induced	Yes, most commonly sulfhydryl compounds	Yes, role of sulfhydryl compounds less clear	No
Insulin autoantibodies	Universal, frequently polyclonal	Universal,frequently monoclonal	Usually no[§¶]
Insulin receptor Antibodies	Usually no[§]	Usually no[§]	Universal
Response to therapy[#]	Variable	Variable	Usually good

* Artefactual; [§] Few cases with no prior exposure to exogenous insulin and having both insulin and insulin-receptor antibodies have been reported; [¶] Treatment with exogenous insulin may be associated with both insulin and insulin-receptor antibodies; [#] For those cases with no spontaneous remission.

Comparison Between Autoimmune Hypoglycaemia and Other Causes of Hyperinsulinaemic Hypoglycaemia

Hyperinsulinaemic hypoglycaemia in individuals not receiving exogenous insulin is most commonly caused by insulinoma. However, other causes, including autoimmune hypoglycaemia, should be investigated. In the presence of hypoglycaemic episodes, factitious hypoglycaemia should always be considered. The surreptitious administration of insulin is typically associated with high insulin and low C-peptide and proinsulin levels.

Treatment of Autoimmune Hypoglycaemia

For many autoimmune diseases, autoantibodies are valuable quantifiable disease markers but do not mediate the underlying pathologic tissue destruction, as in, for example, type 1 diabetes. In autoimmune hypoglycaemia syndromes, in contrast, the autoantibody itself drives the metabolic derangement and there is no associated tissue destruction unless there is another concomitant autoimmune disease. Thus, the goal of therapy is to deplete and ideally eliminate the autoantibody.

The insulin autoimmune syndrome and type B insulin resistance have a different clinical course and response to treatment. Approximately 80% of patients with insulin autoimmune syndrome show transient hypoglycaemia with spontaneous remission [1]. In all patients, medications possibly triggering the onset should be discontinued, and dietary modification to include small low-carbohydrate meals (low-glycaemic index diet) at regular intervals would help maintain normal blood glucose levels. Some patients with severe or prolonged symptoms may require pharmacologic treatment. Several different immunomodulatory treatments have been described, including plasmapheresis, glucocorticoids, azathioprine, 6-mercaptopurine, methotrexate and rituximab [1, 9, 11, 25, 26], but no standardized protocol has emerged to date. Treatments aimed at limiting endogenous insulin secretion, including acarbose, diazoxide, octreotide, and partial pancreatectomy, have also been employed [1, 7]. These therapies show variable efficacy in inducing remission.

The approach at the NIH has been to use high-dose steroids for short time periods (60 mg of prednisone/day for not more than 3 weeks with a rapid taper). This aims for immediate relief from hypoglycaemia and an initial reduction of antibody titre. This is followed by azathioprine for variable periods to sustain remission. This course may be repeated if necessary [27].

Type B insulin resistance is associated with high mortality, mostly related to the severity of the underlying systemic autoimmune disease. Other causes of death include hypoglycaemia, cardiovascular or cerebrovascular disease, or malignancy [19]. Treatment of type B insulin resistance has two main goals. The first goal is to reverse the severe catabolic state and hyperglycaemia seen in most patients. To achieve this goal, massive amounts of insulin, ranging from several hundred to several thousand units per day, are usually needed. Use of concentrated insulin U-500 is thus preferred. In patients showing hypoglycaemia, treatment with high-dose corticosteroids results in prompt resolution of the hypoglycaemia, usually within 24 hours. This effect occurs before any detectable change in the antibody titre and is likely mediated by stimulation of gluconeogenesis [19].

The second goal of treatment is to eliminate autoantibodies to the insulin receptor. About one-third of the patients with type B insulin resistance undergo spontaneous remission, but the time course is unpredictable and variable. Immunosuppressive treatment is usually required to correct the metabolic derangements. Several therapeutic approaches have been tried with no clear benefit, including plasmapheresis, glucocorticoid regimens, azathioprine, mycophenolate mofetil and cyclophosphamide [28, 29]. More

recently, the NIH has developed and tested a standardized therapeutic regimen combining rituximab, pulse steroids, and cyclophosphamide. Rituximab is a monoclonal antibody against CD-20, a molecule expressed on B-cell progenitors' surface, and is used to deplete antibody-producing B-lymphocytes and reduce the production of new autoantibodies. Pulses of high-dose steroids suppress the activity of pre-existing plasma cells. Four-day administration of oral dexamethasone 40 mg/day, or 2-day administration of intravenous methylprednisolone 1 g/day are associated with better tolerance than continuous low-dose steroid therapy. Cyclophosphamide is used as an adjunctive immunomodulatory agent to further suppress B—and T-cell function. If severe neutropenia occurs, cyclosporine can be chosen instead of cyclophosphamide. The administration of the NIH standardized therapeutic regimen is associated with an average time to remission of 5 months, with most patients showing reduction in their insulin requirements and improvement of their symptoms after the first cycle of treatment. Once remission is achieved, with improvement of the hyperglycaemia and discontinuation of insulin therapy, maintenance immunotherapy with azathioprine is indicated for at least 1 year [28, 29]. Beside the necessity of monitoring the patient's haematologic status during this therapy, there is a special precaution of ovarian toxicity in reproductive age women receiving cyclophosphamide and this drug should not be used longer than 6 months.

In type B insulin resistance, patients initially presenting with hypoglycaemia are rare, and currently it is not known whether the NIH combination therapy would be beneficial. Two case reports have recently described complete and partial remission with rituximab or bortezomib respectively, in patients with type B insulin resistance and hypoglycaemia [30, 31]. However, to date, available data are too limited to recommend a specific treatment.

Conclusion

Autoimmune forms of hypoglycaemia are rare. However, they should be considered in the differential diagnosis of hyperinsulinaemic hypoglycaemia. Patients may develop hypoglycaemia during the fasting and/or postprandial state. Insulin, C-peptide, and proinsulin levels are extremely elevated, with variable patterns of derangement of the insulin to C-peptide molar ratio depending on the underlying condition. The measurement of insulin or insulin-receptor antibodies can confirm the diagnosis and help differentiate autoimmune hypoglycaemia from insulinoma, therefore sparing patients from unnecessary invasive imaging or pancreatic surgical procedures. Administration of combined immunomodulatory therapies is beneficial for those patients who do not undergo spontaneous remission.

In rare cases, antibodies against endogenous or exogenous insulin may play a role in causing unstable glycaemia in patients with type 1 diabetes treated with exogenous insulin. However, the production of insulin antibodies is often induced by insulin therapy and usually these antibodies do not affect glycaemic control. In these patients, factors influencing blood glucose stability, including the site and technique of injection, altered absorption of insulin or compliance to the prescribed treatment need to be taken into account before considering the use of immunosuppressive therapies, which are associated with significant side effects and toxicity.
