Paget's Disease of Bone

Socrates E. Papapoulos

Introduction

In 1876, Sir James Paget presented to the Royal Medical and Chirurgical Society of London an account of his experience with a previously unrecognized disease of the skeleton, which he termed osteitis deformans and has since born his name. Paget's disease of bone is a focal skeletal disorder which progresses slowly and leads to changes in the shape and size of affected bones and to skeletal, articular, and vascular complications. In some parts of the world it is the second most common bone disorder after osteoporosis. The disease is easily diagnosed and effectively treated but its pathogenesis is incompletely understood.

Epidemiology

Paget's disease affects typically older people, slightly more men than women, and seldom presents before the age of 35 years. Its prevalence increases with age and it affects 1 to 5% of those above 50 years of age. However, only a small proportion of individuals with Paget's disease comes to clinical attention, most commonly these with symptomatic or severe disease [1–3]. There is a distinct geographical distribution; the disease is common in central, western, and parts of southern Europe, the United States, Australia, New Zealand, and some countries of South America, while it is uncommon in Scandinavia, Asia, and Africa. There may also be variations in prevalence in regions within the same country [4]. For example, in northeast USA the prevalence is about fivefold higher than in south USA [5] and in parts of northwest England in 1974 the age- and gender-standardized prevalence rate was 8.3% compared to 4.6% in southern towns and cities [6]. Notably, a more recent radiographic survey in the same centres with identical methodology [7] reported a decline in the overall prevalence of the disease, as has also been observed in other, but not all, countries where comparative studies were performed. In addition, reports from New Zealand, United Kingdom, and Spain suggested that the clinical severity of the disease has attenuated in recent years [2, 8, 9]. These changes in prevalence and severity of the disease strongly suggest that environmental factors are involved in its pathogenesis.

Pathogenesis

Normal Bone Metabolism

The adult skeleton is continuously renewed throughout life by the process of bone remodelling. Old bone is removed by the osteoclasts whereas new bone is formed in the same location by the osteoblasts. This occurs in an orderly fashion through temporary anatomic structures called basic multicellular units (BMUs). A basic multicellular unit comprises a team of osteoclasts at the front and a team of osteoblasts at the back supported by blood vessels, nerves, and loose connective tissue. Osteoclasts and osteoblasts are derived from different precursors in the bone marrow. Osteoclasts originate from haematopoietic precursors of the monocyte/macrophage lineage while osteoblasts originate from multipotent mesenchymal stem cells, which give also rise to bone marrow stromal cells, chondrocytes, adipocytes, and muscle cells. The formation and lifespan of bone cells are controlled by mechanical, systemic, and local factors. Important regulators of osteoclast formation and activity belong to a ligand/receptor/soluble (decoy) receptor system involving proteins of the TNF receptor superfamily [10, 11]. These are RANK ligand, RANK, and OPG. RANKL is produced by osteocytes and osteoblastic/stromal cells, reacts with RANK, which is localized in haematopoietic osteoclast precursors, stimulates the formation and activity of osteoclasts, and prolongs their lifespan. OPG is a soluble receptor which counteracts the biological effects of RANKL preventing its binding to RANK and thereby suppressing bone resorption.

Pathology

Paget's disease of bone is a focal disorder of bone remodelling characterized by an increase in the number and size of osteoclasts in affected sites while the rest of the skeleton remains normal. The typically large osteoclasts, which may contain up to 100 nuclei per cell, induce excessive bone resorption associated with an increased recruitment of osteoblasts to the remodelling sites, resulting in increased bone formation and, hence, an overall increase in the rate of bone turnover. The increase in bone formation is thought to be secondary to the increased rate of bone resorption due to the coupling of the two processes. Some evidence, however, suggests that osteoblastic/ stromal cells might also be primarily affected in Paget's disease and contribute to the increased rate of bone formation [12, 13]. The accelerated rate of bone turnover is responsible for the deposition of bone with disorganized architecture and structural weakness. The bone packets lose their lamellar structure and are replaced by woven bone with a characteristic mosaic pattern while bone marrow is infiltrated by fibrous tissue and blood vessels.

Cell Biology

In clinical studies the likelihood of a bone being affected by Paget's disease was related to the amount of bone marrow present in that bone, leading to the postulation that the development of bone lesions may be related to specific properties of pagetic bone marrow [14]. In bone marrow cultures from patients with Paget's disease the rate of formation of osteoclasts and their number is markedly increased, suggesting that intrinsic abnormalities of the bone marrow microenvironment and/or of osteoclast precursors may contribute to the upregulation of osteoclastogenesis. A number of studies supported these notions and documented two major abnormalities. First, pagetic osteoclasts and their precursors express high levels of osteotropic factors (e.g. IL-6), a bone resorbing cytokine which has been proposed as a possible paracrine/autocrine factor contributing to the pathogenesis of the disease [13, 15, 16]. In addition, enhanced expression of RANKL was detected in bone marrow stromal cells from patients with Paget's disease and might contribute to the increased number of osteoclasts [17]. Second, compared to controls, bone marrow and peripheral cells from patients are hypersensitive to the action of RANKL and calcitriol [18, 19] and there is evidence suggesting that TAFII-17, a component of the transcription complex that binds vitamin D receptor, may be responsible for the hypersensitivity to calcitriol [20]. Thus, while the molecular characteristics of the cellular abnormalities of the disease are currently understood, the precise mechanism(s) that trigger these changes remain to be elucidated.

Aetiology

Several, not mutually exclusive, hypotheses have been proposed to explain the pathology of the disease, the most relevant being the viral and the genetic hypotheses. Studies of the distribution of bone lesions in patients with Paget's disease showed that the probability of a bone being affected is very similar to the probability of a bone being affected with haematogenous osteomyelitis, suggesting that the disease may be caused by a circulating infectious agent. An infection by a slow virus of the paramyxovirus family (measles virus, respiratory syncytial virus, canine distemper virus) was supported by the detection of nuclear and cytoplasmic inclusions resembling paramyxoviral nucleocapsids in osteoclasts and of measles virus nucleocapsid transcripts in bone marrow and peripheral blood monocytes from patients with the disease [21]. However, paramyxoviral-like structures have also been found in specimens from patients with other bone diseases, questioning the specificity of this finding. In addition, further search for viral presence in the osteoclasts provided conflicting results [22] and in a large cohort of patients with Paget's disease no evidence supporting an association between the disease and persistent infection with measles or other paramyxoviruses was found [23]. There is, however, good evidence that paramyxoviruses and viral proteins can promote the formation of osteoclasts with features similar to those of pagetic osteoclasts [24–26].

In familial aggregation studies the risk of first-degree relatives of patients with Paget's disease to develop the disorder was seven to ten times greater than the risk of individuals without such relatives. Furthermore, a positive family history has been reported in up to 40% of patients with Paget's disease [27–29]. Familial Paget's disease is inherited as an autosomal dominant trait and initial genetic analyses showed evidence of linkage to chromosome 18q21–22 in some families [30, 31]. This chromosome also contains the locus of the rare disease familial expansile osteolysis, which resembles Paget's disease and was found to be associated with activating mutations in the gene *TNFRSF11A*, which encodes RANK [32], while abnormalities of the same gene are responsible for another rare skeletal disease, expansile skeletal hyperphosphatasia [33]. Subsequent studies, however, failed to detect such mutations in patients with familial or sporadic Paget's disease. Other abnormal genes that have been identified in diseases with bone phenotypes similar to that of Paget's disease include *TNFRSF11B*, which encodes OPG in juvenile Paget's disease [34], and *VCP*, which encodes p97 in the syndrome of inclusion body myopathy associated with Paget's disease of bone and frontotemporal dementia [35]. All these genetic defects have in common the up-regulation of the NF-kB signal transduction, an essential process in the differentiation and activation of osteoclasts. These genes have also been investigated in patients with familial or sporadic Paget's disease but no mutations were identified. Analysis of families with Paget's disease identified further possible loci in other chromosomes indicating genetic heterogeneity. However, studies in different parts of the world identified mutations in the *SQSTM1* gene, located on chromosome 5q35, in up to 50% of patients with familial Paget's disease and up to 10% of those with sporadic disease [3, 22, 28, 36]. *SQSTM1* encodes p62, an adaptor protein that binds ubiquitin and is involved in various signalling pathways including the NF-κB pathway. The most common mutation of *SQSTM1* associated with Paget's disease (P329L) has been detected in patients from different European countries suggesting a founder gene defect [37]. In addition, animals overexpressing this mutation in cells of the osteoclast lineage formed more osteoclasts, which were hypersensitive to RANKL but did not develop bone lesions resembling those of Paget's disease in one study while in another they did [22]. In addition, genetic studies of patients with Paget's disease and no *SQSTM1* mutations identified seven loci that contribute substantially to the risk of developing the disease as well as affecting its severity in combination with mutations of *SQSTM1*. These variants include genes important in the differentiation and function of osteoclasts (e.g. *CSF1*) but also genes that have not been implicated in the regulation of bone metabolism [38–41].

The functional significance of these polymorphisms is unknown. Whether mutations of genes associated with Paget's disease are the cause of the disease or whether individuals with a mutation have an increased susceptibility to the disease when exposed to environmental factors, such as paramyxoviruses, is currently unclear.

Clinical Manifestations

The most commonly affected bones are the pelvis, the spine, the femora, and the skull but practically any bone of the skeleton may be affected and there is remarkable similarity in the frequency of affected bones in large series of patients from different countries [1, 42, 43]. About one-third of patients have only one lesion (Figure 4.10.1) but the frequency of single lesions varies among series, probably reflecting referral patterns, and is higher in asymptomatic patients. Notably, the anatomical spread of skeletal lesions in Paget's disease is log normally distributed and the commonly used distinction in clinical practice to monostotic and polyostotic disease is not pathophysiologically appropriate. The anatomical spread of the disease is not related to age or gender, shows no particular symmetry in the body, and remains largely unchanged throughout life. The disease progresses slowly within the affected bone but does not generally appear in other bones. Patients with limited bone involvement should, therefore, be reassured that the disease will not progress to other bones with time.

The majority of patients are asymptomatic and the disease may be diagnosed incidentally during investigation of an unrelated complaint by skeletal radiographs or by the finding of an unexplained elevation of serum alkaline phosphatase activity [44]. About 5–10% of affected patients have symptoms. Skeletal morbidity in Paget's disease is determined by the damage caused and the progression of the disease in affected sites as well as by the number and the localization of the lesions. Extensive disease, as originally described by Sir James Paget, occurs in about 5% of symptomatic patients. This is in agreement with the limited chance of an individual to develop extensive disease, as predicted by the distribution of lesions, but changing patterns of the disease to milder forms may also contribute to that.

The symptoms and complications of Paget's disease,(summarized in Table 4.10.1) [34], can have great impact on the quality of life of affected individuals [45, 46]. In the majority of patients, the presenting complaint is pain. This is related to the extent and site of the disease, it is usually persistent and present at rest, but is not specific. Pain due to secondary osteoarthritis is common and may hamper assessment of the relative contribution of bone and joint pains to the patient's disability. The origin of such pain can be assessed only retrospectively after treatment which reduces mainly the disease-related pain, having a rather limited effect on the arthritic pain. Deformities are present in about 15% of patients at the time of diagnosis and affect mainly weight-bearing bones, the most common deformity being bowing of the lower limbs. About 9% of patients present with fractures, which can be complete or fissure (incomplete) fractures. The latter occur more frequently, can be multiple, can cause pain, and may develop to complete fractures. Fractures heal generally well although in an older report of 182 fractures of the femur the incidence of non-union was 40% [47]. The skin overlying an affected bone may be warm as a result of increased

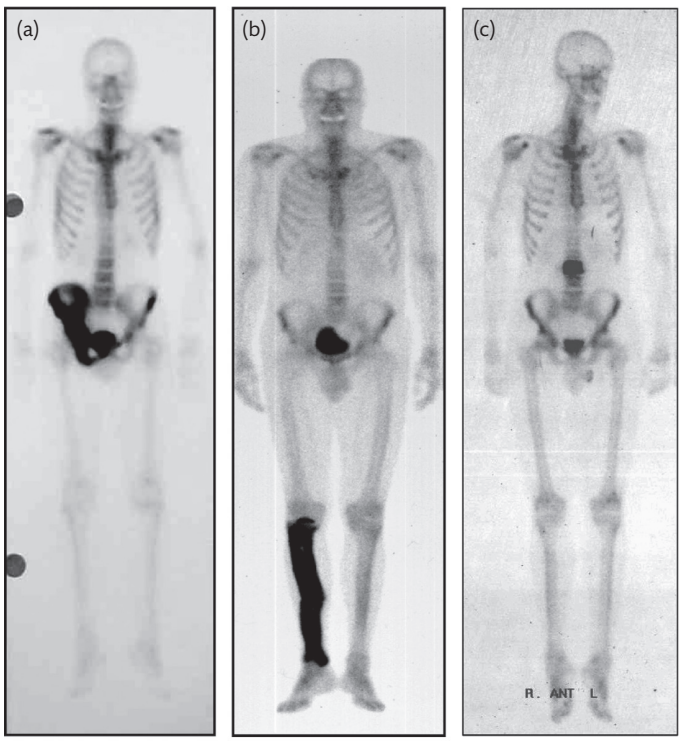

Figure 4.10.1 Monostotic Paget's disease illustrated by bone scintigraphy: (a) right pelvis; (b) right tibia (with deformity and fracture); (c) vertebra.

Table 4.10.1 Symptoms and complications of Paget's disease of bone

System	Complication
Musculoskeletal	Bone pain Bone deformity Osteoarthritis of adjacent joints Acetabular protrusion Fractures Spinal stenosis
Neurological	Hearing loss Cranial nerve deficits (rare) Basilar impression Increased cerebrospinal fluid pressure Spinal stenosis Vascular steal syndrome
Cardiovascular	Congestive heart failure and angina Increased cardiac output Aortic stenosis Generalized atherosclerosis Endocardial calcification
Metabolic	Immobilization hypercalcaemia Hypercalciuria Hyperuricaemia Nephrolithiasis
Neoplasia	Sarcoma (osteosarcoma, chondrosarcoma, and fibrosarcoma) Giant cell tumour

blood flow and bone turnover locally and hypervascularity of affected bones may cause ischaemia of adjacent structures (steal syndrome). Irreversible hearing loss is the most common neurological complication occurring in about one-third of patients with skull involvement. This is thought to be related to structural and/or density changes in the cochlear capsule bone [48]. Neoplastic transformation of pagetic bone is rare (less than 1%) and includes osteosarcoma and giant cell tumours associated more frequently with familial clustering of the disease [49]. Pathogenic mutations of the *ZNF687* gene were identified in a family with Paget's disease with increased prevalence of giant cell tumours of bone but also in patients with or without *SQSTM1* mutations [50, 51]. The *ZNF687* gene is highly expressed during osteoclast and osteoblast differentiation and patients with missense mutations of the gene had an earlier clinical expression and more severe bone disease.

Investigations

Radiographic changes are characteristic of the disease (Figure 4.10.2). Increased bone resorption may be detected as a decrease in the density of affected bones; sometimes a wedge- or flame-segment of bone resorption may be seen in long bones and extensive osteolytic areas in the skull (osteoporosis circumscripta). The osteolytic changes in long bones progress at a rate of about 1 cm/year. Older lesions usually have a mixed sclerotic and lytic appearance and in the last stage of the disease sclerotic lesions predominate. The involved parts of the skeleton are enlarged and deformed, and the cortex can be thickened and dense. The radiological changes can be considered pathognomonic but in some cases differential diagnosis may include fibrous dysplasia and bone metastases, particularly from prostate cancer. Bone scintigraphy is used to assess the extent of the disease. It is not specific but it is more sensitive than plain radiographs; up to 15% of lesions detected by bone scintigraphy may have normal radiographic appearance. Bone scintigraphy should always be included in the investigation of patients with Paget's disease and plain radiographs of the areas of increased radioisotope uptake should be subsequently made to confirm the diagnosis (Figure 4.10.3).

The pathology of Paget's disease is reflected in the proportional increase in biochemical indices of bone turnover [52]. In the past, urinary hydroxyproline excretion was used as an index of bone resorption and serum total alkaline phosphatase activity as an index of bone formation. These can be markedly increased in patients with extensive disease but can be also found within the reference range in patients with limited bone involvement. Patients with skull involvement tend to have the highest values of serum alkaline phosphatase activity. More specific and sensitive biochemical indices of bone formation include the bone-specific isoenzyme of alkaline phosphatase and the N-terminal extension peptide of collagen type I (procollagen I N-terminal peptide, P1NP). Serum osteocalcin concentrations are within the normal range in about half of the patients with elevated serum alkaline phosphatase values and should not be used in the management of patients with Paget's disease. Urinary hydroxyproline is neither specific nor sensitive enough and its determination depends on specific dietary advice. Peptides of the cross-linking domains of collagen type I, such as the N-telopeptide (NTX) or the C-telopeptide (CTX), measured in urine or serum are the most sensitive biochemical markers of bone resorption. Impaired isomerization of C-telopeptide has been reported in patients with Paget's disease but not in patients with increased bone turnover from other causes, leading to the postulation that this abnormality may reflect the defect in bone structure [53]. Degradation products of collagen type II are not increased in urines of patients [54].

In Paget's disease, despite the marked changes in the rate of bone turnover, extracellular calcium homeostasis is generally maintained but some disturbances may occur. Hypercalcaemia may develop in immobilized patients with active, extensive disease or may be due to concurrent primary hyperparathyroidism, the incidence of which

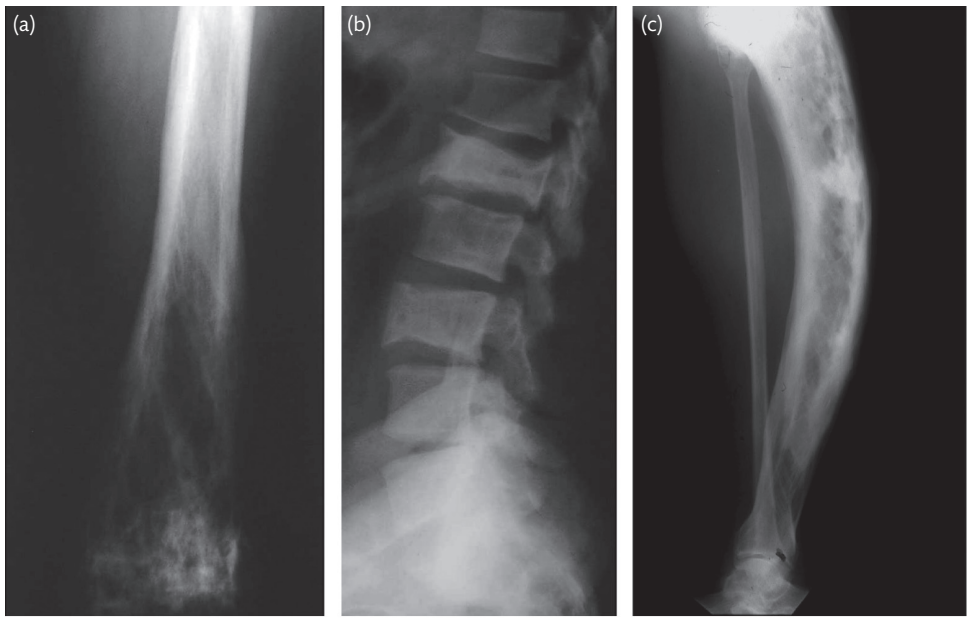

Figure 4.10.2 Radiographs of patients with Paget's disease: (a) distal femur showing extensive and flame-shaped osteolysis; (b) lumbar spine; (c) tibia with characteristic deformity.

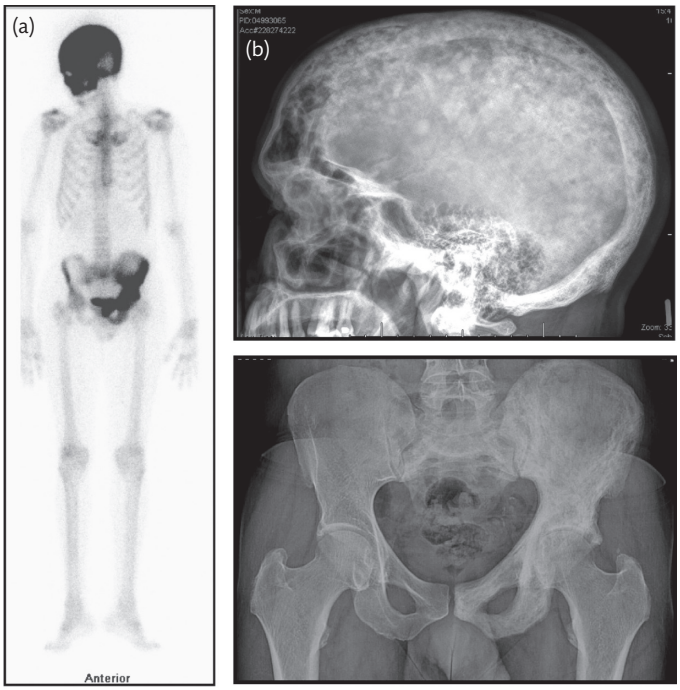

Figure 4.10.3 Bone scintigram of a patient with Paget's disease showing two areas of increased uptake of the isotope. Radiographs of these areas were diagnostic.

is thought to be higher in Paget's disease compared to the general population. Secondary hyperparathyroidism is present in about 20% of patients while serum concentrations of calcitriol are generally normal. Hypercalciuria and renal stone disease occur also more frequently in patients with Paget's disease.

Management

During the past 40 years, the management of patients with Paget's disease has changed dramatically due to the discovery of the therapeutic potential of the calcitonins and later of the bisphosphonates. Other, less frequently used treatments were plicamycin (mithramycin) and gallium nitrate. Bisphosphonates are currently the preferred treatment of Paget's disease.

Aims and Indications of Treatment

Classically treatment is given to patients with Paget's disease to relieve symptoms and improve their quality of life. The disease, however, is progressive and patients with symptoms were previously asymptomatic (Figure 4.10.4). It is currently impossible to identify patients who will develop symptoms and complications or to quantify the risk of complications in an individual. While this may change in the future with the use of genetic markers, anecdotal evidence indicates that patients with localizations close to large joints, in weight-bearing bones and the skull or with high levels of serum alkaline phosphatase activity are at higher risk for complications with time. Treatment with potent bisphosphonates does not only relieve symptoms due to the disease but restores bone quality and improves or even normalizes radiological appearances. Moreover, the bulk of evidence obtained with bisphosphonates strongly suggests that complications can be prevented if bone turnover is adequately suppressed, whereas there are indications that the contrary is true if bone turnover does not normalize [55]. Firm evidence, however, from prospective randomized controlled trials is lacking. A study of a large cohort of patients randomized to intensive bisphosphonate treatment (risedronate) or symptomatic management reported no differences in clinical outcomes between the two groups [56, 57]. Limitations of the study included the already advanced disease in most of the patients, use of bisphosphonates by the majority of patients before trial entry, and the fact that the disease was in biochemical remission in about half of the patients [58, 59].

These considerations led to the following treatment recommendations: (1) symptomatic disease, to reduce complaints and improve the quality of life; (2) preoperative treatment in preparation for an orthopaedic procedure on pagetic bone to reduce the increased blood flow and excessive bleeding; (3) treatment of asymptomatic patients with skeletal localizations at higher risk of future complications, such as those adjacent to large joints, in the skull, the spine, and the weight-bearing bones; and (4) young patients. Studies of treatment of asymptomatic patients with *SQSTM1* mutations are underway. The goal of treatment should be to normalize bone turnover, suppress serum alkaline phosphatase activity well within the normal range, and keep it adequately suppressed, if necessary with additional courses of treatment. Retreatment is generally advocated when a previously normal value of serum alkaline phosphatase activity exceeds the upper limit of normal or when it increases by 20–25% above its nadir value.

Bisphosphonates

The following properties render bisphosphonates as ideal agents for the treatment of Paget's disease: selective uptake at active skeletal sites; specific inhibition of bone resorption; short plasma half-life and lack of circulating metabolites; and persistence of the effect after stopping treatment. The general structure of the molecule of germinal bisphosphonates allows numerous substitutions, which has led to the synthesis of a variety of compounds with considerable differences in potency, activity to toxicity ratio, and mechanism of action [60]. Bisphosphonates are divided into two groups according to the presence or absence of a nitrogen atom in the molecule. The nitrogen increases the potency of the bisphosphonates and determines their mechanism of action. Compounds without a nitrogen atom in the side chain are etidronate, clodronate, and tiludronate. Nitrogen-containing bisphosphonates include alendronate, ibandronate, incadronate, neridronate, olpadronate, pamidronate, risedronate, and zoledronate. Practically all bisphosphonate, either approved or in clinical development, have been used in the treatment of Paget's disease, which in turn has served as a human model for investigating the pharmacological properties of these agents. Bisphosphonates approved around the world for the treatment of Paget's disease are listed in Table 4.10.2.

Pharmacodynamics

For the design of optimal therapeutic strategies of Paget's disease with bisphosphonates their pharmacodynamic properties need to be taken into consideration [61]. When a potent bisphosphonate is given to a patient with Paget's disease, the first measurable effect is the suppression of bone resorption. This occurs within a few days of starting treatment. During this initial period, bone

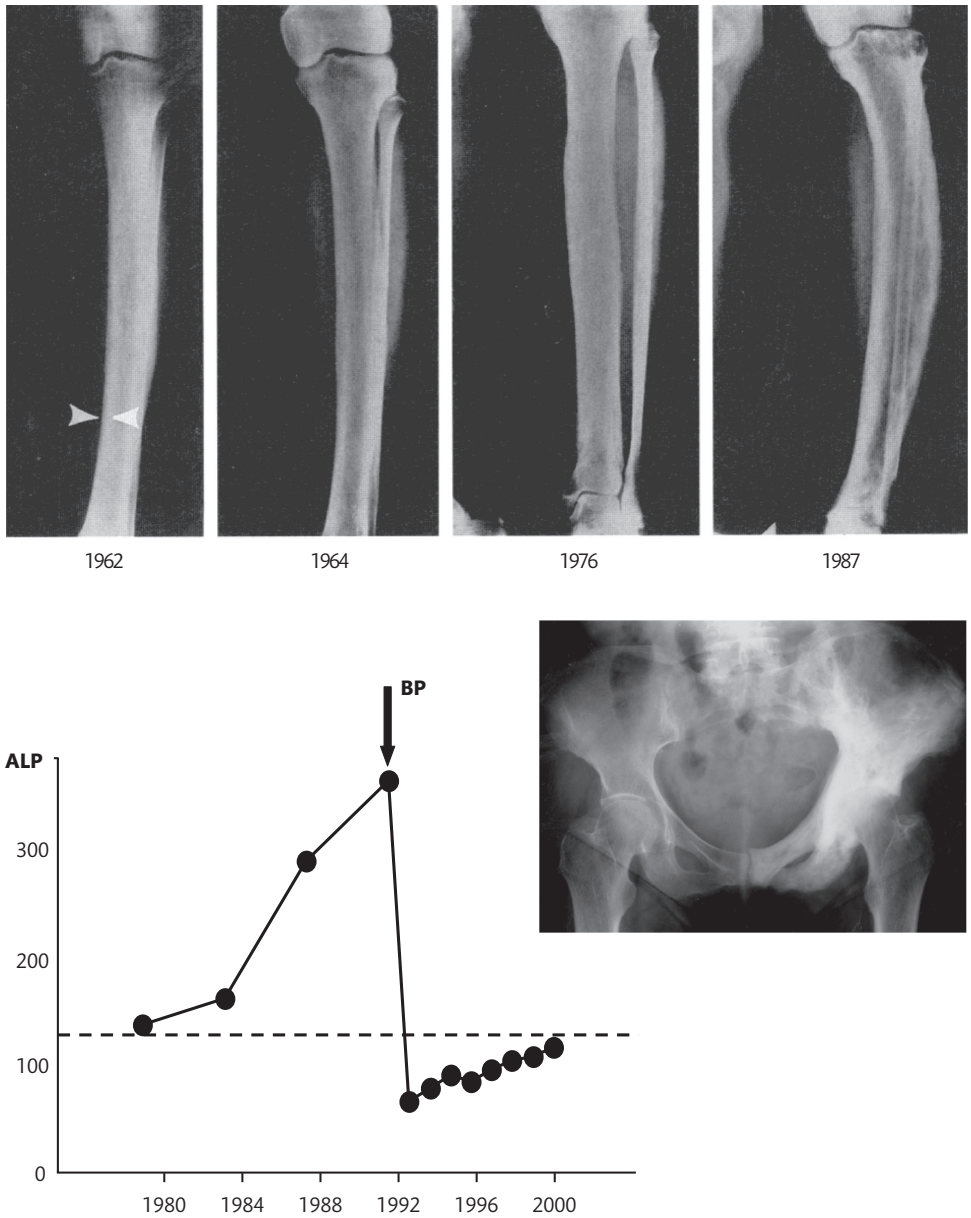

Figure 4.10.4 (upper panel) Serial radiographs (anteroposterior view) of the tibia of an untreated 68-year-old man with Paget's disease illustrating the progression of the disease. (lower panel) Sequential measurements of serum alkaline phosphatase (ALP) activity (U/L) over 20 years in a 51-year-old woman with Paget's disease of the pelvis. Note the progressive threefold increase in serum ALP activity on no treatment. Arrow indicates treatment with oral olpadronate 200 mg/day for 1 month inducing complete, long-lasting remission. Horizontal line represents the upper limit of the normal range. At the time of intervention, the patient had already developed osteoarthritis and required total hip arthroplasty despite successful treatment. BP, bisphosphonate.

formation does not change. This will decrease secondarily, at a slower rate, due to the coupling of bone resorption to bone formation, so that a new equilibrium will be reached after 3–6 months (Figure 4.10.5). Thus, adequate suppression of bone resorption will be predictably followed by an adequate suppression of bone formation. Suppression of biochemical indices of bone resorption early during the course of treatment provides, therefore, an indication of the pharmacological efficacy of the bisphosphonate and can subsequently determine the length of treatment [62]. Because of the predictable changes in bone remodelling that follow bisphosphonate therapy in Paget's disease, it is not necessary to prolong treatment until the lowest level of serum alkaline phosphatase is reached and short courses are usually sufficient to achieve remissions. Moreover, the retention of bisphosphonate in the skeleton is proportional to disease activity and inversely proportional to renal function [63]. Therefore, dose adjustments may be required in patients with impaired renal function, but no specific studies have addressed this issue. In addition, the wide variability of disease activity of affected patients strongly suggest that treatment needs to be individualized.

Table 4.10.2 Bisphosphonates approved for the treatment of Paget's disease

Generic name	Dose
Alendronate	Oral, 40 mg daily for 6 months
Clodronate	Oral, 1600 mg daily for 3 to 6 months
Etidronate	Oral, 400 mg daily for 6 months
Neridronate	Intravenous 100 mg daily for 2 days
Pamidronate	Intravenous, 30–60 mg daily for 3 days[a]
Risedronate	Oral, 30 mg daily for 2 months
Tiludronate	Oral, 400 mg daily for 3 months
Zoledronate	Intravenous, 5 mg (one 15 min infusion)[b]

[a] Lower dose recommended by the pharmaceutical industry, higher dose recommended by investigators; [b] Preferred treatment.

The long-term efficacy of treatment is best assessed by measuring biochemical indices of bone formation, serum alkaline phosphatase activity being still the most commonly used. In the past, the efficacy of treatment was evaluated by its ability to decrease serum alkaline phosphatase activity by more than 50% of its initial value. With the available potent bisphosphonates, this is no longer appropriate and treatment efficacy should be assessed only by its ability to decrease serum alkaline phosphatase values to the normal range (remission). In clinical practice there is no need to measure serum alkaline phosphatase activity earlier than 3 months after the start of treatment, 6 months being the optimal time.

During the initial phase of bisphosphonate treatment, when bone resorption and bone formation are still dissociated, the increased retention of calcium in the skeleton leads to changes in calcium metabolism. There is a fall in serum calcium concentration, which stimulates the secretion of parathyroid hormone secretion and consequently the renal production of calcitriol. These hormones, in turn, increase the renal tubular reabsorption of calcium (parathyroid hormone) and its intestinal absorption (calcitriol). The result is a marked, but transient, increase in calcium balance. The concomitant decrease in serum phosphate concentrations is due to the renal action of parathyroid hormone. Such responses are not observed during etidronate treatment, which has a weak action on bone metabolism. With the attainment of the new equilibrium of bone remodelling, calcium balance returns towards pretreatment levels and the values of the biochemical indices of calcium metabolism normalize. The adaptive changes of calcium metabolism to the marked alterations in bone remodelling prevent the development of symptomatic hypocalcaemia in calcium-replete patients. However, elderly patients frequently have calcium-deficient diets and some investigators advocate the use of calcium supplements during treatment of Paget's disease with potent bisphosphonates, especially if these are given intravenously or the disease is very active. Support for this logical assumption by clinical trials is, however, limited.

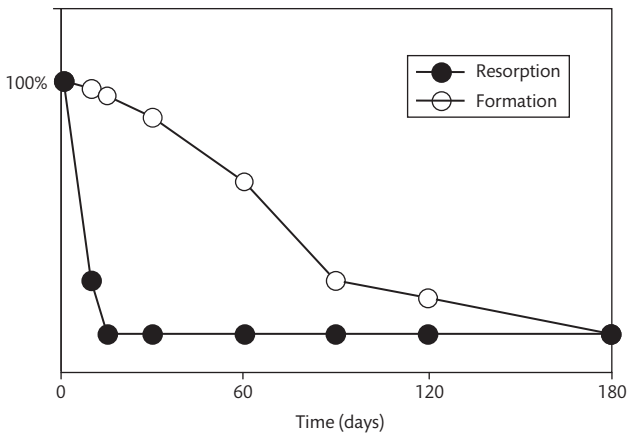

Figure 4.10.5 Schematic presentation of the changes in biochemical indices of bone resorption and bone formation following bisphosphonate treatment of Paget's disease.

Treatment Responses

Clinical responses to treatment include the disappearance or clear improvement of pain in more than 80% of treated patients, when this is due to the activity of the disease. A decrease of bone pain is generally observed 1 to 3 months after the start of treatment and the effect is maximal after 6 months and is maintained for as long as biochemical indices of bone turnover remain within the normal range. Soon after the start of therapy with a potent bisphosphonate, particularly if given intravenously, there may be a transient increase in pain at affected sites and patients should be reassured. Pain due to osteoarthritis is unresponsive to treatment in about 75% of patients; non-steroidal anti-inflammatory drugs can then be used. If the hip joint is affected, hip arthroplasty may be required to control the symptoms. Back pain resulting from involvement of lumbar vertebrae is frequently not relieved by treatment. About half of the patients with pain associated with deformity of the femur or the tibia will respond favourably to bisphosphonate therapy but pain may persist and a corrective osteotomy may be necessary. Deafness is usually not affected but its progression appears to be arrested. There have been also reports of improvement of spinal cord compression with bisphosphonate therapy and fracture frequency of pagetic bones appears to decrease with treatment.

Improvement in bone histology and formation of bone with normal lamellar structure and no evidence of a mineralization defect has been reported with currently used bisphosphonates. Radiologically, an arrest of the progression of the disease is usually seen. Radiological improvement can be dramatic, however, if lesions are lytic and are localized in long bones or in the skull. In other areas, improvement is slow and sometimes difficult to demonstrate by non-experienced radiologists. Treatment induces an exponential decrease in isotope uptake on bone scintigrams. However, even with normalization of disease activity, only about 10–30% of lesions normalize completely and residual uptake (up to 20% of the original) is detected [64]. Notably, more recent case studies showed normalization of radioisotope uptake in affected bones in most patients treated with zoledronate [65]. The possible relation of these scintigraphic changes to future recurrences has not been adequately studied but some investigators advocate normalization of bone scintigrams as one of the aims of treatment.

These clinical, histological, and radiological responses emphasize the need for an intervention with a bisphosphonate early in the course of the disease and before the development of complications.

All bisphosphonates given to patients with Paget's disease significantly decrease biochemical indices of bone turnover [66–73]. Considerable differences exist, however, in their ability to induce remissions. Generally, potent bisphosphonates induce better

responses. Head to head clinical trials have been performed with etidronate 400 mg daily for 6 months as comparator. In all these clinical trials, etidronate was less effective. The limited efficacy, relative to other bisphosphonates, together with the increased risk of osteomalacia, have made etidronate a treatment of the past. Normalization of serum alkaline phosphatase activity has been reported with tiludronate 400 mg daily for 3 months (35%), clodronate 1600 mg daily for 6 months (up to 70%), alendronate 40 mg daily for 6 months (63%), risedronate 30 mg daily for 2 months (up to 70%), and pamidronate, intravenously or orally in variable regimens (up to 90%). It should be noted that comparison of results obtained in different studies is not appropriate due to different selection criteria and disease activity of treated patients. The results of these studies showed, in addition, that despite the availability of effective and convenient treatment regimens with bisphosphonates, there was still need for further improvement. More recently, the efficacy and tolerability of a single 15-min intravenous infusion of zoledronate was compared to oral risedronate 30 mg per day for 2 months in patients with Paget's disease of moderate activity [74]. Results showed that zoledronate was significantly more efficacious than risedronate in inducing biochemical remission that lasts long [75] associated with improvements in some aspects of the quality of life of the patients. Zoledronate is currently considered the treatment of choice of Paget's disease.

Follow-up of patients in remission is indicated every 6–12 months. Remissions, estimated from the time of normalization of serum alkaline phosphatase activity, can be long and can last even longer than 10 years in some patients. We have observed, however, recurrences 12 or 13 years after induction of complete biochemical remission which illustrates the need for continuous follow-up. The duration of remission is determined by the degree of suppression of serum alkaline phosphatase activity and the number of affected bones but is not related to the length or to the mode of treatment (oral or intravenous) as long as a potent, efficacious bisphosphonate is given [70, 76–78]. The lower the serum alkaline phosphatase activity reached with treatment, the longer the period of remission. Suppression of serum alkaline phosphatase activity well within the normal range is a prerequisite for long-term remissions and should be part of treatment strategies. Notably, in a study of 152 (83% with pain complaints) patients with Paget's disease and median time of biochemical remission 78.9 months after short-term treatment with the bisphosphonate olpadronate, worsening of pain scores were significantly related to biochemical relapse probability [78]. These observations underscore the relationship between biochemical indices of bone turnover with pain and the need to retain them within the normal range.

Resistance to Bisphosphonate Treatment

Impaired response to repeated treatment courses with bisphosphonates is usually referred to as acquired resistance and should be distinguished from an intrinsic resistance to a particular compound. Acquired resistance has been reported for etidronate and pamidronate [79, 80] but the underlying mechanism is not known and it is important to differentiate between real and apparent resistance. Some patients may not respond to oral bisphosphonate but may show a prompt response to the same compound given intravenously. In such cases, factors interfering with the already low intestinal absorption of the drug are most likely responsible for the impaired response to oral treatment. Patients retreated with the same bisphosphonate during a recurrence of their disease may show a reduced fractional decrease in biochemical indices of bone turnover compared to earlier treatments. Some consider this response compatible with development of resistance to therapy. However, it has been shown in studies with clodronate and pamidronate that the actual level, rather than the fractional decrease of biochemical indices of bone turnover following every treatment, should be compared to those obtained after the initial therapy (Figure 4.10.6). This is because patients who are offered a new treatment course have generally a lower rate of bone turnover compared to that before the first treatment. Finally, in patients with Paget's disease and concurrent hyperparathyroidism, completeness of response is generally less and recurrences occur quicker which might be considered reduced responsiveness. For optimal responses of patients with Paget's disease and autonomous hyperparathyroidism to bisphosphonates,

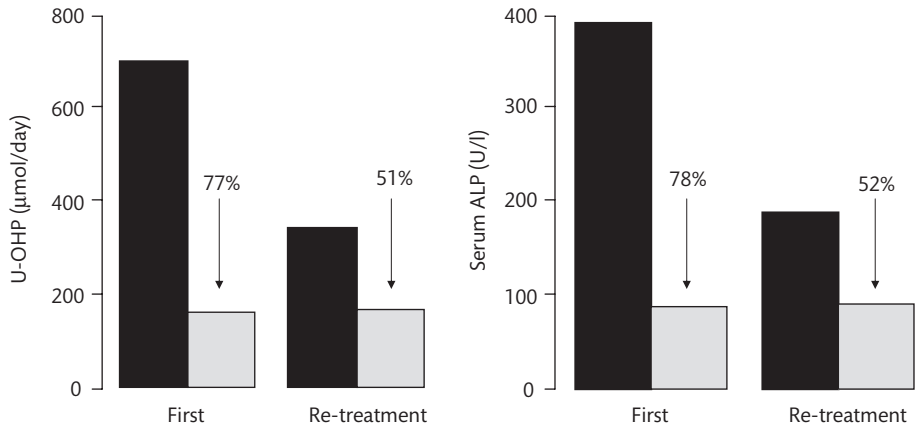

Figure 4.10.6 Apparent resistance to bisphosphonate therapy in Paget's disease. Absolute and percent changes of urinary hydroxyproline excretion (UOHP) and serum alkaline phosphatase (ALP) activity after first treatment with pamidronate or retreatment with the same bisphosphonate for a recurrence of the disease.

Modified from Harinck HI, Bijvoet OL, Blanksma HJ, Dahlinghaus-Nienhuys PJ. Efficacious management with aminobisphosphonate (APD) in Paget's disease of bone. *Clin Orthop Relat Res*, 1987; 217: 79–98. Copyright © 1987, © Lippincott-Raven Publishers.

parathyroidectomy should be considered. However, real resistance to pamidronate can develop. We showed, for example, progressive reduction in responsiveness to this bisphosphonate, which was mainly related to the extent of skeletal involvement but not to the dose of pamidronate or to the biochemical activity of the disease. Patients with three or more affected bones were most likely to develop resistance to pamidronate, a finding consistent with other reports. These patients respond readily to other bisphosphonates. There are scarce data of resistance to other nitrogen-containing bisphosphonates. Using the same approach as in the pamidronate studies, we found no resistance to consecutive treatments of patients with Paget's disease with olpadronate. Thus, within the limitations of existing studies, it appears that acquired resistance is specific for pamidronate and is limited to patients with extensive disease. Such resistance does not seem to occur with other nitrogen-containing bisphosphonates but the evidence for that is still weak. Finally, primary resistance to a specific bisphosphonate, if it exists, is rare.

Adverse Effects

All bisphosphonates given at very high doses can impair the mineralization of newly formed bone and induce osteomalacia. In clinical practice this is, however, relevant only for etidronate. Doses of potent nitrogen-containing bisphosphonates that induce osteomalacia exceed, by many orders of magnitude, those required for effective suppression of bone turnover. Consequently, in all reported controlled studies no adverse effects on bone mineralization have been observed. In only a few patients treated with intravenous pamidronate, at doses higher than those recommended, has impaired bone mineralization been reported. Histological osteomalacia induced by either etidronate or pamidronate is reversible.

In some patients treated for the first time with nitrogen-containing bisphosphonates there is a rise in body temperature and flu-like symptoms during the first 3 days of treatment. These symptoms are transient and subside with no specific measures even when treatment is continued [81, 82]. This response is dose-dependent and is associated more frequently with intravenous than oral treatment. Moreover, it does not generally recur upon retreatment, and, if it does, it is of lower intensity. Previous exposure to another nitrogen-containing bisphosphonate, but not to etidronate, precludes the development of this response. Laboratory findings are consistent with an acute phase reaction [82]. There is a transient decrease in blood lymphocytes and a transient increase in serum C-reactive protein, possibly due to increases in proinflammatory cytokines, such as IL-6 and TNF-α produced by γ,δ T lymphocytes in response to a metabolite of the mevalonate pathway, upstream farnesyl pyrophosphate synthase, which is inhibited by nitrogen-containing bisphosphonates [82, 83]. Rarely, high doses of nitrogen-containing bisphosphonates may induce ophthalmic reactions such as conjunctivitis, iritis, or uveitis. There are case reports of ototoxicity and central nervous toxicity after intravenous pamidronate. Allergic skin reactions have been occasionally observed with most of the bisphosphonates.

Mild gastrointestinal complaints occur with low frequency with the use of all bisphosphonates. Some nitrogen-containing bisphosphonates can induce more severe symptoms such as heartburn, nausea, and vomiting in a few patients, associated with oesophagitis or gastritis. The use of oral alendronate 40 mg daily was associated with higher frequency of epigastric complaints in an open, but not in a controlled, study and the latter was also the case with oral risedronate 30 mg daily. In a comparative study of alendronate 40 mg/day and risedronate 30 mg/day gastric ulcers and/or large numbers of gastric erosions were detected endoscopically in approximately 3% of patients, and their occurrence was comparable with both bisphosphonates. Nitrogen-containing bisphosphonates should be administered orally with one full glass of water and the patient should remain in an upright position for half an hour to allow quick passage through the oesophagus and to avoid oesophageal irritation. Rapid intravenous injection of bisphosphonates may chelate calcium in the circulation and form complexes, which can be nephrotoxic or can damage directly the renal tubule. Bisphosphonates should, therefore, be given by slow infusion. Zoledronate is administered by short intravenous infusion (15 min) because of the low effective dose. Aminobisphosphonates should not be injected intramuscularly because they can cause severe local irritation and necrosis but clodronate has been given intramuscularly. Osteonecrosis of the jaw is extremely rare in patients with Paget's disease treated either with oral or intravenous bisphosphonates.

Notably, impaired renal function is a contraindication for bisphosphonate treatment and zoledronate should not be administered to patients with creatinine clearance <35 ml/min. There is, therefore, an unmet therapeutic need of such patients. Anecdotal evidence suggests that treatment with the RANKL inhibitor, denosumab, which is not eliminated by the renal route, might be efficacious in patients with Paget's disease [84], an observation that needs, however, to be confirmed in appropriate patient groups.

Rickets and Osteomalacia (Acquired and Heritable Forms)

Michael P. Whyte

Introduction

Background

Mineralization of newly formed organic matrix within the skeleton is a complex and highly ordered process. Fundamentally, it requires both adequate extracellular concentrations of calcium (Ca^{2+}) and phosphorous as inorganic phosphate (Pi) as well as normal function of cartilage-forming chondrocytes and bone-forming osteoblasts. Compromise of either aspect can impair how well bones grow and harden. In fact, the causes and mechanisms for impaired skeletal mineralization are many and complex. The term 'rickets' describes the consequences of undermineralization of cartilage and bone matrix (primary spongiosa and osteoid, respectively) throughout a growing skeleton. Infants, children, and adolescents can be affected. The term 'osteomalacia' refers to what follows from impaired bone mineralization in adult life after the growth plates have fused and cartilage mineralization is no longer an issue. However, neither 'rickets' nor 'osteomalacia' denotes a specific aetiology. Both are generic labels for what follows from too little deposition of hydroxyapatite crystals into skeletal tissue. Nevertheless, there are several useful ways that rickets and osteomalacia can be classified. Nearly all individuals with rickets or osteomalacia have low circulating (extracellular) levels of Ca^{2+} and/or Pi. Often, inadequate vitamin D is involved. Sometimes there is instead impaired endogenous bioactivation of adequate vitamin D. Alternatively, kidney tubule dysfunction can lead to urinary Pi wasting and hypophosphataemia, often including impaired renal bioactivation of vitamin D. Skeletal cell-based explanations for undermineralization of cartilage and bone are rare and involve defective synthesis of constituents or conditioners of bone matrix. Hence, the number of disorders that cause rickets or osteomalacia is considerable; some are acquired, and others inherited (**Box 4.11.1**).

In contrast to osteomalacia in which predominantly bone remodelling (turnover) is impaired, rickets compromises all three components of skeletal formation:

- **Growth:** For long bones to lengthen and certain axial bones to enlarge, chondrocytes within their growth plates (i.e. physes, apophyses) must proliferate, hypertrophy, and then degenerate and the matrix they produced mineralize (i.e. endochondral bone formation).
- **Modelling:** Correct shaping of growing long bones requires deposition and removal of mineralized osseous tissue at their outer and inner cortical margins (periosteum and endosteum, respectively).
- **Remodelling:** On innumerable occasions over a lifetime, microscopic areas of mineralized cortical (compact) and trabecular (spongy) bone are resorbed and then reformed so that the skeleton's metabolic, structural, and repair roles can be fulfilled.

Hence, rickets often features short stature (physeal dysfunction), long bone bowing and metaphyseal widening (modelling defects), and frequent and poorly healing fractures (remodelling failure). These disturbances lead to diagnostic radiographic changes. In contrast to rickets, osteomalacia that begins in adult life is usually not deforming unless there are fractures. Because growth plates have fused and bone modelling has largely ceased, disturbed skeletal remodelling becomes paramount in osteomalacia. Osteomalacia is less apparent clinically and has few distinctive radiographic findings compared to rickets. In either disorder, however, defective bone turnover (remodelling) can manifest radiographically as generalized osteopaenia. Occasionally, if skeletal tissue accumulates, there can be hyperostosis (cortical bone widening) and osteosclerosis (trabecular bone thickening). The principal clinical, radiographic, and histological features of rickets or osteomalacia are largely shared among the numerous causes.

Alternatively for some years now, the term 'rickets' has been used by some histologists and clinicians strictly for the disturbance of

Box 4.11.1 Causes of rickets or osteomalacia

Vitamin D deficiency

- Deficient endogenous (cutaneous) synthesis
  - Inadequate sunshine
  - Other factors, e.g. ageing, pigmentation, sunscreens, clothing
- Dietary
  - Classic 'nutritional'
  - Fat-phobic

Malabsorption

- Gastric
  - Partial gastrectomy
- Intestinal
  - Small bowel disorders, e.g. coeliac disease (gluten-sensitive enteropathy)
- Hepatobiliary
  - Cirrhosis
  - Biliary fistula
  - Biliary atresia
- Pancreatic
  - Chronic pancreatic insufficiency

Disorders of Vitamin D bioactivation and action

- Hereditary
  - Vitamin D-hydroxylation deficient rickets, type 1A (OMIM #264700) (1α-hydroxylase deficiency)
  - Vitamin D-hydroxylation deficient rickets, type 1B (OMIM #600081) (25-hydroxylase deficiency)
  - Vitamin D-dependent rickets, type 2A (OMIM #277440) (vitamin D receptor defect)
  - Vitamin D-dependent rickets, type 2B (OMIM %600785) (intact vitamin D receptor)
- Acquired
  - Anticonvulsant therapy
  - Renal insufficiency
- Acidosis
- Distal renal tubular acidosis (classic, type I)
  - Primary (specific aetiology not determined)
    - Sporadic
    - Familial
  - Secondary
    - Galactosaemia
    - Hereditary fructose intolerance with nephrocalcinosis
    - Fabry disease
  - Hypergammaglobulinaemic states
  - Medullary sponge kidney
  - Postrenal transplantation
- Acquired
  - Ureterosigmoidostomy
  - Ileal conduit
  - Obstructive uropathies
  - Drug-induced
  - Acetazolamide
  - Ammonium chloride

Chronic renal failure

Phosphate depletion

- Dietary
  - Low phosphate intake
  - Antacid excess using aluminium hydroxide or other non-absorbable hydroxides
- Impaired renal tubular phosphate reabsorption ('phosphate diabetes')
  - Hereditary
    - X-linked hypophosphataemia (OMIM# 307800)
    - Autosomal dominant hypophosphatemic rickets
    - Autosomal recessive hypophosphatemic rickets, types I and II
    - Syndrome of lipoatrophic diabetes, vitamin D resistant rickets, persistent Müllerian ducts
    - Dent disease (OMIM #300009) (hypercalciuria, nephrolithiasis, X-linked)
  - Acquired
    - Oncogenic (tumour-induced)
    - Neurofibromatosis
    - McCune–Albright syndrome
    - Ifosfamide treatment
    - Cutaneous skeletal hypophosphatemic syndrome (epidermal nevus syndrome)

General renal tubular disorders (Fanconi's syndrome)

- Primary renal
  - Idiopathic
    - Sporadic
    - Familial
  - Associated with a systemic metabolic disease
    - Cystinosis
    - Glycogenosis
    - Lowe's syndrome
- Systemic disorder with associated renal disease
  - Hereditary
    - Inborn errors
    - Wilson's disease
    - Tyrosinaemia
  - Acquired
    - Multiple myeloma
    - Nephrotic syndrome
    - Transplanted kidney
  - Toxins
    - Cadmium
    - Lead
    - Outdated tetracycline

Primary mineralization defects

- Hereditary
  - Hypophosphatasia (OMIM #241500, #146300, #241510)
  - Osteogenesis imperfecta, type VI
  - Congenital sclerosing osteomalacia with cerebral calcification ('Raine syndrome')
- Acquired
  - Bisphosphonate (etidronate) toxicity
  - Skeletal fluorosis
  - Aluminium or strontium intoxication
  - Gallium intoxication

States of rapid bone formation

- Postoperative hypoparathyroidism with osteitis fibrosa cystica

Defective matrix synthesis

- Fibrogenesis imperfecta ossium

Miscellaneous

- Mg^{2+}-dependent
- Calciopaenic
- Steroid-sensitive
- Axial osteomalacia
- Osteopetrosis ('osteopetrorickets')

endochondral bone formation at physes, and 'osteomalacia' for the impaired remodelling typically observed using non-decalcified bone histology after tetracycline 'labelling'. In this context, rickets and osteomalacia both would be present in paediatric patients with impaired skeletal mineralization.

The fundamental pathogeneses of rickets or osteomalacia can be broadly but usefully considered: (1) primary Ca^{2+} deficiency (i.e. nutritional inadequacy for the mineral itself, or more commonly disrupted vitamin D homeostasis leading to inadequate absorption of dietary Ca^{2+}) and called hypocalcaemic rickets or osteomalacia; (2) primary phosphorous deficiency (i.e. binding and malabsorption of Pi within the gastrointestinal tract, or increased renal Pi clearance) and called hypophosphataemic rickets or osteomalacia; and (3) aberrant hydroxyapatite crystal deposition due to skeletal cell dysfunction or abnormal mineral composition.

Medical therapy for rickets or osteomalacia will have greatest success if the aetiology can be identified and thereby reveal a cure (e.g. environmental vitamin D deficiency) [1–3]. Failing a cure, precise understanding of the pathogenesis becomes key for safe and effective treatment. For some underlying disturbances of mineral homeostasis, directly circumventing the pathogenesis may be possible (e.g. providing the deficient form of vitamin D in certain inborn errors of vitamin D bioactivation, or alkaline phosphatase (ALP) in hypophosphatasia). Except for dosage, pharmacological approaches for the specific types of rickets or osteomalacia will generally be alike regardless of patient age. However, additional distinctive complications often trouble paediatric patients with soft bones, and the goals for treatment and necessary follow-up differ from adults. Management of rickets is especially complex and likely to require multidisciplinary skills including orthopaedic care and dentistry. Fortunately, all forms of rickets or osteomalacia now have some type of medical treatment and all patients can benefit.

Vitamin D and Mineral Metabolism

Vitamin D

Much is now understood concerning the biosynthesis, bioactivation, and peripheral actions of vitamin D [2, 3] and regulation of mineral homeostasis [4]. Sufficient antirachitic activity in people can come from cutaneous synthesis in sunshine of vitamin D_3 [5] derived from 7-dehydrocholesterol, but this is often not achieved so fortification of select foods with vitamin D_2 or vitamin D_3 (e.g. 400 IU per quart of milk or infant formula in the United States) acts as a 'safety net' in several countries. Ergocalciferol (vitamin D_2) is the product of UV irradiation of ergosterol extracted from animal or plant substances, and is used in supplements or as a pharmaceutical [2, 3]. For other individuals 290–310 nm ultraviolet (UV) light lamps are used for cutaneous synthesis of cholecalciferol (vitamin D_3). Age, skin pigmentation, and clothing as well as the angle, intensity, and duration of sunshine all condition how much vitamin D_3 is synthesized [5].

Vitamin D should be regarded as a fat-soluble steroid hormone rather than as a nutrient (i.e. 'vitamin') because cholecalciferol or ergocalciferol undergo two bioactivation (hydroxylation) steps to become the fully potent 1,25-dihydroxyvitamin D that circulates to target organs where it binds to the vitamin D receptor (VDR) [6–8]. Vitamin D_2 and D_3 are, therefore, both prohormones that are transported in the blood by their high-affinity binding protein to muscle or fat for storage, or to the liver and subsequently to the kidney for bioactivation or deactivation through targeted hydroxylation steps [2, 3]. The notion that this hormone is a vitamin came from cures of vitamin D-deficiency rickets by giving fish oils (e.g. cod liver oil) rich in this 'vital' substance. This bioactivation occurs first, with little regulation, when cholecalciferol or ergocalciferol are hydroxylated in hepatocyte mitochondria by the enzyme P450c25 to form 25-hydroxyvitamin D, called calcidiol. Then, with precise control reflecting circulating Ca^{2+}, Pi, and parathyroid hormone (PTH) levels, 25-hydroxyvitamin D is further hydroxylated by kidney proximal convoluted tubule cell mitochondrial P450c1α, more commonly called 25-hydroxyvitamin D,1α–hydroxylase (or 1α–hydroxylase) to 1,25-dihydroxyvitamin D, called calcitriol. Low circulating levels of Ca^{2+} and Pi and elevated circulating levels of PTH all activate renal 1α-hydroxylase in order to increase 1,25-dihydroxyvitamin D biosynthesis [6–8]. Other cells can contain 1α-hydroxylase: for example, keratinocytes, macrophages often in granulomas, some tumour cells, and placental decidual cells [7, 8]. However, under physiological conditions other than pregnancy, extrarenal production of 1,25-dihydroxyvitamin D does not significantly contribute to its circulating levels. Hydroxylation at carbon 24 to produce 24,25-dihydroxyvitamin D or 1,24,25-trihydroxyvitamin D (calcitroic acid) occurs in a wide range of healthy tissues and is important for the deactivation and elimination of vitamin D. All of these hydroxylases are mitochondrial mixed-function oxidases containing cytochrome P450 with ferredoxin and haem-binding domains. Vitamin D_2 and D_3 seem equally susceptible to these hydroxylation steps, and their bioactivated forms are essentially equipotent in conditioning mineral homeostasis [2, 3], although some evidence suggests vitamin D_3 is more effective than vitamin D_2 in humans.

In tissues targeted by vitamin D, genomic and non-genomic actions of 1,25-dihydroxyvitamin D can occur [9]. There, 1,25-dihydroxyvitamin D couples to the VDR encoded by its gene that is a member of the nuclear hormone receptor gene superfamily. The VDR has both 1,25-dihydroxyvitamin D-binding and DNA-binding domains. After the complex combines with a retinoid X receptor (RXR) heterodimeric partner, transcription of genes in bone, kidney, and enterocytes is activated to assure adequate extracellular concentrations of minerals [9]. 1,25-dihydroxyvitamin D is considered the active metabolite of vitamin D by its rapidity of action and potency to augment gut absorption of Ca^{2+}. Urinary Ca^{2+} reclamation by the kidneys and bone resorption to provide Ca^{2+} are also increased. However, 1,25-dihydroxyvitamin D suppresses PTH synthesis within the feedback loop [2, 3]. The nomenclature of vitamin D and its activated forms emphasizes the hormonal nature of these secosterols (Table 4.11.1).

Minerals

Extracellular levels of both Ca^{2+} and Pi are maintained principally by three organs: intestine (mainly by absorption), bone (by rapid fluxes as well as slower bone resorption and formation), and kidney (by ultrafiltration and then modulation of tubular reabsorption) [4]. Three hormones interact significantly to achieve mineral homeostasis: (1) PTH activates osteoblasts directly and osteoclasts indirectly, increases renal tubular reabsorption of Ca^{2+} while causing phosphaturia, and promotes 1,25-dihydroxyvitamin D production

Table 4.11.1 Nomenclature of vitamin D (calciferol) and its metabolites

Chemical	Vitamin	Abbreviation
Cholecalciferol	Vitamin D_3	D_3
Ergocalciferol	Vitamin D_2	D_2
25-Hydroxycholecalciferol	25-hydroxyvitamin D_3	25(OH) D_3
25-Hydroxyergocalciferol	25-hydroxyvitamin D_2	25(OH) D_2
1α-Hydroxyergocalciferol	1α-hydroxyvitamin D_2	1α(OH) D_2
1,25-Dihydroxycholecalciferol	1,25-dihydroxyvitamin D_3	$1,25(OH)_2D_3$
1,25-Dihydroxyergocalciferol	1,25-dihydroxyvitamin D_2	$1,25(OH)_2D_2$

Throughout the text, unless specified, the abbreviations D, 25-hydroxyvitamin D, and 1,25-dihydroxyvitamin D refer to either the D_2 or D_3 compound, or a mixture of both.

in proximal renal tubule cells; (2) 1,25-dihydroxyvitamin D promotes Ca^{2+} (and Pi) absorption from the gut by increasing synthesis of the Ca^{2+} transport protein calbindin, probably activates osteoclasts, and regulates the biosynthesis of PTH and the phosphatonin fibroblast growth factor 23 (FGF23) [10]; (3) FGF23, produced by cells of the osteoblast lineage, circulates and then diminishes renal tubular reabsorption of Pi while inhibiting the biosynthesis of 1,25-dihydroxyvitamin D [7]. Thus, changes in circulating (i.e. extracellular) Ca^{2+} levels attributable to PTH come from its direct actions on the skeleton and kidneys and indirect action on the gut mediated instead by 1,25-dihydroxyvitamin D production [2, 3]. Extracellular Pi levels are regulated primarily by the kidney [11] where PTH and FGF23 cause phosphaturia, but to what degree other factors control Pi homeostasis is less well understood. Now, they include action by potentially a variety of phosphatonins [10], discovered from studies of a number of acquired or heritable forms of hypophosphataemic rickets or osteomalacia. Nevertheless, the precise interplay among these three hormones creates a means for controlling mineral homeostasis both acutely and long term, but with circulating levels of Ca^{2+} being more tightly controlled than Pi concentrations [4].

Box 4.11.2 Vitamin D deficiency: age-dependent signs and symptoms

- Metabolic
  - Hypocalcaemia
  - (See Box 4.11.3)
- Muscle
  - Proximal myopathy
  - Waddling gait
  - Asthenia
  - Pot belly with lumbar lordosis
- Dental
  - Delayed eruption
  - Enamel defects
  - Caries
- Skeletal
  - Frontal bossing
  - Widened cranial sutures
  - Craniotabes (skull asymmetry)
  - Harrison's groove
  - Rachitic rosary
  - Sternal indention or protrusion
  - Rib deformity → respiratory compromise
  - Pneumonia
  - Limb deformity
  - Flared wrists and ankles
  - 'String-of-pearls' deformity in hands
  - Bone tenderness
  - Fracture
  - Short stature
  - Kyphosis
  - Low back pain
  - Dystocia
  - Hypotonia
  - Lax ligaments
  - Listlessness

Diagnosis

Medical History

Disturbances in vitamin D and mineral homeostasis that cause rickets or osteomalacia can lead to a considerable number and variety of signs, symptoms, and complications—some of which depend importantly on the patient's age. These can be viewed as metabolic or skeletal in origin (**Box 4.11.2**), and become more likely as circulating Ca^{2+} or Pi levels become progressively lower (**Box 4.11.3**). Reduced levels or ineffective actions of vitamin D are particularly harmful for growing infants and young children (**Boxes 4.11.2** and **4.11.3**). Osteomalacia in adults is less apparent than rickets in children. Both disorders, however, can cause diffuse skeletal achiness and tenderness with focal worse pain due to fractures or pseudofractures. Some symptoms can instead be vague. The importance of a detailed medical history from, and then complete physical examination of, the patient to capture what is needed for diagnosing and treating all metabolic bone diseases was reviewed in 2018 [12], and cannot be overemphasized for rickets and osteomalacia.

Physical Examination

Rickets compromises especially the most rapidly growing bones [13, 14]. Thus, the nature of the skeletal changes depends on the patient's age when the metabolic perturbations began. Congenital forms of rickets may go unnoticed at birth because Ca^{2+} and Pi levels in the fetal circulation are controlled by placental transport from the mother. Such patients with healthy mothers usually develop physical features of rickets during the first 2 years of life. During infancy, the changes involve especially the cranium, ribs, and wrists causing widened cranial sutures, frontal bossing, posterior flattening of the skull (craniotabes), bulging of the costochondral junctions (rachitic rosary), indentation of the ribs at the insertion of the diaphragm

Box 4.11.3 Signs and symptoms of acute or chronic hypocalcaemia

- Nervous system
  - Increased irritability from latent or overt tetany
  - Seizures
  - Mental status change, retardation
  - Basal ganglia calcification
- Cardiovascular
  - Prolonged ST interval with arrhythmia
  - Cardiomyopathy with congestive heart failure
  - Hypotension

(Harrison's groove), and distally widened forearm bones. The rib cage may become so deformed ('bell-shaped') that this predisposes to recurrent pneumonias and respiratory failure. Eruption of the dentition is delayed and defective mineralization ('shell teeth') can include enamel hypoplasia [13, 14]. After infancy, with standing and continued rapid linear growth, skeletal deformities can become severe in the lower limbs. Bowlegs (genu varum), or less often knock-knees (genu valgum), of variable severity develop together with widening of the ends of long bones due to physeal and metaphyseal expansion. Occasionally, the lower limbs bend in the same direction ('windswept' legs) [13]. However, extremity deformity may not occur if the rachitic child is too ill to bear weight or is not growing. When the bones first soften later in childhood or during the adolescent growth spurt, knock-knee deformity becomes particularly common. If unsuccessfully treated, rickets may compromise adult height, predispose to fractures, and leave permanent skeletal deformities that lead to osteoarthritis. Focal bone pain and tenderness can result from fracture. In osteomalacia, pressure on the sternum, percussion over the vertebrae, and squeezing of the ribs and long bones may elicit tenderness.

Skull shape and size can be distorted. Premature fusion of cranial sutures causing craniosynostosis is common in early-onset rickets. In X-linked hypophosphataemia, dolichocephaly often occurs due to closure of the sagittal suture, but is usually only a cosmetic finding unless additional sutures became prematurely fused. In severe instances of hypophosphatasia from ALP deficiency, 'functional' craniosynostosis from profound hypomineralization of the calvarium, or later due to true bony fusion of all cranial sutures, can lead to a scaphocephalic skull sometimes complicated by raised intracranial pressure [15].

In oncogenic (tumour-induced) rickets or osteomalacia, the causal neoplasm is usually benign and may be visible if not palpable, although some are smaller than pea-size and located essentially anywhere. Some have occurred intravaginally or in the nasopharynx, and not infrequently originate within the skeleton. Because extirpation of these tumours is curative, thorough physical examination to find them is essential. If the neoplasm remains elusive, including on radiological studies, the patients should periodically undergo physical examination for subcutaneous bumps because the tumours grow slowly and may appear.

Maternal dystocia due to a narrowed birth canal resulting from childhood vitamin D deficiency was a major cause of obstetrical mortality at the turn of the past century [14]. This deformity should be considered for women of childbearing age with a history of rickets.

Total alopecia represents an important finding concerning management and prognosis in patients with hereditary resistance to 1,25-dihydroxyvitamin D [6, 7].

Hypocalcaemia, if present, can enhance neuromuscular excitability [4]. Infants with compromised vitamin D homeostasis and hypocalcaemia are often 'floppy', hypotonic, listless, and irritable [13]. Symptoms and signs of latent or overt tetany may be reported during the medical history or elicited during the physical examination, respectively (**Box 4.11.3**). Such findings are particularly likely with severe and/or rapid reductions in circulating Ca^{2+} levels. There can be paresthesia of the lips and fingertips and spontaneous muscle contractions in the face, limbs, or elsewhere. Carpopedal spasm features thumb adduction, metacarpophalangeal joint flexion, and interphalangeal joint extension. Latent tetany can be unmasked if there is a positive Chvostek's sign or Trousseau's sign, yet both can be negative despite severe hypocalcaemia. Profound hypocalcaemia can also cause mental status changes, epileptic seizures, lethal stridor from laryngeal muscle spasm, and cardiomyopathy (**Box 4.11.3**) [4].

Additional problems from deranged vitamin D homeostasis and hypocalcaemia include a 'metabolic myopathy' with reduced muscle tone and strength as well as a waddling gait, but no (or nonspecific) changes on electromyography [13]. Weakness is a prominent feature of vitamin D deficiency and tumour-induced rickets or osteomalacia. Proximal muscle weakness is suspected when there is difficulty negotiating stairs, combing hair, or standing from sitting. Gower's sign detects muscle weakness if patients must push up with their hands on their thighs to stand. There can also be lax ligaments and *pectus excavatum* from diaphragmatic and intercostal muscle traction. Validated assessments of muscle strength by functional testing or dynamometry before treatment commences may be useful for follow-up if therapy will not be curative.

Radiological Studies

For rickets of any type, an anteroposterior radiograph of a knee and a posteroanterior radiograph of a wrist (perhaps non-dominant side) before treatment begins best document the characteristic physeal and metaphyseal abnormalities and will be an important basis to judge the patient's response to therapy [16]. Early on, rickets broadens growth plates uniformly (**Figures 4.11.1a** and **b**) and metaphyses are splayed and concave with their epiphysis appearing as though held within a ragged cup (**Figure 4.11.1b**). However, with chronic disease and long bone deformity mechanical forces acting on the lower limbs can cause asymmetrical widening of growth plates especially at the knees (**Figure 4.11.1c**). For a few years after the major appendicular growth plates fuse, rachitic changes may still be discernible in the apophyses of the ischium and ilium [16]. Long cassette radiographs of the lower limbs, taken while

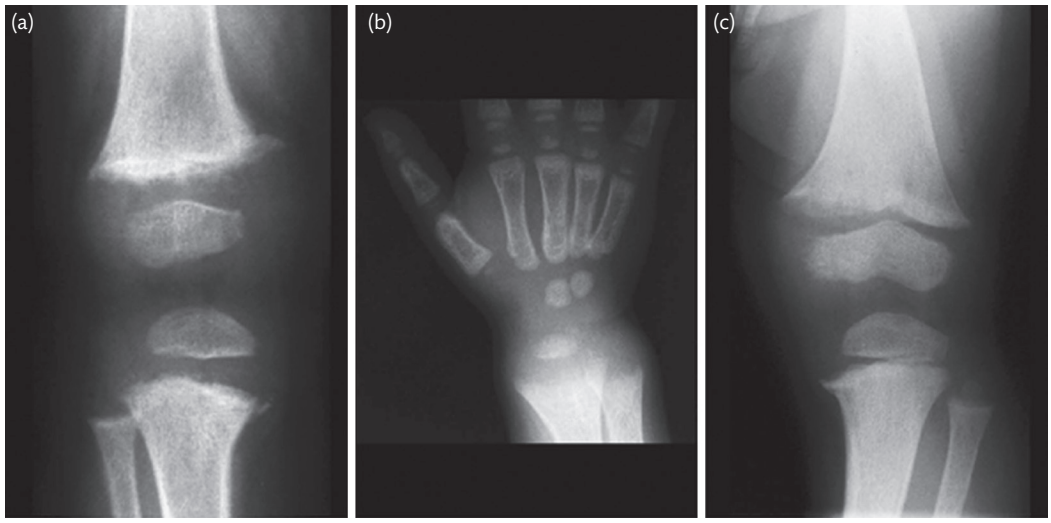

Figure 4.11.1 Rickets: (a) Before treatment, uniform physeal widening and metaphyseal irregularity and flaring are apparent in this knee of a 2-year-old child with vitamin D deficiency, poor dietary Ca^{2+} intake, and seizures treated with phenobarbital. (b) Physes are widened and metaphyses are irregular and flared in this wrist of a 2-year-old girl with untreated X-linked hypophosphataemia. A 'ball-in-cup' deformity is developing at her distal radius. (c) Physeal widening is less apparent in this knee of this 2-year-old girl beginning treatment for X-linked hypophosphataemia. The asymmetrical physeal widening and 'beaking' of the medial tibial metaphysis are due to the bowing deformity of the lower limbs.

the patient stands with reproducible positioning (ankles or knees together), help to explain, quantify, and follow bowing or knock-knee deformity. Now, low-dose X-ray imaging is available for this purpose.

Radiographs can also provide clues to the aetiology or pathogenesis of rickets [12, 16]. Disturbances in vitamin D homeostasis cause secondary hyperparathyroidism often featuring osteopaenia and sometimes evidence of subperiosteal bone resorption. Conversely, in X-linked hypophosphataemia changes of hyperparathyroidism are less usual, but increased skeletal radiodensity is not uncommon. Remarkable osteosclerosis and hyperostosis are characteristic of autosomal recessive hypophosphataemic rickets, type 1 due to dentin matrix protein 1 (DMP1) deficiency. In rickets from ALP deficiency in hypophosphatasia, peculiar 'tongues' of radiolucency commonly project from physes into metaphyses at the knees and elsewhere and there can be patchy osteosclerosis (Figure 4.11.2) [15]. However, not all disorders that cause radiographic growth plate distortion and limb deformity are forms of rickets [16]. Epiphyseal and metaphyseal dysplasias and Blount's disease may suggest rickets, but they do not compromise vitamin D or mineral homeostasis or cause osteomalacia [4].

In osteomalacia, pseudofractures (Looser's zones or Milkman fractures) can occur anywhere except in the skull, and most often involve the pubic and ischial rami, ribs, scapulae, and the medial cortex of the proximal femora (Figure 4.11.3). Intervertebral discs may compress softened vertebral endplates causing biconcave ('cod fish') vertebrae [16].

Radiographic signs of secondary hyperparathyroidism are seen best as subperiosteal erosions involving the radial border of the middle phalanx of the index finger, distal ends of the clavicles, and symphysis pubis [16].

The rapidity of radiographic response to therapy may be of diagnostic significance for rickets. In primary vitamin D deficiency, improvement occurs just several weeks after a single large oral dose of vitamin D [13]. Other forms of rickets often take months to improve radiographically, especially those due to renal Pi wasting treated with conventional medical therapy involving multiple daily doses of oral phosphate salts together with a bioactive form of vitamin D such as 1,25-dihydroxyvitamin D_3 [11].

Bone scintigraphy is useful for uncovering abnormalities in the skeleton, but does not provide a diagnosis. This procedure is usually unnecessary in children with rickets because radiographs are particularly useful. However, when physical examination fails to disclose the cause of tumour-induced rickets or osteomalacia, conventional bone scanning may help to detect the neoplasm. In general for this procedure, enhanced radioisotope uptake occurs where there is increased blood flow, osteoidosis, or rapid bone remodelling. In rickets or osteomalacia, a 'superscan' can result, featuring no apparent radioisotope within the kidneys and in osteomalacia will disclose complications such as fractures and pseudofractures. Octreotide scanning or (PET)/computed tomography (CT) are especially useful for detecting and locating the causal tumour [17]. Rarely, selective venous sampling with FGF23 assay is needed.

Bone densitometry using dual-energy X-ray absorptiometry (DXA) can be imprecise and difficult to interpret in rickets or osteomalacia because of short stature, skeletal deformities or fractures, and osseous tissue accumulation that mineralizes with effective treatment and then undergoes removal when remodelling resumes.

Biochemical Investigation

Laboratory investigation to differentiate among the three aforementioned principal types of rickets or osteomalacia is straightforward. Quantitation of serum Ca^{2+}, Pi, PTH, Mg^{2+}, and ALP is essential. If needed, assay of circulating 1,25-dihydroxyvitamin D, FGF23, and electrolyte levels and 24-hour urinary Ca^{2+} and Pi excretion will help to distinguish among the types of primary hypophosphataemia featuring defects in renal tubular Pi reabsorption.

Hypocalcaemia is usually more severe in vitamin D-deficiency rickets versus osteomalacia, and sometimes results paradoxically in hyperphosphataemia rather than in hypophosphataemia [13].

Figure 4.11.2 Hypophosphatasia: Characteristic tongues of radiolucency (arrows) project from the physes into the metaphyses of this 5-year-old girl who survived the infantile form of this heritable type of rickets.

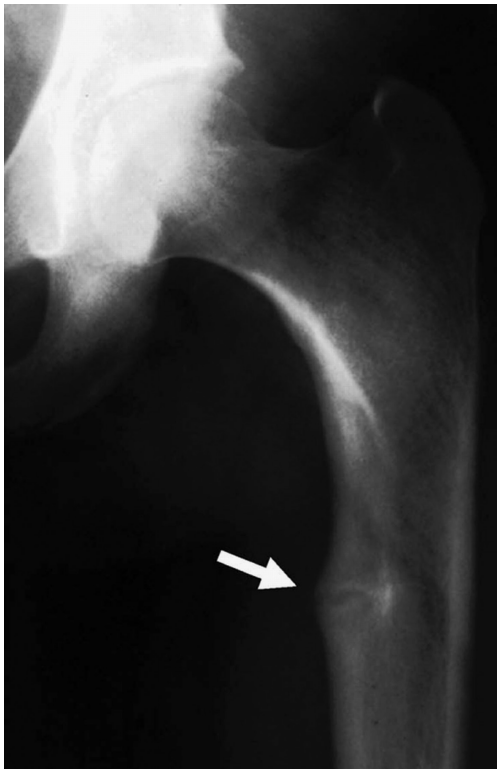

Figure 4.11.3 Pseudofracture: This 20-year-old woman with X-linked hypophosphataemia has a 'Looser zone' (arrow), characteristic of an osteomalacia, in her medial proximal femur.

Secondary hyperparathyroidism may cause a mild hyperchloraemic metabolic acidosis reflecting enhanced renal excretion of bicarbonate due to the elevated circulating PTH level. Significant metabolic acidosis, however, suggests Fanconi syndrome and therefore a different aetiology [11].

Although quantitation separately of circulating vitamin D_2 and D_3 might help to identify any predominance for an exogenous versus endogenous source, assays for these prohormones are not readily available [2, 3]. Fortunately, measuring serum 25-hydroxyvitamin D is a good surrogate for determining if there is vitamin D deficiency, sufficiency, or toxicity. Assay of serum 25-hydroxyvitamin D is offered by many commercial or hospital laboratories and typically detects 25-hydroxyvitamin D_2 and 25-hydroxyvitamin D_3 together. Assays for serum 1,25-dihydroxyvitamin D are also available commercially, but their utility for distinguishing among various types of rickets or osteomalacia is somewhat limited because the level can be low, normal, or high when there is vitamin D deficiency and depending upon the severity of secondary hyperparathyroidism and how much 25-hydroxyvitamin D substrate remains despite accelerated 1,25-dihydroxyvitamin D production [13, 14]. Quantitation of both 25-hydroxvitamin D and 1,25-dihydroxyvitamin D is, however, essential for differentiating among the various genetic disturbances in vitamin D bioactivation, including resistance to 1,25-dihydroxyvitamin D (Table 4.11.2).

Serum ALP activity (bone isoform) from chondrocytes and osteoblasts is elevated in most patients with rickets or osteomalacia. The striking exception is hypophosphatasia, which instead features hypophosphatas*aemia* [15] from deficiency of both the bone and liver isoforms of the 'tissue non-specific' isoenzyme of ALP. Blood and urine levels of other markers of skeletal turnover can be difficult to interpret in rickets or osteomalacia, and need not be measured routinely.

Histopathological Findings

Although the patient's medical history, physical findings, and results from routine radiographic and biochemical studies usually suffice to diagnose and to treat rickets or osteomalacia, if necessary histopathological assessment of bone tissue can provide definitive evidence of the expected defect in mineralization [1].

In clinical practice, the specimen used to detect impaired skeletal mineralization is routinely taken by trephine biopsy from the iliac crest. Beforehand, two 3-day courses of oxytetracycline or demeclocycline hydrochloride (20 mg/kg body weight per day in divided doses) are given orally (separated by a 2-week interval) for *in vivo* tetracycline labelling of mineralizing bone surfaces. The final dose is swallowed several days before the biopsy. The specimen must not be decalcified (see next). The histological picture is described as osteomalacia by histomorphometrists when excessive osteoid ('hyperosteoidosis') is present together with proof of defective bone matrix mineralization using time-spaced tetracycline labelling [18]. Histopathological confirmation of rickets is rarely necessary and would require risky biopsy of a growth plate.

Transiliac biopsy is performed at a standard anatomic site: 2 cm behind the anterosuperior iliac spine and just below the crest. The trephine has a 5.0 or 7.5 mm inner diameter for adults, and a 5 mm or narrower internal diameter for children depending on body size. Ideally, the specimen contains the outer and inner cortex connected by unbroken intervening trabeculae. It is fixed in 70% ethanol/30% water

Table 4.11.2 Biochemical parameters of mineral and skeletal homeostasis in rickets/osteomalacia, by aetiology

Aetiology	Biochemical properties Serum concentrations				
	Calcium	Phosphorous	PTH	Bone-specific ALP	24th urinary Ca^{2+} excretion
Hypocalcaemic, e.g. vitamin D deficiency	Low to low-normal	Low	Elevated	Elevated	Low
Hypophosphataemic, e.g. X-linked hypophosphataemia	Normal	Low	Normal to elevated	Elevated	Low to elevated
Tissue defects, e.g. hypophosphatasia	Normal or elevated	Normal or elevated	Normal to Low	Low	Normal to elevated

PTH, parathyroid hormone; ALP, alkaline phosphatase.

and then embedded in methylmethacrylate, sectioned undecalcified, and examined both unstained and with different stains. Histological assessment may include quantitation of various parameters compared to reference values (i.e. histomorphometry) (Figure 4.11.4).

Bone histology can be important in osteomalacia because radiographic studies are not characteristic as in rickets that is documented radiographically [16]. In osteomalacia or rickets, biopsy allows the increased width and extent of unmineralized osteoid covering mineralized bone surfaces to be quantitated (Figure 4.11.4a). Also, fluorescence microscopy will fail to show at osteoid/mineralized bone interfaces two discrete fluorescent tetracycline 'labels' produced if there is ongoing mineralization (Figure 4.11.4b). Instead, indistinct or absent fluorescence banding characterizes rickets or osteomalacia. Commonly used 'static' histomorphometric parameters [18] include trabecular bone volume, osteoid volume, osteoid surface, osteoid thickness, osteoblast surface, osteoclast surface, and osteoclast number whereas 'dynamic' parameters include double-labelled bone surface, mineral appositional rate, bone formation rate, and mineralization lag time.

Guidelines for Therapy and Follow-up

The last type of rickets or osteomalacia to acquire a medical therapy, hypophosphatasia, obtained one in 2015 [19]. Now, all forms of rickets or osteomalacia can be treated with at least some success. Ideally, the aetiology is corrected (e.g. vitamin D deficiency) (Box 4.11.1) and there is a cure. However, this is often not possible, and instead the pathophysiology must be understood and addressed for safe and effective treatment. Certain heritable forms of rickets or osteomalacia now have a pharmacological treatment aimed at a fundamental element of their pathogenesis; e.g. bone ALP replacement therapy for hypophosphatasia, monoclonal antibody treatment to decrease excessive circulating levels of the phosphatonin FGF23 in X-linked hypophosphatemia, and vitamin D metabolites to bypass errors in vitamin D bioactivation (see next). A correct diagnosis with appropriate follow-up is essential for a favourable clinical outcome while avoiding potential toxicities or complications. Pharmacological doses of cholecalciferol or ergocalciferol (or replacement doses of an active metabolite), sometimes with mineral supplementation, will be necessary when there is deranged bioactivation of vitamin D. Availability

Table 4.11.3 Pharmaceutical preparations of vitamin D and active metabolites

	Ergocalciferol	Dihydrotachysterol[a]	Calcifediol[b]	Calcitriol	Alfacalcidol
Abbreviation	**D_2**	**DHT**	**25(OH) D_3**	**1,25$(OH)_2D_3$**	**1α(OH)D**
Dosage form	Capsules: 1.25 mg Liquid: 200 μg/ml Intramuscular injection: 12.5 mg/ml in sesame oil (not in USA)	Tablets: 0.125, 0.200, and 0.400 mg Liquid: 0.250 mg/ml	Capsules: 20 and 50 μg	Capsules: 0.25 and 0.50 μg Liquid: 1.0 μg/ml Injection: 1.0 μg/ml	Capsules: 0.25 and 1.0 μg Liquid: 0.20 μg/ml Injection: 2.0 μg/ml in propylene glycol
Time to reach maximum biological effects	4–10 weeks	2–4 weeks	4–20 weeks	0.5–1 week	0.5–1 week
Persistence of biological effect after cessation	6–30 weeks	2–8 weeks	4–12 weeks	0.5–1 week	0.5–1 week

[a] This form of vitamin D is no longer generally available, but is listed for historical interest.
[b] Also called calcidiol.

of four vitamin D pharmaceuticals in the United States: vitamin D_2 and D_3, 25-hydroxyvitamin D_3, and 1,25-dihydroxyvitamin D_3 make it possible to replace, substitute for, or bypass various disturbances of vitamin D access, storage, or activation. They differ importantly in potency and biological half-life (Table 4.11.3). Alfacalcidol (1α-hydroxyvitamin D_3), rather than 1,25-dihyroxyvitamin D_3, is available in some countries recognizing it would undergo 25-hydroxylation in the liver. Dihydrotachysterol is no longer prescribed in the United States or the United Kingdom.

Rickets and osteomalacia have numerous and diverse explanations (Box 4.11.1). Successful treatment requires a correct diagnosis with an understanding of the aetiology and pathogenesis, including any deficiency or impaired bioactivation of vitamin D. Also, the nature of the deranged mineral metabolism must be appreciated. Wisely chosen, medical therapy for rickets or osteomalacia can greatly benefit the patient. For rickets, the three disturbances of skeletal development can often be improved, even corrected [1]. Given sufficient time before growth plate closure, reversal of deformity is a major goal of treatment. Relief from bone pain and fracture prevention also follow, and represent important goals of treating osteomalacia. Preventing short stature is also often a concern. Optimum therapy corrects or circumvents the underlying problem. However, a narrow range of safe and effective doses using appropriate pharmaceuticals and/or supplements should be anticipated for some patients. For hypophosphatasia and X-linked hypophosphatemia, weight-based dosing is prescribed precisely for their newer treatments [20–24]. Significant adverse consequences (failed treatment, hypercalcaemia, hyperphosphatemia, nephrocalcinosis, kidney stones, renal damage, and secondary or tertiary hyperparathyroidism) may result from an incorrect diagnosis or excessive and unmonitored therapy.

Physical examination provides important information. Supine length is measured in infants. Linear growth rates are monitored in infants, children, and adolescents. Height is determined best with a wall-mounted stadiometer, with several measurements averaged for distractible young children. Rapid changes in body size and weight during the pubertal growth spurt can increase dose requirements for chronic forms of rickets, and if not dealt with will worsen limb deformity and compromise final height. Furthermore, inordinate weight gain in girls can accelerate puberty and thereby close growth plates. When growth is complete, dosage requirements may diminish for various regimens.

Measurements of height and arm span as well as upper and lower body segment lengths will help to quantify skeletal distortion. With heritable forms of rickets, treatment will be necessary throughout growth, and months may pass before clinical improvement is achieved. It may be the individual who sees the patient perhaps every 6 months who best recognizes any changes in deformities. Accordingly, clinical photography, gait analysis, and videotaping can help assess for gradual changes. Radiographic alterations, such as widening of the growth plates and metaphyseal irregularity, are essential for diagnosing rickets and serve as important landmarks during follow-up to judge the efficacy of any medical treatment. Other radiographic findings are less helpful. Osteopaenia and coarsening of trabecular bone are observed in some patients [16]. Pseudofractures can heal with successful treatment.

The biochemical parameters used to diagnose rickets or osteomalacia are then followed to evaluate treatment. Typically, these are serum Ca^{2+}, Pi, 25-hydroxyvitamin D, ALP, and PTH. Depending on the aetiology and pathogenesis of this disorder, serum 1,25-dihydroxyvitamin D concentrations may or may not be helpful. Excretion of Ca^{2+} in 24-h urine collections (corrected for creatinine content) helps guide therapy as normal levels are aimed for, but also helps to monitor for excesses or toxicities. Eventual normalization of urinary levels of Ca^{2+} can indicate that treatment is now fully effective. If incomplete healing of rickets or osteomalacia is suspected, non-decalcified iliac crest histomorphometry will be definitive [1].

Treatment with vitamin D will be the appropriate way to overcome its deficiency, but pharmacologic doses can also help somewhat when there is defective bioactivation of vitamin D [7]. However, giving the correct active metabolite of vitamin D can circumvent such disturbances and therefore is useful for hereditary defects in vitamin D synthesis (see next) [7]. These pharmaceuticals are more potent than vitamin D_2 or D_3, have more rapid onset of action, and have shorter biological half-lives (Table 4.11.3). Thus, toxicity can appear sooner but will correct faster [7]. Nevertheless, they cannot replete deficient stores of vitamin D. Many different Ca^{2+} and Pi supplements are available [18]. The dose and type of Ca^{2+} may reflect the primary disturbance. $CaCO_3$ given orally is least expensive, but Ca^{2+} citrate is generally better absorbed. Ca^{2+} gluconate is especially costly. For the disorders that feature renal Pi wasting, conventional therapy has involved oral administration of Pi salts and bioactive vitamin D. Tablets rather than liquid preparations for oral Pi supplementation are more convenient, taste better,

and seem less prone to cause diarrhoea. Those with high amounts of sodium are best avoided. Now, since 2018, the anti-FGF23 monoclonal antibody, burosumab, has been available multinationally to treat X-linked hypophosphatemia [23, 24], and is effective for further types of FGF23-mediated rickets or osteomalacia.

Follow-up clinic visits are required for all types of rickets and osteomalacia, but the number and interval should reflect the specific diagnosis and therapeutic response. Because rickets and osteomalacia reflect deficient skeletal mineral content, decreases in treatment dose(s) might be necessary when healing is complete and maintenance becomes the principal issue. Because hypocalciuria characterizes most, but not all, forms of rickets or osteomalacia, urinary Ca^{2+} levels rising into the normal range will help to indicate effective therapy. Satiation of 'hungry bones' indicates the skeleton is no longer such an avid sump for mineral deposition. Normalization of previously aberrant biochemical findings could herald hypercalciuria as the definitive marker calling for dose reduction. Unless there is renal failure or fixed elevation in circulating PTH levels (reclaiming Ca^{2+} from the glomerular filtrate), hypercalciuria would precede hypercalcaemia. Cessation or lower maintenance doses of vitamin D and mineral supplements may then be needed. Thus, 24-h urine collections while consuming the usual diet, not random urine specimens, assayed for Ca^{2+} and creatinine can become important for patient follow-up and safety.

Consultation from the orthopaedic surgeon can be often helpful in managing rickets. As medical treatment is underway, he/she may consider leg bracing, physeal stapling (epiphysiodesis), or osteotomy to improve physical function and protect joint integrity. Straight lower limbs when growth ceases, with alignment of their physes parallel to the ground, helps prevent osteoarthritis. Intramedullary rodding may be necessary to heal pseudofractures and prevent fracturing for some adults with osteomalacia [25].

Pharmacological regimens for specific disorders are provided in the following sections that represent the three principal types of rickets or osteomalacia (i.e. hypocalcaemic, hypophosphataemic, and those with other pathogeneses).

Acquired Rickets and Osteomalacia

Primary Vitamin D Deficiency

Pathogenesis

Vitamin D deficiency reflects inadequate biosynthesis with insufficient acquisition from the diet, sometimes coupled with losses into the gastrointestinal tract. Primary ('nutritional') rickets or osteomalacia is a human-made disorder due to social, economic, and/or cultural factors that prevent sufficient exposure to sunlight for photosynthesis of vitamin D_3 in the skin. In modernity, hypovitaminosis D may also reflect too little intake from dietary (nutritional) sources or supplements containing vitamin D. Secondary deficiency could be from intestinal malabsorption of vitamin D_3 or D_2. Increased vitamin D clearance can result from accelerated catabolism, mainly in the liver, or increased loss via the intestine or the kidneys.

Vitamin D_3 synthesis in the skin requires UV light with a maximal effective wave length between 290 and 310 nm, and is affected by the intensity of the radiation, surface area of the exposed skin, and intrinsic properties of the epidermis [5]. At extreme latitudes during winter, almost no UV light reaches the ground. In the north of the United States, Canada, and north-western Europe, practically no vitamin D_3 is produced by exposed skin between October and March. Clothing, smog, window glass, plastic, and sunscreens [5] effectively block UV radiation and prevent cutaneous synthesis of vitamin D_3. Furthermore, vitamin D_3 production is less in people with dark skin (because melanin absorbs UV radiation), and in older people despite 'thin' skin [5]. Nevertheless, it has been estimated that 20-minute exposure thrice times weekly of the skin of the head and arms to summer sunshine prevents vitamin D deficiency in older people.

Vitamin D content of various unfortified food substances is very low, with the exception of cod liver oil and fatty fish such as herring and mackerel. During unfortified food consumption, it is estimated that less than 20% of total circulating 25-hydroxyvitamin D is from dietary sources. In some countries, therefore, dietary vitamin D is increased by supplementation of certain food products. In the United States, milk is fortified with 400 IU per quart. Improved vitamin D intake could result from multivitamins, which usually contain 400 IU or 800 IU per capsule, or some Ca^{2+} salt preparations that also contain vitamin D. These supplements will increase the relative contribution of dietary vitamin D to the total body pool, and be beneficial when cutaneous production is limited. Now in the United States, substantially higher doses of vitamin D can be obtained in various shops without a prescription.

Diagnosis

Hypovitaminosis D is diagnosed by assaying the serum concentration of 25-hydroxyvitamin D, which is a reliable measure of vitamin D status in almost all clinical situations. However, the necessary level of circulating 25-hydroxyvitamin D and the terms used to describe various low-end serum concentrations are not recognized universally. In fact, many of the clinical signs and symptoms and biochemical perturbations reflecting bone and mineral metabolism from hypovitaminosis D are shared among the disorders of vitamin D action and Ca^{2+} deficiency (Tables 4.11.2 and 4.11.4), including the subsequent low to low-normal serum Ca^{2+} levels, secondary hyperparathyroidism, hypocalciuria, hypophosphataemia, and the

Table 4.11.4 Serum levels of vitamin D metabolites in disorders of vitamin D action, by aetiology

Aetiology	Serum levels	
	25-hydroxyvitamin D	1,25-dihydroxyvitamin D
Vitamin D deficiency	Low	Low to elevated
25-hydroxyvitamin D, 1α-hydroxylase deficiency	Normal to elevated	Very low
Resistance to 1,25-dihydroxyvitamin D	Normal to elevated	Markedly elevated

hyperphosphatasaemia that seems to reflect enhanced willingness of the skeleton to ossify. Therefore, these biochemical parameters can support but not establish the diagnosis of rickets or osteomalacia, help assess the severity, and direct vitamin D dosing depending on the severity of the vitamin D requirement and the response to treatment. Importantly, circulating levels of 1,25-dihydroxyvitamin D can vary from low to elevated (Table 4.11.4), and thus are unhelpful for establishing this particular diagnosis.

In 1998, investigation of patients on a general medicine ward in Boston, Massachusetts, USA revealed that secondary hyperparathyroidism was common when serum 25-hydroxyvitamin D levels were at or below 15 ng/ml [26]. This led to studies to define vitamin D 'insufficiency' and 'deficiency'. Population-based reference values for serum 25-hydroxyvitamin D levels have been, for a considerable time, debatable. They could reflect age, geography, season, dress, eating habits, confinement to bed or home, local regulations concerning food fortification, and customs of vitamin supplementation. An alternative, however, was to define health-based concentrations (i.e. circulating 25-hydroxyvitamin D levels below which adverse health outcomes could occur). This would represent an intervention threshold to prevent detrimental effects on the skeleton, including relatively mild hypovitaminosis D not sufficient to compromise matrix mineralization but instead disrupt mineral homeostasis, cause secondary hyperparathyroidism, increase bone turnover, and lead to bone loss [27]. Multiple studies aimed to define serum 25-hydroxyvitamin D concentrations below which serum PTH levels increase, or for which vitamin D supplementation significantly decreased serum PTH concentrations [27]. Both approaches yielded similar functional thresholds. Accordingly, vitamin D 'adequacy' is accepted by most clinicians as serum 25-hydroxyvitamin D at or above 75 nmol/L (30 ng/ml), whereas some argue that the threshold level is instead between 50 and 75 nmol/L (20 and 30 ng/ml). However, serum 25-hydroxyvitamin D below 50 nmol/L (20 ng/ml) is considered 'inadequacy'. Vitamin D inadequacy has been subdivided into vitamin D 'insufficiency' when levels are between 25 nmol/L (10 ng/ml) and the threshold value, and vitamin D 'deficiency' when levels are below 25 nmol/L (10 ng/ml). Vitamin D deficiency represents a state in which Ca^{2+} homeostasis begins to fail (i.e. decreased serum Ca^{2+} levels despite increased serum PTH concentrations), with the high risk of developing rickets or osteomalacia. The same serum 25-hydroxyvitamin D threshold of ~75 nmol/L (30 ng/ml) was observed for additional physiological variables, such as intestinal Ca^{2+} absorption, changes in bone mineral density, and lower extremity physical performance [28]. Reduction of falls and fractures was positively correlated to the serum 25-hydroxyvitamin D level (up to a certain concentration) [29].

Prevalence of Vitamin D Insufficiency and Deficiency

Although the biosynthetic and bioactivation pathways for vitamin D are known, primary deficiency still seems common worldwide [14, 30]. In the United Kingdom, hypovitaminosis D resurged in the 1970s within the immigrant Asian community [13]. Those most vulnerable cannot move freely, and are at the beginning or end of life. In multiple studies worldwide, vitamin D deficiency was detected in 35 to 65% of older people; more so in institutionalized individuals [31]. In people hospitalized for an osteoporotic fracture, deficiency was recorded in 20–68%; only 1–3% had levels above 75 nmol/L (30 ng/ml). However, any age can be affected, especially when there are physical or mental handicaps. Additionally, the 'safety net' created in some countries by fortifying certain foods with vitamin D may not be available [13, 30]. Among adults, institutionalized or housebound individuals, the poor, older people, food faddists, and some religious groups (because of diet and dress) are at enhanced risk. Infants who are breastfed beyond 6 months of age or drink non-fortified milk or formula are also susceptible [5, 13]. In some populations, low dietary Ca^{2+} intake can be an important or exacerbating factor ('calciopaenic rickets') [30].

In postmenopausal women treated for osteoporosis in various regions of the world, vitamin D 'inadequacy'; that is, serum 25-hydroxyvitamin levels <75 nmol/L (30 ng/ml), was found in 52% of those in North America, 58% in Europe, 53% in Latin America, 71% in Asia, and 82% in the Middle East [32]. Pronounced differences in prevalences were observed among countries, ranging from 30% in Sweden in the summer to ~ 90% in Japan and South Korea in the winter and summer. Vitamin D 'deficiency' was, however, much less common; ~1% in North America, and ~6% and 8% in Latin America and the Middle East, respectively. Values below 25 nmol/L (10 ng/ml) were reported in ~40% of those tested in Sri Lanka and Beijing, and 18% in Hong Kong [33]. But, serum levels below 50 nmol/L (20 ng/ml) were observed in 78% of healthy hospital staff in India, and 90% of young women in Beijing and Hong Kong.

Of special concern is the high prevalence, in some geographic regions, of vitamin D deficiency in pregnant women, their children, and adolescent girls. Maternal serum 25-hydroxyvitamin D levels correlate positively with 25-hydroxyvitamin D levels in cord blood.

Fortunately, the prevalence of osteomalacia from hypovitaminosis D is lower than for the vitamin itself, but depends on the criteria for diagnosis (i.e. clinical, biochemical, bone histology, or bone histomorphometry). In a review of multiple publications describing histomorphometry of the femoral head or iliac crest in approximately 1400 patients with hip fracture, osteomalacia ranged from none to over 30% of patients. Perhaps this reflects different populations and magnitudes and durations of vitamin D deficiency, but also the histological criteria used to define osteomalacia.

Treatment

Although patient or parent education and correction of causal socioeconomic factors might seem best for preventing and treating primary vitamin D deficiency, this is often difficult to achieve. Fortunately, pharmacological or supplementation therapy should be inexpensive, effective, and work rapidly. Vitamin D deficiency should be treated using vitamin D_2 or D_3. Although 25-hydroxyvitamin D_3, 1α-hydroxyvitamin D_3, and 1,25-dihydroxyvitamin D_3 are more potent and act more rapidly than cholecalciferol or ergocalciferol, these active metabolites do not correct the depleted stores of vitamin D and their therapeutic windows are narrow and may not be sustained.

Adequate vitamin D intake has been recommended by the National Osteoporosis Foundation of the USA to be 800–1000 IU/day in adults age 50 years or older [34]. The recommendation for infants was increased to 400 IU/day of vitamin D_3. However, these goals are often unachievable unless certain foods are fortified with vitamin D.

Treatment should recognize those at greatest risk. Vitamin D supplementation for infants up to 1 year of age is required in many countries. However, supplementation may not be routine for older

people. Nursing home residents, institutionalized and hospitalized elderly, patients with hip fractures, and those with neurological disorders are among those in greatest jeopardy [31].

For vitamin D treatment to be fully effective, the recommended daily Ca^{2+} allowance should be achieved, including by Ca^{2+} salt supplementation if necessary. In fact, low dietary Ca^{2+} intake, especially common in some regions of Africa and North China, may itself cause rickets ('calciopaenic rickets') or exacerbate vitamin D-deficiency rickets.

The typical oral maintenance dose of vitamin D is 800 to 1000 IU daily. For patients with severe vitamin D deficiency causing symptomatic hypocalcaemia, it is helpful to administer a 'loading dose' of vitamin D_2 to replete body stores rapidly. Ca^{2+} intake must also be supplemented. Insufficient Ca^{2+} for a suddenly mineralizing skeleton could exacerbate the hypocalcaemia. A single oral dose of 5000 IU of vitamin D per kg body weight can be given. For a 70 kg adult, this is 350 000 IU of vitamin D. Although this quantity of vitamin D seems great, it illustrates the body's storage capacity for vitamin D [2, 3]. With symptomatic hypocalcaemia, Ca^{2+} can be given intravenously over 24 hours (as much as 20 mg of elemental Ca^{2+} per kg of body weight per day). Ca^{2+} infusions should be administered continuously, or slowly in portions, and always regulated by serum Ca^{2+} levels determined several times daily. Oral Ca^{2+} supplementation (1–2 g of elemental Ca^{2+} each day) can be initiated at this time. For patients who are not lactose intolerant and no longer hypocalcaemic, three to four glasses of milk each day will provide both Ca^{2+} and Pi to help remineralize the skeleton. In severe vitamin D deficiency, 4000–8000 IU could be given daily for the first 4–6 weeks. Alternatively, 50 000 IU of vitamin D could be administered two or three times a week for the first 2 weeks, followed by lower doses. Because vitamin D is stored in fat and released slowly, and the circulating half-life of 25-hydroxyvitamin D is 2–3 weeks, dosing can be once weekly, monthly, or every 3–6 months. An oral dose of 100 000 IU every 4 months for 5 years increased serum 25-hydroxyvitamin D to adequate levels. This approach can improve compliance by seeing the prescribed dose taken, both for independent elderly and for dependent institutionalized patients. However, experience with this high-dose regimen is relatively limited.

The response to vitamin D supplementation will depend on the severity of its deficiency and the consequent changes in mineral and skeletal homeostasis. Serum 25-hydroxyvitamin D should return to normal, but the timeframe will reflect the severity of the initial vitamin D deficiency. When the rickets or osteomalacia is severe, symptoms, signs, and laboratory parameters can change rapidly. Bone pain and muscle weakness will improve quickly, pseudofractures can heal, and serum Ca^{2+}, Pi, and PTH should return towards normal levels. In mild vitamin D deficiency or insufficiency, the response can be more subtle. Bone mineral density can increase, and the incidence of fractures should decrease and their rate of healing improve.

For infants and young children with vitamin D-deficiency rickets, liquid preparations of vitamin D_2 are available (Table 4.11.3) and can be dosed at 4000 IU (100 μg) orally each day for several months [13, 14]. If capsules can be chewed or swallowed directly, one 50 000 IU (1.25 mg) dose of vitamin D_2 orally each week for three or four doses is an inexpensive and straightforward regimen. It seems prudent that the physician observe that at least the first capsule is swallowed. Biochemical and radiographic improvement then typically occurs within just a few weeks [13, 14].

After healing their rickets, children who have inadequate sunlight exposure should receive 400 IU vitamin D_2 or D_3 per day, either by consuming fortified foods or using an over-the-counter multivitamin or vitamin D supplement [2, 3].

Failure to show biochemical and radiographic improvement with persistently low serum 25-hydroxyvitamin D levels could reflect failed compliance or malabsorption. Use of inexpensive vitamin D capsules may help to assure that the medication is taken. Alternatively, and if available, a single intramuscular injection of vitamin D in sesame oil will assure long-term access to antirachitic activity if patient compliance for oral treatment is poor, or if there is malabsorption (Table 4.11.3). Visits to a 'tanning salon' have also proved effective. If skeletal disease persists despite sustained correction of circulating 25-hydroxyvitamin D levels, calciopaenia, or one of the vitamin D-dependent or resistant syndromes (Box 4.11.1) must be considered (see next) [7, 9, 13, 30].

Prophylaxis against vitamin D-deficiency rickets could involve outdoor activity in sufficient sunshine but without sunburn, consumption of vitamin D-fortified foods, vitamin D supplements, or brief direct exposure to UV light wearing protective goggles [2, 3]. 'Stoss' therapy, used in Europe for children, consists of one depot intramuscular injection of 600 000 IU of vitamin D_2 during the autumn. However, this dose given once orally has caused hypercalcaemia and renal damage [35].

Secondary Vitamin D Deficiency

Vitamin D deficiency due to enhanced clearance is usually explained by systemic disorders (e.g. protein-losing nephropathy, intestinal malabsorption) or increased liver catabolism sometimes caused by certain drugs (e.g. barbiturates, other antiepileptics, etc.). Gastrointestinal malabsorption interferes with uptake of fat-soluble vitamin D from the gut, but sometimes disrupted enterohepatic recirculation of vitamin D metabolites contributes to the loss. Thus, intestinal malabsorption may decrease input and increase excretion of vitamin D.

Vitamin D deficiency from malabsorption may overcome normal amounts of sunlight exposure [5]. Gastrointestinal, pancreatic, or hepatobiliary disease may be at fault (Box 4.11.1) [2, 3], but the mechanism for the vitamin D deficiency and associated derangements in mineral metabolism is often complex. Malabsorption by the gut may also interfere with the uptake of dietary minerals.

Vitamin D is a fat-soluble secosterol, bile salts enable its absorption, and there is enterohepatic circulation of vitamin D and its derivatives [2, 3]. Hence, hepatobiliary or pancreatic disease or short bowel syndrome can cause deficiency of bile salts, steatorrhoea, and malabsorption leading to depletion of vitamin D stores. Furthermore, the small bowel mediates dietary Ca^{2+} uptake, and malabsorption of Ca^{2+} can exacerbate the consequences from vitamin D deficiency. With secondary hyperparathyroidism, conversion of 25-hydroxyvitamin D to both 1,25- and 24,25-dihydroxyvitamin D is enhanced, and 25-hydroxyvitamin D is depleted also by this mechanism. In fact, vitamin D deficiency and its clinical and biochemical consequences may be the first sign of occult malabsorption due, for example, to coeliac disease (non-tropical sprue). Nevertheless, in some conditions where osteomalacia might be anticipated (e.g. primary biliary cirrhosis), the

associated osteopathy is often osteoporosis. Iliac crest histology is especially useful for such patients.

Although the pathogenesis of secondary vitamin D-deficiency rickets or osteomalacia can be complicated, pharmacological therapy with appropriate follow-up should give gratifying results. As these patients reflect heterogeneous disturbances of wide-ranging severity, individualized therapy is key. Assay of serum 25-hydroxyvitamin D documents vitamin D status and is essential for monitoring progress [26]. Doses of vitamin D_2 or D_3 given orally should prove sufficient to correct any deficiency, and are relatively inexpensive. Repletion of vitamin D stores is a principal goal. Then, cholecalciferol or ergocalciferol can be converted to 25-hydroxyvitamin D, even if there is parenchymal liver disease (2, 3). Here too, a single oral 'loading' dose of about 125 µg (5000 IU) of vitamin D per kg of body weight can expedite treatment prior to maintenance dosing. Intravenous Ca^{2+} for symptomatic hypocalcaemia (as much as 20 mg of elemental Ca^{2+} per kg of body weight daily) over 24 hours by continuous infusion, or slowly in divided doses, is regulated by frequent measurements of serum Ca^{2+} and would be helpful for 'hungry bones'. Serum Mg^{2+} should be assayed for newly diagnosed hypocalcaemia, and treated if levels are low, as this may cause peripheral resistance to PTH or impair PTH biosynthesis [18].

After the loading dose(s) of vitamin D, patients with secondary vitamin D deficiency will require supplemental vitamin D unless the primary disorder can also be corrected. If not, it is impossible to predict the maintenance dose, and therefore clinical and biochemical follow-up is mandatory. Initially, outpatients should be evaluated every few weeks. Adjustments in dosing will be needed when the rickets or osteomalacia heals, or the gastrointestinal, hepatobiliary, or pancreatic disturbance evolves or responds to treatment, but considerable time may pass before the patient achieves a 'steady state' of vitamin D repletion.

For mild disease, a reasonable starting dose of vitamin D_2 or D_3 is 50 000 IU (1.25 mg) orally twice weekly. Assay of the circulating 25-hydroxyvitamin D level about 1 month later, and about every 4 months thereafter, will determine what dose of vitamin D proves useful. Serum 25-hydroxyvitamin D levels should be maintained somewhat above a threshold value of 75 nmol/L (30 ng/ml). If hypocalcaemia with secondary hyperparathyroidism is persisting, Ca^{2+} supplements can be added. Then, assay periodically of the Ca^{2+} and creatinine content of a 24-h urine collections, aiming for a normal calcium/creatinine ratio, can be used to optimize therapy. Attention to urinary Ca^{2+} levels will help to guard against vitamin D toxicity manifesting as hypercalciuria. This approach should show correction of hypocalciuria unless circulating levels of PTH (which reclaims urinary Ca^{2+}) are persistently elevated due to parathyroid gland hyperplasia and do not suppress with treatment. In this situation, assay of serum rather than urine Ca^{2+} levels becomes especially important.

Although oral vitamin D therapy at some dose is nearly always successful (unless there has been almost complete resection of the small intestine requiring total parenteral nutrition), intramuscular injection (if available) of depot vitamin D_2 in oil can be an alternative. Here, 12.5 mg of vitamin D_2 (500 000 IU) dissolved in 1 ml of sesame oil (Table 4.11.3) will provide sustained bioavailability of vitamin D [36]. An increment in the circulating 25-hydroxyvitamin D level may not appear for several weeks after the injection, but vitamin D_2 release will persist for months. Injections of 500 000 IU of vitamin D_2 every few months should provide effective and continuous supplementation for an adult, but biochemical monitoring is important.

Hypophosphataemia due to secondary hyperparathyroidism with renal Pi wasting contributes importantly to the pathogenesis of defective mineralization of skeletal matrix in most patients, but is not treated directly. Notably, some individuals with hypocalcaemia alone from hypoparathyroidism or pseudohypoparathyroidism develop rickets or osteomalacia despite elevated serum Pi levels.

Calciopaenic

Severe deficiency of dietary Ca^{2+} despite intact stores of vitamin D can also lead to defective skeletal mineralization [13, 30]. Calciopaenic rickets has been described in children fed a cereal-based diet [13] and in premature infants [14]. Several religious, ethnic, and other groups have vegetarian members who are at risk because they do not consume dairy products. Also, poor dietary Ca^{2+} intake can exacerbate vitamin D-deficiency rickets [30]. Altering the diet significantly, or using Ca^{2+} supplements, should readily reverse the disorder.

Drug-Induced

Anticonvulsant-Induced

Rickets and osteomalacia have been reported in institutionalized people receiving anticonvulsants, especially when multiple types [2, 3, 14]. Phenobarbital can alter hepatic vitamin D metabolism predisposing to vitamin D depletion [2, 3]. Also, primary deficiency of vitamin D affects many such individuals.

If their serum 25-hydroxyvitamin D level is low, the individual who takes phenobarbital or some other anticonvulsant can receive a 50 000 IU dose of vitamin D orally once weekly for several months, thereafter adjusted by following their serum 25-hydroxyvitamin D concentration.

Phosphate Binder-Induced

Osteomalacia, and rarely rickets, can result from excessive use of Pi-binders (e.g. magnesium and aluminium hydroxide antacids) [18]. Craniosynostosis together with rickets has been documented when such antacids were added to infant formula to treat colic [37]. Significant hypophosphataemia can occur. Assay of urinary phosphorous will reveal low levels, rather than seemingly normal or increased levels when defective skeletal mineralization is from renal phosphate wasting causing hypophosphatemia. Such patients may also hyperabsorb dietary Ca^{2+} and become hypercalciuric because their hypophosphataemia physiologically stimulates renal 25-hydroxyvitamin D, 1α-hydroxylase activity to increase biosynthesis of 1,25-dihydroxyvitamin D. Kidney stones can develop. Despite the increased dietary Ca^{2+} absorption, the hypophosphataemia alone impairs skeletal mineralization. Elimination of Pi-binder use will rapidly correct the disrupted mineral homeostasis and heal the skeletal defects. Pi supplementation or vitamin D therapy will not be necessary. It may take several months for serum ALP activity to correct.

Ifosfamide

This chemotherapeutic drug can cause transient or permanent kidney tubule damage leading to urinary Pi wasting and hypophosphataemic skeletal disease [38].

Intravenous Iron

Patients with iron deficiency anaemia given iron intravenously have developed rickets or osteomalacia. Circulating levels of biologically active FGF23 can rapidly increase and lead to renal phosphate wasting and suppressed 1,25-dihydroxyvitamin D synthesis causing secondary hyperparathyroidism [39].

Etidronate

This first-generation bisphosphonate used for Paget's bone disease and hypercalcaemia of malignancy can, with excessive or prolonged exposure, cause rickets or osteomalacia. Etidronate retains sufficient chemical similarity to the natural inhibitor of biomineralization, inorganic pyrophosphate, to inhibit hydroxyapatite crystal formation and growth [4].

Strontium-Induced

High skeletal levels of strontium have been associated with defective bone mineralization in haemodialysis patients [40]. Rickets seems more prevalent where soil contain high levels of strontium [41].

Toxin-induced

Rickets or osteomalacia can follow long-term exposure to several other inhibitors of skeletal mineralization.

Aluminium

Patients with uraemia exposed to aluminium-containing antacids, contaminated dialysate, or parenteral feedings containing aluminium have developed osteomalacia [18]. Treatment with deferoxamine has been helpful [18]. With use of newer agents for Pi binding and pure dialysate and feedings, this disorder is now rare.

Fluoride

Excessive fluoride from well water, industrial or 'huffing' inhalation, inordinate amounts of tea drinking, or sodium fluoride given for osteoporosis can cause rickets or osteomalacia [18, 42]. Defective bone mineralization will respond gradually to cessation of fluoride exposure, perhaps helped by oral Ca^{2+} supplementation [43].

Oncogenic

Oncogenic rickets or osteomalacia is a rare, sporadic, acquired disorder that is typically caused by a benign 'mixed mesenchymal' tumour in soft tissues (Figure 4.11.5) [11, 18]. However, a considerable variety of indolent neoplasms, non-ossifying fibroma, and (rarely) malignant bone tumours or other cancers can cause this condition [18]. These tumours secrete FGF23 and sometimes other phosphatonins that cause phosphaturia and inhibit renal 25-hydroxyvitamin D, 1α-hydroxylase activity (10). Low circulating 1,25-dihydroxyvitamin D levels can cause malabsorption of dietary Ca^{2+} and mild hypocalcaemia, secondary hyperparathyroidism, and hypocalciuria. Hypophosphataemia is, however, the principal biochemical abnormality, and lowers the blood $Ca^{2+} \times$ Pi product sufficiently to impair skeletal mineralization. Patients are often profoundly weak.

Definitive diagnosis of oncogenic rickets or osteomalacia is achieved by resection of the neoplasm and subsequent cure. Therefore, thorough diagnostic evaluation for this entity is especially important when there is sporadic acquired hypophosphataemic skeletal disease, particularly in an adult. If a soft tissue tumour is not apparent on physical examination, bone scintigraphy, whole body magnetic resonance imaging, octreotide scanning, or positron emission tomography CT using specific tracers with high sensitivity or high specificity have proven extremely useful [17, 18].

When removal of the causal neoplasm is not possible or unsuccessful, Pi supplementation together with 1,25-dihydroxyvitamin D_3 or 1α-hydroxyvitamin D_3 treatment can reverse patient weakness and heal the skeleton. In 2020, the anti-FGF23 monoclonal antibody, burosumab, gained approval for this disorder, and is promising for the similar condition cutaneous skeletal hypophosphatemia syndrome [44].

Figure 4.11.5 X-linked hypophosphataemia: Severe lower extremity bowing deforms an untreated mother and her daughters.

Metabolic Acidosis

Metabolic acidosis can cause rickets or osteomalacia (Box 4.11.1). The pathogenesis is not well understood but complex. Nevertheless, the skeletal disease responds well to vitamin D and alkali therapy. Ca^{2+} and potassium supplementation may be necessary at the onset of alkali therapy to prevent hypocalcaemia and hypokalaemia. Vitamin D (50 000 IU orally thrice weekly) can be used for adults, with careful follow-up until healing occurs. Alkali therapy should be continued after the mineralization defect is corrected. Urinary Ca^{2+} and creatinine levels must be monitored frequently because metabolic acidosis *per se* causes hypercalciuria.

Renal Failure

In uraemia, skeletal disease usually reflects the associated secondary or tertiary hyperparathyroidism leading to rapid bone remodelling (osteitis fibrosa cystica) [4]. However, some patients have instead manifested osteomalacia caused by aluminium or strontium exposure or excessive treatment that has suppressed calcitriol biosynthesis.

Aluminium Intoxication

Aluminium is toxic to osteoblasts and inhibits skeletal mineralization [4]. Contamination of dialysate with this metal has caused 'Newcastle bone disease'. Also, uraemic patients who used aluminium-containing antacids to bind dietary Pi deposited the metal into their skeletal tissue. Serum assays and bone histochemistry for aluminium support the diagnosis [4]. Therapy includes changing to be newer Pi-binders. Deferoxamine has been a useful chelating agent [18].

Hypophosphataemia From Phosphate Binders

Excessive use of Pi-binders in uraemic patients can cause hypophosphataemia leading to rickets or osteomalacia.

Parathyroid Insufficiency

Severe osteomalacia has occurred in chronic renal failure after excessive parathyroidectomy for secondary or tertiary hyperparathyroidism [4]. PTH is necessary for bone turnover in uraemia.

Epidermal Nevus Syndrome

Infants and children with epidermal nevus syndrome (cutaneous skeletal hypophosphataemia syndrome) can develop rickets due to renal Pi wasting [44]. 1,25-dihydroxyvitamin D_3 and Pi supplementation therapy is effective for the generalized impairment of skeletal mineralization, but not for the underlying focal pathogenetic bone disease. If circulating FGF23 levels are elevated, burosumab therapy may be useful [44].

Miscellaneous Disorders

Several rare sporadic conditions manifest with osteomalacia despite normal circulating concentrations of Ca^{2+}, Pi, PTH, and 25-hydroxyvitamin D [18]. There is no established therapy. A correct diagnosis is important in part because excessive doses of vitamin D or an active metabolite and Ca^{2+} supplementation could cause hypercalcaemia and hypercalciuria.

Fibrogenesis imperfecta ossium, reported in about a dozen patients, is an enigmatic acquired abnormality of the skeletal matrix. Growth hormone may be an effective treatment [45]. Axial osteomalacia is characterized radiographically by coarsening of trabecular bone in the axial skeleton, seemingly from a primary defect in osteoblasts, and may be heritable [46].

Heritable Rickets and Osteomalacia

Genetic disorders that cause rickets or osteomalacia are numerous (Box 4.11.1). Some feature renal Pi wasting, some reflect disturbances in the bioactivation or action of vitamin D, and some are inborn errors of metabolism due to enzyme deficiencies (throughout this section, heritable disorders are referred to by their McKusick symbol and OMIM number provided in Online Mendelian Inheritance In Man) [46].

Hypophosphataemic Bone Disease

Several heritable forms of rickets or osteomalacia reflect disturbances in vitamin D metabolism that lead to reduced levels of Ca^{2+} in the extracellular fluids [14]. These disorders can also diminish extracellular Pi concentrations partly from phosphaturia due to secondary hyperparathyroidism. Hypocalcaemia and hypophosphataemia together engender a decreased blood $Ca^{2+} \times$ Pi product that explains why there is impaired mineralization of newly synthesized osteoid [1].

The importance of Pi alone for skeletal mineralization is, however, best illustrated by the types of rickets or osteomalacia due to renal phosphate wasting without significant decreases in circulating Ca^{2+} levels [11]. 'Hypophosphataemic bone disease' is a generic term that emphasizes the skeletal consequences of this biochemical disturbance. Although pharmacological treatment for these disorders shares certain themes, optimal regimens may differ.

X-linked Hypophosphataemia

X-linked hypophosphataemia (XLH) is the most common heritable form of rickets or osteomalacia (OMIM #307800) [11]. Its prevalence in North America is approximately 1:20 000 live births. All races have affected individuals.

XLH was first identified in 1937 when vitamin D-deficiency rickets, a plague of Northern industrialized cities at the turn of the last century, became treatable with vitamin D [47]. Discovery of vitamin D in 1919, and then successful therapy and preventive measures for 'nutritional' rickets, represented a triumph of medical science [2, 3]. Nevertheless, some cases of refractory rickets were puzzling because they were not cured even by massive doses of vitamin D_2 [47]. Therefore, XLH was at first called 'vitamin D-resistant rickets' until 1958 when its X-linked dominant inheritance became appreciated [48]. Females and males are affected in a 2:1 ratio with no male-to-male transmission. Hypophosphataemia from renal Pi wasting became appreciated as a key pathogenetic factor in 1969 [49]. Inappropriately normal circulating levels of 1,25-dihydroxyvitamin D despite hypophosphataemia was recognized in 1982. In 1995, an international consortium identified the causal gene designated *PHEX* (phosphate-regulating gene with homology to endopeptidases on the X-chromosome) [50].

XLH causes short stature and bowing of the lower limbs beginning in affected toddlers when they bear weight to walk (Figure 4.11.6). Subsequently, they may seem clumsy, yet strong and are generally well in contrast to nearly all other forms of rickets. The skull is often dolichocephalic from early closure of the sagittal suture and Chiari

Figure 4.11.6 X-linked hypophosphataemia: Severe lower extremity bowing deforms an untreated mother and her daughters.

1 malformation from craniosynostosis can occur. The chest and upper extremities are not deformed. Fractures during childhood are uncommon. Occasionally, the skeletal disease presents later in childhood with knock-knees. Without treatment, height Z scores will be minus 2–3 standard deviations [51, 52].

Adults with XLH typically suffer five principal complications [51]. Arthralgias, primarily involving the lower limbs and especially the knees, are explained by osteoarthritis. The degree of residual lower extremity rachitic deformity predicts the likelihood of this knee joint deterioration [51]. Bone pain palpable in the thighs is often explained by femoral pseudofractures (**Figure 4.11.3**). Pseudofractures can occur elsewhere. Dental abscesses develop because brittle 'shell' teeth form early in life due to defective mineralization of dentine. Enthesopathy (calcification of tendons, ligaments, joint capsules, etc.) is common and spinal stenosis may be a result, but it is unclear how often symptoms develop. Sensorineural hearing loss seems to have increased prevalence. Obstetrical histories seem benign, but as for all types of rickets dystocia should be considered a potential problem [51]. The impact of XLH in older people is being studied. Life expectancy is probably not compromised.

Radiographs of children with XLH show physeal widening, that in the knees becomes especially pronounced medially when there is bowing deformity of the lower limbs (**Figure 4.11.1c**). Osteopaenia and evidence of secondary hyperparathyroidism are generally absent unless dietary Ca^{2+} intake is poor. In fact, the skeleton often appears radiographically dense, contrasting with other forms of rickets that characteristically increase circulating PTH levels. In adults with XLH, axial skeletal mass is typically normal, although sclerotic bones are not uncommon [53].

The biochemical hallmark of XLH is hypophosphataemia from selective renal Pi wasting [11]. Serum Ca^{2+} levels are low-normal, but usually not distinctly reduced [51, 52]. Hypophosphataemia must be documented recognizing important age-related effects on reference ranges for serum Pi. Healthy children have considerably higher serum Pi concentrations (and ALP activity) compared with healthy adults. Because circulating Pi levels may increase or decrease depending upon what is eaten, fasting blood specimens are best for assay [52]. In XLH, quantitation of renal Pi reclamation by calculating the transport maximum for phosphorous per glomerular filtration rate (TmP/GFR) shows that the hypophosphataemia reflects decreased renal tubular reabsorption ('phosphate diabetes') [51, 52]. Occasionally, trace glucosuria is detected, however, other parameters of proximal renal tubule function (e.g. serum potassium, bicarbonate, uric acid levels) are normal; that is, Fanconi's syndrome (see later) is absent. Serum 1,25-dihydroxyvitamin D levels in XLH are generally normal or low-normal despite the hypophosphataemia, which physiologically increases renal 25-hydroxyvitamin D, 1α-hydroxylase activity [11]. During treatment, unless Pi supplements are insufficiently matched by doses of 1,25-dihydroxyvitamin D_3 to prevent malabsorption of dietary Ca^{++} (see next), circulating PTH levels are usually normal [51, 52]. Without treatment, serum ALP is increased in children, but not always in adults. Serum FGF23 levels are elevated in nearly all untreated XLH patients, in keeping with this key factor in the disorder's pathogenesis [10].

Histopathological examination of the skeleton shows rickets or osteomalacia in untreated patients with XLH (**Figure 4.11.4a**) [51]. Elevated circulating PTH levels predict features of hyperparathyroidism, including abundant osteoclasts and peritrabecular fibrosis. Additionally, in appropriately stained non-decalcified sections [1], there are halos of hypomineralized bone surrounding osteocytes (**Figure 4.11.4a**) [51]. This peculiarity has been considered characteristic of XLH, reflecting an osteoblast defect that persists despite successful 1,25-dihydroxyvitamin D_3 and Pi therapy when these cells become osteocytes. Accumulation of osteopontin seems to be the explanation [54].

The aetiology of XLH is loss-of-function mutation of *PHEX*, but the pathogenesis is incompletely understood [10, 11]. Kidney transport of Pi is diminished across proximal tubule cells where normally PTH and FGF23 decrease urinary Pi reclamation [11]. Here, Pi movement across the brush border membrane is the rate-limiting step. In XLH, there is diminished Na^+-dependent Pi transport [11]. However, blunted response to the activators of 1,25-dihydroxyvitamin D biosynthesis is also present in kidney mitochondria [11] where Pi deprivation and supplementation physiologically accelerate and suppress, respectively, 1,25-dihydroxyvitamin D formation. Nevertheless, the precise intracellular disturbances that diminish renal Pi transport and alter vitamin D bioactivation are not known [10, 11]. Parabiosis and renal transplantation studies using the *Hyp* mouse implicated a phosphaturic factor(s) [55], now appreciated to be an excess of circulating FGF23 [10]. Malabsorption of dietary Ca^{2+} in XLH is poorly understood, but considered a feature of the vitamin D resistance.

In XLH, no gene dosage effect emerged from a study of prepubertal heterozygous girls and hemizygous boys (**Figure 4.11.6**) [56]. Nevertheless, the complications of pseudofracture and enthesopathy seem more severe in men compared to women [51]. Accordingly, gender (sex steroids and/or physical labour, etc.) may condition long-term outcomes [51].

XLH maps to chromosome Xp22.31–21.3 [46]. Many different mutations involving the coding sequence or splice sites of *PHEX* have been discovered in XLH worldwide [46]. They are expected to diminish PHEX protein function. An early preliminary study indicated that defects compromising the exons encoding the PHEX protein *per se* cause more severe XLH [57]. Indeed, a missense mutation within the *PHEX* 3'UTR has been found to cause a distinctly mild variant of XLH in American patients [58]. Nevertheless, the putative substrate for PHEX remains uncertain [10, 11]. PHEX could act at cell surfaces to inactivate a phosphaturic factor, or activate a suppressor of phosphatonins such as FGF23 [10, 11, 59].

Renal Pi wasting is the key pathogenetic abnormality that causes defective skeletal mineralization in XLH. TmP/GFR correlates positively with height Z score in paediatric patients [56], and decreases reflect the degree of bowing deformity in affected adults [51]. Accordingly, in conventional therapy, this disturbance is targeted together with decreases in 1,25-dihydroxyvitamin D biosynthesis.

Bioactivated forms of vitamin D have been used for decades to treat XLH because high doses of vitamin D (e.g. 100 000 IU daily) can somewhat improve, but will not heal, the rickets [60]. Large doses of vitamin D_2 are readily converted to 25-hydroxyvitamin D, however, the affinity of the VDR for 25-hydroxyvitamin D is two to three orders of magnitude lower than for 1,25-dihydroxyvitamin D [2, 3]. Furthermore, excessive vitamin D_2 given to patients with XLH sometimes caused prolonged hypercalcaemia, hypercalciuria, nephrocalcinosis, and renal failure [61] reflecting the long biological half-life of vitamin D (**Table 4.11.3**). Hypercalcaemia can persist for

months, requiring dietary Ca^{2+} restriction and glucocorticoid treatment. Additionally, high-dose vitamin D_2 therapy has required cessation months in advance of osteotomy to avoid hypercalciuria or hypercalcaemia if postoperative immobilization is prolonged.

When the pathogenetic renal Pi wasting of XLH became addressed, improved clinical, biochemical, and radiographic responses were noted [49, 52]. Transient augmentation of circulating Pi levels was achieved using frequent oral Pi dosing to supply, depending on body size, about 1–2 g of phosphorous (as Pi) each day. Combined use of 1,25-dihydroxyvitamin D_3 or 1α-hydroxyvitamin D_3 and Pi supplementation became the best regimen for XLH [52]. The active metabolite of vitamin D would augment both Ca^{2+} and Pi uptake from the gut, while better Ca^{2+} absorption would prevent secondary or tertiary hyperparathyroidism provoked by Pi lowering blood Ca^{2+} levels directly or binding Ca^{2+} in the intestine. Nevertheless, this regimen only transiently corrected hypophosphatemia and rarely would safely fully correct the radiographic rickets [23, 24]. This conventional therapy required a medical/orthopaedic approach for XLH best provided by experienced centres where 1,25-dihydroxyvitamin D_3 and Pi supplementation could improve the defects in skeletal growth, modelling, and remodelling in compliant patients [52]. However, since 2018, the human anti-FGF23 monoclonal antibody burosumab (Crysvita®), that neutralizes circulating FGF23, has been commercially available multinationally to better treat XLH in patients aged 6 months or older [23, 24].

There are two principal goals of therapy for XLH: (1) correction of limb deformity by the time growth plates fuse to prevent osteoarthritis; and (2) satisfactory height. The principal complications of active vitamin D and Pi treatment are: (1) secondary or tertiary hyperparathyroidism that compromise clinical outcomes and perhaps necessitate partial parathyroidectomy; and (2) nephrocalcinosis that may cause renal compromise.

This treatment may begin for toddlers to help promote their growth and to avoid lower extremity distortions, but oral dosing and monitoring is understandably difficult especially at first. Control, but not complete correction, of the rickets seemed a reasonable objective. Both 0.25 and 0.50 μg capsules of 1,25-dihydroxyvitamin D_3 are commercially available. The contents can be put into applesauce, etc., but a liquid preparation is also now marketed (Table 4.11.3). Approximately 40 ng (i.e. 0.040 μg) per kg of body weight of 1,25-dihydroxyvitamin D_3 daily (divided doses are ideal) may be achieved safely over 2 to 3 months by gradually increasing the dose and monitoring its biochemical effects. In the United Kingdom and Europe, a solution of 1α-hydroxyvitamin D is available. Pi supplementation, given three to four times daily, is introduced simultaneously and also gradually increased. Tablets of neutral sodium/ potassium phosphate (e.g. K-Phos Neutral; Beach Pharmaceuticals, Tampa, FL) are most convenient and generally well tolerated. Occasionally, Pi causes diarrhoea. In some ways, 1,25-dihydroxyvitamin D_3 and Pi produce opposite effects on Ca^{2+} homeostasis [52]. Accordingly, if either Pi or 1,25-dihydroxyvitamin D_3 is stopped, both should stop. Sudden decreases (or especially cessation) in Pi supplementation alone should be avoided, because 1,25-dihydroxyvitamin D effects can persist and urinary and then blood Ca^{2+} levels may rapidly rise. Accordingly, patients should be cautioned not to run out of these medications.

Careful biochemical surveillance is essential because 1,25-dihydroxyvitamin D_3 is especially potent in enhancing gastrointestinal Ca^{2+} absorption. Ca^{2+} and creatinine should be assayed in 24-hour urine collections (not random specimens) [52]. Initially, monitoring should occur monthly, but then every 3 months. Urinary Ca^{2+} to creatinine ratios of about 150–180 mg/g reflect adequate gut effects of 1,25-dihydroxyvitamin D_3 helping to suppress circulating PTH levels. If hypocalciuria is a persisting problem, increased dairy consumption or Ca^{2+} supplementation may be helpful. Unless PTH levels are elevated and non-suppressible (predicting hypercalcaemia before hypercalciuria), hypercalciuria will herald excessive 1,25-dihydroxyvitamin D_3 or 1α-hydroxyvitamin D_3 dosing. Fortunately, they both have short biological half-lives, permitting rapid corrections of excessive effect (Table 4.11.3). Urine levels of approximately 3.0 g phosphorous per g creatinine have been a good target in our experience, and seem less likely than greater values to cause nephrocalcinosis. Renal ultrasonography, creatinine clearance, and serum PTH levels should be monitored at least yearly. Dosage increases will be necessary as the child grows. Nephrocalcinosis in XLH seems to represent Ca^{2+}–Pi deposits, and this emphasizes the importance of Pi levels in this complication. However, it seems that subradiographic nephrocalcinosis does not compromise renal function [60]. Partial parathyroidectomy may become necessary if elevated serum PTH levels become persistent and are associated with hypercalcaemia. Some have used calcimimetics to control hyperparathyroidism. Hypercalciuria (>4 mg Ca^{2+} per kg of body weight, or >220 mg Ca^{2+} per g creatinine) can occur when skeletal mineralization is fully restored or when growth plates fuse. Lower doses may provide maintenance therapy until skeletal 'consolidation' is complete and cessation of medical treatment can be considered.

Orthopaedic evaluation should occur at least yearly during childhood, and twice yearly during the adolescent growth spurt, because limb bracing or epiphysiodesis may be helpful. Osteotomies are sometimes postponed until growth ceases to minimize the possibility of postoperative deformity. Unless patients are weight-bearing within 2 days of surgery (or fracture, etc.), 1,25-dihydroxyvitamin D_3 and then Pi therapy should be held until standing resumes to avoid immobilization hypercalciuria and hypercalcaemia.

Closure of physes after puberty does not mean that XLH is cured [51]. The metabolic derangements persist lifelong. Accordingly, affected adults should be followed perhaps yearly. Some may benefit from continuing 1,25-dihydroxyvitamin D_3 and Pi therapy to prevent fractures or worsening deformity [51].

In 2018, the medical treatment possibilities for paediatric and adult XLH changed substantially with the multinational approval of burosumab (Crysvita®) [23, 24]. Subcutaneous injection every two or four weeks, respectively, of this fully human monoclonal antibody against FGF23 rapidly and safely increases TmP/GFR and corrects hypophosphatemia with only a small increase within the normal range of circulating 1,25-dihydroxyvitamin D levels. Radiographic rickets can improve compared to continuing conventional therapy with oral 1,25-dihydroxyvitamin D and Pi supplementation [23, 24]. Growth and functionality also benefit [23, 24]. In adults with XLH given burosumab, pseudofractures may heal together with osteomalacia seen on iliac crest biopsy.

Dent's Disease

X-linked recessive hypophosphataemia (Dent disease 1) (OMIM #300009) maps to chromosome Xp11.22 and is due to

deactivation of the *CLCN5* gene involved in chloride transport [62]. Hypercalciuria nephrocalcinosis, β_2-microglobinuria, and progressive glomerular disease affect hemizygous males. Renal Pi wasting sometimes causes mild rickets. Treatment consists of Pi supplementation with caution not to cause hyperparathyroidism or to exacerbate nephrocalcinosis. Dent disease 2 (OMIM #300009) is caused by mutation of the *OCRL* gene.

Autosomal Dominant Hypophosphataemic Rickets

This rare form of renal Pi wasting (OMIM #193100) causes relatively mild rickets appearing during adolescence. The disorder maps to chromosome 12p13 and involves activating mutations in the gene encoding FGF23 (59). Treatment is similar to XLH, but lower doses of 1,25-dihydroxyvitamin D_3 and Pi are required. Treatment of any iron deficiency can be important.

Autosomal Recessive Hypophosphataemic Rickets

Deactivating mutations in the gene that encodes dentine matrix protein 1 (*DMP1*) causes a very rare autosomal recessive form of hypophosphataemic rickets featuring elevated circulating FGF23 and a diffusely sclerotic skeleton (OMIM #241520) [63]. A second type (OMIM #613312) involves deactivation of *ENPP1* gene.

Fanconi's Syndrome

Fanconi's syndrome features renal Pi wasting causing hypophosphatemia together with other manifestations of proximal renal tubule dysfunction including low serum levels of potassium, bicarbonate, and uric acid as well as aminoaciduria. There are many aetiologies including cystinosis, tyrosinaemia, and Lowe's syndrome (Table 4.11.1). Therapy with 1,25-dihydroxyvitamin D_3 and Pi supplementation (see XLH) seems helpful, but urinary Ca^{2+} levels must be monitored especially carefully because hypercalciuria can be present.

McCune–Albright Syndrome

McCune–Albright syndrome (OMIM #174800) often causes acquired hypophosphataemic rickets [18]. Treatment with 1,25-dihydroxyvitamin D_3 and Pi helps control only the rachitic skeletal disease superimposed on polyostotic fibrous dysplasia, but therapy in affected adults may be especially difficult to assess because of premature closure of growth plates and the underlying widespread fibrodysplastic disease. In fact, bone biopsy looking for osteomalacia may be challenging because of the fibrous dysplasia precluding a suitable biopsy site. Renal Pi wasting may diminish as the fibroblastic disease 'burns out' in middle age.

Vitamin D-Dependent Rickets

Vitamin D-dependent rickets (VDDR) types I and II (VDDR I and VDDR II) are rare, autosomal recessive disorders (OMIM #264700, #600081, #277440, %600785) that mimic vitamin D-deficiency rickets [5–8, 64]. However, there is no deficiency in cutaneous synthesis or accelerated loss of vitamin D. Patients are typically replete with vitamin D as shown by normal circulating levels of 25-hydroxyvitamin D [65].

VDDR I and II feature diminished biosynthesis of, and target tissue resistance to, 1,25-dihydroxyvitamin D, respectively. Because there is either disturbed conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D (VDDR I) or peripheral resistance to 1,25-dihydroxyvitamin D (VDDR II), serum levels of 1,25-dihydroxyvitamin D are low and high, respectively (Table 4.11.4) [5–8, 64]. Nevertheless, both types of VDDR alter mineral homeostasis in a similar way. Dietary Ca^{2+} is malabsorbed, leading to hypocalcaemia, secondary hyperparathyroidism, and hypophosphataemia. Decreased extracellular fluid levels of Ca^{2+} and Pi together impair mineralization of skeletal matrix. Because the pathogenesis of VDDR I involves defective production of 1,25-dihydroxyvitamin D by the kidney, physiological doses of 1,25-dihydroxyvitamin D_3 control the disorder [64]. However, in VDDR II even enormous doses of 1,25-dihydroxyvitamin D_3 may prove ineffective and Ca^{2+} may need to be administered intravenously [5–8]. Both VDDR I and II are understood at the gene level and as indicated next, now have more informative names [18, 46].

25-Hydroxyvitamin D, 1α-Hydroxylase Deficiency (Vitamin D-Dependent Rickets, Type I)

1,25-dihydroxyvitamin D deficiency can be defined as low circulating levels of this hormone despite normal or elevated (depending on preceding vitamin D therapy) concentrations of 25-hydroxyvitamin D. In theory, this situation could result from decreased production or increased clearance of 1,25-dihydroxyvitamin D. Indeed, decreased production of 1,25-dihydroxyvitamin D can be hereditary, but in other circumstances acquired. Acquired deficiency is usually explained by systemic disease, such as chronic renal failure or acquired Fanconi's syndrome, etc., which affect bone and mineral metabolism in multiple and complex ways. In contrast, increased clearance is uncommon and typically accompanies loss of other vitamin D metabolites, such as 25-hydroxyvitamin D, and would therefore fit within the definition of secondary vitamin D deficiency. The genetic entity discussed here (OMIM #264700) is now also called hereditary 1,25-dihydroxyvitamin D deficiency, and is an inborn error of metabolism featuring defective enzymatic biosynthesis of 1,25-dihydroxyvitamin D.

Prader and colleagues first characterized this disorder when they described two young children who showed all of the usual clinical features of vitamin D deficiency despite adequate intake of the vitamin. Complete remission depended upon continuous therapy with high doses of vitamin D—thus, the term 'vitamin D-dependent rickets'. They had instead coined the term 'pseudovitamin D deficiency'. Remission could, however, be achieved by physiological (microgram) doses of 1α-hydroxylated vitamin D metabolites [66, 67]. VDDR I is now understood at the molecular level and is, therefore, best described as 25-hydroxyvitamin D, 1α-hydroxylase deficiency [64].

Patients with 1α-hydroxylase deficiency appear healthy at birth. Subsequently, features consistent with nutritional rickets are usually noticed before 2 years of age, and often during the first 6 months of life. There is growth retardation and poor gross motor development. Muscle weakness, irritability, pneumonia, seizures, and failure to thrive are prominent findings.

Serum 1,25-dihydroxyvitamin D levels are low or undetectable despite normal levels of 25-hydroxyvitamin D. Malabsorption of dietary Ca^{2+} leads to hypocalcaemia, secondary hyperparathyroidism, and hypophosphataemia. Serum ALP activity is elevated.

The radiographic changes are in keeping with nutritional rickets. In addition to growth plate abnormalities and rachitic deformities, osteopaenia, and other features of secondary hyperparathyroidism

are present. Undecalcified bone documents defective matrix mineralization and secondary hyperparathyroidism including osteoclastosis and peritrabecular fibrosis [64].

Early reports of affected siblings in inbred kindreds indicated that VDDR I is an autosomal recessive condition, especially prevalent in French-Canadians [46]. A founder effect seems to have occurred in this population and, in 1990, linkage studies mapped the disorder to chromosome l2q14 [64]. The molecular defect compromises the kidney's mitochondrial cytochrome P450clα enzyme responsible for rate-limiting, hormonally regulated, 25-hydroxyvitamin D bioactivation to 1,25-dihydroxyvitamin D (i.e. 25-hydroxyvitamin D, lα-hydroxylase). Actually, this enzyme has several components, cytochrome P-450D10t, ferredoxin, and ferredoxin reductase [64]. A variety of mutations have been found in the P450clα gene (*CYP27B1*: OMIM 609506) [66]. French-Canadian patients are commonly homozygous for a 958ΔG defect in this single copy gene. None of these mutations engenders an enzyme with decreased (rather than absent) activity [66].

Serum concentrations of 25-hydroxyvitamin D are normal in VDDR I (elevated if pharmacological doses of vitamin D or 25-hydroxyvitamin D are given), yet 1,25-dihydroxyvitamin D levels are low, or remain only partially corrected by vitamin D or 25-hydroxyvitamin D therapy [63]. Because pharmacological doses of vitamin D_2 or D_3 or 25-hydroxyvitamin D_3 produce therapeutic responses in VDDR I similar to physiological (replacement) doses of 1,25-dihydroxyvitamin D_3, it is apparent that 25-hydroxyvitamin D (or some metabolite) at sufficient levels can activate the VDR. Alternatively, perhaps enhanced local 1,25-dihydroxyvitamin D biosynthesis occurs with pharmacological doses of the prohormones.

The 1α-hydroxylase gene from more than 25 families with this disorder has been studied by site-directed mutagenesis and cDNA expression in transfected cells. All patients had homozygous mutations. Most French-Canadian patients have the same mutation causing a frame shift and a premature stop codon in the putative haem-binding domain. However, the same mutation was then observed in additional families of diverse origin. All other patients had either a base-pair deletion causing a premature termination codon upstream from the putative ferredoxin and haem-binding domains, or missense mutations. No 1α-hydroxylase activity was detected when the mutant enzyme was expressed in various cells. The 1α-hydroxylase gene sequence in keratinocytes and peripheral blood mononuclear cells is identical with the renal gene.

The differential diagnosis for VDDR I includes especially defects in the VDR-effector system, where serum concentrations of 1,25-dihydroxyvitamin D and the response to treatment with 1α-hydroxylated vitamin D metabolites are greatly different (**Table 4.11.2**).

Clinical remission has followed daily, high-dose therapy with 1–3 mg of vitamin D_2, or with 0.2–0.9 mg of 25-hydroxyvitamin D. Because there is no defect in hepatic conversion of vitamin D to 25-hydroxyvitamin D, vitamin D rather than 25-hydroxyvitamin D is cheap yet effective. However, a physiological ('replacement') dose of 1,25-dihydroxyvitamin D, 0.25–1.0 μg daily, bypasses the lα-hydroxylase defect and provides an effective and direct treatment [49]. Although 25-hydroxyvitamin D_3 or 1,25-dihydroxyvitamin D_3 therapy is expensive, it has advantages. The physiological half-lives of these metabolites are much shorter than vitamin D, and excessive dosing will respond more rapidly to temporary cessation of therapy. Most patients, however, can be managed with vitamin D, but follow-up is essential for any regimen.

Hereditary Resistance to 1,25-Dihydroxyvitamin D (Vitamin D-Dependent Rickets, Type II)

This disorder was characterized in 1978 when a patient with features of 'pseudovitamin D deficiency' (see earlier) was found instead to have high serum levels of 1,25-dihydroxyvitamin D [66]. Thus, 'hereditary resistance to 1,25-dihydroxyvitamin D' or VDDR II refers to this condition (OMIM #277440) [5, 6]. Autosomal recessive inheritance is well established, and parental consanguinity has been reported in approximately 50% of cases [46].

There is a striking clustering of patients around the Mediterranean, including patients reported form Europe and America who originated from the same area [7, 8]. A notable exception is a cluster of kindreds from Japan [46]. Obligate heterozygotes do not have clinical or biochemical manifestations. Patients appear normal at birth, but typically then develop features resembling vitamin D deficiency during the first year of life [5–8]. Although several sporadic cases first manifested skeletal disease as late as their teenage years or middle age, they represent the mildest form of the disease and had complete remission when treated with vitamin D or its active metabolites. It was unclear if the adult-onset patients belong to this entity. In general, the earlier the presentation, the more severe the clinical and biochemical features [5–8].

Hypocalcaemia causes secondary hyperparathyroidism, hypophosphataemia, and elevated serum ALP activity. However, 1,25-dihydroxyvitamin D levels are elevated, sometimes as much as 10-fold [5–8]. This abnormality reflects peripheral resistance to 1,25-dihydroxyvitamin D causing malabsorption of dietary Ca^{2+} and the subsequent combined effects of three activators of renal 25-hydroxyvitamin D, lα-hydroxylase activity: hypocalcaemia, increased circulating PTH, and hypophosphataemia together with diminished feedback inhibition by 1,25-dihydroxyvitamin D on the kidney 1α-hydroxylase.

The radiographic and histological findings of VDDR II resemble those of nutritional rickets, as described before, including growth plate disturbances, rachitic deformities, osteopaenia, fractures, and evidence of secondary hyperparathyroidism.

A peculiar feature, appearing in more than half of the affected individuals, is total alopecia or sparse hair. Alopecia usually manifests during the first year of life and there may be additional ectodermal anomalies including oligodontia, epidermal cysts, and cutaneous milia [5–8]. In a patient with total alopecia, hair follicles were present.

Alopecia seems to be a marker for a more severe form of the disease, as judged by earlier onset, severity of the clinical features, proportion of patients who do not respond to treatment with high doses of vitamin D or its active metabolites, and the extremely elevated serum levels of 1,25-dihydroxyvitamin D during therapy. Although some patients with alopecia achieve clinical and biochemical remission of their bone disease, none have shown hair growth. The notion that total alopecia reflects a defective VDR-effector system is supported by the fact that alopecia has only been associated with hereditary defects in the VDR system (i.e. with end-organ resistance to the action of the hormone. Indeed, hair follicles normally contain the VDR).

Patients with VDDR II with normal hair can respond fully to high doses of bioactive vitamin D metabolites. However, only some with total alopecia do so. Remarkably, some patients with VDDR II may no longer need 1,25-dihydroxyvitamin D_3 therapy, or require lower doses, later in life [5–8]. A VDR-positive mild variant has been reported in Columbia, South America (OMIM % 600785) [46, 68].

The nature of the resistance to 1,25-dihydroxyvitamin D and aberrations in the VDR/effector system have been elucidated [5–8, 9]. A variety of VDR, or post-VDR, defects block the peripheral action of 1,25-dihydroxyvitamin D. There can be absence of the VDR, diminished binding capacity or binding affinity of the VDR for 1,25-dihydroxyvitamin D, or failure of the 1,25-dihydroxyvitamin D–VDR complex to localize to the nucleus or bind to DNA [8]. Patients without hormone or DNA binding by the VDR are the most difficult to treat [5, 6]. A mouse model has been developed by targeted ablation of the *VDR* gene.

If untreated, most patients with VDDR II die in early childhood [5–8]. However, good control of the disorder is possible with therapy, especially in individuals without alopecia. Depending upon severity, VDDR II may require calciferols that enhance endogenous production of 1,25-dihydroxyvitamin D, administration of high doses of both calciferols and Ca^{2+} to compensate for the target tissue resistance to 1,25-dihydroxyvitamin D, or high doses of Ca^{2+} alone (given orally or intravenously) to circumvent the target cell 1,25-dihydroxyvitamin D resistance [8, 60]. Whereas most patients may respond to very high oral doses of 1,25-dihydroxyvitamin D_3 (10–40 μg daily), some can have clinical, radiographic, and biochemical corrections with high doses of vitamin D_2 or 25-hydroxyvitamin D_3 [5–8]. Some patients have unexplained disease fluctuation.

Before therapy, serum 1,25-dihydroxyvitamin D concentrations range from the upper normal limit to markedly elevated. With vitamin D treatment, they may reach the highest levels found in any living system (≥100 times the upper normal limit).

The near ubiquity of a similar if not identical VDR-effector system among various cell types helped clarify the nature of the intracellular and molecular defects in these patients [7, 8]. A defect that compromises RXR heterodimerization with the VDR (essential for nuclear localization and probably for recognition of the vitamin D responsive element in the DNA as well) was characterized in several kindreds with and without alopecia [7, 8]. In kindreds with defects in VDR binding to DNA, different single nucleotide mutations in the DNA-binding region were found [7, 8]. All point mutations affected the region of the two zinc fingers of the VDR essential for functional interaction of the hormone receptor complex with DNA. Interestingly, all altered amino acids are highly conserved in the steroid receptor superfamily. In all such patients, no response followed very high doses of vitamin D or its active 1α-hydroxylated metabolites.

Normal hair is usually associated with milder and usually complete clinical and biochemical remission on high doses of vitamin D or its metabolites [7, 8]. In contrast, only ~50% of patients with alopecia have satisfactory clinical and biochemical remission to high doses of vitamin D or its active 1α-hydroxylated metabolites, and the dose requirement is about 10-fold higher than those with normal hair.

It seems that defects characterized as deficient hormone binding affinity and deficient heterodimerization with RXR achieve remission on high doses of vitamin D or its active 1α-hydroxylated metabolites. Most with other defects could not be cured.

Typical clinical and biochemical features (Table 4.11.4) support the diagnosis. The issue becomes more complicated when the clinical features are atypical, i.e. late onset, sporadic cases, and normal hair. Failure of a therapeutic trial with Ca^{2+} and/or physiological replacement doses of vitamin D or its active metabolites may support the diagnosis but now mutation analysis should reveal the aetiology and pathogenesis.

Based on the clinical and biochemical features, the following additional disease states should be considered: (1) extreme Ca^{2+} deficiency, and (2) severe vitamin D deficiency, because during the initial stages of vitamin D therapy in children with severe vitamin D-deficient rickets, the biochemical picture may resemble 1,25-dihydroxyvitamin D resistance, but this is a transient condition differentiated by the history of vitamin D deficiency and the final therapeutic response to vitamin D.

An adequate therapeutic trial must include vitamin D at sufficient doses to maintain high serum concentrations of 1,25-dihydroxyvitamin D because patients can produce high serum 1,25-dihydroxyvitamin D levels if supplied with substrate. If high serum levels are not achieved, 1α-hydroxylated vitamin D metabolites should be given in daily doses up to 6 μg/kg weight or a total of 30–60 μg and up to 3 g of elemental Ca^{2+} orally daily; therapy must continue for a period sufficient to mineralize the abundant osteoid (usually 3–5 months). Therapy may be considered a failure if no change in the clinical, radiological, or biochemical parameters occurs while serum 1,25-dihydroxyvitamin D concentrations are maintained at approximately 100 times average normal values. Several patients have shown unexplained fluctuations in response to therapy or at presentation of the disease [7, 8].

In some patients unresponsive to vitamin D or its metabolites, clinical and biochemical remission, including catch-up growth, accompanied administration of large amounts of Ca^{2+} achieved by long-term (months) intracaval infusions of up to 1000 mg of Ca^{2+} daily. Alternatively, increasing oral Ca^{2+} intake was used successfully in only very few patients and this approach was limited by dose and patient tolerability [69].

Hypophosphatasia

In 1948, 'hypophosphatasia' (OMIM #241500, #146300, #241510) was coined to distinguish a rare heritable form of rickets characterized biochemically by hypophosphatasaemia due to deficient activity of the tissue non-specific (liver/bone/kidney) isoenzyme of ALP (TNSALP) [15]. More than 400 different mutations in the *ALPL* gene (OMIM *171760) have been discovered in patients with hypophosphatasia (HPP) worldwide [70]. HPP is the instructive inborn error of metabolism that confirmed the theory promulgated by Robert Robison, PhD beginning in 1923 that ALP promotes the mineralization of cartilage and bone.

More than 800 cases of HPP have been reported. The severity is remarkably broad-ranging and spans intrauterine death from profound skeletal hypomineralization to loss of teeth or calcific arthritis in adults [15]. Now, six clinical forms are reported depending primarily on patient age when skeletal disease is documented. Perinatal, infantile, mild, or severe childhood, and adult HPP feature skeletal complications [15]. Children and adults who manifest tooth loss without skeletal disease (radiographically or on bone biopsy) have odonto HPP. Although artificial, this clinical classification provides information concerning recurrence risks and prognosis.

Perinatal HPP is diagnosed at birth and is almost always rapidly lethal [15, 70]. Stillbirth is common. Profound skeletal hypomineralization with caput membranaceum and short and deformed limbs is obvious. Severe osteogenesis imperfecta or cleidocranial dysplasia may be suspected, but can be distinguished radiographically and by gene testing [16]. Occasionally, bony spurs protrude from the shafts of major long bones. Failure to gain weight, irritability with a high-pitched cry, unexplained fever, anaemia, periodic apnoea with bradycardia, and intracranial haemorrhage can occur. Respiratory compromise proves fatal from chest weakness and deformity and perhaps pulmonary hypoplasia.

Infantile HPP becomes clinically apparent postnatally before 6 months of age with failure to thrive, poor feeding, rickets, widened fontanelles, hypotonia, and sometimes vitamin B_6-dependent seizures [15]. Hypercalcaemia and hypercalciuria may explain bouts of vomiting and nephrocalcinosis, sometimes with significant renal impairment. Rachitic deformity of the chest and rib fractures predispose to recurrent pneumonias. Seizures and spells of apnoea may occur. Despite the impression from palpation or radiographs that cranial sutures are widely open, functional craniosynostosis from skull hypomineralization is common. Infantile hypophosphatasia often features progressive clinical and radiographic deterioration, and untreated ~50% of patients die within the first year of life. However, the prognosis seems better if there is survival past infancy spontaneously, although persisting skeletal disease seems likely [15].

Childhood HPP is especially variable [14]. Premature loss of deciduous teeth (age <5 years) from hypoplasia and hypomineralization of cementum may be the most remarkable clinical manifestation. Cementum anchors dentition to the periodontal ligament, therefore, deciduous teeth in HPP are shed without root resorption. Mandibular incisors are usually lost first, but the entire dentition can be exfoliated early. Enlarged pulp chambers and root canals result in 'shell' teeth characteristic of disorders that cause rickets. Skeletal deformity can include scaphocephaly with frontal bossing, a rachitic rosary, bowed legs or knock-knees, short stature, and wrist, knee, or ankle enlargement. When radiographs disclose rickets, delayed walking and a characteristic waddling gait are common. Childhood HPP may improve clinically when growth plates fuse after puberty, but recurrence of symptoms seems likely sometime during adult life [15, 70].

Adult HPP presents during middle age [15, 70]. Approximately 50% of these patients recall being told of rickets and/or premature loss of teeth during childhood. Often, there are recurrent, poorly healing, metatarsal stress fractures. Subtrochanteric femoral pseudofractures may be found proximally in the lateral cortices [25]. Chondrocalcinosis is common and inorganic pyrophosphate deposition may also cause arthritis including pseudogout.

Radiographic findings in HPP are helpful for diagnosis, especially in paediatric patients. Perinatal HPP features pathognomonic changes as the skeleton can be so hypomineralized that only the skull base is apparent. Individual vertebrae can be 'missing', and bony spurs may protrude from major long bones. Alternatively, severe rachitic changes are seen. Calvarial bones can be mineralized only centrally, giving the illusion that sutures are widely patent. Fractures are common. In infants, abrupt transition from well mineralized diaphyses to hypomineralized metaphyses suggests sudden metabolic deterioration. Relentless skeletal demineralization with worsening rachitic disease and progressive bony deformity and fracturing as well as vitamin B_6-dependent seizures predict a lethal outcome. Bone scintigraphy showing little tracer uptake in widely separated cranial 'sutures' suggests functional suture closure. Severely affected patients who survive infancy can develop true premature cranial sutures fusion causing a 'beaten copper' radiographic appearance and raised intracranial pressure (**Figure 4.11.7**). In affected children, characteristic 'tongues' of radiolucency extend from physes into metaphyses of major long bones where there can also be patchy osteosclerosis (**Figure 4.11.2**). Adult HPP causes recurrent, poorly healing, metatarsal stress fractures and femoral pseudofractures that appear laterally (rather than medially as in other forms of osteomalacia). There can also be osteopaenia and chondrocalcinosis with changes of pyrophosphate arthropathy.

Subnormal serum ALP activity for age and sex (hypophosphatasaemia) is the biochemical hallmark of HPP. Generally, the levels reflect disease severity [15, 70]. Patients with odonto HPP have mild but discernible hypophosphatasaemia. In fact, this finding is especially impressive because rickets or osteomalacia typically cause hyperphosphatasaemia [14]. Several other conditions, some with skeletal manifestations, lower blood ALP levels [15], but are distinguished from HPP partly because the patients do not accumulate TNSALP substrates (see next). Serum levels of Ca^{2+} and Pi are not diminished in HPP. In fact, hypercalciuria and hypercalcaemia often complicate the infantile form where the pathogenesis seems to involve a 'dyssynergy' between gut absorption of dietary Ca^{2+} and defective skeletal mineralization; however, skeletal demineralization may also become a factor. Serum levels of PTH, 25-hydroxyvitamin D, and 1,25-dihydroxyvitamin D are usually unremarkable in HPP unless there is hypercalcaemia or renal compromise. Serum Pi concentrations are above control mean levels, and mild hyperphosphataemia occurs in more than half of

Figure 4.11.7 Hypophosphatasia: The 'beaten copper' skull of this 2-year-old boy with the childhood form of hypophosphatasia results from premature closure of cranial sutures. Previously, he underwent craniotomy.

affected children and perhaps adults. The pathogenesis involves enhanced renal reclamation of Pi [70].

Three phosphocompounds, natural substrates for TNSALP, accumulate endogenously in HPP: phosphoethanolamine, inorganic pyrophosphate (PPi), and pyridoxal 5′-phosphate (PLP) [15, 70]. Assays are commercially available for urinary and blood phosphoethanolamine and plasma PLP. Mild phosphoethanolaminuria occurs in several metabolic bone diseases [15]. Fortunately, increased plasma PLP concentration is a particularly sensitive and specific marker for HPP. However, patients must not be taking vitamin B_6 for at least one week before tested. Endogenous accumulation of PPi seems to be the key pathogenetic factor accounting for the defective hard tissue mineralization (see next), yet quantitation of PPi remains a research technique.

Defective skeletal mineralization occurs in all clinical forms of HPP except odonto HPP [2]. Unless evaluation of the ALP activity in the skeleton is undertaken, the histopathological findings are those of other types of rickets or osteomalacia lacking secondary hyperparathyroidism.

HPP occurs in all races, and is especially prevalent among Mennonites and Hutterites in Canada. In North America the incidence of severe disease is ~ 1/100 000 live births [15]. Perinatal and nearly all cases of infantile HPP are transmitted as an autosomal recessive trait. Carriers can have diminished or low-normal levels of serum ALP activity, and sometimes modest elevations in plasma PLP levels [15, 70]. The inheritance pattern(s) for childhood, adult, and odonto HPP is autosomal recessive or autosomal dominant. Generation-to-generation transmission is typically associated with relatively mild clinical expression.

The *ALPL* gene has 12 exons and to exists as a single copy in the haploid genome on the tip of the short arm of chromosome 1 (lp36.1–lp34). In 1988, a missense mutation was identified in a severely affected infant from an inbred Canadian kindred [70]. Subsequent studies have disclosed > 400 different *ALPL* mutations [70]. Most are missense defects. Perinatal and infantile HPP reflect homozygosity or compound heterozygosity for these mutations. The childhood and adult forms of HPP can be the 'same' disease [15]. Mouse models first recapitulated the infantile form of HPP [71], but now some match the mild forms.

ALP (orthophosphoric monoester phosphohydrolase (alkaline optimum), EC 3.1.3.1), found in nearly all organisms, is a glycosylated, plasma membrane-bound enzyme [70]. Discovery of the endogenous accumulation of phosphoethanolamine, PPi, and PLP in HPP revealed how TNSALP functions [15, 70]. Accumulation of PLP, the principal cofactor form of vitamin B, indicated that TNSALP acts as a cell-surface enzyme. Patients with HPP typically do not have symptoms or signs of vitamin B_6 deficiency or toxicity despite their markedly increased plasma PLP levels.

In 1965, discovery of elevated urinary and then blood levels of PPi in HPP disclosed the pathogenesis of the rickets and osteomalacia. PPi is a potent inhibitor of biomineralization. Matrix vesicles are devoid of ALP activity in HPP, but do contain hydroxyapatite crystals [4]. However, only a few isolated crystals are observed outside these extracellular structures. The excess PPi in HPP blocks hydroxyapatite crystal formation in the extracellular matrix of affected bone.

Unless documented, conventional treatments for rickets or osteomalacia are generally best avoided in HPP because patients are usually vitamin D replete and serum levels of Ca^{2+} and Pi are not low [15]. Indeed, such treatment could exacerbate or provoke hypercalcaemia and hypercalciuria. Hypercalcaemia in infantile HPP generally responds to reduction in dietary Ca^{2+} intake, but may require glucocorticoid therapy. Supportive therapy is important for HPP. Fractures do mend, but delayed healing after casting or osteotomy has been observed. In affected adults, placement of intramedullary rods, rather than load-sparing devices (e.g. plates), seems to be preferable for the acute or prophylactic treatment of fractures and pseudofractures [25]. Expert dental care is especially important for children, because their nutrition can be impaired by premature tooth loss. Craniotomy may be crucial for children with craniosynostosis. Fetuses that are severely affected (perinatal form) can be detected *in utero* early on by ultrasonography, but a relatively mild 'benign prenatal' form of non-lethal HPP must be considered. *ALPL* gene mutation testing has improved diagnosis [15].

Enzyme replacement by intravenous infusion of various natural soluble forms of ALP has generally been disappointing for HPP [70]. Two infants who seemed destined to die from infantile HPP showed clinical and radiographic improvement following transplantation of marrow or bone-derived cells [72]. This suggested that TNSALP must be increased within the skeleton itself. Hydroxyapatite-targeted enzyme replacement therapy (Strensig®) using subcutaneous injections of a recombinant TNSALP fusion protein (asfotase alfa) was approved multinationally in 2015 typically for paediatric-onset HPP [73]. Results of clinical trials of HPP patients of all ages have documented clinical and skeletal improvements [20–22].

Glucocorticoid-Induced Osteoporosis

Gherardo Mazziotti, Ernesto Canalis, and John P. Bilezikian

Introduction

Over the past two decades, significant advances in our understanding of glucocorticoid-induced osteoporosis (GIO), the most common form of secondary osteoporosis in women and men, have been made [1]. While it can be caused by endogenous glucocorticoid excess, as seen in Cushing's syndrome [2], GIO is almost always due to exogenous glucocorticoids which are used in a wide variety of disorders including autoimmune, pulmonary, and gastrointestinal diseases, as well as in patients following organ transplantation and in individuals with malignancies. Despite the widespread therapeutic use of glucocorticoids, and its acknowledged major role in causing osteoporosis, many patients receiving long-term glucocorticoid therapy neither undergo an evaluation for skeletal health nor do they often receive specific preventive or therapeutic agents when indicated [2].

This chapter deals with the pathophysiological, clinical, and therapeutic aspects of exogenous and endogenous GIO.

Epidemiology

Despite advances in targeted therapies for many autoimmune disorders, long-term use of glucocorticoids occurs in an estimated 1% of the population [3]. In a multinational population-based prospective, observational study of 60 393 postmenopausal women who had visited their primary care medical provider within the last 2 years, the Global Longitudinal Study of Osteoporosis in Women, up to 4.6% were currently taking oral glucocorticoids [4]. Vertebral fractures are the hallmark of GIO and they occur in about one-third of patients exposed to glucocorticoid excess [5]. After starting glucocorticoid therapy, fracture risk, a function also of dose and duration of use, increases rapidly. Prolonged exposure to doses of prednisolone—or the equivalent—as low as 2.5–5 mg daily are associated with an increased risk of hip and vertebral fractures [6]. In Amiche *et al.*'s Bayesian meta-analysis of fracture risk associated with oral glucocorticoid use, the annual incidences of vertebral fracture were 5.1% and 3.2% in individuals with exposure to glucocorticoid therapy shorter or longer than 6 months, respectively [7]. As expected, the greatest increase in fracture incidence was seen in postmenopausal women and elderly men. Even for those whose glucocorticoid exposure is cyclic, the risk of osteoporotic fractures remains increased [8]. It is noteworthy that fracture risk decreases after discontinuation of oral corticosteroids, although the time it takes to reduce risk is variable [1].

Inhaled glucocorticoids have effects on skeletal markers of bone metabolism and on bone mineral density (BMD), but the effects are variable and their significance as it relates to fracture risk is uncertain [9, 10]. Dose, duration of treatment, and degree of absorption, as well as the underlying disease, are all confounding factors.

Endogenous hypercortisolism is less frequently a cause of GIO because the disease itself is uncommon [11]. However, up to 10% of subjects attending an outpatient clinic of osteoporosis were suspected to have subclinical Cushing's syndrome [12]. Either clinical or subclinical fragility fractures can be the presenting manifestation of Cushing's syndrome [13]. In cross-sectional studies, the prevalence of fractures has been reported to be 15–50%, with the most frequent site of fracture involving the ribs and vertebrae [13]. These rates are likely to be an underestimation of real fracture risk in endogenous hypercortisolism, since not all patients underwent a complete morphometric and radiological evaluation to detect asymptomatic vertebral and rib fractures [13]. In fact, when searched by a systematic radiological approach, to detect vertebral fractures, the prevalence in those with Cushing's disease was a remarkable 78%, with only half clinically evident with pain, functional limitation, and loss of height [14]. Even among young patients with endogenous hypercortisolism, fracture prevalence is high [15]. Vestergaard *et al.* reported a sixfold increase in the risk of clinical fractures in the 2 years prior to the diagnosis of endogenous hypercortisolism, without a significant difference between Cushing's syndrome due to pituitary or adrenal disease [16]. High risk of fractures was reported

even in patients with subclinical endogenous hypercortisolism [17]. When Cushing's syndrome is effectively treated, recovery of bone loss occurs but it is gradual and often incomplete [13].

Pathophysiology

The effects of glucocorticoids on bone are biphasic. Under physiological conditions, endogenous glucocorticoids can be positive regulators of mesenchymal cell differentiation into mature osteoblasts, as suggested by some *in vitro* studies [13]. Cultures overexpressing 11β-hydroxysteroid dehydrogenate type 2 (11β-hsd2), are resistant to glucocorticoids and exhibit reduced osteoblastogenesis and predominant adipogenesis when compared with wild-type cultures [18]. Consistent with these observations, transgenic mice overexpressing 11β-hsd2 in mature osteoblasts exhibit vertebral osteopaenia [19].

In human subjects, the pathophysiology of bone loss in the context of glucocorticoid excess involves direct and indirect deleterious effects on the skeleton [20].

The central pathophysiological mechanism of GIO is reduced bone formation, due to actions that affect osteoblast differentiation and function. The early effect, however, is a significant increase in bone resorption, this mechanism perhaps accounting for the early increase of risk of fractures.

Direct Effects of Glucocorticoids on Bone Cells

Glucocorticoids decrease the number and the function of osteoblasts. These effects lead to a suppression of bone formation, a central feature of the pathogenesis of GIO. Glucocorticoids decrease the replication of cells of the osteoblastic lineage, reducing the pool of cells that may differentiate into mature osteoblasts. The mechanism by which this occurs may relate to redirecting multipotential bone marrow stromal cells into the adipocyte line and away from osteoblast lineage precursors. Thus, glucocorticoids impair osteoblastic differentiation and maturation at the early stages of osteoblast development.

Mechanisms involved in this redirection of stromal cells include induction of nuclear factors of the CAAT enhancer binding protein family and the induction of peroxisome proliferator-activated receptor γ 2 (PPARγ 2), both of which play essential roles in adipogenesis [21].

A fundamental mechanism by which glucocorticoids inhibit osteoblast cell differentiation is by opposing Wnt/β-catenin signalling. Wnt signalling has emerged as a key regulator of osteoblastogenesis [21] and osteoclastogenesis [22]. In skeletal cells, the canonical Wnt/β-catenin signalling pathway operates. When Wnt is absent (or inhibited), β-catenin is phosphorylated by glycogen-synthase kinase-3β (GSK-3β), and then degraded by ubiquitination in the cytoplasm, thus preventing translocation into the nucleus. The binding of Wnt to specific receptors, called Frizzled, and to coreceptors, such as low-density lipoprotein receptor related proteins (LRP)-5 and -6, leads to an inhibition of GSK-3β activity. When GSK-3β is not active, stabilized β-catenin is able to translocate to the nucleus, where it associates with transcription factors to regulate gene expression. Inactivation of either Wnt or *Ctnnb* (encoding for β-catenin) results in impairment of osteoblastogenesis, and increased osteoclastogenesis, since canonical Wnt signalling results in a direct inhibitory effect on osteoclast progenitors and induction of osteoprotegerin (OPG) production [22, 23]. The Wnt pathway can be opposed by Wnt antagonists, such as Dickkopf-1 and sclerostin that prevent Wnt from binding to its receptor complex. Glucocorticoids enhance Dickkopf-1 and sclerostin expression, and maintain GSK 3-β in an active state, leading ultimately to the inactivation of β-catenin [21]. The importance of sclerostin in mediating the effects of glucocorticoids on bone formation is emphasized by the demonstration, in mice with sclerostin deficiency, that bone integrity is maintained in the presence of glucocorticoid excess [24].

Glucocorticoids also suppress bone morphogenetic protein (BMP) signalling in osteoblasts either directly [25] or indirectly by microRNAs which are small endogenous single-stranded non-coding ribonucleic acids (RNAs) that repress gene expression and bind to mRNA [26]. BMPs are members of the transforming growth factor β (TGF-β) superfamily of polypeptides, which includes TGF-βs, activins, and inhibins [27]. BMPs signal through the small molecules against decapentaplegic (SMADs) and the mitogen activated protein kinase signalling pathways [28].

Notch is a family of transmembrane receptors regulating cell fate decisions. In immature cells of the osteoblastic lineage, Notch suppresses cell differentiation by inhibiting Wnt signalling and by interacting with Runx2 to prevent osteoblast maturation [29]. Although glucocorticoids stimulate Notch1 and Notch2 expression in osteoblasts, Notch signalling is not induced by glucocorticoids [30].

In addition to inhibiting the differentiation of osteoblasts, glucocorticoids inhibit the function of the differentiated mature cells directly, and indirectly by suppressing the expression of insulin-like growth factor 1 (IGF1) by skeletal cells [31]. Glucocorticoids inhibit osteoblast-driven synthesis of type I collagen, the major component of the bone extracellular matrix, with a consequent decrease in bone matrix available for mineralization. The decrease in type I collagen synthesis occurs by transcriptional and post-transcriptional mechanisms [20].

Glucocorticoids have pro-apoptotic effects on osteoblasts and osteocytes due to activation of caspase 3, a common downstream effector of several apoptotic signalling pathways. Caspases are synthesized as proenzymes and are activated through autocatalysis or a caspase cascade. Active caspases contribute to apoptosis by cleaving target cellular proteins. Caspase 3 is a key mediator of apoptosis and is a common downstream effector of multiple apoptotic signalling pathways. The inhibitory effects of glucocorticoids on osteoblastic cell replication and differentiation and the increased apoptosis of mature osteoblasts, all contribute to the depletion of the osteoblastic cellular pool and decreased bone formation [20].

Osteocytes serve as mechanosensors, and play a role in the repair of bone microdamage [32]. Loss of osteocytes disrupts the osteocyte-canalicular network resulting in failure to detect signals that normally stimulate processes associated with the replacement of damaged bone. Disruption of the osteocyte-canalicular network can disrupt fluid flow within the network adversely affecting the material properties of the surrounding bone, independently of changes in bone remodelling or architecture. Glucocorticoids affect the function of osteocytes, by modifying the elastic modulus surrounding osteocytic lacunae. Glucocorticoids induce the apoptosis of osteocytes. As a result, the normal maintenance of bone through

this mechanism is impaired and the biomechanical properties of bone are compromised [20].

The initial bone loss occurring in patients exposed to glucocorticoids may be secondary to increased bone resorption. In fact, glucocorticoids increase the expression of receptor activator of NF-k B ligand (RANKL) and decrease the expression of its soluble decoy receptor, OPG in stromal and osteoblastic cells [20]. The combination of an increase in RANKL, a necessary signal for osteoclastogenesis, and a reduction in OPG, an inhibitor of RANKL action, leads to the initial phase of rapid bone loss. Glucocorticoids also enhance the expression of macrophage colony-stimulating factor (M-CSF), which in the presence of RANKL induces osteoclastogenesis. Moreover, glucocorticoids upregulate receptor subunits for osteoclastogenic cytokines of the gp130 family. Furthermore, glucocorticoids may decrease apoptosis of mature osteoclasts. Consequently, there is increased formation of osteoclasts with a prolonged life span explaining, at the cellular level, the enhanced bone resorption observed in the initial phases of GIO.

Indirect Effects of Glucocorticoids on Bone Metabolism

Calcium-phosphate homeostasis is usually impaired in patients exposed to glucocorticoid excess. Glucocorticoids impair the complex process of transcellular calcium absorption in the duodenum which is regulated by the epithelial Receptor Potential–Vanilloid 6 (TRPV6) and TRPV5 (D ECaC1) and then by calcium binding calbindin-D9K [33]. Moreover, glucocorticoids inhibit renal tubular calcium reabsorption favouring calcium renal loss, leading to negative calcium balance. In addition to these effects on calcium metabolism, glucocorticoids elicit phosphaturia by reducing tubular reabsorption of phosphate through antagonism of the tubular expression of the sodium gradient-dependent phosphate transporter [34]. The abnormalities of calcium-phosphate homeostasis in GIO may be favoured by the effects of glucocorticoids on vitamin D metabolism and activity. Glucocorticoids do not directly compete with 1,25-dihydroxyvitamin D binding to its receptor, but rather regulate vitamin D receptor expression [35]. Prolonged exposure to glucocorticoids was associated with diminished expression of duodenal vitamin D receptor which in turn causes a` decrease in transcription of duodenal calbindin-D9K, TRPV5, or TRPV6 activity [36]. Glucocorticoids also modulate vitamin D metabolism with a decrease of 1α-hydroxylase and an increase in 24-hydroxylase activity [37]. Moreover, glucocorticoids inhibit hydroxylation of vitamin D3 in the liver which can lead to reduced plasma 25-hydroxyvitamin D levels [38].

Parathyroid hormone (PTH) and the PTH receptor play a major role in regulating calcium homeostasis. PTH regulates the conversion of 25-hydroxyvitamin D to the active metabolite 1,25-dihydroxyvitamin D. PTH activates dihydropyridine-sensitive channels that mediate calcium entry into the cell. 1,25-dihydroxyvitamin D inhibits PTH secretion and parathyroid cell proliferation via the vitamin D receptor. PTH secretion is regulated by serum ionized calcium levels. While negative calcium balance is expected to cause a secondary hyperparathyroidism in GIO, glucocorticoids do not induce hypertrophy of parathyroid glands in experimental animals [36]. Moreover, fasting PTH values are not consistently reported to be increased in patients exposed to glucocorticoid excess [39]. Perhaps more revealing than static measurements of PTH after glucocorticoid exposure are studies related to the pulsatility of PTH [39]. Chronic glucocorticoid exposure is associated with a redistribution of spontaneous PTH secretory dynamics by reducing tonic and amplifying pulsatile secretion of PTH [40]. This finding may be clinically relevant since it can represent either a compensatory or a pathophysiological mechanism [39].

Glucocorticoids modulate growth hormone secretion (GH) by various and competing effects on the hypothalamus and pituitary gland, all dependent on hormone concentrations and time of exposure [41]. Specifically, under physiological conditions, glucocorticoids stimulate GH secretion either by direct effects on pituitary cells or by increasing their GH secretory response to GH-releasing hormone [42]. However, when glucocorticoid levels exceed the physiological range, an increase in hypothalamic somatostatin tone may occur with a consequent impairment of GH secretion [41]. This inhibitory effect on pituitary GH secretion was observed even when glucocorticoid excess was mild, as in patients treated with inhaled corticosteroids and in those with subclinical endogenous hypercortisolism [2]. Moreover, glucocorticoid excess may suppress the peripheral expression of GH receptors impairing the GH-mediated synthesis of IGF-1 and thus amplifying the impact of a functional GH deficiency (GHD) on target tissues [2]. On the other hand, there is a cross-talk between glucocorticoids and the GH-IGF-I axis, since peripheral metabolism of glucocorticoids by 11-βHSD is modulated by GH and activation of cortisone to cortisol in target tissues is amplified by GHD [13]. The real impact of GHD on fracture risk in GIO is largely unknown. However, since GH is an osteoanabolic hormone, one could argue that GHD may contribute to the impairment in bone quality in patients exposed to glucocorticoid excess [41]. As a matter of fact, both exposure to glucocorticoid excess and GHD are associated with 'low-turnover osteoporosis' and high risk of vertebral fractures [13].

Glucocorticoids inhibit the release of gonadotropins, and as a result oestrogen and testosterone production [20]. Central hypogonadism may contribute to bone loss and fractures in GIO not only via negative effects on bone mass but also on muscle function. In particular, hypogonadism may enhance the glucocorticoid-induced sarcopenia, thereby increasing the likelihood of falls and consequent fractures.

Effects on Muscle

In addition to the direct effects of glucocorticoids on bone cells, the catabolic effects of glucocorticoids on muscle may contribute to fracture risk since these steroids cause muscle weakness, which can increase the incidence of falls [20]. Glucocorticoid-induced myopathy may occur following early or chronic exposure to glucocorticoids. Chronic glucocorticoid-induced myopathy is generally manifested by weakness particularly of the pelvic girdle muscles and may affect up to 60% of patients treated with glucocorticoids. The myopathy involves muscle loss due to glucocorticoid-induced proteolysis of myofibrils. This is mediated by activation of negative regulators of muscle mass, such as myostatin [43] and NF-κB-inducing kinase [44].

Effects of the Underlying Chronic Disease

An important point that should be considered is that many disorders for which the glucocorticoids are prescribed are themselves a cause of osteoporosis. One has to take into account, therefore, the underlying disease itself along with the use of glucocorticoids when

considering the management of GIO. Inflammatory bowel disease, rheumatoid arthritis, and chronic obstructive pulmonary disease (COPD), for example, all are associated with bone loss, independent of glucocorticoid treatment [20]. The systemic release of inflammatory cytokines, which affect bone formation and bone resorption seems to underlie the pathophysiology of the bone loss in these settings [20]. However, there are additional factors that may play a role in the bone loss. In inflammatory bowel disease, bone loss may be due, in part, to malabsorption of vitamin D, calcium and other nutrients [20]. In COPD, hypoxia, acidosis, reduced physical activity, and smoking may all contribute to bone loss, independent of the use of glucocorticoids [20].

Differential Skeletal Susceptibility to Glucocorticoids

Individual susceptibility to glucocorticoids varies considerably, possibly because of differences in the absorption, distribution, or metabolism of the steroid, or because of differences in the number and affinity of glucocorticoid receptors. Polymorphisms of the glucocorticoid receptor gene are associated with differences in BMD and body composition [45]. An attractive explanation to account for interindividual variability among those exposed to glucocorticoids is related to peripheral enzymes that interconvert active and inactive glucocorticoid molecules [46]. 11-βHSD regulate the interconversion of the inactive hormone cortisone and hormonally active cortisol. This enzyme plays a critical role in the regulation of glucocorticoid activity [46]. Two distinct 11-βHSD enzymes have been described in humans. 11-βHSD type 2 is expressed in tissues with high levels of glucocorticoid receptors, such as liver and adipose tissue, and acts as an inactivating enzyme by converting cortisol to cortisone. This enzyme was identified also in rat and human osteosarcoma cells where glucocorticoid inactivation by this mechanism was demonstrated. In contrast, 11-βHSD type 1 is primarily a glucocorticoid activator, converting cortisone to cortisol. This enzyme is widely expressed in target tissues of glucocorticoid action, including bone. The activity of 11-βHSD type-1 and its potential to generate cortisol from cortisone in human osteoblasts is increased by pro-inflammatory cytokines and by glucocorticoids [46]. These effects of glucocorticoids appear to be mediated by the C/EBP family of transcription factors. An inverse relationship between 11-βHSD type 1 activity and osteoblast differentiation appears to exist, although mice with targeted deletions of 11-βHSD type-1 do not develop a skeletal phenotype [45]. An increase of 11-βHSD type 1 activity occurs with ageing, possibly providing an explanation for the enhanced glucocorticoid effects in the skeleton of elderly subjects [45].

Clinical Manifestations

Despite the recognition that glucocorticoids can cause bone loss and fractures, many patients receiving, or being considered for, long-term glucocorticoid therapy are not evaluated for their skeletal health [2].

Fractures occur more frequently at sites enriched in cancellous bone, such as the vertebrae and femoral neck. As with vertebral fractures occurring in postmenopausal osteoporosis, vertebral fractures associated with glucocorticoid therapy or endogenous hypercortisolism often are asymptomatic, in which case a radiological approach with morphometric analysis is often necessary [5], as is the case with many causes of secondary osteoporosis [13]. Vertebral fractures occur early after exposure to glucocorticoids, at a time when BMD declines rapidly. However, a direct relationship between BMD and fracture risk in GIO has not been established. It is likely to be different from that established in postmenopausal osteoporosis because fractures in GIO occur at higher BMD values [47]. This point has to be considered when making treatment decisions in GIO, since therapeutic intervention should be considered at T-scores that may be in the osteopaenic range [48].

Trabecular bone score (TBS) provides an indirect index of trabecular bone architecture that can be obtained from bone densitometry (DXA) images of the lumbar spine, and has predictive value for fracture independent of BMD [49]. In postmenopausal women exposed to glucocorticoid excess, TBS was significantly lower as compared to control subjects, notwithstanding comparable BMD T-scores [50]. Interestingly, decreases in TBS are substantial in individuals with fractures [51], supporting the concept that TBS values may be useful for predicting fractures in this clinical setting [1]. A more direct measurement of bone architecture and strength can be provided by high-resolution peripheral computed tomography, but data in subjects with exogenous and endogenous GIO using this approach are sparse [52, 53].

Fracture Risk Assessment (FRAX), an algorithm that calculates the 10-year probability of major osteoporotic and hip fractures, can be used to estimate fracture risk in GIO. However, its value was initially limited by the fact that the use of glucocorticoids is entered as a dichotomous risk factor without considering the dose or length of exposure to glucocorticoids. Ways to correct for this limitation have been proposed [54], but this modification has not been rigorously tested. Another confounder to the utility of FRAX in the context of glucocorticoid exposure is the use of the femoral neck BMD which may result in underestimation of fracture risk in patients with differentially low spine BMD. A correction factor for this discordance when there is a greater than a 1 T-score difference between lumbar spine and femoral neck BMD has been proposed [55]. Assessment of fracture risk using FRAX is recommended in several guidelines for the management of GIO, including those from the National Osteoporosis Guideline Group (NOGG) [56], the updated recommendations by the American College of Rheumatology (ACR) [57] and those published by the International Osteoporosis Foundation (IOF) and the European Calcified Tissue Society (ECTS) [58]. However, FRAX can be used only in individuals at age 40 and older. In children and young adults, fracture risk assessment should be performed using BMD measurement, together with consideration of other risk factors, particularly previous fractures [1]. It should also be recognized that in children and young adults, their young age is a powerful protection against what otherwise in older subjects would be substantial fracture risk. Based on radiological/historical assessment of prevalent fractures, glucocorticoid dose, age of patients, BMD values, and FRAX calculations, the guidelines proposed a stratification of fracture risk in GIO for identifying patients for whom treatment with bone-active drugs is cost-effective and indicated (Table 4.12.1) [56–58]. It is unclear whether these algorithms may simplify the approach to the prevention and treatment of GIO in real-life clinical practice.

The guidelines recommend evaluation of calcium metabolism in all subjects in order to select those for whom vitamin D and/or

Table 4.12.1 Criteria proposed for starting treatment with bone-active drugs in patients exposed to glucocorticoid treatment

Criteria*	ACR [57]	IOF/ ECTS [58]	NOGG [56]
Clinical fractures/morphometric vertebral fractures	YES At any age	YES At any age	YES At any age
Age of patients	NS	≥70 yrs	≥70 yrs
Glucocorticoid dose**	≥30 mg/day (≥30 yrs)	≥7.5 mg/day (≥50 yrs)	≥7.5 mg/day (≥50 yrs)
BMD	T-score ≤–2.5 SD (≥50 yrs) Z score ≤–3.0 SD (≤40 yrs) ≥10%/year loss (≤40 yrs)	T-score ≤–1.5 SD (≥50 yrs)	NS*
FRAX	10-year risk of major fracture ≥10% (≥40 yrs) 10-year risk of hip fracture ≥1% (≥40 yrs)	10-year risk of major fracture ≥ threshold*** (≥50 yrs)	10-year risk of major fracture ≥ threshold**** (≥50 yrs)

ACR, American College of Rheumatology; BMD, bone mineral density; ECTS, European Calcified Tissue Society; FRAX, Fracture Risk Assessment; IOF, International Osteoporosis Foundation; NOGG, National Osteoporosis Guideline Group; NS, not specified; SD, standard deviation; yrs, years. *, one criterion is sufficient for starting treatment; **, expressed as daily dose of prednisolone; ***, variable according to the country and age of patients; ****, variable according to age of patients and dose of glucocorticoids.

calcium supplementation are indicated [58]. The role of biochemical markers of bone turnover in the diagnostic work-up in GIO has not been established, and their levels vary and are dependent on the different stages of the disease. Following the initial exposure to glucocorticoids, there is an increase in biochemical markers of bone resorption, which is followed by a prolonged suppression of markers of bone formation and bone resorption.

The assessment of gonadal function may be useful for the subsequent treatment of GIO. In men receiving glucocorticoids, low total and free-testosterone concentrations are frequently found. Combined with low or normal serum gonadotropin levels, such low testosterone levels are likely to be as manifestation of secondary hypogonadism [45].

Therapy

Various guidelines advocate the following measures for the prevention and treatment of GIO: general health awareness, administration of sufficient calcium and vitamin D, use of the minimal effective dose of corticosteroids and, when indicated, therapeutic intervention with bisphosphonates and other agents [57, 58]. A cost-effectiveness analysis demonstrated that treatment of GIO is cost-effective in patients with a prior fracture, in individuals ≥ 75 years of age or in younger subjects with T-scores ≤–2.0 [59]. Recent guidelines emphasize the importance of starting bone protective therapy early in high-risk individuals, because of the rapidity with which bone loss and increased fracture risk occur [56–58]. It is unknown whether such recommendations may be adapted to patients with endogenous GIO, since it is difficult to translate corticosteroid dosages to different degrees of endogenous hypercortisolism and there are no data on validation of the FRAX stratification method in patients with endogenous hypercortisolism [60].

Despite several guidelines and consensus recommendations stating that patients are at increased fracture risk, little attention is being paid to this risk and less than 50% of patients meeting guideline criteria for treatment are indeed being treated [61, 62].

Various pharmacological agents have been assessed for the prevention and treatment of GIO. In most studies, the primary endpoint was a change in BMD; fracture outcomes were measured in selected studies as secondary endpoints.

Calcium and Vitamin D

The negative calcium balance induced by glucocorticoids provides a rationale for maintaining a daily calcium intake of about 1200–1500 mg in patients with GIO [58]; the upper limit of daily calcium intake set by the Institute of Medicine is 2500 mg [63]. However, calcium alone does not prevent glucocorticoid-induced bone loss, even when administered at high doses [64]. Vitamin D is a key adjunct to the therapeutic use of calcium in GIO, particularly with regard to monitoring by BMD [65]. Vitamin D increases the intestinal absorption of calcium and reabsorption of calcium in the distal renal tubules leading to increased bone mineralization. Because glucocorticoids inhibit the 25 hydroxylation of vitamin D, the use of calcitriol or alfacalcidol has been proposed in place of vitamin D in individuals with GIO but the results have been variable [66, 67]. Since the potential advantages of using active analogues of vitamin D are unclear, native vitamin D_3 is considered the gold standard for treatment of hypovitaminosis D in patients exposed to glucocorticoid excess [68]. In patients with higher body mass index and in those receiving higher doses of glucocorticoids, calcidiol was shown to be more effective than cholecalciferol to reach adequate 25-hydroxyvitamin D levels most probably bypassing the inhibition of 25 hydroxylase of chronic corticosteroid therapy [69]. Moreover, some trials have demonstrated an advantage of calcidiol in improving BMD in transplant patients [70].

It is important to note that subjects receiving glucocorticoids may display vitamin D resistance. Consequently, patients often require up to 1000–2000 IU of vitamin D_3 daily, to maintain supraoptimal 25 hydroxyvitamin D_3 levels of ≥40 ng/ml or 110 nmol/L [71].

Hormonal Replacement Therapy

GIO can be associated with suppressed gonadal function in men and women since glucocorticoids inhibit gonadotropin release and as a consequence oestrogen and androgen synthesis. In men with GIO, testosterone administered intramuscularly induced a significant increase in lumbar spine BMD, without significant effects on BMD at the femoral neck. The studies had BMD as primary endpoint, whereas no information on bone fractures is available. Testosterone also was shown to improve muscular performance and quality of life in men with GIO [72]. Therefore, substitution treatment of hypogonadism in men and in women may prove beneficial in the management of GIO. However, potential benefits should be weighed against the risks of side effects.

Bisphosphonates

Bisphosphonates are currently the major class of drugs used for the treatment of osteoporosis, including GIO [73] and current guidelines recommend these drugs as first-line therapy in patients receiving glucocorticoids [56–58]. There are no specific guidelines for the management of skeletal fragility in individuals with endogenous hypercortisolism [13] since evidence of efficacy and safety of bone-active drugs in this specific clinical setting is insufficient based on results of few clinical studies evaluating the effects of bisphosphonates in patients with Cushing's syndrome [13, 60]. Obviously, correction of the endogenous glucocorticoid excess is a key therapeutic approach, if possible. Bisphosphonates are stable analogues of naturally occurring inorganic pyrophosphate and have been shown to be effective in postmenopausal osteoporosis and in osteoporotic men.

The evidence of benefit for bisphosphonate therapy is weaker than for postmenopausal osteoporosis, since fracture reduction has not been a primary end point of any study. This reflects the acceptance by regulatory authorities of bridging studies, using BMD, for agents proposed for GIO that reduce fractures in postmenopausal osteoporosis [74]. Oral alendronate (5 or 10 mg daily or 70 mg once weekly) and risedronate (5 mg daily or 35 mg once weekly), and intravenous zoledronic acid (5 mg once yearly by intravenous infusion) are approved for treatment of GIO. A meta-analysis performed on nine studies including 1134 patients revealed that alendronate increased BMD at the lumbar spine (mean difference = 3.66%), total hip (mean difference = 2.08%) and trochanter (mean difference = 1.68%), however alendronate had no effect on vertebral and non-vertebral fractures due to lack of statistical power [75]. Indeed, in some studies, bisphosphonates induced a significant decrease of vertebral fracture risk [76–78]. This effect was confirmed by an observational cohort study of 11 007 women aged >65 years treated with glucocorticoids and receiving alendronate or risedronate [79]. The incidence of fractures was significantly decreased in both alendronate (33% lower at non-vertebral sites and 59% at vertebral sites) and risedronate (28% lower at non-vertebral sites and 54% at vertebral sites) cohorts. Moreover, in three matched cohorts derived from healthcare administrative data from Ontario, Canada, Amiche *et al.*, reported that in individuals initiating long-term glucocorticoid therapy treated during the first six months with alendronate or risedronate there was a decrease in incident hip fractures (hazard ratios 0.49 and 0.58, for alendronate and risedronate, respectively) [80].

Zoledronic acid was shown to have a greater effect on BMD than risedronate in both prevention and treatment trials [81] but the fracture rate was too limited to assess antifracture efficacy.

The use of bisphosphonates in eugonadal premenopausal women has to be considered carefully, since bisphosphonates may cross the placenta and affect embryonic skeletal development. The guidelines recommend to use bisphosphonates in eugonadal premenopausal women with a history of fragility fractures, or in those continuing glucocorticoid treatment for more than 6 months at a dose of higher than 7.5 mg/day who have either a hip or spine BMD Z score <–3 SD or bone loss of at least 10% yearly at the hip or spine as assessed by dual X-ray absorptiometry [57].

Denosumab

Denosumab is a human monoclonal antibody that binds and neutralizes the activity of human RANKL similar to the action of endogenous OPG. In postmenopausal osteoporosis, denosumab increases BMD and reduces vertebral, non-vertebral, and hip fracture risk [82]. In a recent phase 3, randomized, double-blind, double-dummy, active-controlled study, denosumab was both non-inferior and superior to risedronate in increasing BMD at lumbar spine (+2.2% vs. risedronate after 12 months) and total hip (+1.5% vs. risedronate after 12 months) with a comparable safety profile, in 505 glucocorticoid-continuing and 290 glucocorticoid-initiating patients at moderate to high risk of fractures [83]. The increase in lumbar spine BMD induced by denosumab was of similar magnitude as the effect observed with alendronate or zoledronic acid in former studies on GIO [81, 84]. Denosumab is approved by the Food and Drug Administration and the European Medicines Agency for use in GIO.

Osteoanabolic Therapy

PTH is an attractive candidate for the treatment of GIO because it protects against osteoblast apoptosis and increases osteoblast cell number and activity [85]. PTH rapidly stimulates osteoblastic function, inducing an upregulation of osteoblast-derived RANKL, which eventually leads to osteoclast differentiation and bone resorption [21].

The efficacy of teriparatide was demonstrated in a randomized, double-blind, controlled study directly comparing teriparatide at 20 μg/day with alendronate at 10 mg/day for 18 months [84]. The study enrolled men and women with GIO whose average T-score was –2.5 SD, almost half of whom had evidence for non-vertebral fractures. Teriparatide induced a greater increase in BMD than alendronate at the lumbar spine, hip, and femoral neck. While not a prespecified endpoint, there was a significantly greater reduction in morphometric vertebral fractures in subjects on teriparatide than in those treated with alendronate. This statistically significant difference was present after 18 and 36 months of intervention [86]. Clinically evident vertebral fractures were statistically lower after 36 months in subjects receiving teriparatide than those receiving alendronate. The results were independent of the amount of glucocorticoid exposure [87]. Subgroup analyses showed BMD changes favouring teriparatide among men and premenopausal women in the same manner as postmenopausal women [88]. Similarly, teriparatide caused larger increments in spinal BMD as compared to risedronate along with greater effects on mechanical parameters of bone strength, as assessed by high-resolution peripheral quantitative computed tomography [89]. In addition to the favourable effects on bone structure and strength, an improvement of glucose homeostasis was demonstrated in patients with diabetes and GIO undergoing treatment with teriparatide [90].

Unresolved issues with the use of teriparatide and other forms of PTH in GIO are its use in the prevention of GIO, its use in patients who are resistant to bisphosphonate therapy, its use in younger populations with open epiphyses (e.g. theoretical risk of osteosarcoma), and whether teriparatide should be followed by antiresorptives in GIO, as it is recommended in postmenopausal osteoporosis. Moreover, there are no clinical studies evaluating the effects and safety of teriparatide in endogenous hypercortisolism,

while only anecdotal data showed favourable effects of this drug on BMD and TBS after cure of Cushing's syndrome [13].

GH or IGF-I administration could revert some of the negative effects of chronic glucocorticoids on the skeleton [31]. However, glucocorticoids decrease the activity of GH on skeletal cells and there are no controlled trials to determine the effectiveness of either GH or IGF-I as treatments for GIO. Increases in serum osteocalcin, carboxy-terminal propeptide of type I procollagen, and carboxy-terminal telopeptide of type I collagen are observed following short-term use of recombinant human GH treatment in a selected population of patients receiving chronic corticosteroid treatment for non-endocrine diseases [91]. Combined therapy of GH and IGF-I counteracts selected negative effects of glucocorticoids on bone in healthy volunteers, receiving short-term glucocorticoid therapy [41]. Observational and controlled studies in children receiving glucocorticoid therapy for juvenile idiopathic arthritis demonstrated that GH restored normal height velocity with a concomitant enhancement of bone mineralization [41]. However, the efficacy and safety of GH and IGF-I treatment in GIO is unknown and well-designed prospective controlled studies are necessary before their use can be recommended.

SECTION 5

Adrenal Diseases

5.1

Adrenal Imaging

Peter Guest

Introduction

Evaluating the adrenal gland with imaging can be challenging. The adrenal glands may be morphologically within normal limits even in the presence of clear hyperfunction. Hyperplasia and small nodules may coexist. Non-functioning nodules are frequent and need to be differentiated from hyperfunctioning adenomas or malignancy. However, the high-resolution anatomical imaging provided by computed tomography (CT) and magnetic resonance imaging (MRI), together with the functional characterization afforded by radionuclide imaging, allows correlation with clinical and endocrine parameters.

Anatomy

Embryologically, the adrenal cortex derives from coelomic mesoderm and the medulla from neural crest cells. Development is independent of the kidney and adrenal glands will normally be present even in the absence of a kidney. In the newborn, the adrenal glands are large, being one-third of the size of the kidneys. The fetal adrenal zones involute rapidly, however, and in the adult the adrenal glands are small. They are situated in the retroperitoneum immediately above and anteromedial to the upper pole of the kidneys. The right adrenal lies immediately behind the inferior vena cava, alongside the right diaphragmatic crus. The left adrenal lies behind the splenic vein, lateral to the left crus.

The normal adrenal has a characteristic inverted Y- or V-shape, with the two limbs fusing anteromedially. The most cranial section has a triangular appearance. Cross-sectional appearance varies according to the exact level. Each limb measures 2.5–4 cm in length and 3–6 mm in thickness. Accessory adrenal tissue (rests) may be found in the kidney, testis, or ovary, and elsewhere in the retroperitoneum, arising from the fetal urogenital ridge during its separation into adrenal and gonads.

Arterial supply is from three sources: superior–multiple arteries from the inferior phrenic artery; middle—direct from the aorta; and inferior arising from the renal artery. A single vein drains each adrenal. The left is a tributary of the left renal vein, the right leads directly to the cava, although rarely may join a hepatic vein first. The right adrenal vein is short.

Imaging Modalities

The diagnosis of hyperfunction is made clinically and endocrinologically, not radiologically. Imaging is reserved for localization and characterization of adrenal lesions [1, 2].

Radiography

The adrenals may be calcified as a result of previous haemorrhage, infarction, or granulomatous infection (e.g. tuberculosis). Adrenal cysts may be large and show calcification of the wall. Of adrenal tumours, 10–14% are calcified on CT, but this is rarely demonstrable on plain films. Large adrenal masses may be inferred from displacement or distortion of bowel gas or adjacent organs such as the kidney. Rarely, malignant adrenal lesions will invade the kidney and masquerade as a renal tumour on intravenous urography.

Ultrasonography

Ultrasonography is widely available, and does not involve exposure to ionizing radiation. It is, however, very poor at visualizing the normal adrenal or small masses, and a normal

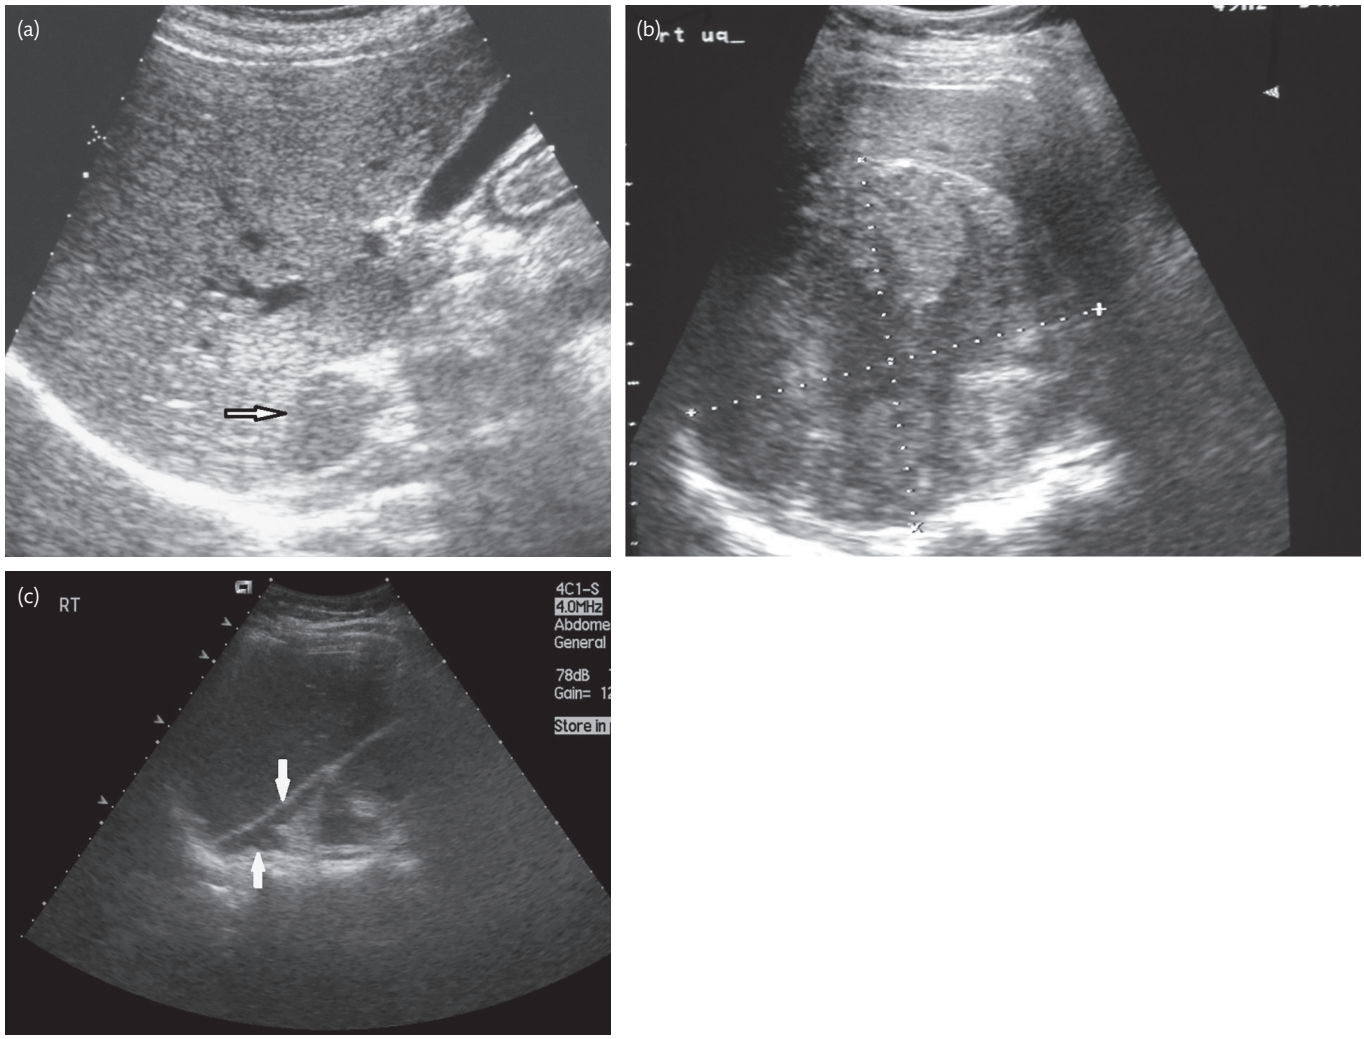

Figure 5.1.1 (a) 2 cm right adrenal Conn's adenoma (arrowed) adjacent to liver. (b) Large adrenocortical carcinoma (measured), with a heterogeneous appearance due to central necrosis (c) A v-shaped hyperplastic adrenal (arrowed) in congenital adrenal hyperplasia.

examination would therefore not exclude an adenoma, adrenal hyperplasia, or small malignant tumours. It could be expected to demonstrate tumours of 2 cm or more in size if the examination is technically complete (Figure 5.1.1) It is more helpful in children where body fat is less of a problem, and when it is particularly desirable to avoid the radiation exposure of a CT examination.

Computed Tomography

CT is the mainstay of adrenal imaging. The normal adrenal gland can almost always be visualized. The right may be more difficult to identify, being in close apposition to the back wall of the cava and the overlying liver. Modern multidetector scanners routinely use thin (1 mm) slices and are capable of resolving tumours as small as 5 mm. Multiplanar reconstructions can clarify anatomy or adjacent organ involvement. The use of contrast media is not necessary for detection of adrenal masses, the anatomical demonstration is sufficient. In some instances, however, the pattern of enhancement may help characterize the lesion (e.g. phaeochromocytomas) may be vascular and enhance strongly.

Staging of malignant adrenal tumours requires scanning of the chest, abdomen, and pelvis for local organ invasion, lymphadenopathy, and metastases. Intravenous contrast medium is necessary for maximum sensitivity for hepatic metastases. Hypervascular metastases (e.g. phaeochromocytoma) may be more conspicuous with scans obtained in the arterial phase rather than the portal venous phase of enhancement.

Magnetic Resonance Imaging

As with CT, MRI allows visualization of the normal and abnormal adrenal gland in the majority of cases. It does not involve exposure to ionizing radiation and hence is preferred in children, the young adult, and the pregnant patient. It has a valuable role particularly in characterization of the indeterminate adrenal lesion using chemical shift imaging. The ability to image in multiple planes allows improved recognition of adjacent organ involvement, and possibly determination of the suprarenal origin of a mass (Figure 5.1.2). However, when staging malignancy, it is usually difficult to evaluate the whole body as the examination time would be prolonged, and it is poorly sensitive to small metastases in the lung.

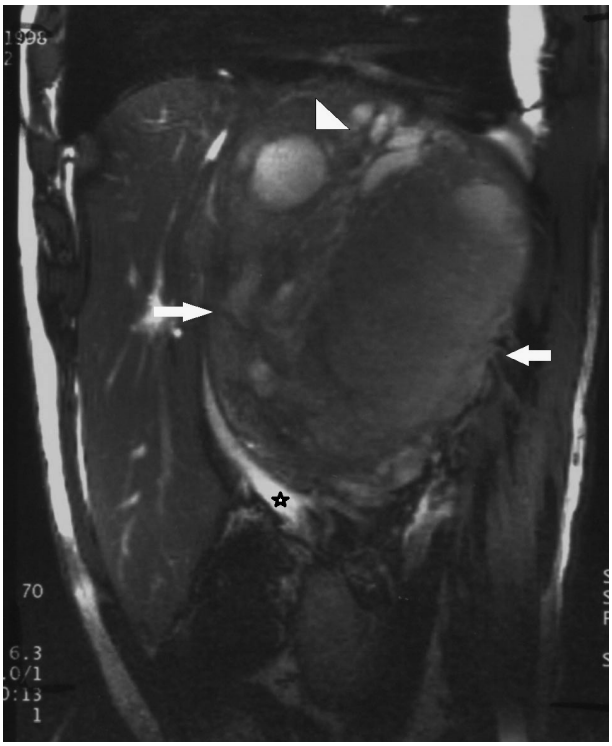

Figure 5.1.2 Large phaeochromocytoma (arrows). Sagittal T_2-weighted magnetic resonance image with flowing blood and areas of fluid necrosis (arrowhead) as white. Note anterior displacement of inferior vena cava (star) and heterogeneity of tumour.

Radionuclide Imaging

The functional information afforded by imaging with radioisotopes is complementary to the anatomical demonstrations of CT and MRI. Various radiopharmaceuticals are available. Standard isotope imaging of the adrenal medulla uses the noradrenaline analogue meta-iodobenzylguanidine (MIBG) [3]. The tracer is actively taken up in postsynaptic nerve terminals where it is resistant to degradation and can hence be used to demonstrate accumulation in such tissue as in phaeochromocytomas, paragangliomas, and neuroblastomas. Other neuroendocrine tumours such as carcinoid and medullary thyroid tumours also take up the radiopharmaceutical. MIBG is labelled with ^{123}I- or ^{131}I-iodine; ^{123}I gives a lower radiation dose and better quality images but is less readily available and more expensive. A number of drugs inhibit MIBG uptake: opioids, tricyclic antidepressants, sympathomimetics, antipsychotics, cocaine, and, importantly, antihypertensive agents including labetalol and calcium channel blockers, and such drugs need to be withdrawn, if possible, before this examination [3].

MIBG scans are usually performed at 24 h and 48 h. Planar whole-body images are best supplemented by SPECT-CT (single photon emission computed tomography-computed tomography), an image fusion technique of isotope and CT data, giving increased sensitivity, specificity and anatomical localization (**Figure 5.1.3**) [4]. Physiological uptake is seen in liver, spleen, myocardium, and salivary glands. Occasionally, bowel uptake is seen which may hinder interpretation, although SPECT-CT usually resolves any difficulties. Normal adrenal glands are usually not well visualized although there may be faint uptake.

An alternative radiopharmaceutical used for neuroendocrine tumours is the somatostatin analogue octreotide acetate labelled with ^{123}I or ^{111}In (indium), which localizes to somatostatin receptor-bearing tumours including phaeochromocytomas and neuroblastomas [3]. However new positron emission tomography (PET) pharmaceuticals are supplanting octreotide and MIBG [3].

Historically isotope imaging of the adrenal cortex has used labelled cholesterol analogues: 6-β-iodomethyl-19-norcholesterol labelled with ^{131}I (NP-59). Adrenocortical scintigraphy is not now widely available or used [5]. This may be due to the number of patient visits required, the lag time to final result, a relatively high radiation dose, limited availability, but perhaps most importantly the use of endocrine assessments in conjunction with high-resolution anatomical imaging with CT, and metabolic information from PET. Recent work has used radionuclides containing metomidate, derived from the specific CYP11B1/2 inhibitor etomidate, thereby targeting uptake to adrenocortical tissues. Both [^{123}I]-metomidate SPECT-CT [6] and [^{11}C]-metomidate PET-CT [7] have been used,

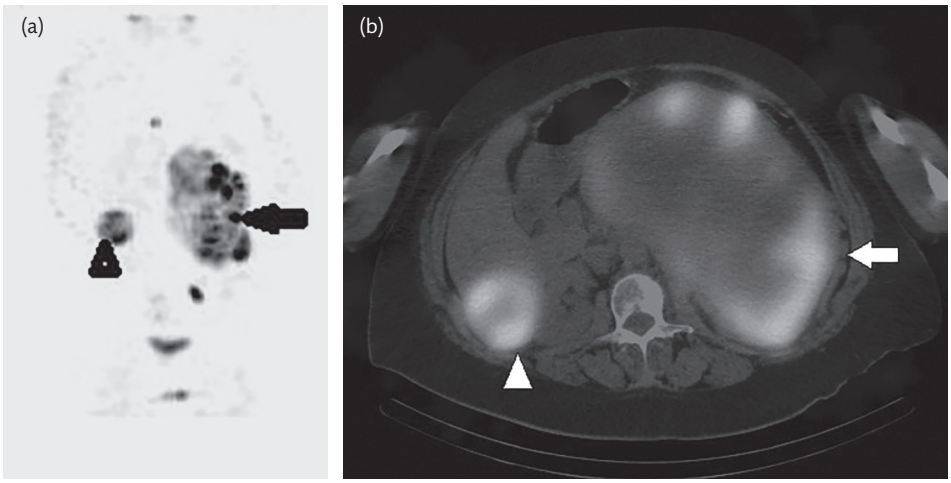

Figure 5.1.3 MIBG scan (a) showing a large MIBG avid left upper quadrant phaeochromocytoma (arrowed) also shown on the CT-SPECT fused image (b) with an FDG avid liver metastasis (arrowhead).

Figure 5.1.4 FDG-PET showing hypermetabolic mass above the right kidney (arrowhead).

but are not yet widely available, pending full assessment of their diagnostic potential in the assessment of adrenocortical tumours.

PET has an increasingly recognized role in the assessment of adrenal masses [8–10]. The most commonly used radiopharmaceutical is [^{18}F]2-fluoro-2-deoxy-D-glucose (FDG), a glucose analogue that is actively taken up and trapped in hypermetabolic cells, usually reflecting malignancy. FDG-PET can thus be used to detect metastases to the adrenals, to indicate that the likelihood that a mass is malignant, and whole-body staging. (Figure 5.1.4) [10]. Although not widely available, other fluorinated pharmaceuticals such as ^{18}F-fluorodopamine, ^{18}F-fluoroDOPA have been used for evaluation of adrenal and other neuroendocrine tumours [10, 11]. Gallium 68 (^{68}Ga) 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA)–octreotate (DOTATATE) uses a different positron emitter (^{68}Ga) conjugated with a somatostatin receptor imaging agent [12, 13]. This is used for neuroendocrine tumour imaging—detection of primary tumours and staging. The physiological affinity of DOTATATE is greater than octreotide. The resolution, sensitivity, and specificity afforded by PET are much greater than that of octreotide CT-SPECT. Other similar analogues are available (DOTATOC (GaToc), and DOTANOC (GaNoc)). Therapeutic octreotide administration should be discontinued prior to imaging to avoid competitive inhibition of uptake. Physiological uptake is seen in the spleen, liver, urinary tract, salivary glands, thyroid, and the pituitary. There is high uptake in phaeochromocytoma and paragangliomas, and it is now the functional imaging technique of choice for neuroendocrine tumours (Figure 5.1.5). FDG-PET is complementary as it will highlight more aggressive tumours,

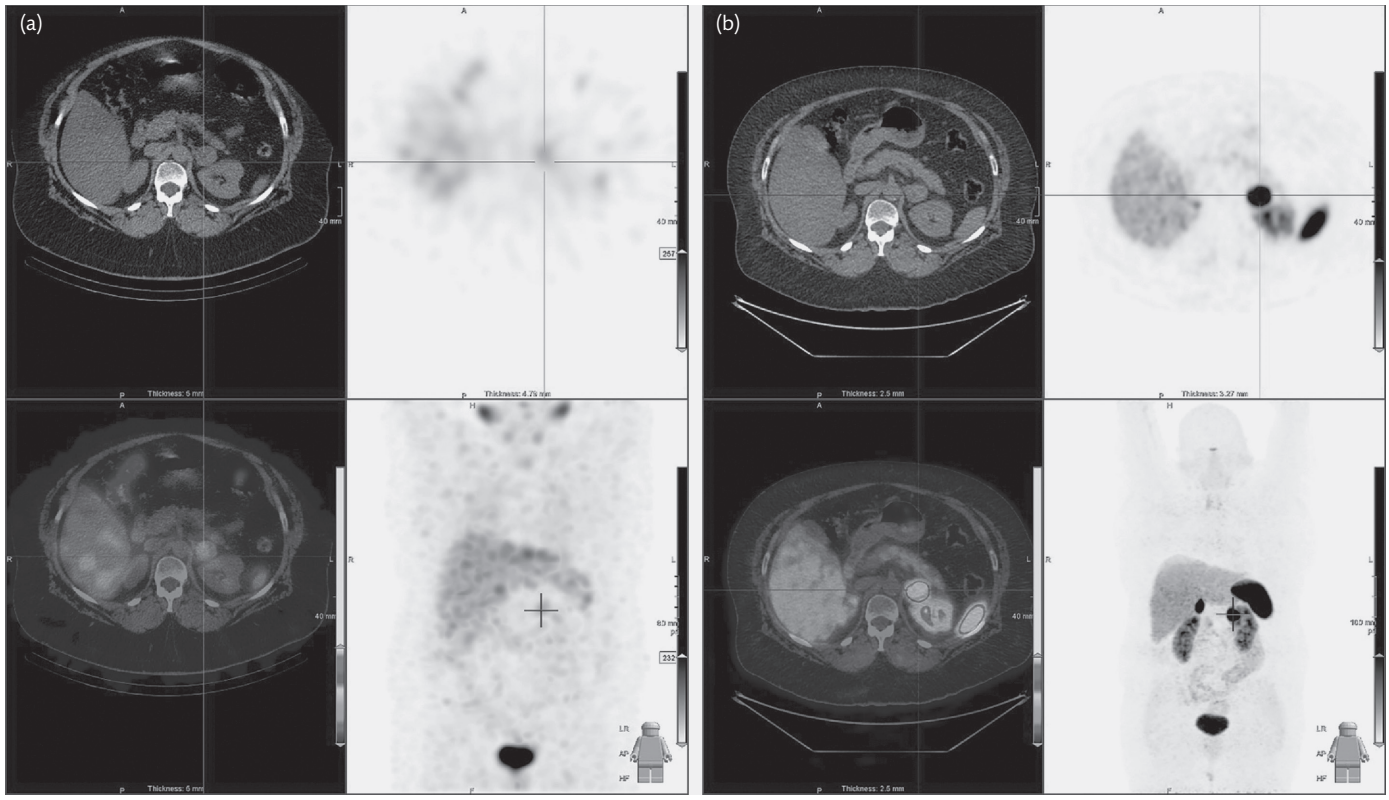

Figure 5.1.5 MIBG (a) and ^{68}Ga DOTATATE (b) scans showing a left sided phaeochromocytoma with only mild uptake on the MIBG scan, but marked avidity on DOTATATE (cross hairs). A second tumour is seen above the right kidney on the DOTATATE scan coronal image.

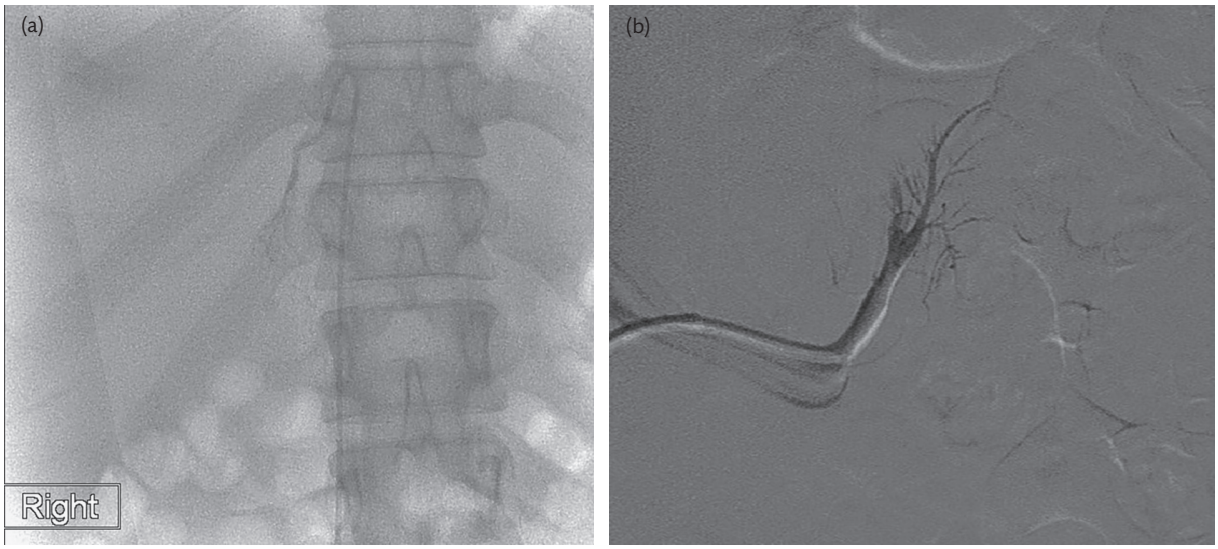

Figure 5.1.6 Adrenal vein sampling (a) right direct from the cava (b) left via the left renal vein.

whereas somatostatin receptor imaging shows better differentiated functioning tumours [14].

Arteriography

The vascular supply and drainage have been described in the anatomy section. Arteriography is rarely indicated for diagnostic purposes. Occasionally it may help indicate an adrenal origin of an uncertain abdominal mass, or be used as a prelude to embolization of vascular tumours.

Venous Sampling

Sampling of the adrenal effluent is used to determine whether aldosterone production originates from one or both adrenals, and to determine if nodules detected on CT are functional or not in patients with primary hyperaldosteronism (Conn's syndrome). The left adrenal vein is relatively easy to cannulate via the renal vein but the anatomy of the right is less favourable (direct drainage to the inferior vena cava between the T11 and L1 vertebrae.) and success rates between 74% and nearly 100% have been reported [15–17]. The venogram images are not used for diagnosis but to confirm correct catheter placement (Figure 5.1.6). Optimal results arise from close collaboration between clinicians, radiologists and laboratory staff; intraprocedural rapid cortisol measurement can improve the success rate. Extravasation and venous infarction may complicate injection of the adrenal veins.

Biopsy

The indeterminate lesion that is discovered when imaging for other purposes may need histological evaluation. However, endocrine assessment and the newer CT and MR characterization techniques have significantly reduced the requirement for biopsy [18]. Biopsy accuracy rates range between 80% and 100% [18, 19]. However, it is important to note that biopsy cannot differentiate between an adrenocortical adenoma and an adrenocortical carcinoma and thus should be avoided if an adrenocortical carcinoma is suspected. Also there is a risk of tumour seeding of the track and a higher likelihood of recurrence and metastasis if the capsule has been violated [20]. However, biopsy can be helpful in other scenarios (e.g. to differentiate between a tumour of adrenal origin and an adrenal metastasis of a solid organ tumour distinct from the adrenal). Haemorrhage and pneumothorax are the most common complications of adrenal biopsy.

CT guidance is usual except where the tumour is relatively large when ultrasonography is a good alternative. A posterior approach with the patient prone is the least hazardous but the posterior costophrenic angles may be deep, and transgression of the lungs may be unavoidable with consequent risk of pneumothorax. A transhepatic approach is an alternative on the right, or on rare occasions a safe anterior approach may be identified. Endoscopic ultrasound guided transgastric approach gives access to the left adrenal (Figure 5.1.7).

Most operators remain reluctant to biopsy adrenal masses that may be phaeochromocytomas due to the risk of precipitating a hypertensive crisis [16]. Prior blood or urine biochemistry for exclusion of catecholamine excess is therefore mandatory before any adrenal biopsy.

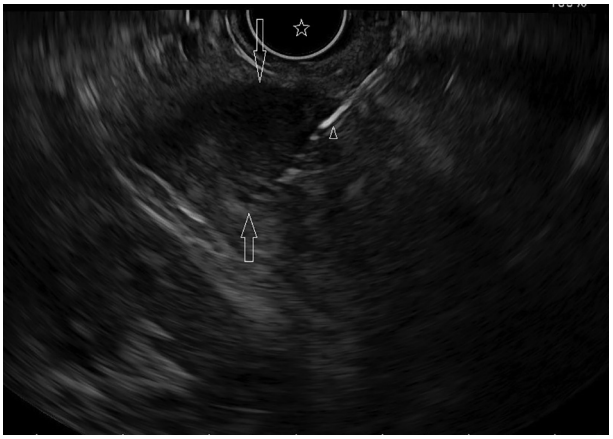

Figure 5.1.7 Left adrenal mass (between arrows) undergoing endoscopic biopsy (needle indicated by arrowhead, endoscopic probe by star).

Cushing's Syndrome

Cushing's syndrome is the result of overproduction of cortisol by the adrenal cortex. The distinction between pituitary or ectopic adrenocorticotrophic hormone (ACTH)-driven cortisol production and primary adrenal disorders is made on a clinical and biochemical basis and imaging directed appropriately.

MRI is the best imaging modality for pituitary tumours, which account for about 80% of cases of Cushing's (Figure 5.1.8a). The multiplanar presentation is ideal, and intravenous contrast medium administration mandatory, for the detection of small tumours. CT is a reasonable alternative. Thin-section coronal examinations with intravenous contrast are most sensitive for small tumours. There is no justification for imaging the adrenals in pituitary-driven or ectopic Cushing's, although bilateral adrenal hyperplasia can be expected (Figure 5.1.8b). Adrenal hyperplasia is manifest as thickening and elongation of the limbs of the adrenal gland. The hyperplasia may be smooth or multinodular, but the glands may look normal.

Adrenal tumours are the cause of Cushing's syndrome in 15–25% of cases and are well shown with CT and MRI [21]. Adenomas are usually between 2 cm and 4 cm in size. They are uniform in attenuation, rounded, and well demarcated (Figure 5.1.8c), identical to non-functioning tumours. They may be large enough to be seen on ultrasonography although increased body fat may hinder the examination. An active adrenal adenoma will be accompanied by atrophy of the rest of the gland and the contralateral adrenal. Carcinomas are usually larger (more than 4 cm) and may show necrosis, haemorrhage, or calcification [21]. Histology cannot be definitive of malignancy but large tumours are predictive of subsequent malignant behaviour, that is, metastasis or recurrence.

Rarely Cushing's syndrome is the result of primary pigmented nodular hyperplasia when multiple small nodules are shown arising from an otherwise atrophic gland; or ACTH-independent macronodular hyperplasia when the glands are markedly enlarged and nodular but maintain their shape [21].

There are other radiological features of Cushing's syndrome. Increased body fat may be evident, especially on CT and MRI.

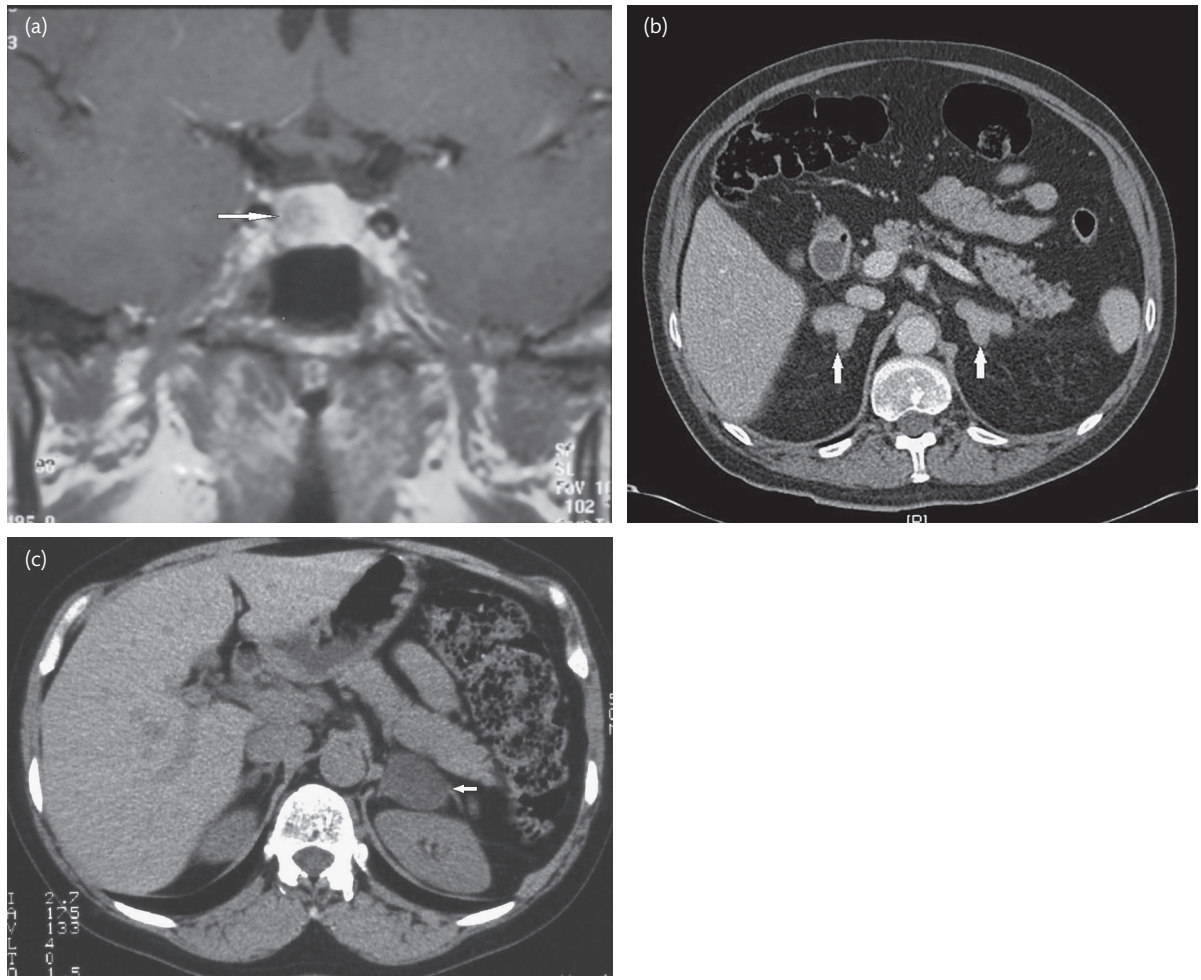

Figure 5.1.8 (a) Cushing's disease: pituitary adenoma (arrowhead) on coronal gadolinium-enhanced MR image. (b) Cushing's syndrome due to ectopic ACTH production. Marked bilateral adrenal hyperplasia (arrows) secondary to an unidentified source of ectopic ACTH. The patient was subjected to bilateral adrenalectomy for treatment. (c) Adrenal Cushing's syndrome: unenhanced CT. Low attenuation, 3 cm left adrenal mass (arrow).

Chronic glucocorticoid overproduction results in skeletal osteoporosis. Diagnosis of osteoporosis is best done by bone mineral densitometry usually with DEXA (dual energy X-ray absorptiometry).

Primary Hyperaldosteronism (Conn's Syndrome)

Conn's syndrome results from overproduction of aldosterone either from an adrenal adenoma or bilateral hyperplasia [16]. The distinction is crucial as it directly affects surgical management. A unilateral adrenalectomy is often curative for unilateral secretion while bilateral hyperaldosteronism is usually treated medically. The pitfall is to remove an incidental non-functional nodule from the innocent side. Adrenal venous sampling is therefore required. Conn's is very rarely (less than 1%) the result of an adrenocortical carcinoma, usually presenting as a larger tumour (>4 cm).

Aldosterone-producing adenomas are often small (less than 2 cm), compared to cortisol-producing adenomas requiring thin-section CT for detection (**Figure 5.1.9a**). The average diameter is between 12 mm and 18 mm and 20% are less than 10 mm. Tumours less than 1 cm can be difficult to identify. Conn's tumours are characteristically lipid rich and usually have the lowest attenuation values of all hyperfunctioning adenomas (**Figure 5.1.9b**) [22].

Hyperplastic glands may appear normal or show obvious symmetric enlargement. MRI has no real advantage over CT although high signal returned from a lesion on T_2-weighted imaging may aid detection.

The definitive test is adrenal venous sampling with an accuracy rate of close to 100% (**Figure 5.1.6**) [15–17]. The ratio between aldosterone and cortisol in the venous blood from each adrenal is compared with peripheral samples. Samples following ACTH stimulation may be taken in some centres though no consensus exists whether this improves diagnostic accuracy. A lateralizing result for a functioning adenoma is achieved if the aldosterone:cortisol ratio is four times the opposite side [16, 17].

^{11}C metomidate PET is not widely available but appears to be non-invasive alternative to adrenal venous sampling (AVS) for lateralization [23], pending more detailed, prospective evaluation of accuracy.

Androgen Excess and Oestrogen Excess

Androgen excess may be of ovarian (rarely testicular) or adrenal origin. Tumorous adrenal causes are mostly malignant. Imaging choices are similar to the investigation of Conn's syndrome, that is, CT or MRI with venous sampling (with the addition of ovarian venous aspirates).

Feminization, for example gynaecomastia, due to adrenal oestrogen excess is rare. As with androgen excess of adrenal origin, the cause is most often an adrenocortical carcinoma of such a size that CT and ultrasonography are invariably helpful.

Adrenocortical Carcinoma

This may be responsible for any of the aforementioned syndromes or be clinically non-functional. They are readily seen on ultrasonography, CT, or MRI, as tumours are usually large at presentation although hyperfunctioning tumours present at a smaller size, as a result of the endocrine effects [24]. Heterogeneity of some degree is usual. Calcification occurs in 30%. An adrenal origin may be difficult to determine on standard axial CT imaging if the tumours are large and invasive, but CT reconstructions or MRI are more informative, using multiple planes and different sequences. Significant growth over time, local invasion of adjacent organs or metastatic disease are features of malignancy (**Figure 5.1.10a, b**). As with renal cell carcinoma, there may be invasion of the adrenal vein and extension into the cava (**Figure 5.1.10c, d**). They rarely contain significant amounts of intracellular lipid, which can be exploited diagnostically as malignant tumours do not therefore show low attenuation density values (<10 Hounsfield units (HU)) on CT and rarely lose signal on opposed-phase MRI.

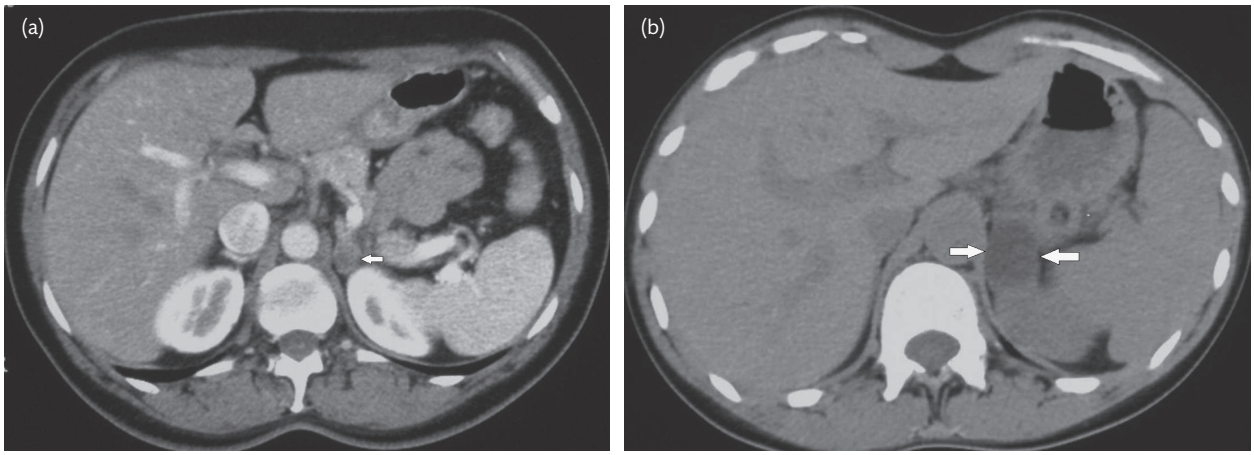

Figure 5.1.9 (a) Small Conn's tumour: enhanced CT showing a small mass (arrow) arising from the medial limb of the left adrenal. (b) Large Conn's tumour: unenhanced CT showing a typically low attenuation left adrenal mass (arrowhead).

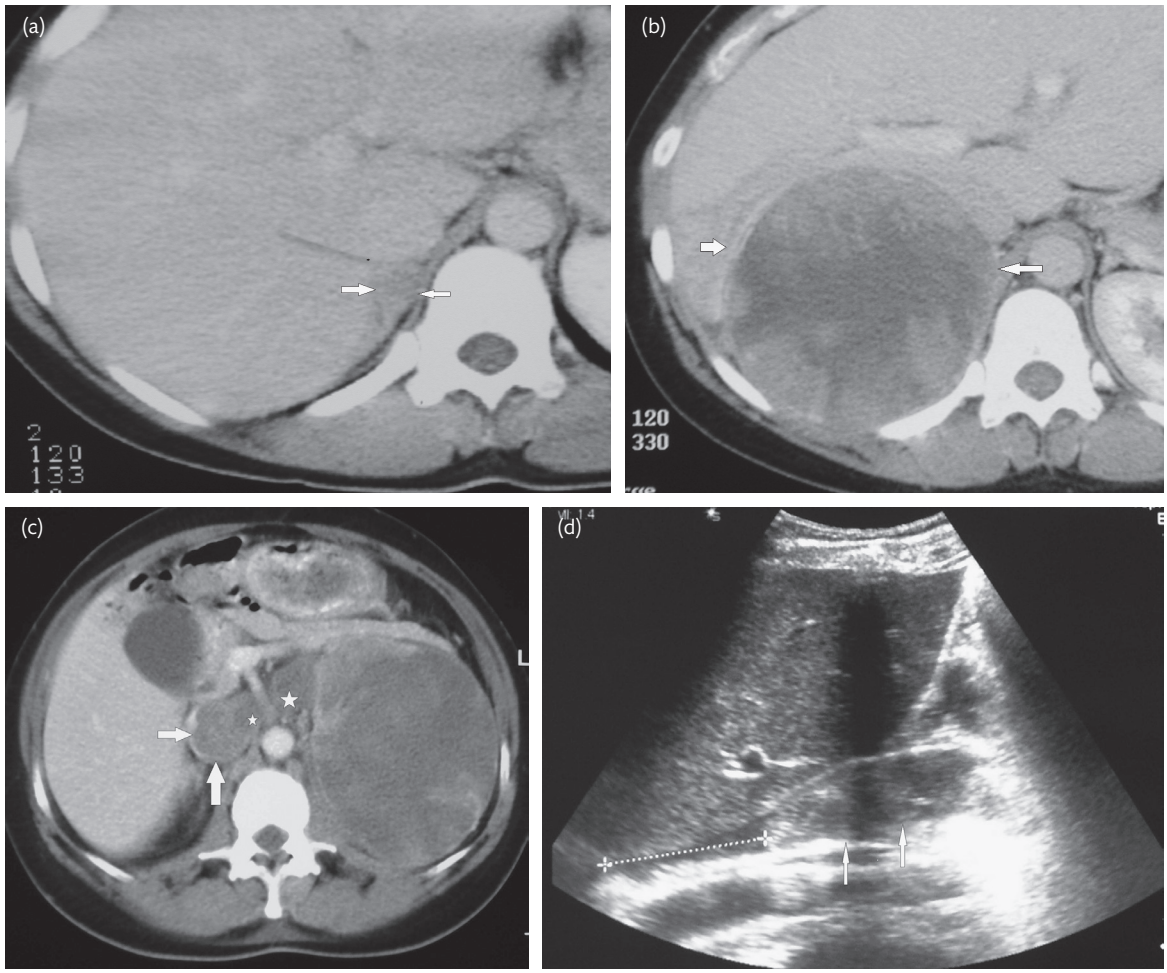

Figure 5.1.10 (a) CT shows an adrenocortical carcinoma, initially small (arrows). demonstrating growth over time (b, arrows). (c) Adrenocortical carcinoma: CT showing a large mass in the left suprarenal region, invading left renal vein (stars) and inferior vena cava on CT and ultrasound (d) (arrows). Measurement marks show length of uninvolved hepatic cava.

Addison's Disease

This term refers to adrenal insufficiency. Autoimmune mechanisms are the commonest cause now that the incidence of tuberculosis has reduced. CT may show atrophy or calcification. Tuberculous infection in the subacute stage produces enlarged adrenals (Figure 5.1.11a), which may show peripheral enhancement around central necrosis. In the long term the glands calcify (Figure 5.1.11b). Histoplasmosis produces similar appearances and half of patients with disseminated disease develop Addison's disease [25].

Bilateral adrenal metastases, even when large, can result in adrenal insufficiency, however usually in less than 20% of cases. This carries the risk that symptoms of Addison's disease may be confused for those of the underlying malignancy (Figure 5.1.12) [26].

Acute adrenal insufficiency as the result of bilateral adrenal haemorrhage or severe hypotension may complicate shock, sepsis, or bleeding disorders. High-attenuation swelling of the adrenals is the finding on CT performed acutely.

Rare causes of hypoadrenalism include haemochromatosis, when CT may demonstrate increased attenuation of liver and pancreas as a result of iron deposition and Wolman's disease (lipid storage abnormality due to a deficiency of liposomal acid lipase) when the adrenals are enlarged and show diffuse punctate calcification.

Phaeochromocytomas

These tumours arise from the chromaffin cells of the sympathetic nervous system. Thus, they most commonly arise in the adrenal medulla (=phaeochromocytoma), but can also be extra-adrenal (=paraganglioma) in the neck, the mediastinum (including intrapericardiac), in a para-aortic position, in an accumulation of sympathetic ganglia at the base of the inferior mesenteric artery known as the organ of Zuckerkandl, and in the pelvis and bladder (Figure 5.1.13) [27].

At least about 25% of apparently sporadic tumours are associated with familial conditions such as neurofibromatosis, von Hippel–Lindau and multiple endocrine neoplasia (MEN) syndromes. These patients are more likely to have bilateral or multiple lesions (Figure 5.1.14) [28].

Phaeochromocytomas are usually, but not always, benign. As with other adrenal tumours, benign and malignant phaeochromocytomas

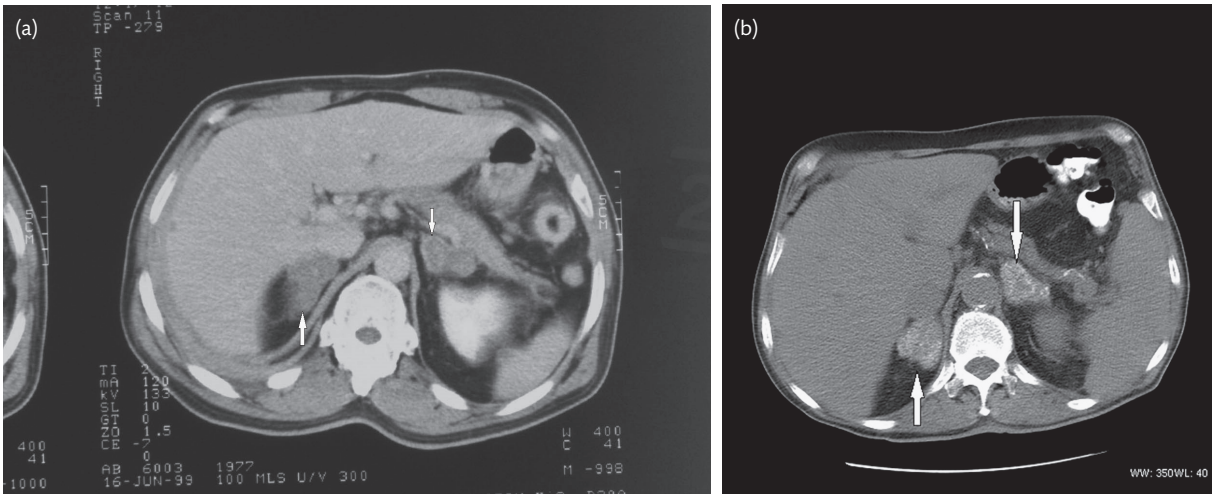

Figure 5.1.11 (a) CT—Active tuberculosis of adrenals—swollen peripherally enhancing adrenals (arrows). (b) Unenhanced CT in a different patient presenting with adrenal insufficiency shows calcified enlarged adrenals (arrows) following previous tuberculous infection.

are distinguished by behaviour (i.e. metastasis or local invasion) rather than histology or radiology [29]. However, the results of genetic analysis are usually predictive of malignancy risk and determine screening and follow-up strategies.

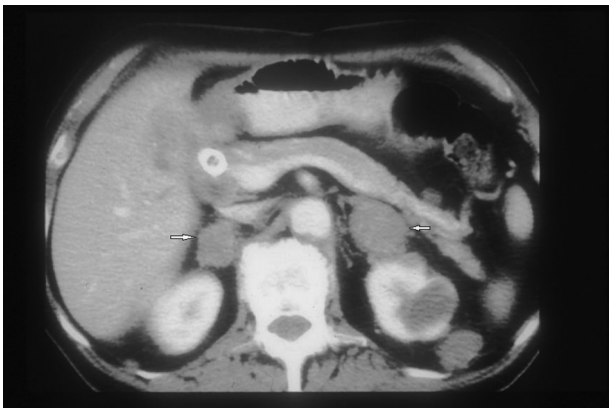

Figure 5.1.12 Bilateral adrenal metastases (arrows) that resulted in adrenal failure.

Adrenal medullary tumours are usually sizeable (greater than 5 cm) except when associated with the MEN syndromes. Therefore they can often be shown with ultrasonography and appear either homogeneous or heterogeneous with cystic or necrotic elements. CT is preferred, however, and will demonstrate the majority of adrenal phaeochromocytomas [28]. About 10% may show calcification. These lesions usually enhance strongly on CT and heterogeneity corresponding to haemorrhage or necrosis is better appreciated after contrast medium enhancement. They are characteristically of high signal on T_2-weighted MR sequences [24]. The older intravenous iodinated ionic contrast agents could precipitate hypertensive crisis in the absence of pharmacological alpha- and β-blockade [30]. The almost ubiquitous non-ionic contrast media used now do not carry the same risk and blockade is not now regarded as necessary anymore [31–33].

CT is generally used to evaluate the adrenals and to search for ectopic sources. MRI does not usually have any additional benefit. However, surgical planning for large or locally invasive tumours is helped by the multiplanar facility of MRI (Figure 5.1.2) (CT also now offers multiplanar reconstructions). The tumour can be

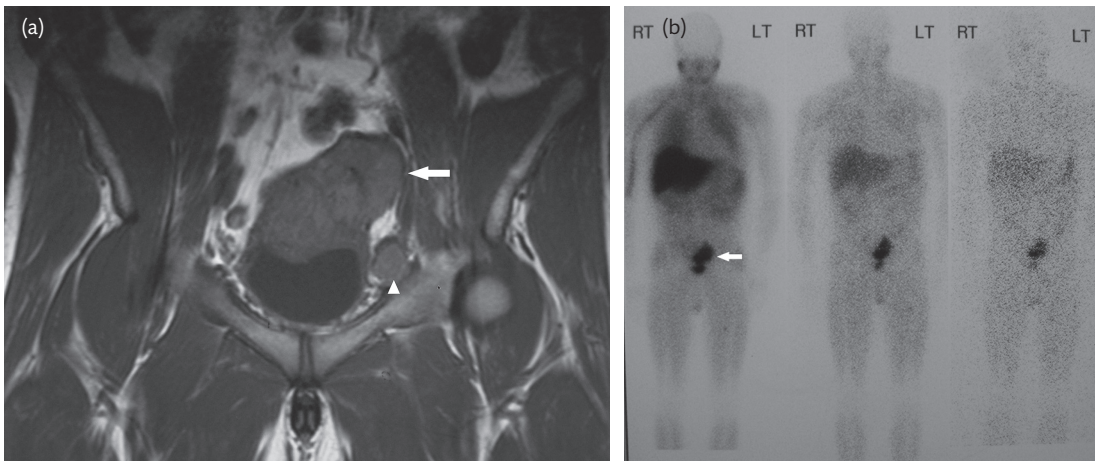

Figure 5.1.13 Bladder phaeochromocytoma. (a) Coronal MR of bladder showing a polypoid tumour (arrow) arising from the left side of the bladder dome (and an enlarged metastatic left pelvic node—arrowhead). (b) Corresponding anterior whole-body MIBG images at 1, 2 and 3 days show an MIBG avid tumour (arrow) above excreted activity in the bladder.

Figure 5.1.14 MEN type 2 associated bilateral phaeochromocytoma. Enhanced CT showing a large left adrenal and smaller right adrenal masses (arrowed) both showing typical marked peripheral enhancement, with central necrosis.

markedly hyperintense on T_2-weighted imaging ('lightbulb' sign) [29, 34, 35]. These lesions are often heterogeneous and vascular. Haemorrhage may occur leading to fluid–fluid levels and areas of high signal on T_1-weighted images. Extension of abdominal tumours into the inferior vena cava is shown with flow-sensitive sequences, or with intravenous contrast enhancement [27, 35]. Mediastinal tumours, and especially intrapericardiac lesions, are well shown with electrocardiographically gated MRI.

The functional technique of MIBG scanning is of value in the imaging of phaeochromocytomas. It is especially useful for the detection of extra-abdominal tumours and for the staging of malignant lesions, as the metastases are active [2, 3, 25]. Whole-body imaging is supplemented by SPECT-CT (Figure 5.1.3) and may be used for the initial imaging test, or to search for an ectopic tumour following a negative adrenal CT (Figure 5.1.15) [4]. MIBG is not specific for phaeochromocytoma; other tumours of neural crest origin such as neuroblastoma, carcinoid tumours, medullary carcinoma of the thyroid, Merkel-cell skin tumours, and non-functioning paragangliomas also show uptake, but this is not usually a clinical dilemma.

As discussed earlier, other radionuclide methods used to demonstrate phaeochromocytomas include ^{111}In-octreotide scanning and PET with FDG (Figure 5.1.16). ^{111}In octreotide is more useful for demonstration of metastatic disease than benign tumours [1]. FDG and MIBG scanning are complementary depending on the degree of differentiation and malignant potential [8]. Other radiopharmaceuticals such as ^{18}F-fluoroDOPA, ^{18}F-fluorodopamine, and particularly Ga-68 DOTATATE are being utilized [6, 10, 11, 36, 37]. Ga-68 DOTATATE is now the functional imaging agent of choice for neuroendocrine tumours), offering greater anatomical resolution and sensitivity (Figure 5.1.5) [12, 14].

Neuroblastoma

This tumour of infancy and childhood can arise in the adrenals (50%), in the abdominal sympathetic chain, or in the mediastinum. MIBG uptake is a feature, and can therefore be used for assessment

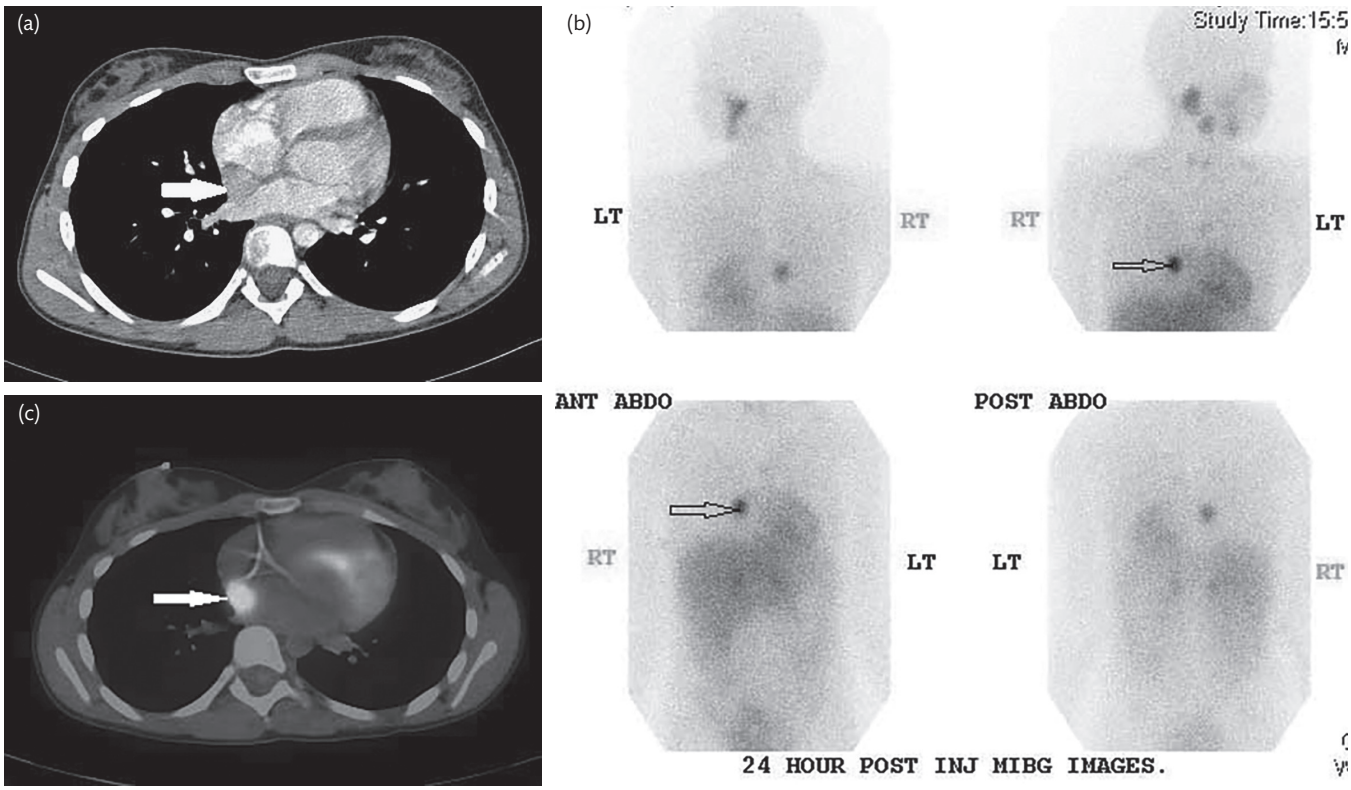

Figure 5.1.15 Paracardiac paraganglioma (arrow) demonstrated on (a) CT (not prospectively identified), (b) MIBG, and (c) 18-FDG-PET scans.

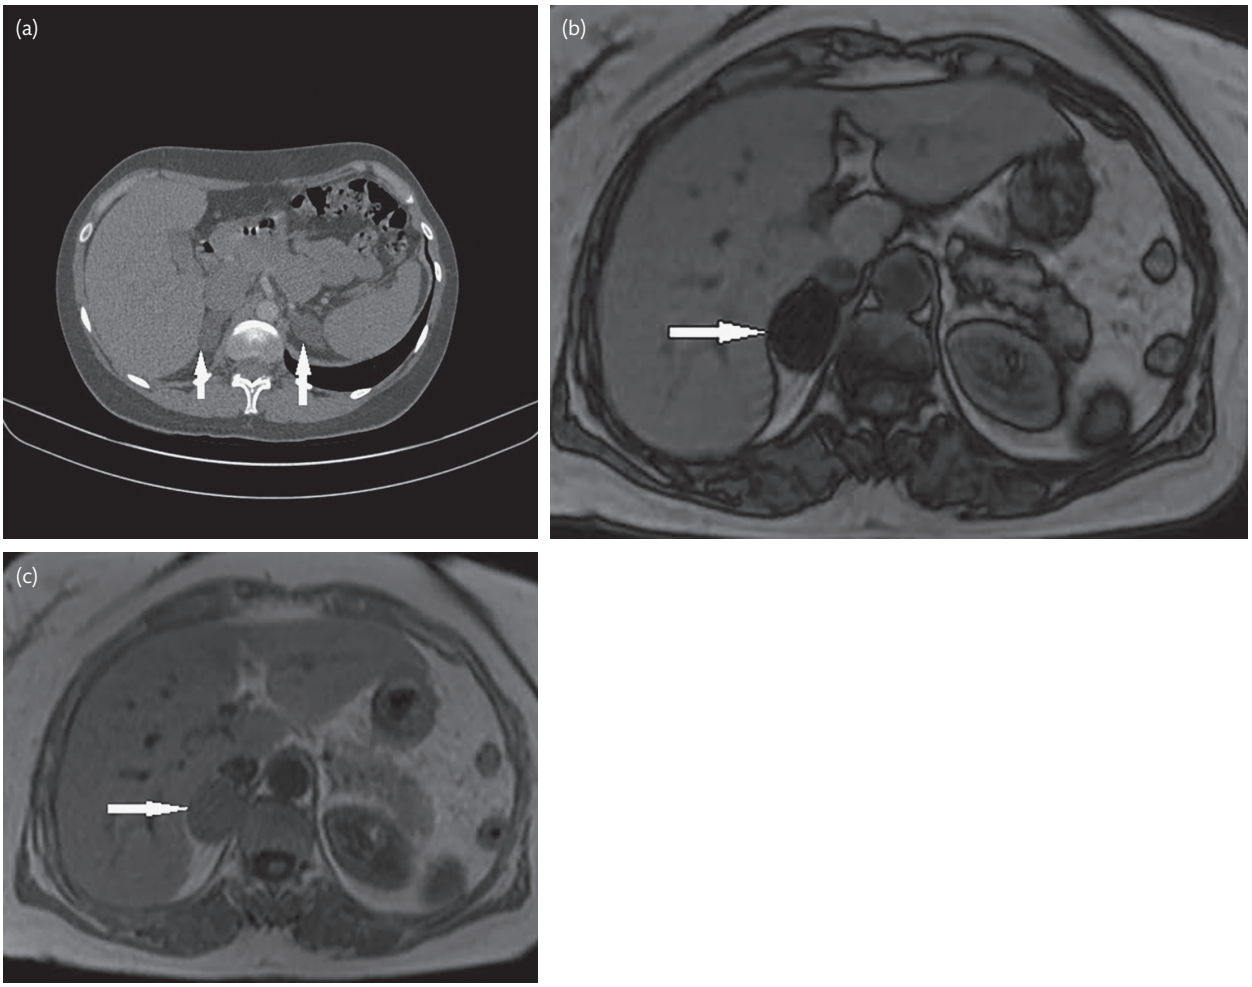

Figure 5.1.16 (a) Unenhanced CT showing bilateral low attenuation adrenal tumours (subjectively less than liver and spleen and less than 10 HU on measurement indicative of bilateral benign lipid-rich adenomas). MR showing marked signal loss (arrowed) on opposed-phase T_1-weighted MR (b); compared to the in-phase study (c); and therefore a lipid-rich right adrenal adenoma.

of metastatic disease, although CT or MRI is more appropriate for the assessment of the local disease. Tumours are often non-homogeneous on CT and MRI, and calcification is characteristic (which helps differentiate it from Wilm's tumour of the kidney). Local invasion into the spine, and skeletal metastatic disease, can occur. The multiplanar capability of MRI allows demonstration of vascular and liver involvement, intraspinal spread, and marrow disease [37].

The Incidental Adrenal Mass

With the exponential increase in the use of modern cross-sectional imaging techniques, adrenal masses are increasingly incidental findings (4–6%). They may be functional in terms of hormone synthesis and this is determined endocrinologically. The vast majority are, however, endocrinologically irrelevant, and are likely, statistically, to be benign if small. They are much more likely to be malignant if there is known primary, extra-adrenal malignancy, although even in this situation less than 50% are metastatic. The differentiation of metastasis or malignancy from an incidental adrenal adenoma is therefore very important [38].

Comparison with old scans or follow-up examination is important—a lesion that significantly changes in size over 3–6 months is highly likely to be malignant. Biopsies are helpful to clarify whether a new adrenal lesion is a metastasis of a known extra-adrenal malignancy; however, a biopsy is not useful for differentiating benign from malignant adrenocortical lesions [39] and should only ever be performed if the results are certain to affect management and after biochemical exclusion of phaeochromocytoma.

The CT appearance may give some indication of the nature of an incidentally discovered adrenal mass. It may be evidently a cyst (i.e. thin-walled, well-defined, and of fluid density). If solid, benign lesions are usually homogeneous, although there may rarely be calcification. Frank areas of fat is virtually diagnostic of a benign myelolipoma, particularly if calcification is also present. Malignant lesions may be irregular in outline, heterogeneous, perhaps with necrotic areas. The morphological appearance following contrast may be of value. Adjacent organ invasion or demonstration of metastasis is diagnostic of malignancy.

The presence of a high proportion of intracellular fat in 70% of adenomas is an important finding allowing the use of CT density measurements and chemical shift MR imaging to diagnose a benign

lesion. Adenomas are often readily apparent as hypoattenuating compared to kidney or liver on unenhanced CT (Figure 5.1.8c, 9b, and 16a). Mean attenuation values of adenomas are 2 HU, and of non-adenomas 30 HU [40]. Phaeochromocytomas invariably present with attenuation <10 HU [41]. On thin-section unenhanced scans a density of 10 HU or less is indicative of a high proportion of intracellular fat, which suggests an adenoma with high specificity (98%) though poorer sensitivity (71%) [42, 43]. Lipid content cannot be assessed on single phase contrast-enhanced scans where density measurement is not of any value (unfortunately, as these lesions are often incidental findings on enhanced scans).

Quantitative enhancement and washout characteristics have been used by many and relates to the fact that benign lesions lose enhancement more rapidly than malignant. The most commonly used threshold is >40% relative washout on a 15 min delayed scan, or >60% absolute washout [38, 44, 45]. Phaeochromocytomas, however, may also show early washout [45]. Refinements using dual energy subtraction techniques to generate a virtual unenhanced CT from an enhanced study has been promising, but dual energy scanners are not widely available [45–47]. However, in contrast to unenhanced CT attenuation, the evidence base for the use of washout CT in differentiating benign from malignant adrenal lesions is very limited [48].

Early users of MRI suggested that high signal intensity on T_2-weighted images indicated a malignant lesion, benign lesions generally having signal intensity similar to normal adrenal; however, it became apparent that there was too much overlap (20–30%) for this to be a useful feature. Gadolinium contrast medium enhancement was likewise unreliable, even with the use of dynamic acquisitions. The most robust technique appears to be the use of chemical shift imaging [38, 45, 49]. This utilizes the fact that the presence of fat within benign adenomatous cells alters the local magnetic environment, and hence the resonant frequency of the processing protons. This results in a reduction of signal intensity of benign lesions (whose cells contain both lipid and water) on out-of-phase imaging (Figures 5.1.16b and c). It appears to be useful in cases where CT attenuation is less than 30HU [34, 45]. Normal adrenals also display this phenomenon but non-adenomatous lesions do not. The principle is entirely different to saturation sequences used for fat suppression, which apply to macroscopic fat. Visual assessment can be supplemented by quantification (e.g. signal intensity index of adrenal/spleen intensity ration but results are similar).

There is work indicating that MR spectroscopy can characterize adrenal masses as adenomas, carcinomas, phaeochromocytomas, or metastases but at present this can only be used for masses larger than 2 cm [50, 51].

FDG-PET relies on the altered metabolism of cancer cells trapping this radiopharmaceutical which enters the glycolytic pathway in the place of glucose. It has been shown to accurately differentiate benign and malignant adrenal masses in the cancer patient with specificities of 90–96%, and sensitivities of 93–100% [8, 9]; however, this is best on series of limited numbers. It is the most accurate test therefore to confirm that an adrenal mass is metastatic in the patient with an underlying extra-adrenal malignancy.

A meta-analysis found little evidence for clear superiority of any imaging test for characterization of incidental adrenal masses (although unenhanced CT was of value) [48]. A reasonable approach to the incidentally discovered adrenal lesion, whether in the setting of a known malignancy or not, is to perform density measurement on thin-section unenhanced CT. On unenhanced CT if the density is less than 10 HU, malignancy is almost certainly excluded. In the range 10–20 HU in- and out-of-phase MRI might be helpful. If greater than 20 HU, MRI is less likely to resolve the issue due to the lack of intracellular lipid, and FDG-PET may be helpful [52].

Non-Adenomatous Adrenal Abnormalities

Myelolipomas are benign and contain elements of fat and bone marrow [38]. The fat is diagnostic and can be demonstrated on ultrasonography (hyperechoic), CT (low attenuation), or MRI (high signal on T_1-weighting, focal loss of signal on fat-suppressed images, but not on opposed-phase sequences) (Figure 5.1.17). However, fat is not always a dominant feature and the appearance of the lesion is then non-specific. Calcific elements may be present. Haemorrhage may complicate the imaging features.

Adrenal cysts are endothelial (lymphangiomas and haemangiomas), epithelial (retention cysts, embryonal, or cystic adenomas), pseudocysts (resulting from previous haemorrhage), or echinococcal (hydatid). Of adrenal cysts, 15% show mural calcification, particularly in hydatid disease [53, 54].

The CT appearance of acute adrenal haemorrhage is of high-attenuation material expanding the adrenal gland or periadrenal haemorrhage leading to stranding, and an indistinct adrenal contour (Figure 5.1.18a). The high attenuation may not be appreciated if only contrast-enhanced scans are available. Subacute haematomas are isodense with normal adrenal tissue and indistinguishable from adenomas. Old adrenal haematomas may lead to calcification. Because of the paramagnetic effects of blood such as haemosiderin and methaemoglobin, MRI can be diagnostic of adrenal haematoma, although there will be a complex variation depending on the age of the lesion (Figure 5.1.18b, c, and d).

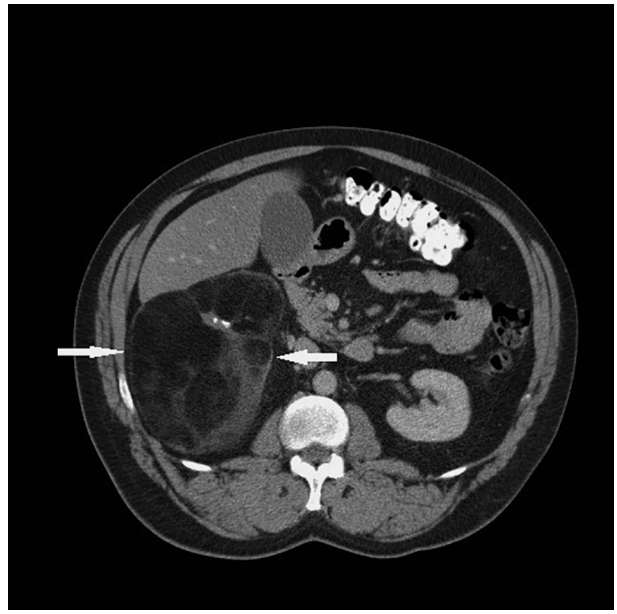

Figure 5.1.17 Adrenal myelolipoma. CT showing a left adrenal mass with macroscopic fat (dark grey elements) and small foci of calcium.

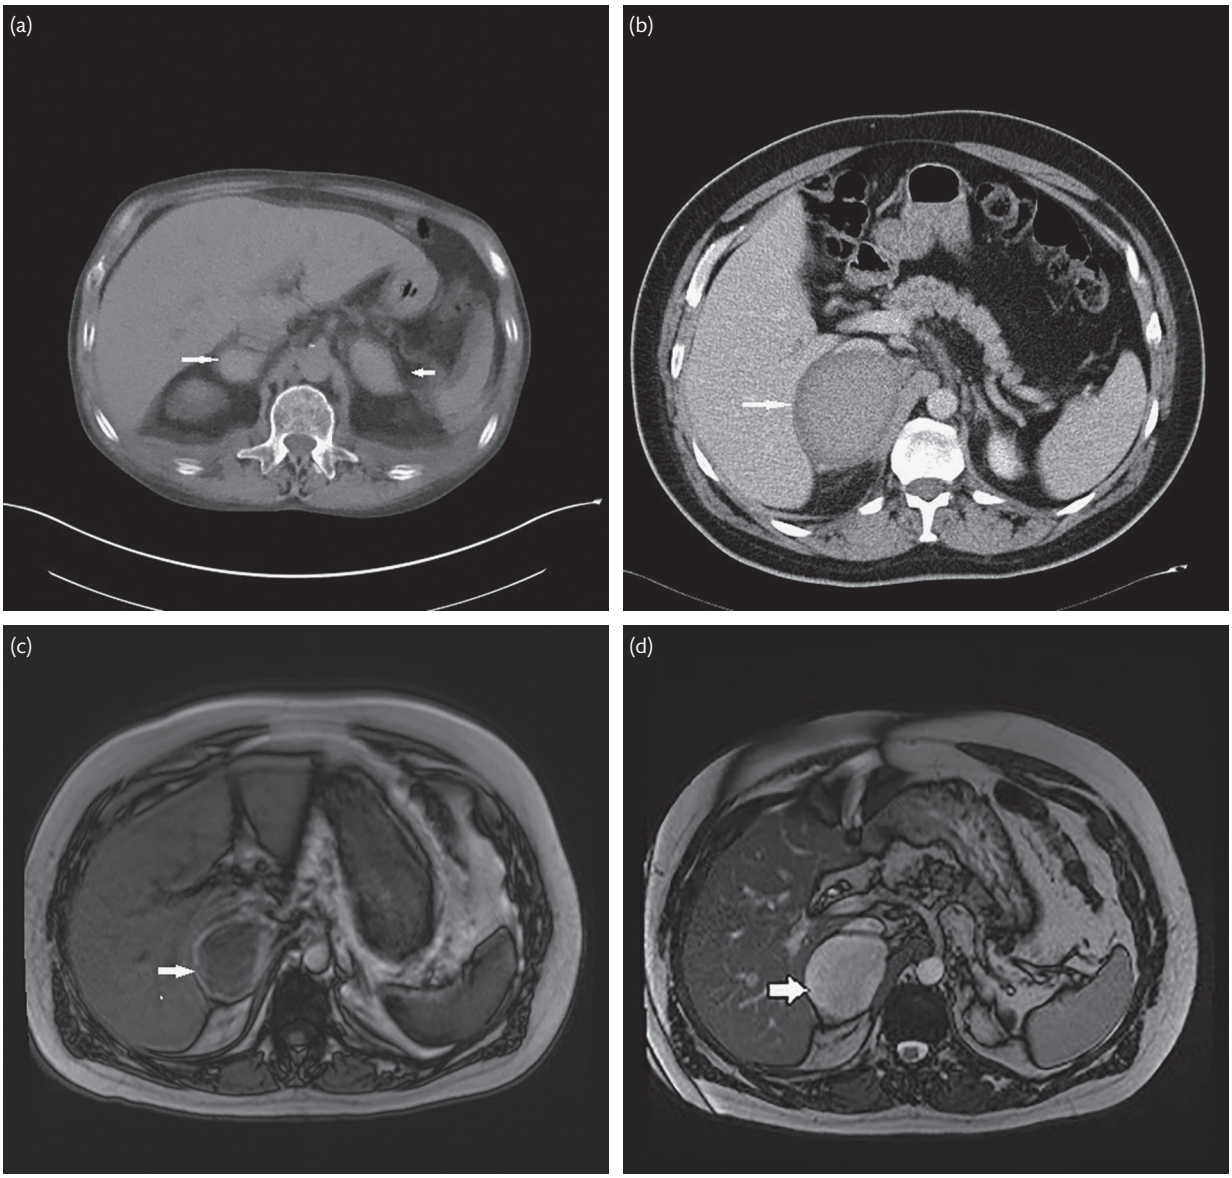

Figure 5.1.18 (a) Acute haemorrhage into both adrenals caused by excess anticoagulation. The non-enhanced CT scan shows increased density and expansion of both adrenals, diagnostic of haemorrhage (arrows). (b–d) Acute haemorrhage into the right adrenal caused by excess anticoagulation (arrows). Although an enhanced CT scan there is increased density and expansion of the right adrenal on indicating fresh blood. The T_1-weighted MRI (c) shows peripheral high signal consistent with blood products and high signal centrally on T_2-weighting (d) indicative of fluid.

Adrenal Rests

Adrenal tissue can be found in ectopic sites such as the coeliac plexus region, the broad ligaments, the testes, and the ovaries. These rests arise during fetal development when the urogenital ridge separate into adrenals and gonads, therefore, often have properties of both. Hence, adrenal rest tissue may enlarge due to ACTH stimulation (e.g. in pathological conditions such as congenital adrenal hyperplasia; Figure 5.1.19) [55], or Addison's or ectopic Cushing's disease. This phenomenon may lead to the misdiagnosis of testicular or other tumours [56], in particular in congenital adrenal hyperplasia.

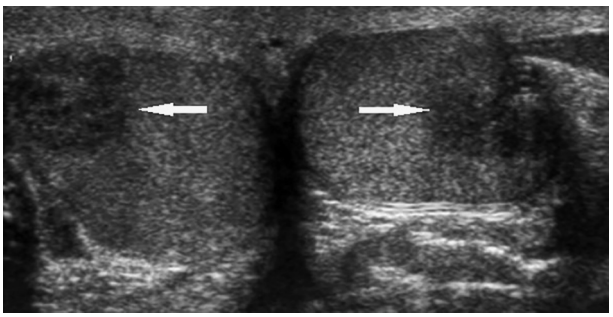

Figure 5.1.19 Bilateral adrenal rest 'tumours' in the testicles of a patient with congenital adrenal hyperplasia (arrows) (same patient as Figure 5.1.1b).

5.2

Adrenal Surgery

Fausto Palazzo and Radu Mihai

Introduction

The last two decades have witnessed a significant increase in the diagnosis of both functioning and non-functioning adrenal tumours. The widespread use of cross-sectional imaging has unveiled a previously undiagnosed reservoir of as many as 10% of adults with enlarged adrenal glands. Increasingly sensitive oncological staging has led to the identification of patients with previously undiagnosed solitary adrenal metastases. The (slow) acceptance of screening of hypertensive populations for hyperaldosteronism has been encouraged by the recognition of the potential benefits of adrenal surgery in hyperaldosteronism. All of these changes have increased the number of patients considered for adrenal surgery.

The operative approach to the adrenal gland, in particular for benign lesions, has now been consolidated towards one of two main minimal access approaches proven to be associated with a faster recovery and reduced morbidity compared to traditional open surgery. However, studies in both the United Kingdom and United States have demonstrated that the results of adrenal surgery tightly correlate with surgical volume and that most surgeons undertaking an adrenalectomy have unacceptably small volume practices [1, 2]. The centralization of adrenal surgery remains one of the challenges for the future.

Despite the changes in adrenal practice over the years, the surgical principles in adrenal disease remain unchanged and the perioperative management of adrenal patients mandates a multidisciplinary collaboration with colleagues in endocrinology, biochemistry, and radiology. The key principles in adrenal surgery are that:

- Functional studies are used to confirm or exclude a syndromic diagnosis;
- The patient should be made safe with the appropriate pharmacological treatment;
- Radiological studies are required to confirm the anatomical characteristics of the abnormality;
- The need for surgical intervention should be ratified in the context of a multidisciplinary team meeting.

This chapter will focus primarily on the background history, functional embryology, and anatomy of the adrenal glands and the surgical aspects of treatment. The pathology of adrenal disease, details of biochemical and radiological investigations, and the non-surgical modalities of treatment are covered elsewhere.

Historical Perspective

Landmark events in our knowledge about the existence and function of the adrenal glands are summarized in Table 5.2.1. While

Table 5.2.1 Timeline of understanding the role of adrenal glands

1552	The adrenal glands were first described by Bartholomaeus Eustachius in his *Opuscula Anatomica* as 'glandulae renis incumbentes' (glands lying on the kidney)
1629	Jean Riolan of Paris introduced the term *capsulae suprarenales*
1716	the Academie des Sciences de Bordeaux offered a prize for the answer to the question 'What is the purpose of the suprarenal glands?' but no progress was achieved
1805	Cuvier defined the anatomic division into a cortex and a medulla
1855	Thomas Addison of Guy's Hospital published his clinical observations of 11 patients with destruction of both adrenal glands and described the eponymous clinical syndrome
1856	Brown-Séquard performed adrenalectomy in animals and provided the first experimental confirmation of Addison's theory that the adrenal glands were essential to life
1901	Epinephrine was purified from the adrenal gland
1904	Epinephrine and norepinephrine were first synthesized by Frank Stolz in Germany
1950	Edward Kendall, Tadeus Reichstein, and Philip Hench receive the Nobel Prize in Physiology or Medicine for the discovery of the hormones of the adrenal cortex, their structure, and biological effects

the Italian anatomist Bartholomaeus Eustachi first described the adrenals in the sixteenth century, another 300 years passed until the role of the adrenal gland was clarified and the clinical impact of some adrenal tumours understood. In 1865, DeCrecchio first reported congenital adrenal hyperplasia in a female pseudohermaphrodite. In 1886, Frankel described a type of tumour for which the pathologist Pick in 1912 proposed the name phaeochromocytoma, from the Greek *phaios* (dark or dusky) and *chroma* (colour). In 1912, Harvey Cushing described the classic features of his eponymous syndrome and, in 1955, Conn reported the first patient with primary hyperaldosteronism.

The first reported adrenalectomy was performed by Knowsley-Thornton, in London in 1889, for what is presumed to have been an adrenal malignancy. The first successful adrenalectomy for a phaeochromocytoma is attributed to Cesar Roux, in 1926 in Switzerland, and phaeochromocytoma surgery was immediately recognized to be associated with a high morbidity and mortality. This remained the case at least until the arrival of adrenergic receptor blockers in the 1960s, which, along with improved surgical technique, probably made the largest impact on the safety of this type of surgery [3]. Starting from the 1990s adrenal surgery has benefited greatly from technological advances of fibreoptic scopes and laparoscopic instruments and devices that allow laparoscopic and retroperitoneoscopic surgery to be performed safely in all but the largest adrenal tumours.

Surgical Embryology

The adrenal gland has a dual origin: the cortex arises from the mesoderm and the medulla is neuroectodermal.

The cortex starts to develop in the fifth week of gestation as a proliferation of coelomic mesothelium close to the urogenital ridge (the mesonephros and the developing gonad). In the initial phase the *adrenogonadal primordium* is distinguished and after the eighth week of gestation it separates into two distinct structures, the adrenal and the gonadal primordial. The cortex is divided into three layers: the outer zona glomerulosa, the middle zona fasciculata, and the inner zona reticularis, predominantly secreting aldosterone, cortisol, and sex steroids, respectively.

The medulla develops after the fourth week of embryonic life, when a portion of the neuroectoderm adjacent to the neural tube separates and remains between the neural tube and the definitive ectoderm as the *neural crest*. Cells derived from the neural crest (sympathogonia, primitive spinal ganglia) migrate ventrally from the apex of the neural tube to the dorsal aorta (where they aggregate and differentiate into neuroblasts to form sympathetic neurons) or to the adrenal primordia (where they differentiate into pheochromoblasts to form chromaffin cells). Some primitive adrenal medulla cells remain closely associated with the developing sympathetic nervous system and give rise to the extra-adrenal chromaffin cells and chromaffin bodies. The adrenal medulla functions as postganglionic neural tissue, secreting catecholamines and their metabolites.

Surgical Anatomy

The adrenal glands are golden-brown in colour (Figure 5.2.1) and located in the retroperitoneum in relation to the upper poles of the kidneys at the level of the T11–T12 vertebrae (Figure 5.2.1). The right adrenal gland is a distorted pyramidal structure that lies anterior to the diaphragm and the right kidney and partially posterior to the inferior vena cava and the right lobe of the liver (Figures 5.2.2 and 5.2.3). Superiorly, the gland is in contact with the bare area of the liver. The left adrenal gland is semilunar in shape and extends further inferiorly on the medial margin of the kidney. It is related anteriorly to the stomach and pancreas and posteriorly to the diaphragm and posterior abdominal wall. Surgeons regularly undertaking adrenal surgery will become aware of not infrequent ectopic adrenal tissue or adrenal rests which may exist along the path of testicular descent in males and near the broad ligament and uterus in females but which may only become apparent as a source of continued cortisol production after bilateral adrenalectomy or in rare adrenal malignancies found separate from the adrenal gland (Figure 5.2.2).

Both adrenal glands are enclosed in a layer of fat within Gerota's fascia that envelops the kidney and perinephric fat. The adrenals are supplied by three main groups of arteries: the inferior phrenic artery, the aorta, and the renal artery. In addition to these three regular sources of blood supply, pathological glands may have additional vessels due to neovascularization and on occasion also branches originating from the intercostal, the left ovarian, or the left internal spermatic arteries. Arterial branches ramify over the capsule before entering the gland and divide within to form a *subcapsular plexus* from which short cortical arteries give rise to an extensive network of sinusoidal capillaries in the interstices among clusters of cells. The venous drainage of the gland is usually into a single large suprarenal (central) vein on the right, which tends to be short and drains directly into the inferior vena cava on its posterior aspect. Control of this vessel can be hazardous. On the left side, the suprarenal vein is longer and is usually joined by the inferior phrenic vein, often described surgically as the *accessory adrenal vein*, before draining together into the left renal vein. The lymphatic drainage of the adrenal is irregular and profuse and ends in the lateral aortic lymph nodes and in the para-aortic nodes near the crus of the diaphragm and the origin of the renal artery. Given the absence of a defined lymphatic pathway radical surgical lymphadenectomy is of unproven value in adrenal malignancy. Some lymphatic vessels pierce the diaphragm and drain towards the thoracic duct or the posterior mediastinum, which explains the development of distant and early metastases of cortical malignant tumours.

Indications for Adrenal Surgery

Adrenalectomy is indicated for clinically significant functional tumours of the adrenal medulla or cortex and/or the presence of suspected or established primary or solitary secondary malignant tumours.

Of the functional tumours, **phaeochromocytoma** represents the commonest indication for adrenalectomy among surgeons submitting data to the British Association of Endocrine and Thyroid Surgery national registry, but with the growing diagnosis of primary hyperaldosteronism this may change in time. However, department of health Hospital Episode Statistics (HES) data for England suggests that surgery for apparently non-functioning adrenal tumours is particularly common among lower volume

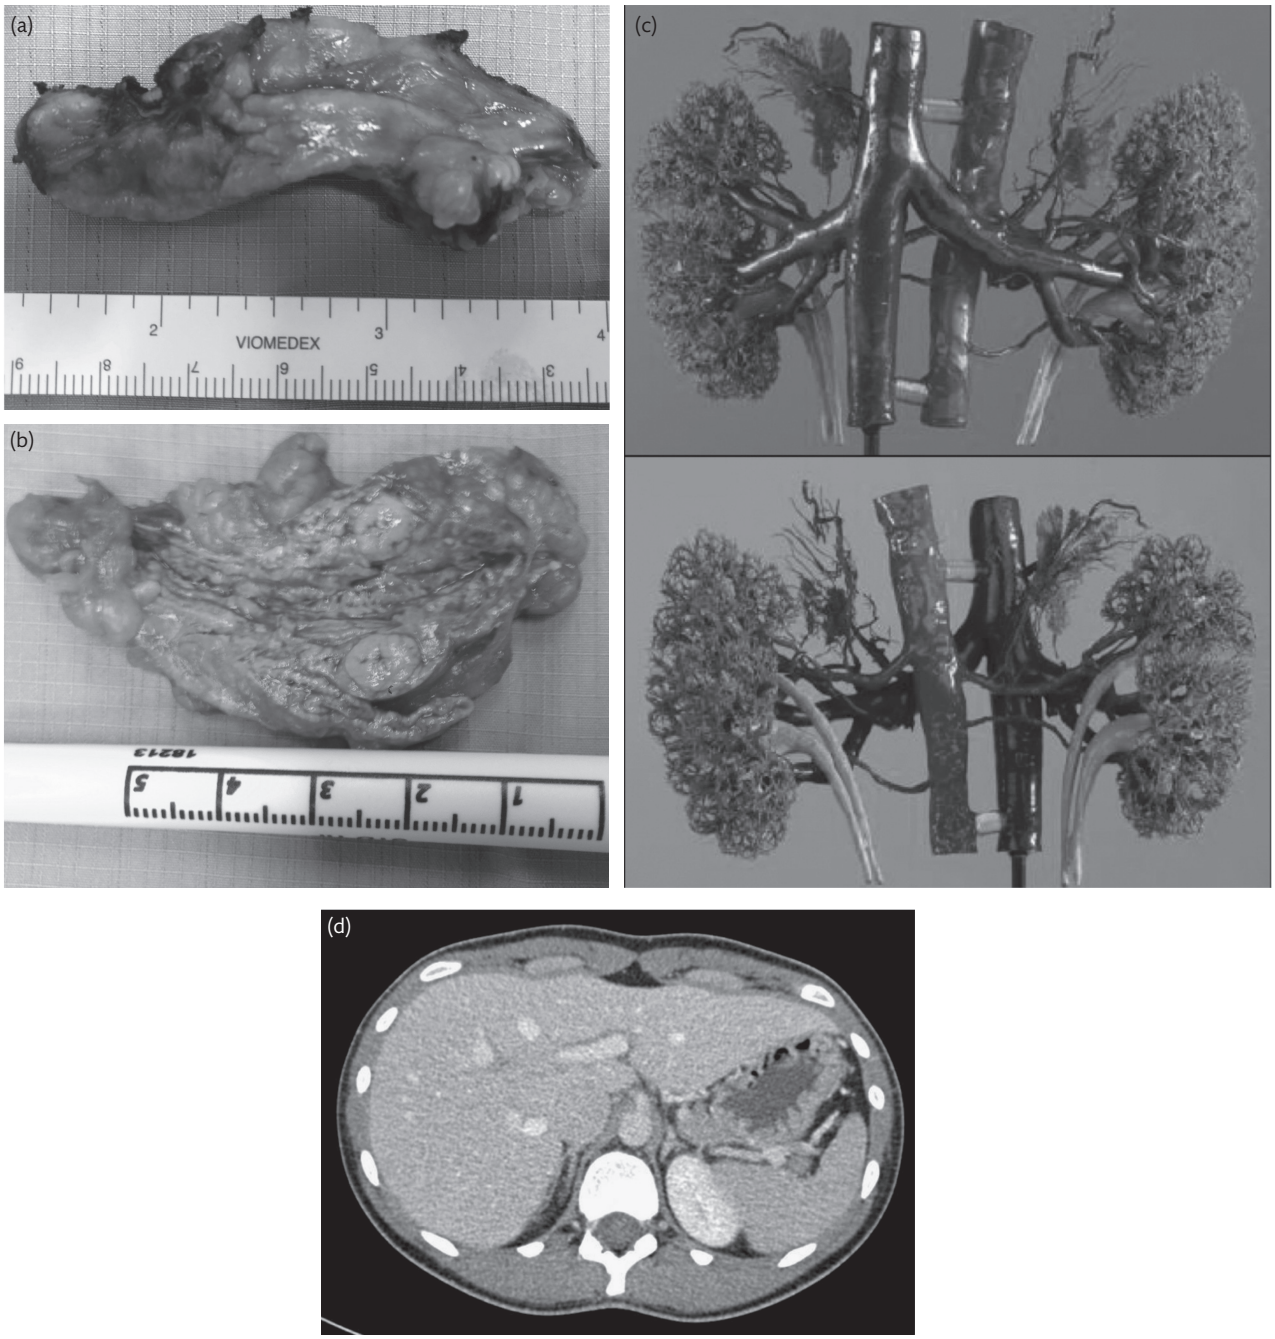

Figure 5.2.1 Macroscopic appearance of the adrenal gland.

surgeons. Bilateral adrenalectomy for familial cases with bilateral phaeochromocytomas tumours is uncommon (22 of 446 cases recorded on the BAETS database) and the *cortex sparing* or subtotal adrenalectomy is an option in such cases. Extra-adrenal chromaffin tumours (paragangliomas) represent approximately 10% of cases and may be treated in a similar fashion although their risk of malignancy is considerably higher than in adrenal phaeochromocytomas.

Cushing's syndrome or ACTH-independent hypercortisolism accounts for approximately 1 in 6 patients with endogenous hypercortisolism. Most patients with adrenal Cushing's syndrome have an underlying benign adrenocortical adenoma but the presence of mixed steroid secretion and combination with androgenization or feminization increase the index of suspicion for a functional adrenocortical carcinoma. Bilateral adrenalectomy is sometimes also considered in ACTH-independent hypercortisolism in patients with bilateral nodular hyperplasia or primary pigmented nodular adrenal disease (Figure 5.2.4). The role of surgery in patients with subclinical Cushing's syndrome is unclear and the current subject of a multicentre pan-European randomized controlled trial. The only randomized controlled trial (RCT) published to date was from a single centre and included only 45 patients recruited over a decade [4]. These results suggested that adrenalectomy resulted in significant improvement, not only of biochemical parameters, but also associated medical conditions such as diabetes, hypertension,

Figure 5.2.2 Anatomical view during a right laparoscopic adrenalectomy.

hyperlipidaemia, and obesity, which was supported by a systematic review [5] and a recent meta-analysis [6], albeit based on low-to-moderate quality evidence.

Cushing disease or **ACTH-dependent hypercortisolism secondary to unsuccessfully treated** pituitary tumours or paraneoplastic ectopic ACTH secretion may also require a bilateral adrenalectomy, especially when severe and when alternative treatment options have been attempted. The results of pituitary surgery have improved with centralization but medium-term recurrence remains a problem after trans-sphenoidal pituitary surgery even in the best hands [7, 8]. In both Cushing's syndrome and bilateral adrenalectomy for Cushing's disease, the hypercortisolaemia needs to be controlled for a prolonged preoperative period of at least one month to minimize the deleterious effects of excess glucocorticoids on perioperative morbidity. This can be achieved with metyrapone or ketoconazole. These patients also require steroid hormone replacement postoperatively since a cortisol secreting adrenal adenoma causes profound suppression of contralateral adrenal cortical activity as a result of inhibition of ACTH secretion, which may take up to 1 year to recover. The arrival of minimal access adrenal surgery has reduced the need for high perioperative steroid doses with physiological hydrocortisone replacement at 10/5/5 mg daily usually achieved within days. Patients that have undergone bilateral adrenal surgery require hydrocortisone as well as fludrocortisone for life.

Primary hyperaldosteronism is an increasingly frequent indication for adrenal surgery because of the realization that up to 10% of hypertensive patients may have primary hyperaldosteronism. Of these, up to 60% of have unilateral or dominant unilateral aldosterone hypersecretion that may benefit from adrenal surgery. Confirmation of lateralization still requires selective adrenal vein sampling (AVS) in all patients except younger patients with a clear adrenal adenoma. However, AVS requires interventional radiological skills that are not universally available; therefore, a reliable noninvasive lateralization imaging method would be welcome. It is hoped that the advent of ^{11}C-metomidate PET-CT or other modalities may fill this gap in the coming years, thus allowing more patients to benefit from intervention [9]. If patients are appropriately diagnosed with unilateral disease, 90% will benefit from the removal of the disease-causing adrenal, with as many as 50% coming off all hypertensive medication. The patients most likely to benefit are young and with a short history of hypertension and/or hypokalaemia. Another 40% achieve a reduction in their antihypertensive burden and lose the need for potassium supplements if present preoperatively [10].

Adrenal metastasectomy currently accounts for approximately one-tenth of the almost 800 adrenalectomies performed in England each year. Previously the presence of metastasis was treated as a terminal event but adrenal surgery is now considered a part of multimodality treatment in several malignancies. Lung cancer, colon cancer, renal cancer, melanoma are the most common causes of solitary adrenal metastases considered for surgery. Adrenal metastases should also be considered in the radiologically identified asymptomatic and non-functioning adrenal lesions in patients with a previous history of malignancy. Indeed, patients with a known history of cancer have a 50% chance of an incidentally discovered adrenal lesion being a metastasis, especially when the malignancy was recently diagnosed. The benefits of a solitary adrenal metastasectomy are contested and, therefore, decisions should be individualized in the context of risk-benefit analysis, especially if an R0 resection is unlikely [11].

A special category is represented by the unfortunately named adrenal 'incidentaloma'. Few diseases have been defined and named by their modality of discovery. **Adrenal incidentaloma** describes a clinically non-functioning adrenal lesion detected incidentally on imaging performed for reasons other than suspected adrenal disease. These lesions are usually solid and less frequently cystic and

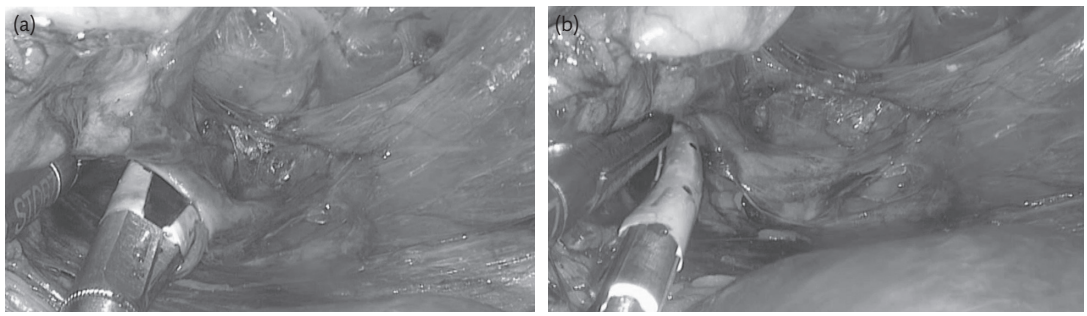

Figure 5.2.3 Anatomical view during a left retroperitoneoscopic adrenalectomy.

Figure 5.2.4 Bilateral pigmented micronodular hyperplasia.

Figure 5.2.5 Large ACC resected with spleen, kidney, tail of pancreas.

the vast majority are benign. Computed tomography can usually aid in the definition of these lesions as benign, especially when of low density, indicating a high fat content, or the less frequent but more challenging radiological diagnosis of ganglioneuroma. Once identified, adrenal masses require pragmatic management with a functional endocrinological assessment. Functional adrenal adenomas are treated like any other functional adenoma. Most adenomas discovered incidentally are non-functioning and their subsequent management depends on their malignancy risk, with surgery considered only when the balance of risk and benefit shifts towards the risk of missing a malignancy. Data based on removed tumours demonstrates that the size of an adrenal growth appears to correlate with the risk of malignancy—less than 2% in lesions smaller than 4 cm in size but a significant climb in risk as the diameter increases [12]. Surgery is indicated for indeterminate lesions larger than 4 cm in size, but improvements in imaging may desirably reduce the amount of diagnostic adrenal surgery. Low density (less than 10 Hounsfield units on unenhanced CT) and well-defined MRI lesions are likely to be benign. A negative FDG PET scan may also permit a conservative approach, especially when used in combination with conventional imaging, and can allow patient discharge. The role of a multidisciplinary team (MDT) discussion to avoid overtreatment in such patients cannot be overemphasized.

Adrenal tumours presenting at a young age, those with rapid enlargement at any age and/or a picture of mixed hormonal secretion with virilizing or feminizing features represent those with the highest risk of being malignant. Surgery is the mainstay of treatment and the only potential cure for **adrenocortical cancer (ACC)**. Even with optimal care, ACC has a dismal prognosis and an overall 5-year survival of less than 30%. Locally advanced tumours require an en-bloc compartmental resection that mandates an open adrenalectomy approach (Figure 5.2.5). The complex perioperative decisions necessary for such patients have recently been reviewed in guidelines written by a collaboration between the European Society of Endocrine Surgeons (ESES) and European Network for the Study of Adrenal Tumours (ENSAT) [13]. Surgery may be considered in patients with locally advanced or recurrent tumours as resection may improve control of hormonal symptoms; however, recurrence within 12 months of primary surgery usually indicates a rapidly growing tumour that might suggest consideration of medical rather than surgical options. Non-surgical options such as radiofrequency ablation for local recurrence have been used with success [14] and may also be considered.

Minimal access adrenalectomy, whether laparoscopic or retroperitoneoscopic, is now the gold standard for benign tumours so long as tumour size does not affect the technical feasibility for a safe resection. There is no universally accepted maximum size since this will depend on the patient body size and habitus, the perceived malignancy risk, and the experience of the operating surgeon. The gold standard of open adrenalectomy for malignant adrenal tumours has in recent years been challenged in smaller tumours without local invasion where malignancy is suspected but not certain. The same applies to adrenal metastases from primaries elsewhere.

Surgical Preparation

In addition to the specific preparation described earlier, all patients undergoing adrenalectomy require a thorough preoperative clinical assessment to determine comorbidities that may need optimization prior to surgery. Hypertension is common in all adrenal hyperfunction syndromes and diabetes and ischaemic heart disease are frequent sequelae of long-standing cortisol excess. A full blood count, renal and liver function tests, clotting screen, and blood grouping are performed. For patients with large tumours/phaeochromocytoma, critical care facilities, while not always required, should be available. Patients with cortisol excess tend to have visceral obesity and have skin and musculoskeletal fragility such that special care is required to avoid soft tissue injury pre-, intra- and postoperatively. Single dose antibiotic prophylaxis and prophylaxis against venous thromboembolism with low molecular weight heparin (especially in patients with hypercortisolism) is given unless specifically contraindicated.

Particular emphasis is placed on the perioperative care of phaeochromocytoma patients that require pharmacological controlled vasodilatation with restoration of blood volume with oral fluid intake. In the United Kingdom, this is most typically achieved with a non-competitive α-blocker such as phenoxybenzamine, with a β-blocker such as propranolol to control the tachycardia that may follow. Alternatives include a selective α1-blocker such as doxazosin to reduce the side effects such as nasal stuffiness, postural hypotension, and somnolence that may occur with phenoxybenzamine. Calcium channel blockade is another alternative that is widely used in mainland Europe. Whichever pharmacological approach is adopted, preoperative hospital admission for at least 24 hours prior to surgery to optimize blockade is preferable. Ideally patients can achieve a systolic blood pressure of ≤120 mmHg with a postural drop without a postural tachycardia. Despite optimal blockade some intraoperative cardiovascular instability is commonplace and requires expert anaesthesia. Postoperatively, close observation is also required since postoperative hypotension requiring treatment beyond i.v. fluids may be required. This should not continue beyond several hours and ongoing hypotension in an ideally prepared patient necessitates the investigation for other causes of the hypotension. Postoperative hypertension is rarer still, and may suggest undetected bilateral or extra-adrenal disease. Hypoglycaemia may occasionally occur in diabetics, as a result of the withdrawal of the anti-insulin effects of catecholamines.

The process of informed consent of patients undergoing adrenal surgery requires careful explanation so that the patient is fully aware of indications, benefits, consequences, and risks of surgery quantified based on the surgeon's personal practice. A clear explanation of the alternatives to surgery where present is mandatory.

Surgical Techniques

Open Anterior Approach

Minimal access approaches—laparoscopic and retroperitoneoscopic—to the adrenal are now the gold standard approach so a direct adoption of an open approach is reserved for those cases where minimal access surgery is inappropriate. Currently open adrenalectomy is reserved for tumours that are technically too large to remove safely via minimal access approaches and those with characteristics suggestive of ACC. There is no absolute size criterion for the technical limitation of a laparoscopic approach since this will depend also on the size of the patient, the consistence of the tumour and the experience of the surgeon.

The open transperitoneal approach invariably involves a long incision that may be a curved transverse incision ('roof top') or unilateral subcostal incision extended to the flank. Other options include a vertical usually midline incision.

Left adrenalectomy for large left adrenal tumours requires mobilization of parietal peritoneum lateral to the left colon, continued upward, dividing the splenorenal ligament up to the diaphragm to allow the medial rotation of the spleen, tail of the pancreas and colonic flexure (Figure 5.2.5). Alternative potential routes to consider are through the gastrocolic omentum, opening the lesser sac (without injury of the gastroepiploic arcade) or through the left mesocolon but these are options in smaller tumours only.

Right adrenalectomy requires the mobilization of the hepatic flexure of the colon and the right lobe of the liver is carefully retracted upward and rotated medially. This is achieved via division of the falciform ligament and the right triangular ligaments. The duodenum is mobilized in its second portion (Kocher's manoeuvre) by incision on its lateral avascular peritoneal reflection, allowing exposure of the inferior vena cava, the right adrenal gland, and the upper pole of the right kidney. The critical step is the clamping of the right adrenal vein because it is short, leaves the gland on its anterior aspect, and enters the vena cava on its posterior surface.

Complex multidisciplinary operations. Malignant tumours invading the IVC (Figure 5.2.6) create operative challenges that are beyond the scope of this chapter. There is concern that such patients could be labelled as inoperable in centres where there has been no previous experience with such operations and where a collaboration with cardiac or liver surgeons is not feasible.

Laparoscopic Transperitoneal Adrenalectomy

Right laparoscopic adrenalectomy is achieved in the same way as an open adrenalectomy but via four ports of 10 mm and 5 mm under the right rib cage. The hepatic mobilization is performed in the same way, but without the need for the division of the falciform ligament. The peritoneum is divided under the liver edge—the right coronary ligament—and along the inferior vena cava (IVC). A 'groove' is created between the IVC and the adrenal gland, which is mobilized laterally (Figure 5.2.2). In this groove, the right adrenal vein can be identified, clipped, and divided. The lower border of the adrenal gland is dissected off the renal pole.

Left laparoscopic adrenalectomy is performed usually with three ports inserted below the left rib cage. The descending colon is mobilized by dividing the peritoneal reflection and identifying the plane in front of the Gerota's fascia. This plane facilitates mobilization of the splenic flexure and the division of the spleno-colic ligament. The spleen is mobilized by dividing the lateral peritoneal reflection with care shown to avoid injury to the diaphragm or the short gastric vessels, which can be encountered at the superior pole of the spleen. Gerota's fascia is incised vertically and the dissection aims to create a 'groove' with the spleen and the tail of the pancreas medially and with the adrenal and the perinephric fat laterally. A small left adrenal gland might not become apparent until the posterior aspect of the kidney is demonstrated.

Retroperitoneoscopic Adrenalectomy

This technique allows direct access to the adrenal gland via the retroperitoneum. The patient is placed in a prone position with hip flexion. Three ports are inserted using the twelfth rib as a landmark. A space is created using high-pressure insufflation of 20 mmHg (or more). The upper pole of the kidney is identified, and the anterior aspect of the kidney is mobilized. On the left the dissection continues towards the left renal vein to allow the identification of the left adrenal vein and from this landmark the dissection continues upwards to mobilize the entire adrenal gland (Figure 5.2.3). On the right the aim is to demonstrate the IVC and to identify the short right adrenal vein. Retroperitoneoscopic adrenalectomy unquestionably presents a challenging learning curve due to the need to familiarize with

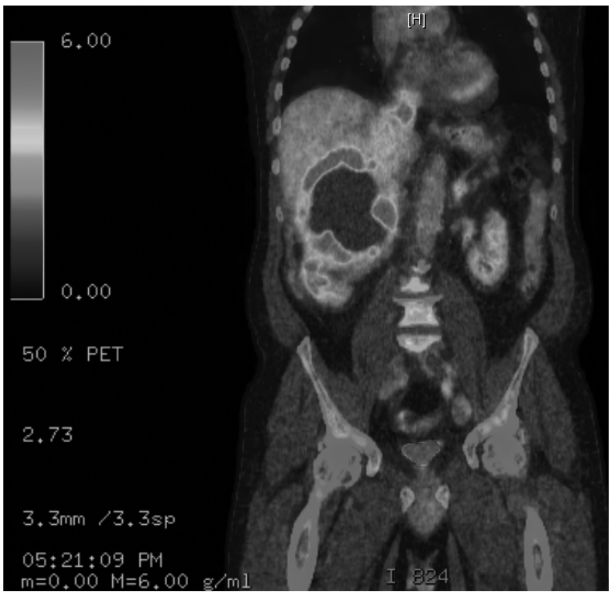

Figure 5.2.6 PET scan of patient with adrenocortical cancer extending to the IVC and the right atrium.

anatomical relationships and landmarks seen from another perspective due to the approach from the posterior abdominal wall.

Summary

Adrenal surgery is required for the treatment for syndromes of hormonal excess arising from the adrenal gland and adrenal tumours or neoplasms with malignant potential. A multidisciplinary approach with protocolled perioperative planning, and an experienced surgeon are essential for good outcomes. Most of the controversies in adrenal surgery have been resolved but some areas remain controversial. These include:

- the appropriateness of laparoscopic surgery when malignancy is likely (but without adrenal malignancy)
- the role of surgery in subclinical Cushing's syndrome
- the use of cortical sparing/subtotal adrenalectomy
- the role of adrenalectomy in patients with adrenal metastasis
- the centralization of services based on the volume-outcome data

The rarity of adrenal disease, the heterogeneity of clinical conditions, and the multifactorial influences on outcome makes it unlikely that surgical decisions can be based on evidence from randomized trials. The best available quality data from observational series and the insight and judgement of experienced endocrine surgeons and multidisciplinary working represents the best acceptable alternative.

5.3

Adrenal Incidentaloma

Irina Bancos, Massimo Terzolo, and Wiebke Arlt

Introduction

Adrenal incidentalomas are adrenal tumours discovered incidentally on around 5% of cross-sectional imaging studies performed for indications unrelated to adrenal disease [1, 2]. The incidental discovery of an adrenal mass has evolved into a common problem, because of the increasingly widespread use of cross-sectional imaging in current clinical practice. Over the last two decades, the number of abdominal computed tomography (CT) and magnetic resonance imaging (MRI) imaging studies performed for various reasons quadrupled, and increasing resolution of these imaging studies allows for detection of ever smaller tumours, explaining the growing numbers of patients with adrenal incidentaloma [3]. Any patient with a newly detected adrenal mass requires further evaluation to assess: (1) whether the adrenal mass is functioning (i.e. overproducing adrenal hormones), and (2) whether the adrenal mass is malignant or benign.

Epidemiology

In autopsy series, the mean prevalence of clinically inapparent adrenal masses is around 2.0%, ranging from 1.0% to 8.7% [4]. This variability reflects different definitions and also the difficulty in distinguishing larger nodules within adrenal hyperplasia from distinct adrenocortical adenomas. Large radiological series reported a 4.4–5.0% prevalence of adrenal tumours [1, 2]. In patients with a history of extra-adrenal malignancy the prevalence of adrenal tumours can be as high as 50–75%, as the adrenal gland is frequently targeted by metastatic spread [5, 6]. Adrenal metastases originate most frequently from lung cancer, kidney cancer, gastrointestinal cancer, melanoma, and lymphoma [7–10].

Adrenal tumours demonstrate different pathology distribution in the population dependent on the patient's age and sex. In clinical reports, adrenal incidentalomas show a peak incidence between 50 and 60 years of age [4]. This pattern could merely reflect a higher number of diagnostic procedures in these age decades or be the consequence of the ageing process of the adrenal glands, which may lead to increased formation of cortical nodules secondary to vascular changes [4]. The frequency of adrenal incidentalomas is very low in childhood and adolescence (0.3–0.4% of all neoplasms in children) [11].

While previous studies reported a higher proportion of women with adrenal tumours, possibly explained by a referral bias (i.e. more imaging studies are done in women due to higher prevalence of biliary disease), more recent studies describe a roughly equal sex distribution in patients with adrenal tumours overall, though higher in certain adrenal tumour subtypes (such as female predominance in patients with adrenocortical carcinoma and male predominance in patients with other adrenal malignancies) [1, 4, 12, 13]. Adrenocortical adenomas are more frequent on the left side and can be bilateral in 14–18% of cases, while no significant lateralization is observed in pheochromocytomas, adrenocortical carcinomas and other benign and malignant adrenal tumours [12, 14]. Adrenal metastases may affect both adrenal glands in 22–42% of patients [8, 10, 12], however bilateral adrenal involvement is less frequent in patients with pheochromocytoma (8–10%), other benign tumours (10%), and almost never observed in patients with adrenocortical carcinomas [12, 15].

Aetiology

Aetiology of adrenal incidentalomas includes both benign and malignant lesions. However, an adrenal incidentaloma is most likely benign, representing an adrenal adenoma in approximately 80–90% of cases (of which cortisol-secreting adenomas are seen in 1.0–2.9%

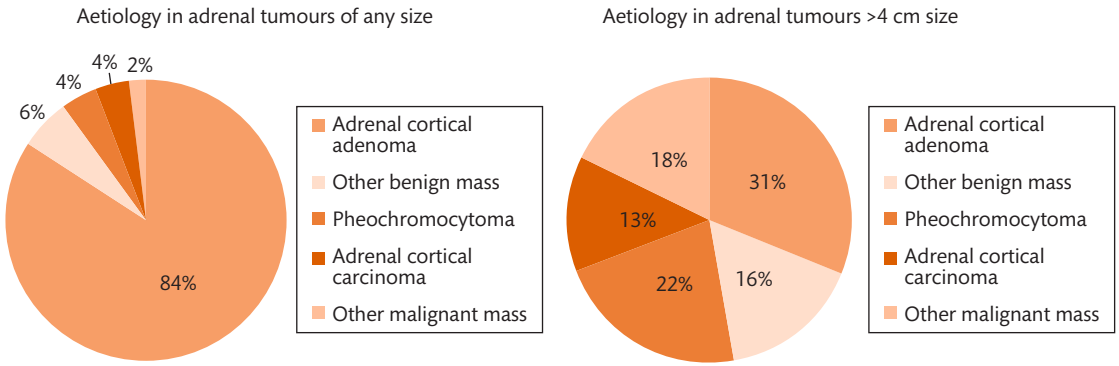

Figure 5.3.1 Distribution of diagnoses among patients with adrenal tumours. (Adapted from [2, 12, 16, 17, 21, 22]).

and aldosterone-secreting adenomas in 1.6–2.3%) [16, 17]. The frequency of pheochromocytoma is estimated to be 1.5–23%, that of adrenocortical carcinoma varies from 1.2% to 11% [16, 17]. It is important to note that despite the fact that the majority of adrenal incidentalomas are adrenocortical adenomas, 40–60% of adrenocortical carcinomas, pheochromocytomas, and adenomas with biochemically overt hormonal excess are diagnosed incidentally [12, 15]. The risk of an adrenal incidentaloma being an adrenal cancer is proportional to tumour size, especially in patients with adrenocortical lesions, as most adrenocortical carcinomas are larger than 4–6 cm (median size 10 cm), while most adrenocortical adenomas are smaller than 4 cm (median size of 1–3 cm) [2, 12, 14, 17, 18]. Other benign causes of adrenal incidentaloma are adrenal cysts, ganglioneuromas, myelolipomas, haematomas, while malignant causes include metastases of other malignancies, sarcomas, and primary adrenal lymphomas. Certain genetic syndromes predispose to an increased likelihood of developing an adrenal mass. Pheochromocytomas are common in patients with multiple endocrine neoplasia type 2, Von Hippel Lindau syndrome, Neurofibromatosis type 1, and Succinate dehydrogenase mutations [15, 19, 20] (see Chapter 5.5.1). Moreover, adrenal lesions are found in inherited endocrine cancer syndromes (McCune–Albright syndrome, multiple endocrine neoplasia type 1), and in suboptimally controlled congenital adrenal hyperplasia.

In a multi-institutional, retrospective survey performed in Italy including 1004 patients, of whom 380 underwent surgery, the most frequent pathological diagnoses were adrenocortical adenoma (52%), adrenocortical carcinoma (12%), phaeochromocytoma (11%), and myelolipoma (8%) (6). However, in more recent cohorts, lower prevalence of malignancy and pheochromocytoma was noted [12, 21] (Figure 5.3.1). Distribution of adrenal pathologies differs based on tumour size. For example, in a large retrospective single centre consecutive series of 705 patients with large adrenal tumours (>4 cm), 31% were malignant tumours (ACC—18%, other malignant tumours—13%), 22% pheochromocytomas, and 47% benign adrenal tumours [12].

Differential Diagnosis

The differential diagnosis of adrenal masses should take several key factors in consideration, including demographics, mode of discovery, clinical, and biochemical presentation, presence of any genetic predisposition syndrome, as well as imaging characteristics (Table 5.3.2). While prevalence of adrenal tumours in children is <0.5% [11, 17], risk of malignancy is high, with up to 60–80% represented by adrenocortical carcinomas [11]. Overall, adrenocortical carcinoma represents 1.3% of all malignancies in patients younger than 20 years of age [4]. Adrenal tumours discovered incidentally are less likely to be malignant or hormonally active in comparison to patients presenting with symptoms suggestive of hormone excess or undergoing imaging for the purposes of cancer staging [2, 8, 12]. However, malignant tumours and pheochromocytomas are not infrequently discovered incidentally, as was reported in 42–54% of large tumours, reflecting the non-specific of symptoms and/or subclinical presentation of adrenal hormonal excess [12]. See Table 5.3.1 and Figure 5.3.2.

Risk of malignancy increases with the size of the adrenal mass [12, 22–24]. In a multicentre study of 1096 patient with incidentally discovered adrenal tumours, sensitivity of tumour size cut-off of >4 cm to diagnose adrenocortical carcinoma was 93%, though specificity was only 42%. A higher cut-off of 6 cm improved specificity to 71–73%, but at a cost of lower sensitivity of 61–74% [12, 24]. In a large retrospective cohort of patient with adrenal tumours >4 cm, prevalence of malignancy was reported to be 31% (18% adrenocortical carcinoma and 13% other malignant tumours). Similarly, 20% of patients with adrenal tumours >4 cm were found to have adrenocortical carcinomas in a prospective cohort of patients [21].

Radiological Assessment

In addition to tumour size, imaging characteristics are helpful in diagnosis of adrenal malignancy. Unenhanced CT is the most commonly used in evaluation of adrenal tumours. Unenhanced attenuation values of less than 10 Hounsfield Units (HU) indicates a lipid-rich benign adrenocortical adenoma, while HU values >10HU, and especially >20HU are suspicious of malignancy. HU values can only be determined in homogeneous tumours, thus, heterogeneous tumour appearance on CT also has to be considered suspicious. CT washout studies do not have a sufficient evidence base for reliable use in clinical practice, as demonstrated in a recent meta-analysis [13]. MRI also evaluates tumour fat content, similarly to CT, where the loss of signal intensity between in-phase

Table 5.3.1 Key points on the differential diagnosis of adrenal incidentalomas: consider history, demographics, clinical presentation, adrenal mass imaging phenotype, and any presence of genetic predisposition syndromes

• History of extra-adrenal malignancy/active extra-adrenal malignancy	→ higher likelihood of adrenal metastasis
• Genetic syndromes	→ higher likelihood of pheochromocytoma (e.g. VHL, NF-1, MEN, SDH) or adrenocortical carcinoma (e.g. TP53, Lynch syndrome)
• Young age	→ higher likelihood of adrenocortical carcinoma
• Signs and symptoms of adrenal hormonal excess	→ adrenocortical adenoma, carcinoma, or pheochromocytoma, based on type of hormonal excess
• Bilateral adrenal masses	→ higher likelihood of bilateral metastases, bilateral adrenocortical adenomas, macronodular hyperplasia, or bilateral pheochromocytomas → extremely unlikely to be adrenocortical carcinoma
• Large tumour size (>4–6 cm)	→ higher likelihood of adrenocortical carcinoma, sarcoma, lymphoma, pheochromocytoma, as well as other benign tumours, such as myelolipomas
• Imaging characteristics: unenhanced CT attenuation <10 HU, or present chemical shift on MRI	→ extremely unlikely to be pheochromocytoma, adrenocortical carcinoma or any kind of malignancy, very likely to be lipid-rich adenoma or myelolipoma,
• Imaging characteristics: unenhanced CT attenuation 10–20 HU	→ low likelihood of malignancy and pheochromocytoma, likely a cortical adenoma
• Imaging characteristics: unenhanced CT attenuation >20 HU or absent chemical shift on MRI	→ higher likelihood of pheochromocytoma, adrenocortical carcinoma or other malignancy

and out-of-phase T2-weighted sequences (chemical shift analysis; also see Chapter 5.1) indicates a lipid-rich adrenal tumour. If an adrenal mass is considered indeterminate on CT or MRI, Fluorodeoxyglucose positron emission tomography (FDG-PET) can be considered in patients with and without a history of extra-adrenal malignancy. FDG-PET/CT offers superior specificity (84% for an adrenal-liver-ratio (ALR) >1.8 of the maximum standardized uptake value, SUVmax) for diagnosis of malignant adrenal mass [25–27]; however, at present, this is based on limited data. Additional imaging features such as irregular borders, heterogeneity of the adrenal mass, signs of local invasion, or evidence of rapid growth indicate underlying adrenal malignancy. See Table 5.3.3.

Adrenal Biopsy

Guidelines on the management of adrenal incidentalomas developed by the European Society of Endocrinology (ESE) and the

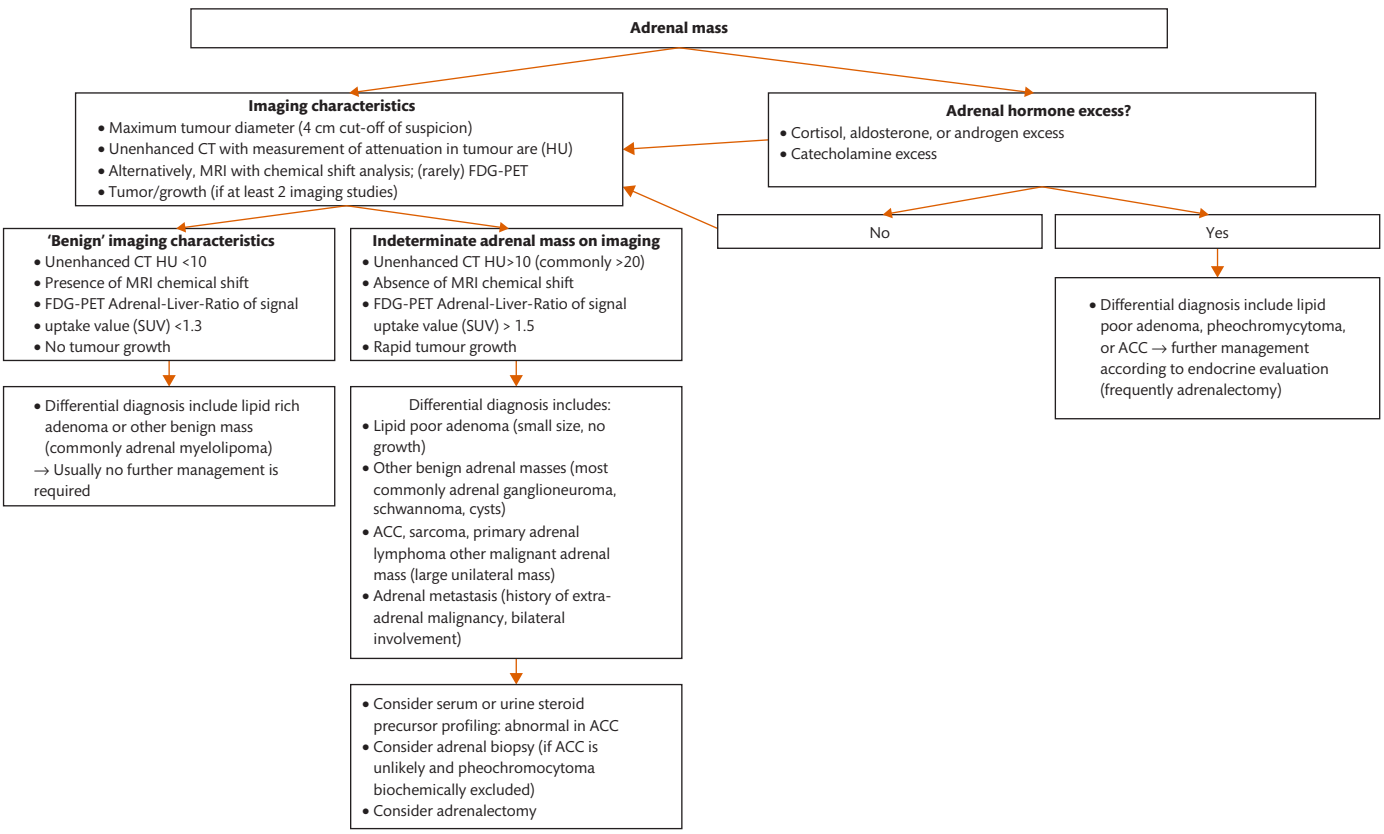

Figure 5.3.2 CT images of (a) adrenocortical carcinoma, (b) phaeochromocytoma, and (c) metastases from extra-adrenal cancer.

Table 5.3.2 Differential diagnosis of adrenal tumours

	Adrenocortical adenoma	Other benign tumour	Pheochromocytoma	Adrenocortical carcinoma	Other malignant tumours
Age, median, years	50–60	Wide spectrum	Wide spectrum	40–50	60–70
Women, %	50–60%	50%	50%	65%	35%
Genetic predisposition syndrome	Very rare	Very rare	Up to 40%	Rare	Very rare
Incidental mode of discovery	85%	90%	50–60%	40%	20–50%
Tumour size	Usually <4 cm	Wide spectrum	Usually >4 cm	Usually >6 cm	Wide spectrum
Unenhanced attenuation	Most <20 HU	Most <20 HU	>20 HU	>20 HU	>20 HU
Bilateral	15–20%	10%	10%	<1%	20–42%
Hormone excess	10–50%	0%	>95%	50%	0%

(Adapted from [7, 8, 10, 11, 12, 15–17, 23–25]).

European Network for the Study of Adrenal Tumors (ENSAT) in 2016 recommend adrenal biopsy only for patients with an indeterminate adrenal mass and a high suspicion for metastasis, infection, or another infiltrative process [16, 28]. The adrenal glands are common sites of metastases, mainly from lung, kidney, gastrointestinal, breast cancers, but also lymphomas and melanomas [10, 29]. While only 2–13% of adrenal incidentalomas represent metastases, the risk is 28–75% when patients have a history of and/or active extra-adrenal malignancy [5, 6, 12, 30–32]. In situations where an adrenal mass remains indeterminate after initial imaging, adrenal biopsy can be rarely considered for diagnostic purposes, especially in patients at high risk for metastatic disease [13, 33] (i.e. patients who underwent imaging as part of cancer staging or follow-up monitoring).

Adrenal biopsy is an invasive procedure with a 5% non-diagnostic rate. In addition, it is important to consider the risk of adrenal biopsy complications that was reported in 0 to 13%, likely dependent on location, technique, and experience [7–9, 34].

It is mandatory to exclude pheochromocytoma before proceeding with adrenal biopsy, even in the presence of extra-adrenal malignancy. Pheochromocytomas present with indeterminate imaging characteristics, similar to malignant adrenal tumours [23, 35, 36] and can present incidentally, without symptoms suggestive of catecholamine excess [15, 37]. Biopsy of pheochromocytoma may lead to hypertensive crisis, haemorrhage, and even death [37–40].

Guidelines do not recommend adrenal biopsy for suspected adrenocortical carcinoma in a patient with a unilateral, large adrenal mass, especially when evidence of adrenal hyperfunction is present.

Table 5.3.3 Diagnostic accuracy of commonly employed adrenal imaging studies

Diagnostic test	Sensitivity	Specificity
Tumour size >4 cm	80–93%	34–61%
Tumour size >6 cm	61–74%	71–73%
Unenhanced CT (HU >10)	93–100%	33–72%
Unenhanced CT (HU >20)	96–98%	64–70%
MRI, loss of signal intensity	86–99%	85–93%
PET ALR (adrenal to liver ratio) SUV max	87–100%	84–96%
PET SUV max	87–93%	69–73%

(Adapted from [7, 12, 13, 16, 26]).

There are several reasons for this recommendation, including suboptimal diagnostic performance in adrenocortical tumours (with pathologists often struggling to make a diagnosis of ACC on the whole tumour specimen) and risk of the needle track tumour dissemination [15, 33, 41–44]. Biopsy performs best in confirming metastasis of an extra-adrenal tumour, in particular if histology of the primary is available.

Hormonal Assessment

Around 15% of adrenal tumours present with adrenal hormone excess including clinically pheochromocytoma, overt Cushing syndrome, primary hyperaldosteronism and, uncommonly, adrenal androgen excess [4, 24]. Every patient with adrenal mass should undergo clinical and biochemical assessment for adrenal hormone excess (Table 5.3.4). Independent of clinical presentation, work-up should include diagnostic tests for Cushing syndrome and pheochromocytoma, while work-up for primary hyperaldosteronism should be performed in all patients with hypertension, whether hypokalaemia is present or not. In addition, presentation with hirsutism or virilization in a woman with adrenal mass is suspicious for adrenocortical carcinoma, and should prompt work-up for androgen excess. In very rare instances, isolated adrenal androgen excess can be seen in the context of a benign adrenal adenoma, but in most cases an adrenocortical carcinoma is the root cause, which can be taken as proven if androgen excess is combined with overproduction of other steroid hormones, such as cortisol, or also aldosterone or oestradiol.

Table 5.3.4 Initial work-up for adrenal hormone excess

Type of hormone excess	Initial diagnostic work-up
Cortisol excess (Cushing syndrome or MACS)	1 mg dexamethasone suppression test, consider 24 h urine cortisol, plasma ACTH, midnight serum, or salivary cortisol
Primary aldosteronism (in patients with hypertension)	Paired plasma renin and plasma aldosterone, serum potassium
Catecholamine excess	Plasma or 24 h urine metanephrines
Androgen excess (in patients with hirsutism or virilization)	Serum DHEAS, androstenedione, testosterone

Steroid profiling has recently emerged as a promising tool for differential diagnosis of adrenocortical carcinoma [21, 45]. In a proof-of-concept study published in 2011, authors reported on urinary steroid profiling by gas chromatography-mass spectrometry (GC-MS) combined with computational data analysis utilizing a machine learning-based approach [46]. This study revealed a distinct steroid pattern that diagnosed an adrenocortical carcinoma with 90% sensitivity and specificity. The three most informative steroid metabolites included the glucocorticoid precursor metabolite tetrahydro-11-deoxycortisol (THS) derived from 11-deoxycortisol, as well as pregnanediol (5-PD) and pregnanetriol (5-PT), derived from pregnenolone and 17-hydroxypregnenolone, respectively. Recently, a large prospective international multicentre test validation study (EURINE-ACT) carried out within the European Network for the Study of Adrenal Tumours (ENSAT) has been successfully completed and demonstrated that urine steroid metabolomics has superior accuracy to commonly used imaging tests in the detection of adrenocortical carcinoma [45]. Once introduced into clinical practice, steroid profiling will allow a noninvasive diagnosis of adrenocortical carcinoma in patients with indeterminate adrenal masses.

Mild Autonomous Cortisol Secretion (Previously Known as Subclinical Cushing's Syndrome)

Mild autonomous cortisol secretion (MACS, or also mild autonomous cortisol excess, MACE) is a syndrome characterized by a spectrum of hypothalamic-pituitary-adrenal axis abnormalities in a patient with adrenal mass presenting without clinically overt features of Cushing's syndrome [16]. The diagnosis of MACS represents a challenge due to limitations of the currently used diagnostic tests, differences in the definitions, and unclear clinical implications of MACS. Multiple definitions have been proposed for diagnosis of MACS [47]. These include dexamethasone suppression tests, 24 h urine cortisol measurements, midnight salivary and serum cortisol measurements, morning and afternoon cortisol measurements to assess cortisol secretory circadian rhythm, measurements of adrenocorticotrophic hormone (ACTH) (corticotropin), and dehydroepiandrosterone sulphate (DHEAS). The recent ESE-ENSAT guidelines on the management of adrenal incidentalomas suggested using the 1 mg overnight dexamethasone suppression test as a first step, with 'possible' MACS diagnosed when post-dexamethasone serum cortisol is >50 nmol/L and 'confirmed' MACS if cortisol is >140 nmol/L [16], in the absence of clinically overt signs of Cushing's syndrome. Guidelines further suggest that low or suppressed plasma ACTH and DHEAS concentrations can help confirm MACS [16, 48].

The reported prevalence of MACS among patients with adrenal incidentaloma ranges from 5–50% [16, 17, 49, 50]. This heterogeneity is explained, at least in part, by the different work-up protocols and variable criteria used to define MACS as well as in different inclusion criteria and probably referral bias of the reported series [7].

MACS very rarely progresses towards overt Cushing syndrome, however, patients with MACS present with increased prevalence of cardiovascular comorbidities, cardiovascular events, osteopaenia, osteoporosis, and fractures, as well as increased mortality [16, 25, 47, 51–57]. Rates of hypertension, prediabetes, or diabetes mellitus type 2, dyslipidaemia, obesity, and fractures have been reported to be higher than in controls or patients with non-functioning adrenal tumours [24, 47, 58]. Limited data on the effectiveness of adrenalectomy suggests that this leads to improvement of cardiovascular risk factors and decrease in fractures in patients with MACS, especially when the degree of cortisol abnormality is higher [25, 48, 57]. However, identifying patients most likely to benefit is still challenging and many patients with MACS are age-advanced and have multiple comorbidities, which increases the potential risk of surgery. At present, approach to patients with MACS remains both a diagnostic and management challenge. Diagnostic criteria for MACS are summarized in **Box 5.3.1**, and the major areas of uncertainty are summarized in **Box 5.3.2**.

Box 5.3.1 Diagnostic criteria for MACS

1. Incidentally discovered adrenocortical adenoma
2. Lack of features suggestive of overt Cushing syndrome (moon facies, proximal myopathy, striae, abdominal fat redistribution)
3. Abnormal cortisol after 1 mg overnight dexamethasone suppression test (>50 nmol/L), low ACTH, and DHEAS

Natural History and Management

Management of adrenal incidentaloma is a complex decision-making process, which involves considering a range of possible diagnoses as opposed to respective natural history, and weighing the risks and benefits of interventions in light of the patient's age and the tumour size and imaging characteristics. Surgery is the appropriate therapeutic measure for ACC, pheochromocytoma, and other functional adrenal tumours causing overt glucocorticoid, mineralocorticoid, or adrenal sex hormone excess; treatment of metastasis depends on individual clinical circumstances and the nature of the primary extra-adrenal cancer.

The available follow-up data of patients with clinically inapparent adrenal mass suggests that the large majority of adrenal lesions classified as benign at diagnosis remain stable over time [16, 24, 25]. The risk of malignant transformation at long-term follow-up is very low, estimated at 0 to <1:1000 incidentalomas [16, 24, 25]. Tumour growth or decrease in size over time may occur in benign tumours (around 5%) [4, 16, 24, 25]. Guidelines for management of adrenal incidentaloma suggest against imaging follow-up for adrenal tumours <4 cm and clear benign imaging characteristics, while in patient with an indeterminate adrenal mass, options include (1) adrenalectomy or (2) either another imaging by a different modality or repeat imaging after 6–12 months [16]. Similarly, guidelines recommend against repeated hormonal work-up in patients with normal initial evaluation unless new signs suggestive

Box 5.3.2 Unsolved issues with subclinical Cushing's syndrome

- Individualized diagnostic criteria to diagnose clinically relevant MACS?
- Identification of patients at risk of developing comorbidities related to MACS?
- Identification of patients with MACS to benefit from adrenalectomy prior to development of MACS-related comorbidities

of adrenal hormonal excess develop [16]. Management of patients with MACS requires an individual approach based on the degree of hypercortisolism and presence of comorbidities, with options including adrenalectomy or annual clinical reassessment for cortisol excess [16], with medical strategies for reducing cortisol excess currently undergoing evaluation by research studies.

Adrenocortical Cancer

Anne Jouinot, Rossella Libè, and Jérôme Bertherat

Essential Information

Adrenocortical cancer (ACC) is a rare tumour with an overall poor prognosis, with a 5-year survival rate lower than 35% in most series. By contrast, adrenocortical tumours (especially non-hypersecreting benign adenomas) are frequent, emphasizing the importance of a correct diagnosis of malignancy in incidentally discovered adrenal masses. Recent advances in the molecular genetics of adrenal tumours demonstrate the importance of genomic alterations in ACC tumorigenesis. Integrated genomic studies identify different subgroups of ACC, characterized by distinct genomic alterations, including specific patterns of gene expression, chromosome alterations, and DNA methylation profiles, as well as somatic mutations in *p53* (TP53, CDKN2A) or *ß-catenin* (CTNNB1, ZNRF3) pathways. These genomic subgroups are remarkably associated with patient outcomes. Correct management of ACC requires a multidisciplinary specialist team. The diagnosis and extensive work-up of a malignant adrenocortical tumour is an important step, and relies on careful investigations of clinical, hormonal, and imaging features before surgery, and precise pathological examination after tumour removal. Most tumours appear steroid-secreting after careful hormonal investigations. Mixed steroid excess, most frequently the cosecretion of androgens and cortisol, is highly suggestive of a malignant tumour. ACC are most often large, heterogeneous tumours with a low lipid content on computed tomography (CT) or magnetic resonance imaging (MRI). Imaging investigations are also important for preoperative tumour staging and follow-up. ^{18}F-fluorodeoxyglucose positron emission tomography ((18)-FDG-PET) is increasingly used for that purpose. Stage 1 and 2 tumours are limited to the adrenal and present a better prognosis. Histopathological analysis with the use of the Weiss score is important for ACC diagnosis, especially in such localized tumours. Ki-67 immunostaining is useful for ACC prognostication. Stage 3 and 4 tumours extend locally or present with distant metastases, mainly liver, lung, lymph nodes, and bone. These advanced tumours are most often associated with a poor survival. Surgery by an expert surgeon aiming at complete tumour removal and avoiding tumour spillage is the best initial treatment, when achievable. In case of tumour recurrence or in metastasized ACC, medical therapy with the adrenolytic drug mitotane is used, alone or in combination with etoposide-doxorubicin-platinum cytotoxic chemotherapy. Mitotane should be considered as adjuvant therapy after complete removal of a tumour with a significant risk of recurrence. It is expected that a better understanding of the pathophysiology of ACC and the use of molecular tools for tumour classification will beneficially impact patient management in the near future. Similarly, international efforts in therapeutic trials will help to better define the respective roles of the various medical therapies currently available and facilitate the development of new targeted therapies. For this goal; as this is often the case for aggressive rare diseases, patient management in coordination with expert centres and networks of clinical research are important drivers of progress.

Introduction

Adrenocortical cancer (ACC) is among the most aggressive endocrine tumours with an overall poor prognosis. Morbidity and mortality can be secondary to tumour-related steroid hormone excess and/or tumour growth and metastases. This potentially poor outcome explains why the early detection of adrenocortical malignancy is paramount for the investigation of adrenal masses, alongside exclusion of hormone excess. The diagnosis of adrenocortical carcinoma relies on careful investigations of clinical, endocrine, and imaging features before surgery, and histopathological examination after tumour removal. Appropriate management and follow-up by an expert multidisciplinary team is critical to improve prognosis and drive progress for this rare cancer.

Pathogenesis and Genetics

Germline Alterations: ACC and Hereditary Tumour Syndromes

ACC can occur in the context of several tumour susceptibility syndromes (Table 5.4.1).

Historically, ACC has been first described as part of Li–Fraumeni syndrome in 1969 [1], which was later linked to germline *TP53* mutations [2]. This syndrome displays dominant inheritance and confers susceptibility to breast cancer, soft-tissue sarcoma, brain tumours, osteosarcoma, leukaemia, and ACC. Germline mutations in *TP53* have been observed in 50–80% of children with apparently sporadic ACC in North America and Europe. In Southern Brazil, a founder germline mutation, R337H in exon 10, is observed in almost all paediatric cases [3]. Germline *TP53* mutations are found much more rarely in adult ACC (<5%).

Another historic germline alteration is observed in the imprinted 11p15 region, carrying *IGF2*. This locus is altered most often through uniparental disomy, with loss of the maternal allele, responsible for *IGF2* overexpression, implicated in Beckwith–Wiedemann syndrome [4, 5]. This overgrowth disorder is characterized by macrosomia, macroglossia, organomegaly and developmental abnormalities (in particular abdominal wall defects with exomphalos), nephroblastoma, ACC, neuroblastoma, and hepatoblastoma.

More recently, ACC was described as part of other tumour susceptibility syndromes, such as Lynch syndrome and multiple endocrine neoplasia type 1 (MEN1). The *MEN1* gene, located at the 11q13 locus, is a tumour suppressor gene. A heterozygous inactivating germline mutation of *MEN1* is found in about 90% of families affected by multiple endocrine neoplasia type 1. The principal clinical features of this autosomal dominant syndrome include parathyroid (95%), endocrine pancreas (45%) and pituitary (45%) tumours and thymic carcinoids. Benign adrenocortical tumours and/or hyperplasia are common (25–40%), whereas ACC is rarely observed in MEN1 patients (<2%) [6]. Lynch syndrome is dominantly inherited and due to germline mutations in DNA mismatch repair genes *MLH1, MSH2, MSH6*, and *PMS2*. This syndrome typically confers an increased risk for colorectal, endometrial, small bowel, and upper tract urothelial cancers (Amsterdam Criteria), but also for sebaceous tumours, ovarian and pancreatic cancers, and ACC. Lynch syndrome accounts for up to 5% of ACC cases [7].

ACC has been described in several other hereditary tumour syndromes, including *APC, NF1, PRKAR1A, FLCN*, or *BRCA2* germline mutations [8].

Overall, germline predisposition affects 10% of adult ACC patients. Therefore, patient with newly diagnosed ACC should be considered for a genetic evaluation. In the absence of obvious inherited genetic syndrome, a next generation sequencing panel including *MSH2, MSH6, PMS2, MLH1, EPCAM, MEN1, APC*, and *TP53* could be proposed [8].

Somatic Alterations: IGF2, TP53, and Wnt/β-Catenin Pathways

In various cancers, the study of chromosomal rearrangement led to the identification of the oncogenes or tumour suppressor genes

Table 5.4.1 Main genetic predispositions to adrenocortical tumours and the molecular genetics of sporadic ACC. The table describes the main hereditary syndromes associated with adrenocortical tumours for which the locus and/or genes have been identified at the germline level. The alterations of these genes and chromosomal regions as somatic defect observed on tumour DNA of sporadic tumours are listed.

Genetic hereditary syndrome and MIM reference number	Genes, chromosomal localization, and type of defect	Tumours and non-tumoural manifestations observed in the hereditary syndrome	Somatic genetic defect observed in sporadic adrenocortical tumours
Li–Fraumeni syndrome (MIM 151623)	*TP53* (17p13) Inactivative heterozygous mutations of the tumour suppressor gene *TP53*	Soft-tissue sarcoma, breast cancers, brain tumours, leukaemia, ACC	*TP53* somatic mutations in sporadic ACC (30%) 17p13 LOH in sporadic ACC (>80%)
Multiple endocrine neoplasia type 1 (MIM 131100)	*MEN1* (11q13) Inactivative heterozygous mutations of the tumour suppressor gene *Menin*	Parathyroid, pituitary, pancreas tumours, adrenal cortex (25–40%), among which are adrenocortical adenomas, adrenocortical hyperplasia, and rare ACC	Very rare somatic *menin* gene mutations in sporadic adrenocortical tumours Frequent 11q13 LOH in ACC (90%)
Beckwith–Wiedemann syndrome (MIM 130650)	11p15 locus alterations *IGF2* overexpression *p57kip2* (*CDKN1C*) (genetic defect) *KCNQ1OT* (epigenetic defect) *H19* (epigenetic defect)	Exomphalos, macroglossia, macrosomia, hemihypertrophy, nephroblastoma, ACC	Frequent 11p15 LOH in ACC (>80%) Frequent *IGF2* overexpression in ACC (>85%)
Familial adenomatous polyposis (MIM 175100)	*APC* (5q12-22) Inactivating heterozygous mutations of the tumour suppressor gene *APC*	Multiple adenomatous polyps and cancer of the colon and rectum. Possible extracolonic manifestations include periampullary cancer, thyroid tumours, hepatoblastoma. Adrenocortical tumours can be diagnosed as adrenocortical adenomas, possibly multiples and/or bilateral, and ACC	Transcriptome analysis shows overexpression of targets of the Wnt-signalling pathway in ACC Immunohistochemistry shows abnormal localization of β-catenin in ACC, suggesting activation of the Wnt/ β-catenin pathway. β-catenin activating somatic mutations in ACC (20–30%)

LOH, loss of heterozygosity. ACC, adrenocortical cancer; MIM, Mendelian inheritance in man.

involved in their development. However, so far in ACC, such genes have been mostly identified by candidate gene approaches through the study of familial diseases responsible for adrenocortical tumours. Nevertheless, the loci of these genes are frequently altered in sporadic ACC, suggesting the importance of these loci and genes in the development of these tumours (Table 5.4.1). Studies using microsatellite markers in ACC have demonstrated a high percentage of loss of heterozygosity (LOH) or allelic imbalance at 11p15 (≥ 90%) and 17p13 (≥ 85%), corresponding respectively to *IGF2* and *TP53* loci. Indeed, *IGF2* is strongly overexpressed in 90% of sporadic ACC [9] and somatic mutations of *TP53* are found in 25% of adult ACC [10].

Genetic alterations of the Wnt-signalling pathway were initially identified in familial adenomatous polyposis coli and have been extended to a variety of cancers. Furthermore, familial adenomatous polyposis coli patients with germline mutations of the APC (adenomatous polyposis coli) gene that lead to an activation of the Wnt-signalling pathway, may develop adrenocortical tumours. The Wnt-signalling pathway is normally activated during embryonic development. ß-catenin is a key component of this signalling pathway. In ACC, ß-catenin delocalization can be observed, consistent with an abnormal activation of the Wnt-signalling pathway. This is explained in a subset of ACC (25%) by somatic activating mutations of *CTNNB1*, the ß-catenin gene [11]. Recently, exome sequencing and single-nucleotide polymorphism (SNP) array studies revealed alterations—mostly homozygous deletions—of *ZNRF3* in 20% of sporadic ACC [12, 13]. *ZNRF3* encodes an E3-ubiquitin ligase and is a known inhibitor of the Wnt/ß-Catenin pathway, by regulating the Wnt receptor turnover [14].

Genomics: Recent Advances Towards a New Classification of ACC

The development of genomics in the last decade has been a source of new progress both for tumour classification and pathogenesis understanding.

Gene expression profile (i.e. transcriptome), of benign tumours differs markedly from that of ACC[15, 16]. *IGF2* appeared as one of the most highly expressed genes in ACC. Adenomas display a steroidogenic signature, whereas ACC are characterized by a proliferative signature, suggesting that a dedifferentiation process might occur during malignant transformation [17]. The differences in gene expression profiles offer new diagnostic tools to discriminate benign from malignant adrenocortical tumours [16].

Moreover, studies analysing genomic (exome and chromosome alterations), epigenomic (micro-RNA expression and methylation) and transcriptomic (gene expression) profiles provided a complete high-throughput molecular characterization of adrenal tumours, in particular two large scale, integrated genomic studies, one from the European Network for the Study of Adrenal Tumours (ENSAT) network [12], and the other from The Cancer Genome Atlas (TCGA) programme [13]. These studies converge in an unsupervised classification of ACC into three groups, characterized by distinct molecular alterations and associated with very different outcomes (Figure 5.4.1). The first group is characterized by the combination a 'C1A' transcriptome profile (with upregulation of proliferative genes), a CpG island hypermethylation, a 'noisy' chromosome alteration profile (i.e. numerous and anarchic alterations), and an accumulation of mutations in cell-cycle and Wnt/ß-catenin related genes. This subgroup is associated with very poor outcome. Conversely, a second group of ACCs is characterized by a 'C1B' transcriptome profile (enriched in immune-related genes), no hypermethylation, a 'chromosomal' genome profile (i.e. extended patterns of LOH), and low mutation rate. This subgroup is associated with a better outcome. Finally, a third group of ACCs is characterized by 'C1A' transcriptome, and either hypermethylation or 'noisy' profile but not both, and shows an intermediate prognosis. These findings led to the development of new molecular markers for the prognostication of ACC [16, 18].

Epidemiology

ACC is a rare tumour with an estimated incidence between 1 and 2 per million and per year in adults in North America and Europe. The prevalence has been estimated between 4 and 12 per million [19]. As for many rare tumours, the incidence is difficult to determine, and the true numbers might be higher than the current

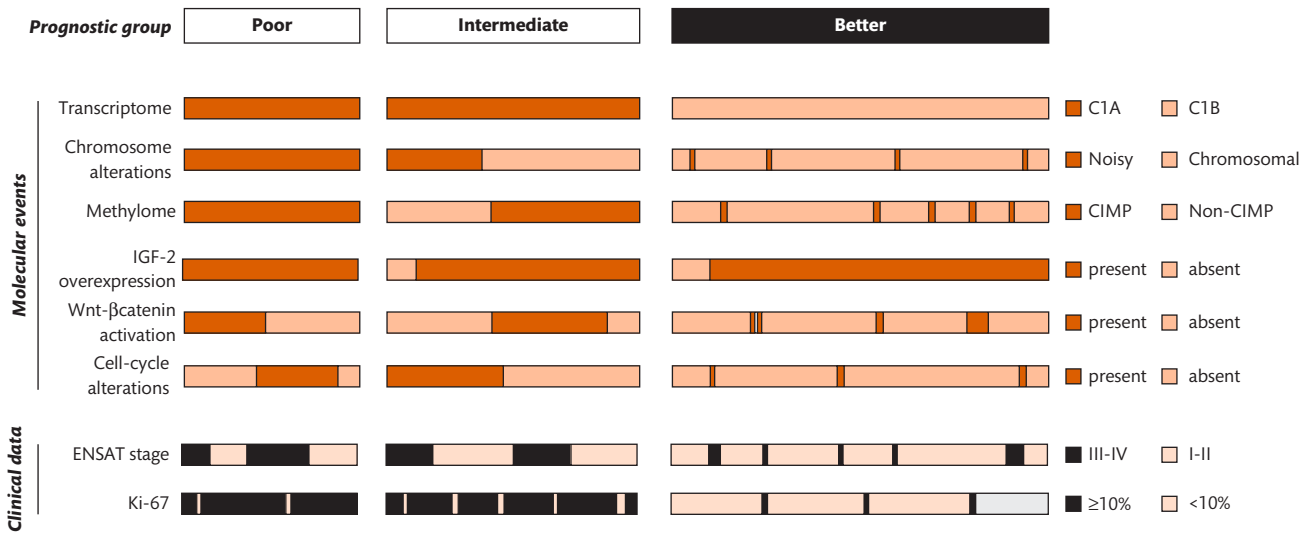

Figure 5.4.1 Genomic classification of adrenocortical cancer. This figure presents a schematic view of the genomic classification of ACC. Tumours are divided into three groups based on their transcriptome 'C1A' or 'C1B', chromosome alterations 'Noisy' or 'Chromosomal', and methylome—CIMP (CpG islands methylator phenotype) or non-CIMP profiles. These three groups are associated with very different prognosis. *IGF2* is overexpressed in 90% of ACC in all molecular groups. Activation of the Wnt-βcatenin pathway (including *CTNNB1* and *ZNRF3* alterations) and alterations in cell-cycle genes (including *TP53* and *CDKN2A*) are found mostly in aggressive ACC subgroups.

estimations. For instance, the prevalence of adrenal incidentaloma range in the general population from 1% in subjects younger than 30 years to 7% in subjects older than 70 years. Among the group of adrenal incidentaloma selected for surgery the frequency of ACC range between 2 to 12%.

In children, the incidence of ACC is considered as ten time lower as in adults, except in South Brazil where there is a higher incidence of paediatric ACC. This high incidence is explained by a specific germline *TP53* mutations as just discussed.

In some series, there is a slightly increased female to male ratio [20], although not always reported. Among female patients with Cushing's syndrome diagnosed during pregnancy, the frequency of ACC is higher than in non-pregnant female patients with Cushing's syndrome [21].

Clinical Features and Hormonal Investigations

Circumstances Leading to the Initial Diagnosis

Symptoms leading to the diagnosis of ACC can be due to steroid excess and/or tumour mass and metastases [22]. Although ACC is not the most frequent diagnosis of incidentalomas, nowadays the diagnosis of ACC is more often made during the diagnostic work-up of an adrenal incidentaloma. This circumstance is important since it might be a way to diagnose an ACC at an earlier stage and to improve the prognosis by an early complete surgical removal. This underlines the need for careful investigations of adrenal incidentalomas in order to decide on timely surgery if malignancy is suspected. Other specific features may be associated with rare genetic diseases such as the Li–Fraumeni and Beckwith–Wiedemann syndromes where ACC is part of a more complex syndrome as just discussed.

Less than a third of ACC are really 'non-hypersecreting' after careful hormonal investigations [22, 23]. In these cases, one should be cautious not to overdiagnose a tumour of the adrenal area as an ACC. These non-hypersecreting ACC can be diagnosed after investigation of adrenal incidentalomas or discovered by the manifestations of the tumour growth or extension: local symptoms (pain, palpation of a tumour, venous thrombosis), or distant metastases (liver, lung, bones). Fever may occur in some after tumour necrosis. However, in non-functional ACC, the general wellbeing of the patient is usually preserved until at a very late stage when the tumour causes signs and symptoms due to tumour expansion, which likely explains that non-hypersecreting ACC are typically diagnosed at a late stage.

Steroid Excess

Most patients will present with signs of steroid excess. Cushing's syndrome associated with signs of androgen excess with rapid onset and progression of clinical symptoms is the most characteristic presentation (**Figure 5.4.2**). Signs of mineralocorticoids or oestrogen excess are less frequent but highly suggestive of the diagnosis of ACC in a patient with an adrenal mass above 3 cm.

More than three-quarters of ACC are secreting tumours when assessed by careful hormonal investigations with current plasma and urine assays. In the absence of steroid excess, one should be cautious before diagnosing a mass of the adrenal area with suspicious imaging findings as an ACC. Hormonal investigations also provide important information for patient management and can serve as a tumour marker for follow-up. In 2018, the ACC guideline of the European Society of Endocrinology (ESE) and ENSAT has recommended a minimal hormonal work-up in patient with ACC [24] (**Box 5.4.1**).

In contrast to benign adrenocortical tumours, which usually oversecrete a single steroid, usually either cortisol or aldosterone, ACC can secrete various types of steroids. Cosecretion of androgens and cortisol is the most frequent and is highly suggestive of a malignant adrenocortical tumour. Cortisol oversecretion will induce centripetal obesity, protein wasting with skin thinning and striae, muscle atrophy (myopathy), and osteoporosis. Cortisol excess can also cause increased infections, diabetes, hypertension, psychiatric disturbances, and gonadal dysfunction in men and women. Androgen oversecretion may induce various manifestations in women: hirsutism, menstrual abnormalities, infertility, and eventually frank virilization (alopecia, deepening of the voice, clitoris hypertrophy). ACC can also secrete mineralocorticoids and steroid precursors. Oversecretion of oestrogens can be observed in rare cases and is very suggestive of ACC in a male patient with an

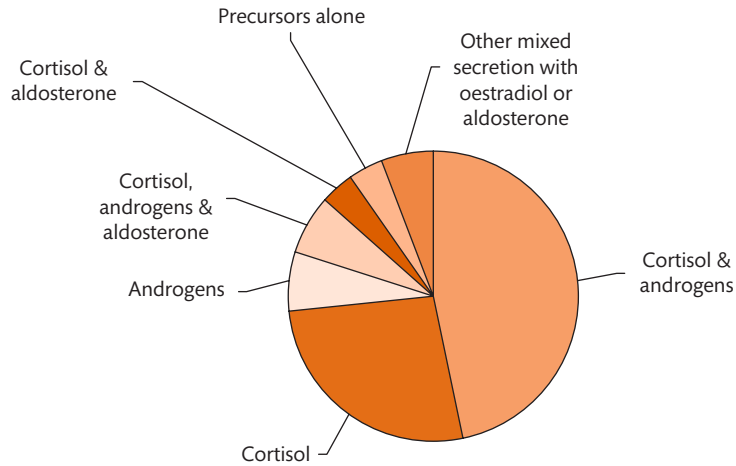

Figure 5.4.2 Steroid secretion. The figure shows the frequency of each steroid secretion profile (expressed as percentage) according to hormonal investigations in secreting ACC (Cochin endocrinology department series, investigated as reported in Abiven *et al*. 2006 [22]). Note that almost half of the secreting tumours are associated with mixed secretion of cortisol and androgens.

Box 5.4.1 Hormonal investigations in patients with ACC

These assays are adapted from the recommendation of the guideline of the European Society of Endocrinology (ESE) and the European Network for the Study of Adrenal Tumors (ENSAT). The steroids in italics are not part of the minimal work-up. This imply prior exclusion of a pheochromocytoma by the assay of urinary or plasma metanephrine and normetanephrine.

1 Glucocorticoid excess (a minimum of two tests):
- 24 hour urinary free cortisol and urinary creatinine
- Dexamethasone overnight suppression test (1 mg)
- Basal ACTH (plasma)
- *Basal cortisol*

2 Sex steroids:
- Testosterone (in women)
- Oestradiol (in men and postmenopausal women)
- Androstenedione
- DHEA-S (*or DHEA*)

3 Precursors:
- 17-hydroxyprogesterone
- 11-deoxycortisol
- *11-desoxycorticosterone*

4 Mineralocorticoids excess:
- Potassium
- Plasma aldosterone and renin (patients with hypertension or hypokalaemia)

adrenal tumour. Oestrogen excess is responsible for gynaecomastia in male.

Adrenocorticotrophic hormone (ACTH)-independent cortisol oversecretion is easily demonstrable: increased urinary cortisol excretion that is not suppressible with high doses of dexamethasone, and associated with undetectable ACTH plasma levels. Plasma 17-hydroxyprogesterone is often elevated at baseline and/or after ACTH stimulation, as well as the adrenal androgen precursor dehydroepiandrosterone sulphate (DHEA-S), which can lead to testosterone excess in females. Secretion of aldosterone by ACC is not frequent and can be detected by plasma aldosterone and renin assays.

Recently, mass spectrometry approaches have allowed detailed steroid profiling including precursor steroids usually not captured with routine assays, revealing a pattern of predominantly immature, early-stage steroidogenesis in ACC versus ACA and healthy controls [25]. Interestingly, urinary steroid metabolite profiling detected abnormal steroid precursor excretion even in ACC that were considered as non-hypersecreting using routine biochemical work-up. Thus, urine steroid metabolomics can be used as a biomarker tool for detecting malignancy in adrenal tumours [25].

Imaging Investigations

Computed Tomography and Magnetic Resonance Imaging

Imaging is an essential diagnostic step for ACC, especially in cases of adrenal incidentaloma. It is important both for the diagnosis of malignancy of an adrenal mass but also for the staging work-up. Adrenal CT is a very informative imaging procedure for adrenocortical tumours [26]. In ACC, it usually shows a unilateral mass, that is most often large (above 5–6 cm, and typically 10 cm and above), lowering the kidney. Apart from the size of the tumour, the features suggestive of malignancy are the lack of homogeneity with foci of necrosis and irregular margins or, in relatively homogenous tumours examined by unenhanced CT, an increased attenuation above 10 HU, indicating a low fat content (Figure 5.4.3). CT also informs about presence of local invasion and/or distant metastases, most frequently in liver and lung and all patients with suspected ACC should undergo preoperate staging of thorax, abdomen, and pelvis. Locoregional vessel invasion through the renal veins and the inferior vena cava can proceed up to the right atrium and result in metastatic pulmonary embolism [27]. Magnetic resonance imaging (MRI) is particularly useful for the detection of liver metastasis and venous invasion.

Nuclear Imaging

More recently, studies have demonstrated that many if not most ACC demonstrate a high uptake of ^{18}F-fluorodeoxyglucose ((18)-FDG). Thus (18)-FDG Positron Emission Tomography ((18)-FDG-PET) can help to distinguish between benign and malignant adrenal tumours [28] and provide useful information in pre- and postoperative staging [29] (Figure 5.4.4). It is especially informative in combination with CT.

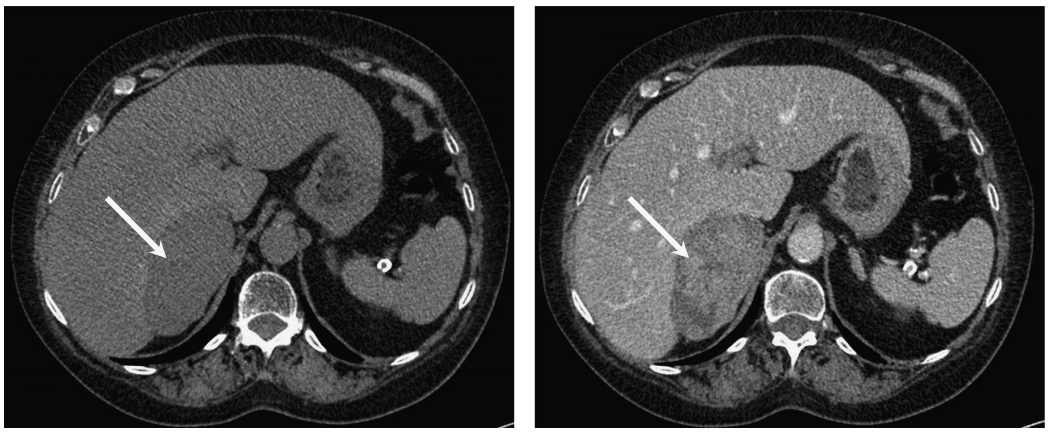

Figure 5.4.3 Computed tomography scan of an adrenocortical cancer. The white arrow points to an ACC arising from the left adrenal gland. The maximum diameter of the tumour is 10 cm. Unenhanced CT attenuation (left) is 27 HU (above the 10 HU cut-off for benign adenoma). After injection (right), the mass appears heterogeneous and the wash-out of contrast agent is below 50%.

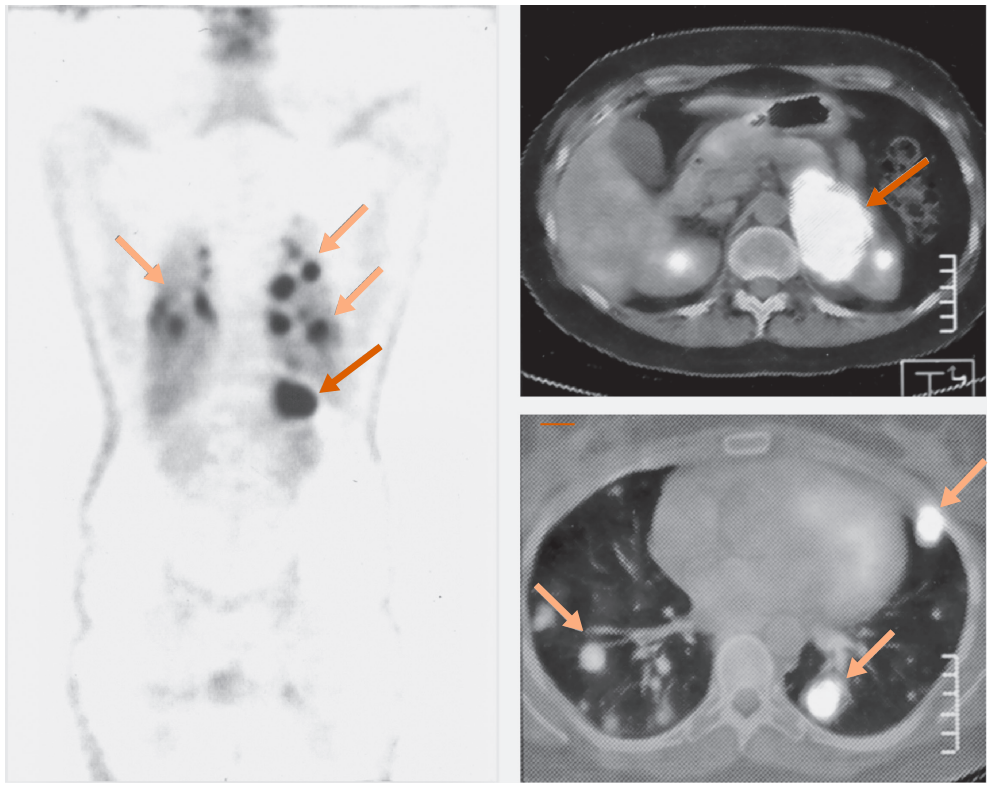

Figure 5.4.4 ^{18}F-fluorodeoxyglucose positron emission tomography ((18)-FDG-PET) of a metastatic adrenocortical cancer. Left panel: the left adrenal tumour shows a high uptake on the (18)FDG-PET scan (light orange arrow) and pulmonary metastases are detected = (dark orange arrows) at diagnosis of this stage 4 tumour. Right panel: combination of the PET imaging with a CT-scan shows the adrenal primary tumour (top) and the pulmonary metastases (bottom). *For a colour version of this figure, please see colour plate section.*

Bone scintigraphy may help evaluate bone metastases. However, in patients with Cushing's syndrome, bone remodelling and/or fracture can induce false positive results and the wider use of (18)-FDG-PET may replace it in the future. New adrenal cortex-specific radiolabelled tracers, such as [^{123}I]-metomidate, are currently investigated and may be promising options in the near future [30].

Diagnostic Criteria and Prognosis

Pathological Diagnosis and the Weiss Score

As just discussed, clinical, hormonal, and imaging investigations can be very suggestive of an ACC. Large adrenocortical tumours (>6 cm) are more likely to be malignant (Figure 5.4.5), but tumour size is clearly not a valid criterion to diagnose or exclude malignancy. On the other hand, a presentation with a large adrenal mass with ACTH-independent steroid excess is almost pathognomonic. However, pathological diagnosis is always a very important step. In the case of non-hypersecreting and/or localized tumours, pathology is key to diagnose both the adrenocortical origin and the malignant nature. The adrenocortical origin of the tumour is based on the histological analysis but also immunohistochemistry. Immunohistochemical markers are also employed to exclude other type of tumour, for instance a pheochromocytoma will stain positive for chromogranin A antibody while an ACC will not. Positive immunostaining in an adrenocortical tumour is either non-specific (e.g. Melan A) or not used on a routine basis (e.g. SF-1 or steroidogenic enzymes).

As often the case with endocrine tumours, the diagnosis of the malignant nature of an adrenocortical lesion can be difficult for the pathologist. There is not a single pathological feature which

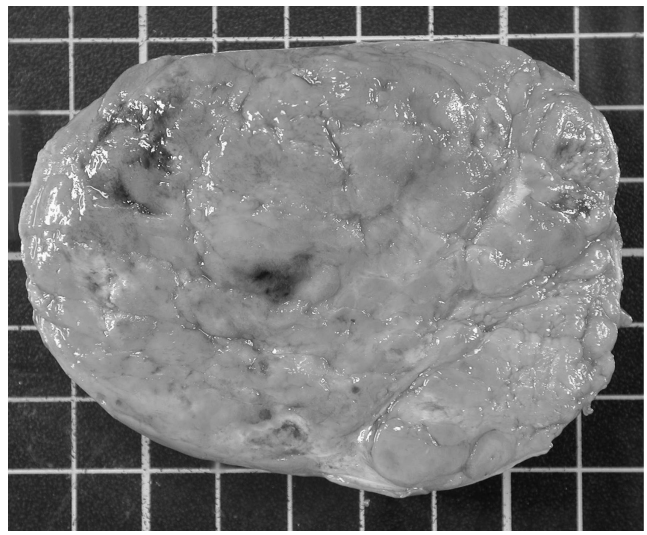

Figure 5.4.5 Macroscopic view of an adrenocortical cancer. The length of each scale is 1 cm. Note the characteristic large and heterogeneous aspect of the tumour.

Box 5.4.2 The nine criteria of the Weiss score for the diagnosis of malignancy of an adrenocortical tumour

The presence of three or more criteria classifies the tumour as a malignant one.

- High nuclear grade
- Mitotic rate above 5 per 50 high-power fields
- Atypical mitosis
- Less than 25 % of clear cells
- Diffuse architecture
- Necrosis
- Venous invasion
- Sinusoidal structures invasion
- Tumour capsule invasion

allows to conclusively diagnose a malignant adrenal cortical tumour. Combinations of various histological parameters that allow to establish a 'score' for a given tumour have been developed. The most widely used is the Weiss score comprising nine different items [31] (Box 5.4.2). Each item is given a value of one when it is present, zero when it is absent. The score represents the sum of the value for each individual item. It is assumed that a score equal or above 3 is most likely associated with a malignant tumour. Other approaches based on microscopic feature analysis have been developed, but are much less widely used and, therefore, less validated than the Weiss score. However, as all these approaches suffer limitations and are highly dependant on the experience of the pathologist, there is an effort to develop molecular markers of malignancy. As just described, *IGF2* overexpression and allelic losses at 17p13 have been suggested as potential molecular ACC markers [9]. More recently, large scale transcriptome analysis using DNA chips was used to develop molecular markers based on the expression level of two genes (*DLGAP5-PINK1*) for the diagnosis of malignancy [16, 32]. It is expected that in the near future such translational research programmes will have important impact for the classification and management of these tumours.

Tumour Staging

Tumour staging is the most important prognostic factor in ACC. Different staging classifications have been proposed over the years. The 2008 ENSAT staging provides superior survival stratification [33, 34] and is now the most commonly used classification. Four different stages are differentiated with this score. Stage 1 and stage 2 tumours are localized to the adrenal cortex and present with a maximum diameter below or above 5 cm, respectively. Stage 3 tumours present with local infiltration reaching the surrounding tissue, invasion into adjacent organs or lymph nodes. Stage 4 tumours are associated with distant metastases. The prognosis of stage 1 and 2 tumours is better than that of stage 3 or 4 tumours [33] (Figure 5.4.6).

Outcome and Long-Term Survival

The metastatic spread of ACC mostly involves liver and lung, observed in about 35 to 50% of the patients. Bone metastases are diagnosed in 10 to 15% of the cases. Metastatic spread to other organs is rare [22, 35].

The overall survival of patients with ACC is poor, with a 5-year survival rate below 35% in most series [36]. However, survival depends on tumour stage at diagnosis. It is likely that progress in the medical management of incidentalomas and better investigations of subtle degrees of steroid excess will increase the detection of localized ACC (stages 1 or 2). This should improve the overall survival rate. A better survival has been reported in younger patients, but this is not a constant finding [22]. Cortisol-secreting tumour appear to be associated with a poorer prognosis [22]. This could be due to the morbidity associated with Cushing's syndrome and/or to different tumour behaviour with more rapid progression. Some pathological features, such as a high mitotic rate or atypical mitotic figures as well as a high Ki-67 labelling, have been shown to be associated with a poor prognosis [37–40]. Recently, a Ki-67 proliferation index ≥10–20% was identified as a major indicator of poor prognosis in stage 1–3 ACC after apparently complete surgery [39]. The routine evaluation of Ki-67 expression in the pathology report is now recommended for the standard prognostic assessment of every resected ACC [24]. However, one limitation of Ki-67 is the low interobserver and intraobserver concordance for intermediate indices (10–30%) [41], which correspond to the cut-offs used for patient management.

Following the recent progress in genomics, targeted molecular markers have been developed for ACC prognostication [36] and may complete the standard pathology assessment. In particular, the prognostic markers derived from the analysis of transcriptome—differential expression of two genes (*BUB1B-PINK1*) [16, 32]—and

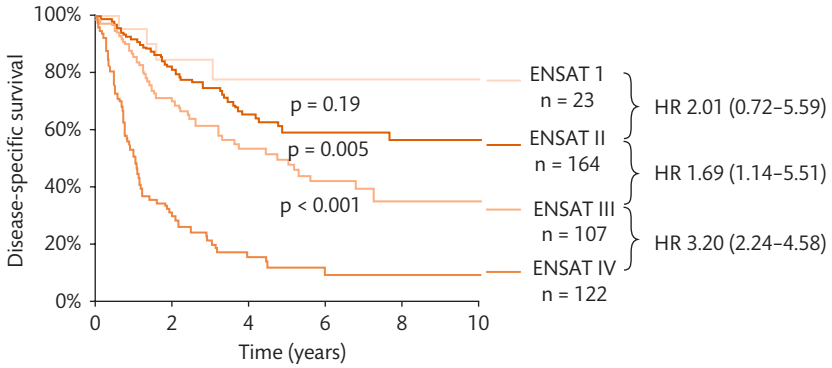

Figure 5.4.6 Survival of patients with adrenocortical cancer according to initial staging. The figure shows the disease-specific survival time (expressed in years) according to the ENSAT stage at presentation

Adapted with permission from Fassnacht M, Johanssen S, Quinkler M *et al.* Limited prognostic value of the 2004 International Union Against Cancer staging classification for adrenocortical carcinoma: proposal for a Revised TNM Classification. *Cancer* 2009;115: 243–50 [33].

from methylome—methylation level of four genes (*PAX5, PAX6, GSTP1*, and *PYCARD*) [18]— have demonstrated independent prognostic value from ENSAT stage and Ki-67, now also reported by large validation studies on the use of molecular markers for ACC prognostication [42, 43].

Treatment

Treatment aims to correct both steroid oversecretion and its clinical consequences in steroid-producing ACC, and, importantly, to eradicate the malignant tumour. The best way to achieve both goals is the complete removal of the tumour if possible, depending on tumour stage and the patient's condition (Figure 5.4.7).

Steroid oversecretion, when clinically significant and not curable by tumour removal, requires therapeutic intervention, in particular in the case of cortisol excess. Mitotane is the drug most often used in this context, because it also has a cytotoxic effect on the adrenocortical cells as discussed next. In the situation of clinically severe Cushing's syndrome requiring rapid control of steroid excess, other drugs can be also used, eventually in combination with mitotane, including ketoconazole, metyrapone, and etomidate [44].

Surgery

Surgery of the adrenal tumour is the major treatment of stage 1 to 3 ACC. It can also be discussed in stage 4 patients. The initial surgery is a crucial therapeutic step in the management of ACC. Therefore, it should be performed by highly trained specialist

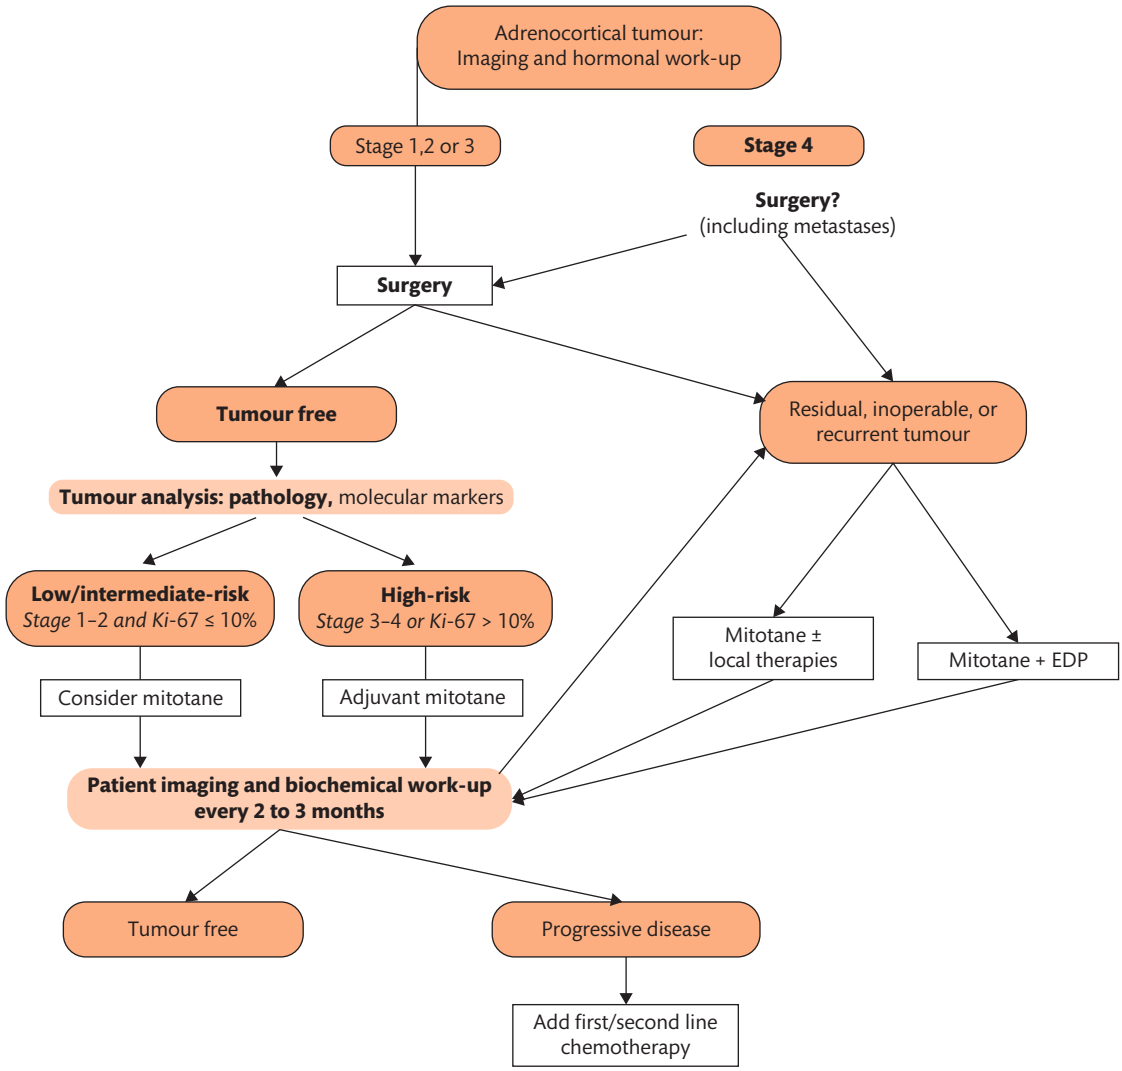

Figure 5.4.7 Schematic view of the management of patient with adrenocortical cancer. Surgery is the primary approach in patients with localized tumours (ENSAT stage 1, 2, and 3). Adjuvant mitotane is recommended for tumours with high risk of recurrence. In patients with distant metastases (stage 4), surgery of the primary tumour should be considered to reduce tumour mass, in particular if steroid excess is present, and also removal of metastases, if feasible, i.e. if no disseminated metastasis is present. Local recurrence without distant metastases usually requires surgery. Local treatments include: radiotherapy (especially for bone metastasis), chemoembolization (mostly for liver metastasis), radiofrequency thermal ablation of lung or liver metastasis, as well as surgical removal of limited metastasis. The delay between imaging and biochemical work-up can be extended to 3–4 months in patients presenting with complete remission and good prognostic factors and might be extended up to 6-month intervals after 2–3 years if there is still no recurrence. Mitotane and cytotoxic chemotherapy with etoposide, doxorubicin, platinum (EDP) is proposed for patients with rapidly progressive metastatic disease.

surgeons, experienced in the management of adrenal tumours and embedded into a multidisciplinary team, to achieve complete tumour removal without tumour spillage. Complete tumour removal is very important to increase the probability of long-term remission [24, 27, 45]. Open adrenalectomy is currently the standard of surgical care, with many advocating locoregional lymphadenectomy [46, 47]. Laparoscopic removal of malignant adrenocortical tumours could be associated with a high risk of peritoneal dissemination and should be restricted to suspected malignant adrenal masses with a diameter of less than 6 cm without evidence of local or lymph nodes invasion and surgical management by a high-volume centre [45]. Glucocorticoid replacement therapy should be started immediately after the removal of cortisol-secreting tumours to prevent acute adrenal deficiency as the contralateral adrenal cortex will be dormant consequent to the longstanding suppression of corticotroph ACTH secretion by the chronic cortisol oversecretion related to ACC.

In stage 4 patients with distant metastases, tumour debulking with removal of the adrenal tumour can be discussed, in order to both improve prognosis and reduce steroid excess. Surgery should be discussed considering tumour bulk and spread, as well as the velocity of observed tumour progression. However, it is important to consider the postoperative recovery period and the expected residual tumour mass as cytotoxic chemotherapy cannot be introduced in freshly operated patients. When the number of metastasis is limited, their surgical removal can also be discussed and downstaging by chemotherapy can also represent a feasible option in some cases.

Surgery is the primary approach in case of local recurrences, if operable. In general, recurrences occurring more than 12 months after the primary ACC surgery appear to be associated with a better prognosis, while early recurrence indicates a rapidly growing tumour.

Local Therapies and Radiotherapy

Radiofrequency thermal ablation of liver and lung metastasis with a maximum diameter less than 5 cm can be an alternative to surgical removal [48]. Bone metastasis can be operated to reduce fracture risk or neurological symptoms due to spinal metastasis. Radiation therapy has often been considered as not very effective to control tumour growth. However, it has been suggested that it could help to prevent local recurrence and potentially prolong survival [35]. Since all studies investigating radiotherapy in ACC are observational with potential confounding effects, adjuvant radiotherapy is not recommended for stage 1–2 tumours after complete tumour resection, but should be considered in addition to mitotane therapy in patients at high risk of recurrence, i.e. with uncomplete resection or stage 3 tumours [24].

Medical Therapy of ACC

When complete tumour removal is not possible or in case of recurrence, medical treatment with o,p'DDD (ortho, para', dichloro-, diphenyl-, dichloroethane, or mitotane) is recommended [24].

Mitotane has a specific cytotoxic effect on adrenal cortical cells [49]; it also inhibits steroid synthesis and, therefore, is usually effective for the control of steroid excess in ACC. Most studies reporting on the efficacy of mitotane in ACC are retrospective analyses, with variable results on tumour progression. An objective tumour regression could be observed in 25% of the cases [50]. Patients with a cortisol-secreting ACC might have a better survival when treated with mitotane in the 3 months following the surgery of the adrenal tumour [22]. A mitotane blood level of at least 14 mg/L seems to improve the tumour response rate [51]. However, the side effects of mitotane (mainly gastrointestinal and neurologic) can limit the ability to reach this suggested optimal level. The daily mitotane dose required to achieve this 14 mg/L level varies from patient to patient. Therefore, close monitoring of mitotane plasma levels is very helpful to remain in the narrow range between 14 and 20 mg/L, considered by most authors as the therapeutic range of mitotane in ACC, with lower levels rarely preventing tumour growth and higher levels associated with neurologic toxicity. Since mitotane invariably induces adrenal insufficiency, glucocorticoid replacement has to be initiated concurrently with mitotane and should be administered at increased doses (e.g. 40–80 mg per day) as mitotane strongly induces CYP3A4, which results in rapid inactivation of cortisol [52]. It is generally accepted that adjuvant therapy with mitotane should be proposed in patients considered to be at high risk of tumour recurrence. However, the benefit of mitotane treatment as an adjuvant medical treatment in low-intermediate risk ACC, i.e. stage 1–3, after 'complete' surgical removal, with Ki-67 index below 10%, remains to be demonstrated. Retrospective analysis have reported conflicting results [53]. This important point is expected to be clarified by an international randomized trial (ADIUVO, NCT00777244).

Several cytotoxic chemotherapy regimens have been used in ACC. Recently, the randomized phase III FIRM-ACT trial has established the association of mitotane with etoposide, doxorubicin, and platinum (EDP) chemotherapy as the best option for patients with unresectable disease [54]. The choice of first-line therapy, either mitotane alone or in combination with cytotoxic chemotherapy, depends on prognostic parameters. Mitotane monotherapy is usually recommended in case of slow progressive disease whereas cytotoxic chemotherapy is proposed as first-line for patients with rapidly progressive tumours, and as second-line therapy for patients with tumour progression despite therapeutic mitotane plasma levels or presenting with severe side effects limiting the use of mitotane [24]. The role of adjuvant Etoposide-Cisplatin chemotherapy will be investigated in the ADIUVO2 phase III trial (NCT03583710).

Several targeted therapies have been investigated in advanced ACC, with disappointing results. Antiangiogenic tyrosine kinase inhibitors such as sunitinib failed to demonstrate efficacy in advanced ACC, although drug efficacy might could have been hampered by pharmacologic interaction with mitotane [55]. Although inhibitors of the insulin-like growth factor (IGF) receptor seemed very attractive, given the major role of *IGF2* overexpression in the pathogenesis of ACC, the phase III GALACCTIC trial showed that linsitinib, an *IGF1R* inhibitor, did not improve progression-free or overall survival versus placebo [56].

Conclusion

Although ACC is a rare condition, significant advances have been made in the last decade to understand its pathophysiology. These have been important both for improving diagnosis of ACC and for a better assessment of disease prognosis. However, much more

progress needs to be achieved with regard to therapeutic options. Due to the rarity of ACC, collaborative work performed in national and international networks dedicated to adrenocortical tumours will be important, with ENSAT working very successfully in this field in Europe.

Areas of Uncertainty or Controversy

The pathological diagnosis of malignancy of an adrenocortical tumour can be difficult in some cases. Although careful analysis by an expert pathologist solves most cases, there are still some suspicious tumours with a borderline Weiss score [31] that are difficult to classify.

The prognosis of a tumour diagnosed as a malignant one, especially after complete surgical resection of a stage 1 or 2 ACC, is heterogeneous and still difficult to predict.

The surgical procedure has not been defined in a homogeneous way. The benefit of large 'en bloc' aggressive surgical resection that could lead to kidney ablation and the strategy for lymph node removal require further studies. The possibility to use laparoscopic resection of small ACC restricted to the adrenal gland by expert surgeons without increasing the risk of local recurrence or peritoneal metastasis need to be determined.

The benefit of radiotherapy remains uncertain. The place for radiotherapy as adjuvant or curative therapy will have to be established.

The benefit of mitotane as adjuvant therapy is most often accepted but needs to be demonstrated in prospective trials, in particular for ACC with lower risk of recurrence.

Likely Developments Over the Next 5–10 Years

The development of new immunohistochemical markers should improve the pathological diagnosis and prognostication of ACC.

Genomic studies have revealed a new classification of adrenocortical tumours leading to the development of molecular markers for the classification and prognostication of these tumours. The use of these markers in clinical practice, including its application to formalin-fixed and paraffin-embedded tissue is expected to improve patient management. Genomics studies are also giving new insights on the pathophysiology of ACC and this should help to define new targeted therapies.

The use of mass spectrometry for urinary steroid metabolite profiling has shown great promises in the diagnosis and follow-up of ACC, in particular when combined with machine learning-based algorithm-driven data analysis. Further studies will analyse the value of non-targeted metabolome and proteome analysis in ACC.

The development of new specific scintigraphies (as ^{123}I-iodometomidate ou ^{11}C-metomidate) is in progress and should improve tumour diagnosis and follow-up. Radiolabelled tracers could also be used for metabolic radiotherapy.

The results of ADIUVO study should clarify the role of adjuvant mitotane in low/intermediate risk patients after complete surgery.

The ADIUVO2 study will determine the role of adjuvant cytotoxic chemotherapy in patients at high risk of relapse.

New targeted therapies are currently in preclinical and clinical studies. Among them, new antiangiogenics inhibitors such as cabozantinib (NCT03612232) will be evaluated after mitotane discontinuation to prevent drug interactions.

ACKNOWLEDGEMENTS

We thank Dr Frédérique Tissier (service d'anatomopathologie, Hôpital Cochin) for help with the figures included in this chapter.

Phaeochromocytoma and Paraganglioma

5.5.1 Genetics of Phaeochromocytomas, Paragangliomas, and Neuroblastoma

Eamonn R. Maher and Ruth T. Casey

Introduction

Phaeochromocytomas, paragangliomas, and neuroblastomas are the main primary tumours that arise from the autonomic nervous system. The autonomic nervous system is subdivided into the sympathetic and parasympathetic systems. Phaeochromocytomas arise from sympathetic nervous system (chromaffin) cells in the adrenal medulla. Paragangliomas may arise from the sympathetic or parasympathetic system. Parasympathetic ganglia-derived paragangliomas (herein referred to as head and neck paraganglioma, HNPGL) develop along branches of the vagal and glossopharyngeal nerves (e.g. carotid body tumours, glomus jugulare) and are only rarely secretory. Phaeochromocytoma, paraganglioma, and HNPGL are rare in childhood but neuroblastomas, which are derived from neuroblasts in the developing sympathetic nervous system and are most common in children under the age of 5 years. Familial forms of neuroblastoma are rare but a major feature of phaeochromocytoma and paraganglioma (PPGL) and HNPGL is the high frequency of inherited cases and the major inherited syndromic and non-syndromic disorders that predispose to these tumours are described in Chapter 6.12.

Phaeochromocytoma and Paraganglioma

Clinical and Pathological Features

The estimated incidence of PPGL is 2 to 8/million of the population per year, giving an estimated annual incidence of 130–520 new patients a year in the United Kingdom [1]. Presenting symptoms of these rare tumours are most commonly related to catecholamine excess, and include headache, palpitations, paroxysmal hypertension, anxiety, abdominal pain, and excessive sweating. PPGL are often diagnosed incidentally following cross-sectional imaging studies [2].

Paragangliomas in the abdomen and pelvis commonly arise from the aortic bifurcation or the so-called organ of Zuckerkandl, but can also occur in the urinary bladder. Mediastinal paraganglioma are rare but can develop from para-aortic (middle mediastinum) and para-vertebral (posterior mediastinum) sympathetic chain ganglia [3]. PPGL and HNPGL may be familial and/or multifocal (in which case a genetic cause should be suspected) and/or there may be a previous history of wild-type gastrointestinal stromal tumour (GIST) or renal cell carcinoma (which are each associated with germline mutations in succinate dehydrogenase (SDH) subunit genes (see next)). Although most PPGL are benign (~85–90%), current predictors of malignant or aggressive tumours are imprecise and therefore in 2017, the World Health Organization (WHO) classification of adrenal tumours abolished the term 'benign' for PPGL, stating that all PPGL should be considered to have metastatic potential [4].

Histologically, PPGL are identified microscopically by a characteristic 'zellballen' pattern, referring to nests of polygonal/spindle shaped cells on a rich vascular network and immunohistochemical stains such as; synaptophysin, chromogranin A and S100 are used to confirm a diagnosis of PPGL [5]. In 2017, the first staging system for PPGL (but not HNPGL) was proposed by the American Joint Committee on Cancer (AJCC) and includes tumour size, lymph node metastases, and distant metastases [6]. Tumour size (>5 cm), local invasion and extra-adrenal abdominal location are predictors of malignancy [7] as is the detection of a germline pathogenic *SDHB* variant [8].

Surgery remains the first line treatment option for PPGL and, when possible, a minimally invasive approach is favoured. In the genomics era, surgical management can also be tailored based on the genetic aetiology of PPGL. Patients with certain hereditary syndromes (e.g. multiple endocrine neoplasia type 2 [MEN2], von Hippel Lindau disease [VHL], neurofibromatosis type 1 [NF1]) are at risk of bilateral phaeochromocytomas (Chapter 6.12) and cortical sparing surgery reduces the morbidity associated with bilateral adrenalectomy and requirement for lifelong glucocorticoid and mineralocorticoid replacement. Although patients with SDH subunit gene (*SDHX*) mutations and *MAX* gene mutations may develop bilateral phaeochromocytoma, the higher risk of malignancy negates the benefit of cortical sparing surgery and total adrenalectomy should be considered for these patients [9].

Long-term surveillance strategies are influenced by the tumour location and the detection of a germline predisposition. Current guidelines recommend lifelong surveillance for young patients, patients with a large or an extra-adrenal tumour and those with a known hereditary predisposition. Patients with a small (<5 cm) presumed sporadic phaeochromocytoma undergo a minimum of 10 years clinical surveillance for disease recurrence [10]. Postoperative surveillance includes annual biochemical testing for patients with secretory PPGL or cross-sectional imaging with CT/MRI every 1–2 years for patients with non-secretory PPGL [10].

Genetics

Despite clinical studies suggesting that PPGL is familial in ~10% of patients, the application of molecular genetic studies to PPGL has revealed that around 40% of individuals with PPGL will harbour a germline mutation in a PPGL predisposition gene and that most of these will not have a family history. The most common causes of inherited predisposition to PPGL are germline mutations in the various succinate dehydrogenase subunit genes (*SDHX*), *VHL, RET*, and *NF1* genes, but mutations in multiple other genes (including *MAX, TMEM127, HIF2A/EPAS1, FH, MDH2, SLC25A11*) have also been described to predispose to PPGL. The clinical characteristics of germline mutations in different inherited PPGL genes differ and are described in detail in Chapter 6.12.

The somatic (acquired) genetic and epigenetic alterations associated with PPGL tumourigenesis have been described in both inherited and sporadic forms of PPGL. Most inherited PPGL genes are classed as tumour suppressor genes and the germline mutations are loss of function variants. Initiation of tumourigenesis requires inactivation of the wild-type allele and this can occur through a variety of mechanisms including large chromosomal deletions (most often), somatic mutations, or promoter methylation with transcriptional silencing. For example, PPGL from patients with von Hippel–Lindau disease frequently demonstrate loss of the short arm of chromosome 3p (so the wild-type (non-mutated) VHL allele at 3p25 is lost) and in PPGL from patients with NF1 chromosome 17q loss is found (the *NF1* tumour suppressor gene is located at 17q11.2). As germline *RET* mutations activate the oncogenic function of RET, chromosome 10 deletions are not a feature of phaeochromocytomas from patients with MEN2. Secondary epigenetic alterations (e.g. genome-wide hypermethylation) are a characteristic feature of PPGL associated with germline mutations in *SDHX, FH, MDH2,* and *SLC25A11*. The gene products of these genes encode key components of cellular metabolic pathways and their inactivation leads to accumulation of metabolites (e.g. succinate with *SDHX* and fumarate with *FH* mutations) that inhibit alpha-ketoglutarate-dependent enzymes including the TET (ten-eleven translocation) proteins that are require for active DNA demethylation and lead to silencing of tumour suppressor genes through aberrant promoter methylation [11, 12].

Various genome-wide copy number abnormality studies have demonstrated recurrent areas of loss and gain in PPGL including chromosome 1p, 3p, 3q 11p, 17, 21q, and 22q loss. Interestingly 11p loss in PPGL preferentially affects the maternally inherited chromosome suggesting that imprinted genes (e.g. the paternally expressed *IGF2* and maternally expressed *CDKN1C*) are implicated in the pathogenesis of PPGL and the parent-of-origin effects on tumour risks seen with mutations in the chromosome 11q *SDHD* and *SDHAF2* genes (see Chapter 6.12).

Large-scale next-generation sequencing studies of somatic mutations in sporadic PPGL have identified mutations in a wide variety of genes including genes known to be associated with inherited PPGL (*VHL, NF1, RET*) and also genes in which only somatic mutations occur [13]. Though some important inherited PPGL tumour suppressor genes map to regions of recurrent copy number loss in sporadic PPGL (including *SDHB* to 1p36, *VHL* to 3p25, and *NF1* to 17q11.2) the frequency of somatic mutations in inherited PPGL genes in sporadic PPGL varies markedly. For example, whereas somatic mutations in *NF1* and *VHL* are relatively common, somatic mutations in *SDHX* subunit genes are infrequent. Gain of function mutations in *RET* and *HIF2A*/*EPAS1* can occur as both germline and somatic mutations. The most strongly activating mutations (e.g. *RET* M918T which is associated with MEN2B) are more often found as somatic than germline variants. Polycythaemia and PPGL can be features of somatic (rarely germline) *HIF2A* mutations [14]. Importantly, *HIF2A* variants have been associated with mosaicism and, therefore, if an *HIF2A* variant is identified in an apparently sporadic tumour, it is recommended that efforts are made to further clarify the presence of the variants in other tissue types, to inform the extent of disease and the appropriate surveillance approach for the patient and relatives [15]. Somatic mutations in *HIF2A* (which encodes the alpha subunit of the heterodimeric HIF-2 hypoxia responsive transcription factor) usually occur at or adjacent to the proline residue (P531) that is critical for binding to the VHL gene product (pVHL). The pVHL protein has a key role in targeting the HIF2A protein for proteosomal degradation and somatic inactivating mutations in *VHL* and activating mutations in *HIF2A* will both result in stabilization of HIF2A and activation of hypoxic gene response pathway [16]. Furthermore, *SDHX* and *FH* mutations are also associated with stabilization of HIF2A as both are associated with an inhibition of Pro531 hydroxylation which is required for pVHL binding and there are rare reports of PPGL patients with germline mutations in EGLN1/PHD2 which encodes one of the proline hydroxylase enzymes that act on HIF2A.

A wide variety of genes have been reported to be somatically mutated in PPGL but not implicated in familial PPGL [13]. These include activating mutations in the *HRAS* and *BRAF* proto-oncogenes and *CSDE1* (a *wnt*-pathway regulator). In a comprehensive genomic study, a further *wnt*-pathway related abnormality, *MAML3* fusion genes was identified in PPGL [13]. Other reported targets for somatic mutation include *SETD2, FGFR1, TP53, ATRX, ARNT, IDH1, H3F3A, MET* [13, 17] (see **Figure 5.5.1.1**). Though a large number of genes have been reported to harbour germline and/or somatic mutations in PPGL, the number of driver mutations per tumour is low and in many cases only a single event is detected [13]. Somatic *HRAS* mutations can be detected in about 10% of sporadic PPGL and, interestingly, it seems that somatic *HRAS* mutations and germline inherited PPGL gene mutations are usually mutually exclusive [18]. It has therefore been suggested that somatic mutation profiling of PPGL to identify driver gene mutations can facilitate management of patients with PPGL. If a mutation in an inherited PPGL gene is identified, then germline sequencing can be undertaken to determine if the mutation is somatic or germline. However, if a *HRAS* mutation is detected in the tumour then the risk of inherited disease will be low.

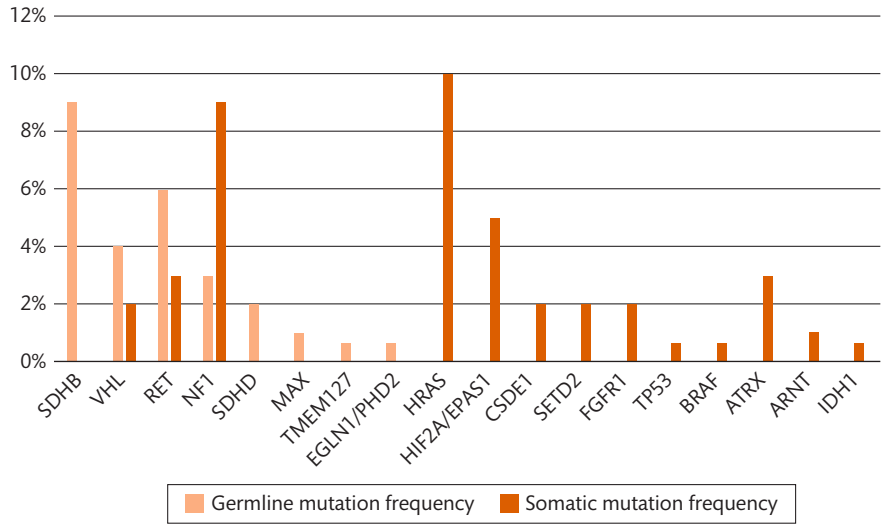

Figure 5.5.1.1 Summary of findings from a comprehensive genomic analysis of phaeochromocytoma and paraganglioma by Fishbein *et al.* [13].

Genotype-Function Correlations

Genomic profiling of PPGL has facilitated the diagnosis of hereditary cases, enabled a better understanding of the molecular pathways implicated in tumour development and provided an opportunity to develop new therapeutic approaches. Transcriptomic analysis of PPGL suggested two distinct categories: Cluster 1 (the 'pseudohypoxic cluster'), characterized by upregulation of hypoxia signalling pathways [19] and 'cluster 2', characterized by an upregulation of kinase signalling pathways [20]. Tumours caused by pathogenic variants in the *VHL, FH, SDHX, MDH, SLC25A11*, and *EPAS1* genes fall into the pseudohypoxic cluster [21], which is characterized by transcriptional upregulation of genes implicated in angiogenesis, and cellular proliferation secondary to hypoxia inducible factor (HIF) complex stabilization [19]. Cluster 2 tumours are associated with germline and somatic mutations in *RET, NF1, TMEM127, MAX*, and *HRAS*, which activate kinase pathways including the (i) PI3K/AKT, (ii) RAS/RAF/ERK, and (iii) mTORC1 pathways. More recently a Cancer Genome Atlas (TCGA) study has extended the molecular classification of PPGL to also include a *Wnt*-pathway altered cluster (associated with somatic *CSDE1* mutations and *MAML3* fusion genes and a small fourth category of cortical admixture PPGL) [13]. Included in this category were a small number (2) of *MAX* mutated tumours, but the relevance of this category as a distinct biological category remains under review. Looking at the somatic variant landscape of PPGL in isolation, the most common molecular pathway implicated is the RAS/RAF/ERK pathway [22]. This pathway is commonly implicated in tumourigenesis and consists of a series of serine-threonine kinases functional in a sequential pathway to regulate cell cycle factors. See Figure 5.5.1.2.

Reduced activity of PHD then stabilizes hypoxia inducible factor subunit alpha (HIFα) and upregulates HIF and downstream HIF targets.

Figure Figure 5.5.1.2B shows the interaction between PI3K/AKT, RAS/RAF/ERK, mTORC1 pathways, and the regulation of these pathways by known PPGL predisposition genes.

Genotype-Phenotype Correlations

Histopathology and Immunohistochemistry (IHC)

Biallelic inactivation of any of the *SDHX* genes usually results in destabilization of the SDH enzyme complex (Chapter 6.12), which can be detected by loss of staining for the SDHB protein by IHC [23]. Thus, SDHB IHC can be used to identify PPGL and HNPGL harbouring a *SDHX* mutation, provides a guide to likely of pathogenicity of an uncharacterized *SDHX* variant and is an indicator of malignancy risk [24]. IHC for *SDHA* expression can predict the presence of pathogenic variants in the *SDHA* gene and is also utilized in clinical practice. IHC may also be utilized for other hereditary causes of PPGL including assessment of MAX expression and the diagnosis of a pathogenic variant in *FH* is facilitated by IHC to detect protein succinylation (a post-translational modification resulting from the reaction of excess fumarate with cysteine residues to generate S-(2-succinyl)-cysteine (2SC)) [25].

Biochemistry

Biochemical testing is an integral component of the diagnostic pathway for PPGL and guidelines recommend urinary or plasma metanephrines and plasma 3-methoxytyramine (3MT) as the first line biochemical tests in the diagnosis of PPGL [1]. The pattern of catecholamine secretion can be determined by paraganglial cell differentiation and therefore biochemistry can be used to predict genotype and or malignant potential. Pseudohypoxic PPGL, including those tumours caused by *TCA* gene mutations and VHL, are characterized by poor differentiation of paraganglia cells and reduced expression of a key catecholamine conversion enzyme; Phenylethanolamine N-methyltransferase (PNMT) which results in reduced conversion of noradrenaline to adrenaline and a predominant noradrenergic secretory pattern [26]. In contrast, 'cluster 2' tumours are predominantly located within the adrenal gland and have a more mature phenotype associated with normal or elevated PNMT expression and a mixed or predominately adrenergic secretory pattern [26]. In addition

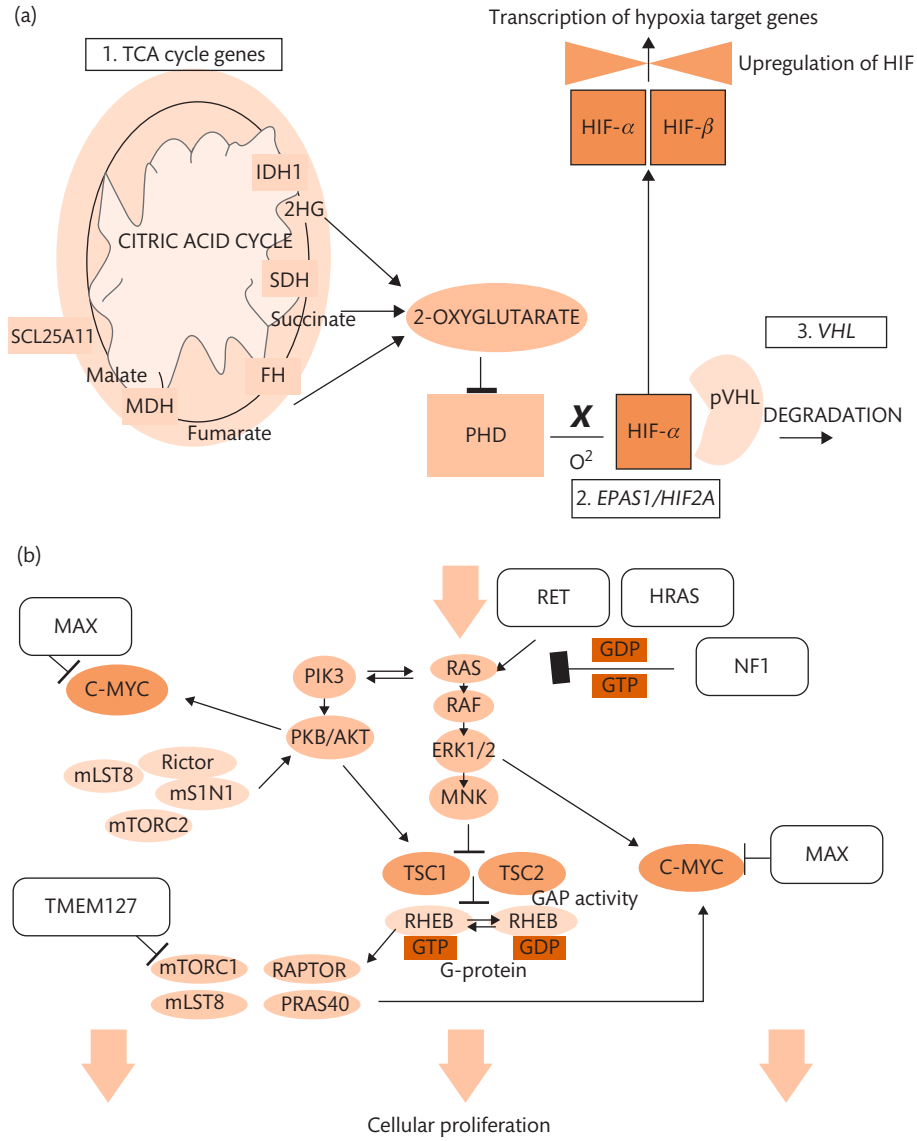

Figure 5.5.1.2 (a) Cluster 1/ 'Pseudohypoxic' genes. (b) Cluster 2 genes.

Figure A demonstrates how oncometabolite accumulation (e.g. succinate, fumarate, etc)

Modified with permission from Casey, R. (2019). A study of succinate dehydrogenase deficient tumourigenesis: From functional assessment of variant pathogenicity to the discovery of new disease biomarkers (Doctoral thesis). https://doi.org/10.17863/CAM.39029.

to reduced expression of PNMT, *SDHX* mutated tumours also have reduced activity of the enzyme dopamine-β-hydroxylase, responsible for the conversion of dopamine to norepinephrine in the catecholamine synthesis pathway. Therefore, elevated levels of dopamine or its metabolite 3-methoxytyramine is characteristic of SDH-deficient tumours [27]. Elevated dopamine is not typically associated with clinical symptoms but is a significant indicator of poor paraganglia cell differentiation and elevated 3-methoxytyramine levels have been validated as an independent biomarker of malignant disease [26]. Finally, non-secretory PPGL are also more commonly associated with *SDHX* mutations and these tumours frequently have reduced or absent activity of tyrosine hydroxylase, the rate limiting enzyme in catecholamine synthesis [27].

Radionuclide Imaging

Nuclear imaging techniques have been utilized as adjuncts to morphological cross-sectional imaging studies, in the diagnosis and management of PPGL for the past four decades and the tracers can be subclassified based on their target ligand into three groups; (i) catecholamine storage and synthesis (^{123}I-metaiodobenzylguanidine, ^{18}F-fluorodopamine (18F-FDA), and 18F-fluorodihydroxyphenylalanine (^{18}F-FDOPA)), (ii) somatostatin receptor (^{111}Indium-pentetreotide and 68Ga-labelled somatostatin analogue peptides) and iii) glucose metabolism (^{18}F-FDG) (Figure 5.4.1.3). It is widely accepted that the selection of the most appropriate tracer for surveillance or diagnosis can be guided by the mutational status of the PPGL [28]. The tracer ^{123}I-metaiodobenzylguanadine (MIBG) is taken up by the noradrenaline

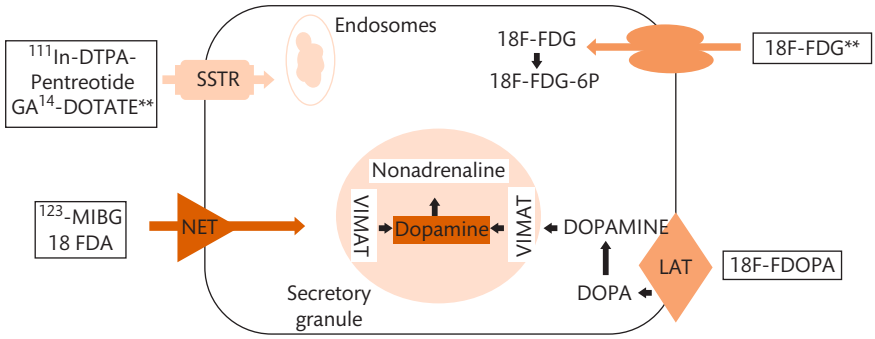

Figure 5.5.1.3 Functional Imaging ligands in PPGL.
** = Improved sensitivity of imaging tracers targeting this ligand in 'pesudohypoxic' PPGL.

transporter (NET) however, the sensitivity of ^{123}I-MIBG scintigraphy is affected by tumour de-differentiation associated with metastatic or aggressive disease, as this is associated with loss of NET expression, therefore increasing the risk of false-negative results using ^{123}I-MIBG scintigraphy. Furthermore, mutations in *SDHX* are associated with a higher risk of false-negative results because of an associated downregulation of the NET transporter in SDH-deficient tumours [29]. Therefore, current recommendations advise that ^{123}I-MIBG scintigraphy should be reserved for those cases being investigated for suitability of treatment with ^{123}I-MIBG radionuclide therapy [10]. Similar issues with sensitivity are seen with the tracer ^{18}F-FDA, also taken up by the NET transporter.

I^{8}F-FDG PET-CT is currently recommended as the molecular imaging modality of choice for the localization of primary and metastatic PPGL [1]. Intriguingly, the sensitivity of ^{18}F-FDG PET-CT also differs depending on the molecular pathways implicated in the development of PPGL, with tumours in the 'pseudohypoxic' cluster demonstrating increased standard uptake values (SUV) of ^{18}F-FDG due to attenuated glycolysis. Recently, evidence has emerged that pseudohypoxic TCA cycle–related PPGL have a high expression of somatostatin receptor type 2 (SSTR2) which improves the sensitivity of somatostatin receptor imaging studies such as 68Ga-DOTATATE PET/CT, which recently demonstrated a sensitivity of 98.6–100% and superior sensitivity to ^{18}F-FDG in two studies [17]. An added benefit of using ^{68}Ga-DOTATATE PET/CT is its predictive value in determining the efficacy of peptide receptor radionuclide therapy (PRRT) with ^{177}Lu-DOTATATE and in the future this may provide an additional therapeutic option for patients with malignant disease.

Chemotherapeutics

Some 10–20% of patients with PPGL will develop malignant disease with the highest risk in patients with germline pathogenic *SDHB* variants [8]. The 5-year survival if malignant disease develops is less than 50% [8]. After surgical resection, effective treatment options are limited and are aimed at controlling tumour proliferation but also tumour secretion of catecholamines to reduce the morbidity associated with excess catecholamines. Systemic treatments currently available include: cytotoxic chemotherapy consisting of a regime of cyclophosphamide, vincristine, and dacarbazine (CVD) and PRRT with radiolabelled (^{131})I-metaiodobenzylguanidine (MIBG) therapy. Recent advances in genomics have suggested novel targeted approaches to molecular therapies for patients with metastatic PPGL. Thus in patients with cluster 1 (pseudohypoxic) PPGL the tumours are characterized by stabilization of HIF and upregulation of glycolytic genes and vascular epidermal growth factor. Receptor tyrosine kinase inhibitors such as sunitinib and other antiangiogenic agents would be predicted to be suitable for PPGL and other tumours harbouring *HIF2A* mutations as well as germline and somatic variants in other cluster 1 genes. Hypermethylation is another unique biological feature of PPGL driven by mutations in the TCA cycle genes and phase 2 clinical trials for demethylating agents are in progress for patients with *SDHX* or *FH* mutated PPGL. In addition, it has been suggested that TCA cycle gene mutation-associated PPGL might be vulnerable to targeting with poly(ADP)-ribose polymerase (PARP) inhibitors [30]. In contrast, for cluster 2 PPGL, though malignant disease is rare in this category, targeted therapies might be directed towards specific kinase pathways (e.g. tyrosine kinase inhibitors (*RET*), ERK1/2 inhibitors (*RAS*), or MEK inhibitors (*NF1*)).

Head and Neck Paragangliomas

Clinical

HNPGL (parasympathetic-derived paragangliomas) are most common in the fourth and fifth decades and are more frequent in females than males. More than 50% of HNPGL arise in the carotid body (known as carotid body paraganglioma or chemodectoma) and, in contrast to sympathetic paragangliomas, metastatic disease is infrequent (<5%). Carotid body HNPGL usually present with a slowly enlarging neck mass and only rarely secrete catecholamines. Glomus jugulare or glomus tympanicum tumours may be associated with partial or complete hearing loss and pulsatile tinnitus. HNPGL may be familial or bilateral (in which case a genetic cause should be suspected) and/or there may be a previous history of PPGL, wild-type gastrointestinal stromal tumour (wtGIST) or renal cell carcinoma (which are each associated with germline mutations in *SDHX* genes. In patients with sporadic HNPGL, about 20% of patients may have a genetic cause [31].

Genetics

Familial and/or multicentric HNPGL most often results from germline mutations in the SDH complex genes (*SDHA, SDHB,*

SDHC, SDHD, and *SDHAF2*). Which *SDHX* gene harbours a mutation is critical for determining the risk to other family members. The most commonly mutated gene in HNPGL, *SDHD*, displays a parent-of-origin effect in penetrance such that individuals who inherit a *SDHD* mutation from their father are at high risk of HNPGL (and also PPGL) whereas if the mutation is inherited from their mother the risk of disease is very low (see Chapter 6.12). Inherited *SDHAF2* mutations show similar parent-of-origin effects on tumour risk. Mutations in *SDHB, SDHC*, and *SDHA* do not demonstrate any parent-of-origin effects and are inherited in a conventional autosomal dominant manner. Though each of these genes encodes an SDH complex protein the tumour-specific risks vary (e.g. for *SDHD* and *SDHC* the risks of HNPGL are higher than those for PPGL whereas the reverse is true for *SDHB* mutations). While *SDHA* mutations are infrequent in patients with HNPGL and PPGL it is the most commonly mutated gene in wtGIST [32]. Individuals presenting with a HNPGL who are found to harbour a *SDHX* gene mutation are at risk of further HNPGL and other *SDHX*-related tumours and require lifelong surveillance and their relatives should be offered genetic investigations/surveillance also (see Chapter 6.12). Occasionally HNPGL may be associated with other inherited causes of PPGL (e.g. *VHL, TMEM127, MAX*) [33].

Management

Symptomatic HNPGL are usually treated by surgery but in some locations (e.g. carotid body tumours, vagal, and jugular paragangliomas) resection of more advanced tumours can be associated with a significant risk of vascular/cranial nerve damage and external beam radiotherapy may be preferable [34]. Small asymptomatic HNPGL may be detected in hereditary mutation carriers and, if multiple, may be kept under surveillance though the risk of malignancy in *SDHB* mutation carriers should be considered.

Neuroblastoma

Clinical

This tumour of developing postganglionic sympathetic neurons occurs in the adrenal medulla or paraspinal ganglia and is the most common solid extracranial tumour in children. Most tumours arise in the abdomen. Mean age at diagnosis is 1.5 years and 90% of cases occur before the age of 10 years [35]. The prognosis is variable with survival ranging from 95% to 50% in low- and high-risk groups, respectively. A variety of clinical, pathological, and molecular characteristics (e.g. age at diagnosis, histopathology, tumour *MYCN* amplification, and chromosomal deletions) are used to categorize affected children into several groups (low to ultra-high) and guide management. A striking feature of neuroblastoma in some patients (particularly young infants) is spontaneous regression, even if metastatic disease is present [35]. Most cases are sporadic and familial cases are rare (up to 2% of all cases) but have provided important insights into the molecular basis of this disorder.

Genetics of Familial Neuroblastoma

Inherited susceptibility to neuroblastoma may be occur as part of well-recognized syndromes such as Beckwith–Wiedemann syndrome and hemihypertrophy, NF1 and RASopathy disorders, congenital central hypoventilation syndrome (Ondine's course) and Hirschsprung disease [36]. In addition, familial (non-syndromic) neuroblastoma may be inherited as an autosomal dominant trait with incomplete penetrance.

Genetic linkage studies in kindreds with familial non-syndromic neuroblastoma localized a gene to chromosome 2p23–p24 and sequencing of the *ALK* (anaplastic lymphoma kinase) proto-oncogene identified recurrent missense variants that act as activating mutations in the ALK tyrosine kinase domain [37]. Germline pathogenic variants in *ALK* are found in about 80% of familial neuroblastoma kindreds [38]. In addition, about 10% of sporadic neuroblastomas harbour somatic *ALK* mutations [39]. Functional studies of mutant *ALK* have identified genotype-phenotype-functional correlations such that the familial mutations with stronger activating effects (e.g. R1275Q) are associated with more complete penetrance than those with weaker activating effects (G1128A) and somatic mutations with the strongest activating effects (e.g. F1174* and F1245*) have only very rarely been detected in the germline but were associated with severe neurodevelopmental anomalies [36].

Idiopathic congenital central hypoventilation syndrome (CCHS) is a rare autosomal dominantly inherited disorder characterized by abnormal autonomic control of ventilation resulting in cyanosis and hypercapnia during sleep. Additional features may include Hirschsprung disease and other features of autonomic nervous system dysfunction (excessive sweating, pupillary abnormalities, disordered body temperature regulation, etc.) [40]. Though the disorder may be fatal in the neonatal period, long-term survivors have been reported. CCHS is the most frequent syndromic cause of neuroblastoma and, in 2003, idiopathic CCHS was shown to be associated with germline mutations in the paired-like homeobox gene *PHOX2B* [37].

RASopathy disorders comprise a group of rare congenital syndromes that result from mutations in genes that encode components of the RAS signalling pathway. These disorders include Costello syndrome (caused by activating mutations in the *HRAS* proto-oncogene), Noonan syndrome (*PTNP11, KRAS, NRAS, SOS1, BRAF, RAF1, MEK1, RIT1*), Cardiofaciocutaneous syndrome (*BRAF, MAP2K1, MAP2K2, KRAS*) and NF1 [41]. Of these disorders, the cancer risk is highest in Costello syndrome, which is characterized by developmental delay, short stature (though birth weight may be increased), facial dysmorphisms, and cardiac anomalies.

Beckwith–Wiedemann syndrome (BWS) is a congenital disorder characterized by variable features including macroglossia, anterior abdominal wall defects, pre-and/or postnatal overgrowth, neonatal hypoglycaemia, lateralized overgrowth (hemihypertrophy and embryonal tumour predisposition in 5–10% of cases. BWS is a human imprinting disorder that is characterized by altered expression/function of the IGF2 growth suppressor and/or the CDKN1C growth suppressor. BWS can be caused by several molecular mechanisms and the embryonal tumour risk varies between molecular subgroups [42]. Overall, the most common embryonal tumour associated with BWS is Wilms tumour, but the neuroblastoma is the most frequent tumour in children with germline *CDKN1C* mutations (~4% of cases) [42].

Neuroblastoma has been associated with germline *TP53* mutations in a few cases (though neuroblastoma is not considered a characteristic Li-Fraumeni syndrome tumour) and rarely has occurred with a germline *SDHB* mutation [41]. In addition, investigations of familial neuroblastoma to identify rare variants in inherited neuroblastoma genes, investigators have undertaken genome-wide association studies (GWAS) in sporadic cases to identify common variants predisposing to neuroblastoma variants. More than 15 susceptibility loci have been identified including variants at (or close to) *BARD1, MLF1, CPZ, CASC15, LIN28B, LMO1, HSD17B12*, and *TP53* [36]. Several of the genes linked to neuroblastoma susceptibility by GWAS studies have also been implicated in tumour behaviour.

Somatic Genetics of Neuroblastoma

More than 30 years ago, amplification of the *MYCN* proto-oncogene was identified as a key driver of neuroblastoma oncogenesis [35]. *MYCN* amplification is associated with advanced tumour stage and poorer patient survival and evaluation of tumour NMYC status is a key component of pretreatment evaluation protocols that use clinical and biological data to categorize patients into the risk groups that determine individual clinical management. A number of recurrent copy number abnormalities have been described in neuroblastoma including loss of 1p, 4p, 6q, 11q, and 14q and gain at 1q, 2p, and 17q. Loss of 1p and 11q are features of high risk neuroblastoma but whereas 1p loss and 17q gain are correlated with *MYCN* amplification, 11q loss is inversely correlated with *MYCN* amplification [35]. Other somatic findings in neuroblastoma include *ALK* amplification (*ALK* and *MYCN* are both map to 2p24) and mutations, *ATRX, ARID1A,* and *ARID1B* mutations, and *TERT* promoter rearrangements. Though investigation for tumour *MYCN* status and copy number abnormalities (e.g. 11q loss) is routinely performed to establish risk group and guide treatment, other genomic profiling investigations (e.g. *ALK* mutation analysis) are not universal though will likely be adopted as targeted therapies become available. A well-recognized feature of neuroblastoma is the occurrence of spontaneous regression in a subset of cases. Several mechanistic aetiologies have been suggested but no genomic biomarker has been identified to date to predict which cases will regress.

Genetic Testing and Surveillance

In non-syndromic patients, testing for germline mutations associated with inherited neuroblastoma is indicated if there is a family history of neuroblastoma or if there are multifocal or bilateral tumours. In addition, the presence of clinical features of a syndrome associated with neuroblastoma predisposition is an indication for specific genetic testing to be initiated.

The neuroblastoma risk in individuals with a germline *ALK* or *PHOX2B* mutation has been estimated at up to 50% and such individuals should be offered regular surveillance as recommended by AACR Childhood Cancer Predisposition Group and including abdominal ultrasound, measurement of urinary catecholamine metabolites (VMA and HVA) and chest radiography until age 10 years [41]. An International Consensus Group recommended three monthly abdominal ultrasound scans until age 7 years in children with *BWS* and a *CDKN1C* mutation [41]. Routine screening for neuroblastoma is generally not indicated in RASopathy disorders but should be considered in Costello syndrome (though elevated urinary VMA and HVA can occur in the absence of a tumour) [41]. About 15% of cases of familial neuroblastoma do not have an identifiable germline mutation and surveillance should also be considered for at risk children with a strong family history.

Conclusions

PPGL, HNPGL, and neuroblastomas are all tumours of the autonomic nervous system but display differing clinical and molecular characteristics. In the past two decades there has been important progress in elucidating the molecular basis of familial and sporadic forms of these disorders and this information has increasingly been used to inform the management of affected individuals and, in inherited cases, their families. For example, the identification of germline mutations in patients with PPGL and HNPGL is now recognized as an important aspect of clinical care. The identification of individuals with inherited neuroblastoma is also important but for this tumour, the characterization of somatic genetic changes (e.g. *MYCN* and 11q deletion status) is an established part of routine clinical management and the role of molecular characterization for prognostic and treatment stratification will undoubtedly continue to expand.

5.5.2 Management of Phaeochromocytoma and Paraganglioma

Henri Timmers

Introduction

Definition

A phaeochromocytoma is a rare neuroendocrine tumour arising from adrenomedullary chromaffin cells that produces one or more catecholamines: adrenaline, noradrenaline, and dopamine [1]. The name is derived from the Greek terms *phaios* (dark, dusky) and *chroma* (colour), referring to the chromium staining characteristics of tumour tissue when treated with chromium salts. Paragangliomas are histologically similar to phaeochromocytomas and also derived from the neural crest, but they do not arise from the adrenal medulla but develop from extra-adrenal sympathetic-derived chromaffin tissues, in particular sympathetic paravertebral ganglia of the thorax, abdomen, and pelvis. Phaeochromocytoma and paraganglioma together will be referred to here as PPGL. The majority of PPGLs, around 80–85%, are located in the adrenal gland. Typical locations for extra-adrenal PPGLs are: (1) the Zuckerkandl body, a sympathetic ganglion located at the root of the inferior mesenteric artery; (2) the sympathetic plexus of the urinary bladder, the kidneys and the heart; (3) the sympathetic ganglia in the mediastinum. Head and neck paragangliomas, located along the glossopharyngeal and vagal nerves in the neck and at the base of the skull, represent the parasympathetic counterparts of PPGL. They are also known as glomus tumours and they mainly derive from the glomus caroticum, glomus (jugulo-)tympanicum, and glomus vagale. In general they do not produce clinically significant amounts of catecholamines.

Epidemiology

The prevalence of PPGL in patients with hypertension in general outpatient clinics varies between 0.2% and 0.6%. In children with hypertension, the prevalence is estimated at 1.7%. Autopsy studies demonstrate undiagnosed PPGLs in 0.05–0.1% of cases and up to 50% of these unrecognized tumours may have contributed to mortality. Therefore, the true prevalence is probably higher. PPGLs are increasingly diagnosed following the incidental discovery of an adrenal mass on abdominal imaging studies for unrelated disorders, nowadays in approximately 30% of cases. Around 7% of adrenal incidentalomas prove to be a phaeochromocytoma [2]. PPGLs can occur at any age, but they mostly present in adults between the ages of 20 and 50 years. Both genders are affected equally. In at least one-third of all patients, PPGL is part of a hereditary syndrome caused by germline mutations. The genetic aspects of PPGL and associated syndromes are discussed in Chapter 5.5.1. Patients with hereditary PPGLs more often present with multifocal disease and at a younger age than those with sporadic neoplasms.

Clinical Significance

The secretion of catecholamines by PPGLs can be devastating due to potentially lethal cardiovascular complications. Therefore, prompt diagnosis is essential for effective treatment, usually by surgical resection, which is curative in most cases. A subset of PPGLs have malignant potential. Metastases develop in around 10–17% of patients, but the malignancy rate is highly variable among different hereditary subforms. Considering the high prevalence of underlying genetic disorders, the diagnosis of PPGL may trigger the discovery of neoplasms in family members. For these reasons, it is crucially important to recognize symptoms and signs and apply an optimal strategy for biochemical testing, tumour localization, and management. In 2014, an Endocrine Society USA clinical practice guideline on the diagnosis and management of PPGL has become available [3].

Pathogenesis

The pathophysiology of PPGL is largely driven by genomic alterations [4]. At least 35% of PPGLs occur as part of a hereditary disorder. In contrast to sporadic PPGLs, which usually involve a unilateral adrenal lesion, familial PPGLs are more often bilateral, extra-adrenal, multifocal, and occur at a younger age. In the context of hereditary disease, PPGL may concurrently present with other syndromal features, including tumours of other neuroendocrine or non-neuroendocrine tissues [5]. The genetic and syndromal aspects of PPGL are discussed in detail in Chapter 5.5.1.

The principal genetic drivers in hereditary PPGL are germline mutations in tumour susceptibility genes, in particular succinate dehydrogenase (SDH) subunits A, B, C, and D and assembly factor 2, Von Hippel–Lindau (VHL), *RET* (causing multiple endocrine neoplasia type 2), neurofibromatosis type 1 *(NF1), MAX, TMEM127*, and more recently discovered fumarate hydratase and malate dehydrogenase 2. Besides these germline mutations, tumourigenesis in 30–40% of PPGLs is driven by somatic mutations, mainly in *HRAS, NF1, EPAS1/HIF2A, RET, VHL*, and *CSDE1*, or by fusions of mastermind-like transcriptional coactivator 3 (*MAML3*).

Based on transcriptional profiling studies, PGLs can be classified into different clusters [6]. Tumours in the first cluster include those associated with *SDH, VHL, fumarate hydratase, malate dehydrogenase*, and *EPAS1/HIF2A* and are characterized by increased expression of genes involved in (pseudo)hypoxia, cell proliferation, angiogenesis, electron transport chain, and the Krebs cycle and abnormal function of oxidoreductases. Tumours in the second cluster include those associated with *RET, NF1, TMEM127* and *MAX* show an increased expression of genes involved in kinase signalling, protein synthesis, endocytosis, and maintenance of a differentiated

chromaffin cell catecholamine biosynthetic and secretory phenotype. The third cluster involves alterations in the Wnt signalling pathway of tumourigenesis and is driven by *MAML3* and *CSDE1*.

SDH subunit B mutations are of particular interest, because they have been associated with large sized aggressive tumours and increased risk of malignancy. SDH is part of the tricarboxylic acid (TCA) cycle where it converts succinate to fumarate and it also serves as complex II of the mitochondrial electron transport chain. *SDH* mutations result in the accumulation of succinate which acts as an oncometabolite and triggers the stabilization of hypoxia-inducible transcription factors which induce the expression of genes with hypoxia response elements that support tumour progression via different signalling pathways [7]. In addition, DNA methylation profiling revealed that *SDH subunit B* mutated PPGLs are characterized by a pattern of global histone and DNA hypermethylation [8]. These epigenetic changes are also induced by succinate through inactivation of histone demethylases and account for several of the characteristics of this subset of tumours, including cell migration/metastatic capacity and catecholamine secretory profile.

Pathology

In general, PPGLs are well-circumscribed, encapsulated tumours [9, 10]. Most PPGL range in size from 3 to 5 cm, but diameters up to 20 cm have been reported. Incidentally discovered PPGLs and those diagnosed during tumour screening in mutation carriers are usually smaller. PPGLs may show a variety of architectural patterns. Typical patterns include nests of cells ('Zellballen'), anastomosing trabecular cords of cells or, most commonly, a mixture of both. See Figure 5.5.2.1.

Occasionally, composite tumours, usually consisting of PPGL combined with ganglioneuroblastoma or ganglioneuroma, are seen. The tumour cells are usually polygonal with an intermediate amount of lightly coloured eosinophilic granular cytoplasm. Cells may vary in size from small to large. Nuclei are well demarcated and generally eccentric in location. Nuclear pleomorphism with enlargement and hyperchromatism may be seen.

According to the revised 2017 WHO classification of endocrine tumours, the qualifiers 'benign' or 'malignant' have no meaning in the context of PPGLs since these tumours all have some metastatic potential, regardless of location or histology [9]. Lesions that qualify as metastases occur in non-chromaffin tissues such as bone, lung, liver, and lymph nodes. Features that are associated with the development of metastases include extra-adrenal tumour location, tumour size larger than 5 cm and **succinate dehydrogenase subunit B** mutations. In addition, various histological features of the primary tumour may help to stratify the risk of subsequent development of metastatic disease. These include the presence of invasion of soft tissue, vascular penetration, hypercellularity, comedo-type necrosis, and a high mitotic count or Ki-67 proliferation index. Coarse nodularity, decreased numbers of sustentacular cells, or absence of hyaline globules may also be associated. On an individual basis, it is difficult to quantify the risk, however. Several histological grading systems have been proposed, such as the most well-known Phaeochromocytoma of the Adrenal Scaled (PASS) score. These scores are hampered by considerable interobserver variability among pathologist and require validation in independent cohorts.

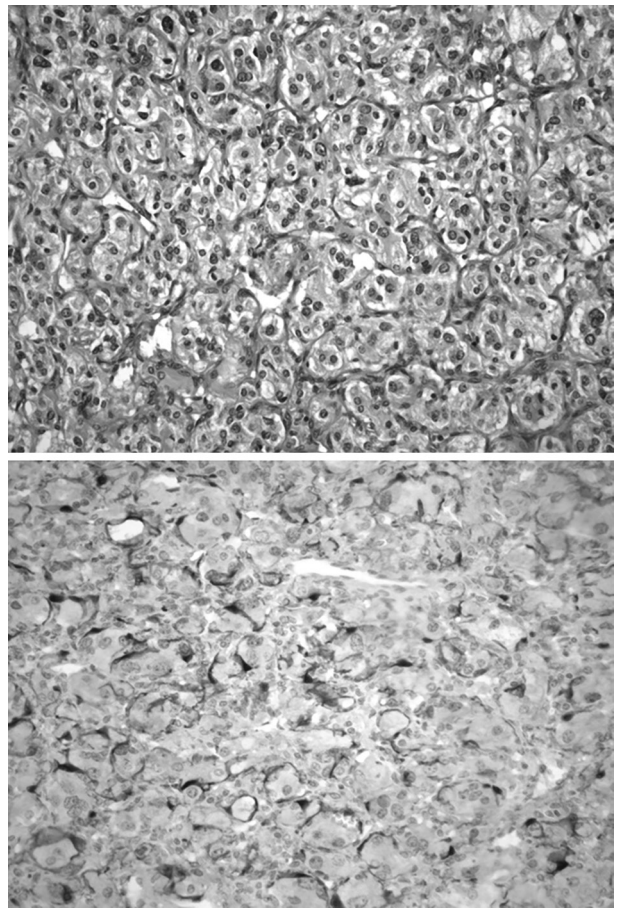

Figure 5.5.2.1 Histology of PPGL. High power view of left adrenal phaeochromocytoma showing typical nested growth pattern ('Zellballen'). Upper panel: haematoxylin & eosin stain. Lower panel: S-100 stain.

Currently there are also no reliable molecular markers for malignancy of PPGL.

The pathological differential diagnosis of PPGL includes oncocytic adrenocortical tumours and (metastases of) renal cell carcinoma and, in case of extra-adrenal paraganglioma, low-grade neuroendocrine tumours. Most, but not all PPGLs show immunohistochemical expression of chromogranin in tumour cells and S100 in sustentacular cells. Presence of steroidogenic factor-1 expression reliably distinguishes adrenocortical tumours from phaeochromocytoma. Staining patterns of keratins may be helpful to distinguish paragangliomas from neuroendocrine tumours.

Clinical Features

Symptoms and Signs

The manifestations of PPGL are diverse, and the tumour can mimic a variety of conditions, often resulting in erroneous diagnoses. Most but not all the clinical signs and symptoms of PPGL are due to the direct actions of secreted catecholamines and the associated short-term activation of the sympathetic nervous system [1]. Hypertension, tachycardia, pallor, headache, and feelings of panic

Table 5.5.2.1 Clinical features of PPGL

Symptoms	Signs
Headaches	Sustained hypertension
Palpitations	Paroxysmal hypertension
Sweating ('diaphoresis')	Tachycardia or reflex bradycardia
Anxiety/panic	Hyperglycaemia
Tremulousness	Postural hypotension
Nausea/vomiting	Weight loss
Abdominal pain	Pallor
Chest pain	Tremor
Tiredness/weakness	Increased respiratory rate
Dizziness	Decreased gastrointestinal motility
Heat intolerance	Psychosis (rare)
Paraesthesiae	Flushing (rare)
Constipation	
Dyspnoea	
Visual disturbances	
Seizures, grand mal (rare)	

Symptoms and signs are listed in order of decreasing frequency

or anxiety, usually dominate the clinical presentation. See Table 5.5.2.1.

Hypertension in patients with PPGL can be either persistent or paroxysmal, but is absent in a minority of patients. Metabolic effects include hyperglycaemia, lactic acidosis, and weight loss. Less common signs and symptoms are nausea, fever, and (pale) flushing. Hypertension is often paroxysmal in nature, in some patients occurring on a background of sustained hypertension, whereas others can have normal blood pressure between paroxysms. Hypertensive episodes can be severe and result in hypertensive emergencies. Blood pressure can also be consistently normal, especially in case of early discovery of small tumours as well as in (very) rare cases of dopamine secretion only or biochemically silent PPGL. Occasionally, patients with predominantly epinephrine-secreting tumours and/or cosecretion of other vasodilatory neuropeptides present with hypotension or even shock. Other substances besides catecholamines that can be secreted by PPGL include vasoactive intestinal peptide, serotonin, histamine, calcitonin, insulin-like growth factor-2, and adrenocorticotrophic hormone, the latter causing ectopic Cushing's syndrome in rare cases. Catecholamine excess may also trigger cardiovascular emergencies, such as myocardial infarction, cardiac arrhythmias, dissecting aortic aneurysm, toxic cardiomyopathy, hypertensive encephalopathy, cerebrovascular accident, neurogenic pulmonary oedema, and even sudden death. See Table 5.5.2.2.

Anaesthesia and tumour manipulation are the most well-known stimuli to elicit a catecholaminergic crisis. Tyramine containing foods, micturition (urinary bladder PPGL), and various drugs such as metoclopramide, tricyclic antidepressants, and glucocorticoids might also induce paroxysms. See Table 5.5.2.3.

Usually, however, spells are unpredictable. For most patients they last between several minutes and one hour. Intervals between attacks may vary from hours to months.

Table 5.5.2.2 Catecholamine-related complications of PPGL

Organ system	Complication
Cardiovascular	Hypertensive crisis
	Shock
	Acute heart failure
	Myocardial infarction
	Arrhythmias
	(Takutsubo) cardiomyopathy
	Dissecting aortic aneurysm
	Limb ischaemia
Pulmonary	Pulmonary oedema
Abdominal	Abdominal haemorrhage
	Paralytic ileus
	Acute intestinal obstruction
	Bowel ischaemia and perforation
	Mesenteric vascular occlusion
	Acute pancreatitis
	Cholecystitis
	Megacolon
Neurologic	Stroke
	Encephalopathy
Renal	Acute renal failure
Metabolic	Diabetic ketoacidosis
	Lactic acidosis
Multisystem	Multiple organ failure, fever

As in adults, PPGLs in children usually present with hypertension and symptoms of catecholamine excess, but the clinical picture may be dominated by central nervous system disturbances such as syncope, cyanotic episodes, cerebral encephalopathy, and blurred vision.

Differential Diagnosis

The individual symptoms are quite non-specific, in particular headaches, palpitations, and sweating, which are the most frequent. This

Table 5.5.2.3 Medications that are contraindicated in PPGL because of potential adverse effects

Dopamine D_2 receptor antagonists	(antiemetics and antipsychotics)
Sympathomimetics	(e.g. ephedrine)
Non-selective β-adrenoreceptor blockers	
Opioid analgesics	
Noradrenaline reuptake inhibitors	(including tricyclic antidepressants)
Monoamino oxidase inhibitors	
Corticosteroids	(particularly if high doses are given)
Peptides	(e.g. ACTH, glucagon)
Neuromuscular blocking agents	(used for anaesthesia)
Serotonin reuptake inhibitors	(rare)

can cause a considerable delay in the diagnosis in many patients. Nevertheless, if all three symptoms present together, the specificity of this combination is reported to be more than 90%. Differential diagnostic considerations are provided in Box 5.5.2.1.

These include anxiety or panic disorder, drug use, baroreflex failure, hyperthyroidism, hypoglycaemia, menopausal flushes, and migraine must also be considered. Many of these conditions can be excluded readily on the basis of a good history and physical examination. When paroxysms involve chest pain, differentiation from an acute myocardial infarction may be difficult because angina pectoris and myocardial damage may occur in the absence of coronary artery disease in a patient with PPGL. Many non-specific electrocardiographic changes have been reported, as well as various supraventricular and ventricular tachycardias. Hypertension from a PPGL during pregnancy can mimic pre-eclampsia.

Biochemical Diagnosis

Clinical Settings for Testing

Testing for PPGL should be considered in several clinical settings [3]. The diagnosis should be prompted by symptoms of PPGL, in particular when they are paroxysmal and when they are precipitated by the use of medications that affect catecholamine release. See Table 5.5.2.3. Screening for PPGL should also be performed in all (non-symptomatic) patients with an accidentally discovered adrenal mass, regardless of the presence of hypertension. In addition, periodic testing is performed in patients with a relevant hereditary predispositions (see Chapter 5.5.1) or a history of previous PPGL [11]. Not all patients who present with new onset hypertension need to be tested but only those with additional clues for catecholamine excess. Initial testing is also required in patients with unexplainable variability of blood pressure or a paradoxical blood pressure response to anaesthesia, surgery, or medications.

Catecholamine Synthesis and Metabolization

The diagnosis of PPGL primarily relies on the measurement of catecholamine metabolites in plasma or urine. Biosynthesis of catecholamines starts with conversion of tyrosine to dihydroxyphenylalanine (DOPA) by the enzyme tyrosine hydroxylase. See Figure 5.5.2.2.

DOPA is converted to dopamine which is translocated from the cytoplasm into catecholamine storage vesicles of chromaffin cells. The presence of the enzyme dopamine-ß hydroxylase within these vesicles is responsible for conversion of dopamine to noradrenaline. In adrenal medullary chromaffin cells, noradrenaline is further converted to adrenaline by phenylethanolamine-*N*-methyltransferase. Since this enzyme is only present in these cells and requires the presence of cortisol as a cofactor, adrenaline is nearly exclusively produced within the adrenal medulla. Metabolism—and thereby inactivation—of catecholamines occurs through different pathways resulting in numerous metabolites. The majority of circulating noradrenaline is derived from noradrenergic neurons of the central and sympathetic nervous system. Deamination of neuronal noradrenaline occurs by monoamine oxidase after neuronal reuptake or after leakage of the transmitter from storage vesicles into the neuronal cytosol. Noradrenaline is also partially metabolized in extraneuronal tissues and adrenal chromaffin cells, where it is converted to normetanephrine by catechol-*O*-methyltransferase. Adrenaline is mainly metabolized within adrenal chromaffin cells into the O-methylated metabolite metanephrine. Metabolism of dopamine follows other pathways resulting in production of the *O*-methylated metabolite methoxytyramine. Plasma-free metanephrines and

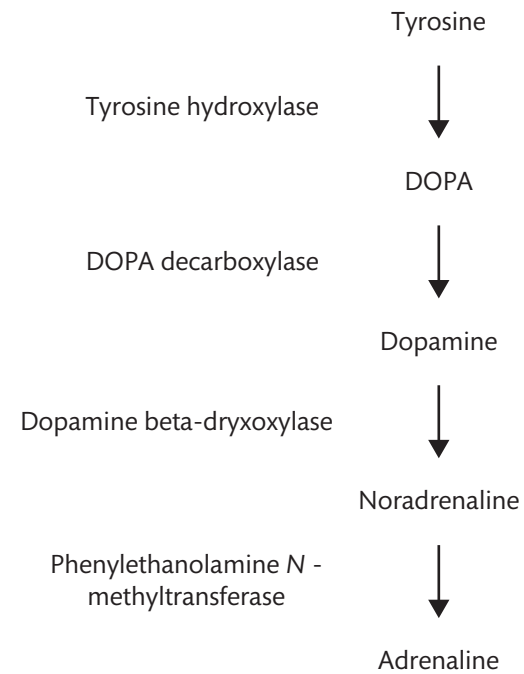

Figure 5.5.2.2 Catecholamine synthesis pathway. Tyrosine is converted to dihydroxyphenylalanine (DOPA) then to dopamine, noradrenaline, and adrenaline. The conversion of noradrenaline to adrenaline is catalysed by the enzyme phenoxyethanolamine N-methyltransferase in the adrenal medulla, which is dependent on cortisol as a cofactor.

methoxytyramine are subsequently conjugated to sulphates by gut wall enzymes and then excreted by the kidneys.

Choice of Biochemical Test

Measurements of plasma-free metanephrines or 24 h urinary fractionated metanephrines are the tests of first choice since they have a higher diagnostic accuracy than the measurement of catecholamines or other metabolites [3]. It is well established that measurements of urinary and plasma catecholamines are insufficiently reliable since catecholamine secretion in PPGLs is often episodic or even negligible in asymptomatic patients. This higher diagnostic accuracy of metanephrines can be attributed to continuous intratumoural production and secretion of metanephrines into the circulatory compartment. This secretion is independent of highly variable catecholamine release caused by the tumour or by sympathoadrenal excitation. Both plasma-free and 24-h urinary fractionated metanephrines offer high sensitivities between 96% and 99% and a specificity between 69% and 93% [12]. In children, the diagnostic performance of plasma or urine metanephrines is similarly high. Plasma concentrations of metanephrine on average are higher in children than in adults, but also higher in boys than in girls. It is advised to apply sex and age adjusted reference intervals [13].

The measurement of metanephrines can be achieved by several analytical techniques. Earlier procedures utilizing radioenzymatic assays have generally been superseded by highly sensitive and specific high-performance liquid chromatography methods utilizing electrochemical detection or, more efficient, in combination with tandem mass spectrometry.

Interpretation of Biochemical Test Results

The interpretation of biochemical test results for the diagnosis of PPGL can be challenging and several pitfalls need to be considered. Elevated plasma levels of catecholamines or metanephrines are not specific for PPGL and do not always prove the presence of PPGL but could also reflect increased sympathetic activity. Several preanalytical factors may affect test results, such as exercise, posture, food, stress, caffeine, smoking, hypoglycaemia, and medications; these factors may alter production or disposition of catecholamines and their metabolites. A blood sample for measurement of metanephrines should ideally be taken after supine rest in a quiet room for at least 20–30 minutes, since samples obtained in sitting position without preceding rest provide a lower diagnostic accuracy. Numerous food products, including banana, pineapple, nuts, and cereals, contain substantial quantities of biogenic amines that may produce false-positive test results. Dietary restrictions prior to testing, however, appear warranted for the measurement of the dopamine metabolite methoxytyramine only.

Medications and intoxications can interfere analytically, pharmacodynamically, and pharmacokinetically, resulting in usually false-positive test results. See Box 5.5.2.2.

Analytical interference can occur with some, but not all, liquid chromatography with electrochemical detection assays. Tandem mass spectrometry is less susceptible to analytical interference. Pharmacodynamic and pharmacokinetic interference involves the effects of drugs on secretion, metabolism, and excretion of catecholamines or metabolites. Numerous drugs are known to increase catecholamine and metabolite concentrations, resulting in falsely elevated test results [14]. Examples are sympathomimetic agents such as ephedrine, amphetamine, cocaine, caffeine, and nicotine, agents that inhibit reuptake of noradrenaline such as serotonin/noradrenaline reuptake inhibitors and tricyclic antidepressants, agents that inhibit catecholamine metabolism such as monoamino oxidase inhibitors and vasodilators such as calcium-channel blockers and α- and β-adrenergic receptor blockers. False-positive results can also occur with Levodopa, used in Parkinson's disease.

Box 5.5.2.2 Medications that may cause false elevated metanephrines

Pharmacodynamic or pharmacokinetic interference
Tricyclic antidepressants
Phenoxybenzamine
Monoamine oxidase inhibitors
Levodopa
Alpha-methyldopa
Sympathomimetics
Calcium-channel blockers
Caffeine
Nicotine
Sympathomimetics

Labetalol
Paracetamol
Sotalol
Alpha-methyldopa
Buspirone
Sulphasalazine
Levodopa
Alpha-methyldopa
Sympathomimetics

Clonidine Suppression Test

Initial test results of plasma-free metanephrines are not always immediately conclusive. When metanephrines are mildly elevated (<3–4 times the upper reference limit) the question arises whether the test result is true or false-positive. First, measurements of plasma-free metanephrines can be repeated after optimizing sampling conditions and elimination of potential interfering drugs and substances which may be responsible for false-positive results. If the tests are still inconclusive, a clonidine suppression test can be performed [15]. Clonidine suppresses release of neuronal noradrenaline (and thereby of normetanephrine) by stimulating brain and prejunctional neuronal α2-adrenergic receptors. For the test, clonidine is administered orally at a dose of 300 μg/70 kg body weight. An abnormal test result indicating a PPGL includes an elevation of plasma normetanephrine at 3 hours after clonidine administration and a less than 40% decrease in levels compared with baseline. If these criteria are not met, sympathetic activation rather than PPGL is the cause of elevation. Both sensitivity and specificity of the test are high. Since clonidine may induce hypotension, blood pressure should be intermittently monitored throughout the procedure. The glucagon stimulation test, previously used to unmask the presence of a PPGL, is obsolete due to substantial risk of hypertensive complications and insufficient sensitivity.

Biochemical Phenotype

Once biochemical diagnosis of PPGL is established, tumours can be divided into three groups according to their biochemical phenotype.

Noradrenergic tumours secrete mainly noradrenaline while adrenergic tumours secrete mainly adrenaline in addition to a varying amount of noradrenaline. The third group is formed by tumours which (co)secrete dopamine. The secretion of metanephrines is relatively higher in noradrenergic tumours than adrenergic tumours and is positively correlated with tumour size [16]. The biochemical phenotype can also be an indicator of tumour location since adrenaline and metanephrine secretion is usually confined to adrenal PPGLs, whereas extra-adrenal tumours secrete predominantly or exclusively noradrenaline and normetanephrine. These differences are attributed to the paracrine action of cortisol, which induces the expression of adrenal phenylethanolamine-*N*-methyltransferase, the enzyme that converts noradrenaline to adrenaline. The biochemical phenotype also strongly depends on the underlying genotype. PPGLs in the context of multiple endocrine neoplasia type 2 and neurofibromatosis type 1 are adrenergic, whereas those related to Von Hippel–Lindau syndrome and **succinate dehydrogenase** mutations are almost always noradrenergic and in the latter case regularly also dopaminergic [17]. Dopamine excess typically does not cause endocrine manifestations.

Tumour Localization

Anatomical Imaging

Localization of PPGL should be initiated only if a biochemical diagnosis has been established. In patients with a hereditary predisposition, less compelling biochemical evidence might justify imaging studies. Particularly, familial PPGLs related to mutations in succinate dehydrogenase subunit B and D can be completely negative on biochemical testing and therefore imaging represents the principal means for diagnosis. The same applies to most head and neck paragangliomas. The goals of imaging studies are localization of the primary tumour, detection of multiple primary tumours and of metastases. First line anatomical imaging modalities for imaging are computed tomography (CT) and magnetic resonance imaging (MRI), the latter being preferred in children and young adults to limit radiation exposure. Both techniques provide a high sensitivity (88–100%) and allow precise tumour delineation, which is critical for presurgical evaluation. Use of ultrasound is usually not recommended due to its suboptimal sensitivity. The administration of both CT and MRI contrast agents is safe and does not require adrenergic blockade [18]. The radiological appearance of PPGL is variable. The tumours can be homogeneous or heterogeneous, including features of necrosis, haemorrhage, cystic changes, and calcifications. In representative areas of the tumour, however, unenhanced attenuation on CT is almost invariably >10 Hounsfield units as opposed to most adrenal adenomas [19, 20]. Contrast washout is unreliable to distinguish between PPGL and adenoma. Disadvantages of CT besides radiation burden are contrast related allergies and nephropathy. On MRI, a high intensity (bright) T_2-weighted signal is typical of PPGL, but this occurs in only one-third of the tumours. Artefacts due to surgical clips of previous surgery may hamper the localization of recurrent disease by MRI. In addition, the specificity of anatomical imaging is limited and therefore functional imaging can be of additional value.

Functional Imaging

Lesions detected by anatomical imaging can be specifically identified as PPGL by functional imaging agents that target the catecholamine synthesis, storage, and secretion pathways of chromaffin tumour cells [21]. In this respect, the most widely used imaging modality is [^{123}I]-metaiodobenzylguanidine (MIBG) single-photon emission computed tomography (SPECT). See Figure 5.5.2.3.

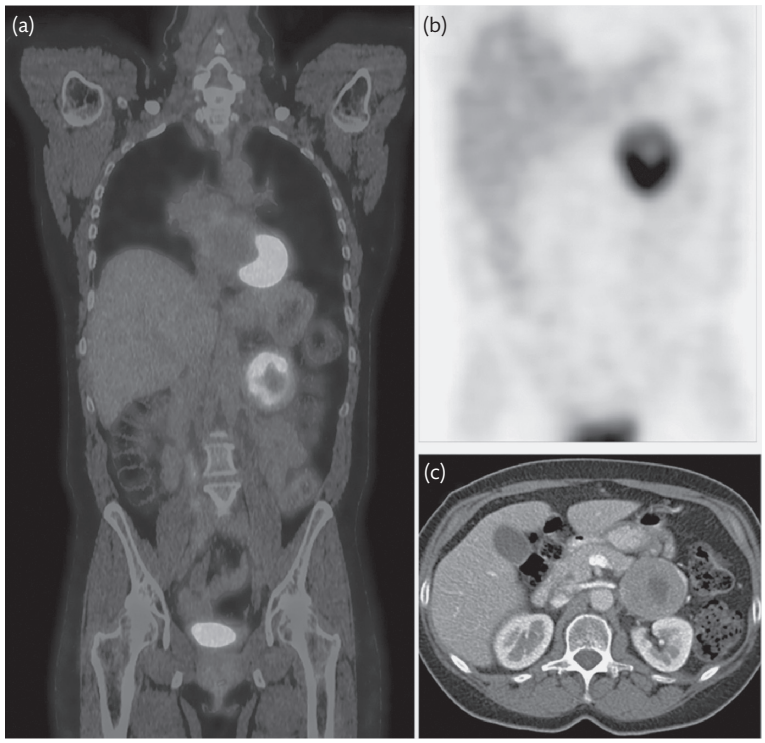

Figure 5.5.2.3 Imaging results in patient with left adrenal phaeochromocytoma. (a) [^{18}F]-FDG PET; (b) [^{123}I]-MIBG single-photon emission computed tomography; (c) computed tomography (CT).

Table 5.5.2.4 Radiopharmaceuticals for the functional imaging of PPGL

Molecular targets	Tracers
Norepinephrine transporter	[^{123}I]-MIBG, 6-[^{18}F]-fluorodopamine, [^{11}C]-epinephrine, [^{11}C]-hydroxyephedrine
Neutral amino acid transporter System L	[^{18}F]-fluoro-L-3,4-dihydroxyphenylalanine
Somatostatin receptors	[^{68}Ga]-DOTATATE, DOTANOC, DOTATOC
Glucose transporters	[^{18}F]-fluorodeoxyglucose

The norepinephrine analogue MIBG targets the norepinephrine transporter of the PPGL cell membrane and the vesicular monoamine transporters in the membrane of intracellular vesicles. See Table 5.5.2.4.

[^{123}I]-MIBG is typically preferred to [^{131}I]-MIBG for imaging because [^{123}I] lacks β emissions and has a shorter half-life (13.2 hours compared with 8 days), resulting in overall lower radiation exposure for the patient. Alternative tracers that accumulate in the tumour cells through the same mechanisms, but are detected by positron emission tomography (PET), are 6-[^{18}F]-fluorodopamine, [^{11}C]-epinephrine and [^{11}C]-hydroxyephedrine. However, the availability of these latter radiotracers for clinical practice is limited. MIBG scanning can be used in patients with an increased risk for metastatic disease due to large size of the primary tumour or to extra-adrenal, multifocal or recurrent disease [22]. Its use is essential in patients with metastatic PPGL when radiotherapy using [^{131}I]-MIBG is planned. Because up to 50% of normal adrenal glands demonstrate physiological uptake of MIBG, false-positive results can occur when the uptake is asymmetric. The sensitivity of MIBG scans to detect PPGL is 85–88% for adrenal, 56–75% for extra-adrenal and 56–83% for metastatic tumours. False negative results are most common (~50%) in PPGLs related to mutations in succinate dehydrogenase. Practical disadvantages of MIBG scintigraphy are a delay in scanning until 24 h post-injection, potential drug interference (e.g. false negative results due to labetalol, tricyclic antidepressants, sympathomimetics, and calcium-channel blockers) and the need for thyroid protection by pretreatment with iodine.

A clearly better sensitivity for detection of metastases than that achieved by MIBG SPECT can be provided by PET. 2-[^{18}F]-Fluoro-2-deoxy-D-glucose (FDG) PET provides an index of intracellular glucose metabolism and is taken up by the tumour cell through the membranous glucose transporters. Its routine application is recommended for the staging and monitoring of metastatic PPGL, in particular when caused by SDH subunit B mutations [23]. Similar or even higher sensitivities can be accomplished by using [^{18}F]-fluoro-L-3,4-dihydroxyphenylalanine (DOPA), which targets the amino acid transporters of neuroendocrine cells, or by using the [^{68}Ga] or [^{111}In] labelled somatostatin analogues DOTATATE, DOTANOC, or DOTATOC [24]. Moreover, for comprehensive localization of metastases of the bone, a frequent site of involvement in malignant PPGL, PET is superior to anatomical imaging.

Treatment and Prognosis

Medical and Surgical Management

Optimal management of PPGL warrants a multidisciplinary team of (paediatric) endocrinologists, surgeons, anaesthesiologists, genetic counsellors, radiologists, and cardiologists with expertise in the field. This calls for centralization of care for these patients. Non-metastatic PPGL can be cured by surgical resection. However, before any surgery is undertaken, the deleterious effects of catecholamine secretion should be under control. The main goals of preoperative management are to relieve symptoms and signs of catecholamine excess, including normalization of blood pressure and heart rate, volume repletion and prevention of anaesthesia and surgery-induced catecholamine storm and its consequences on the cardiovascular system [25]. Potentially lethal complications, including hypertensive crisis, myocardial infarction, congestive heart failure (e.g. due to (Takutsubo) cardiomyopathy) and cerebrovascular events, should be minimized. Retrospective studies suggested that risk factors for haemodynamic instability during surgery include large tumour size, high noradrenaline concentration, and high preoperative blood pressure. There are no evidence-based protocols for the medical management. Local practices are wide ranging and there are international differences in available and approved medical therapies. An example approach to the preoperative management is provided in Box 5.5.2.3.

There is extensive clinical experience with the irreversible and non-selective α-adrenergic receptor blocker phenoxybenzamine. Treatment is primarily aimed at blocking catecholamine-mediated vasoconstriction. Adverse reactions include postural hypotension, syncope, nasal congestion, reflex tachycardia, drowsiness, and fatigue. Over at least 2–4 weeks prior to surgery, doses are gradually increased until blood pressure is steadily controlled. This preoperative medical preparation takes place either in the outpatient or inpatient clinic, depending on patient-related factors (e.g. disease severity, geographical considerations) and local experience. In general, suggested targets are a supine systolic/diastolic blood pressure below 130/80 mmHg and a systolic blood pressure in the upright position between 90 and 110 mmHg. Doses of phenoxybenzamine up to 70 mg twice daily maybe necessary. Alternatively, doxazosin,

Box 5.5.2.3 Preparation for PPGL surgery (to be customized for the individual patient)

Start α-adrenoreceptor blocker at least 14 days before surgery
(e.g. phenoxybenzamine 10 mg twice daily or doxazosin 4 mg once daily)
Monitor side effects, supine and upright blood pressure, and heart rate (at least twice daily) and body weight (daily)
Oral salt and fluid loading
(e.g. NaCl 250 mmol = 15 grams daily)
Gradually increase α-adrenoreceptor blocker until haemodynamic goals* are met
(e.g. until maximum dose of phenoxybenzamine 70 mg twice daily or doxazosin 24 mg twice daily)
Add β-adrenoceptor blocker after at least 3–4 days of β-adrenoreceptor blocker, when significant tachycardia or a catecholamine-induced arrhythmia occurs
(e.g. metoprolol, atenolol, or propranolol)
Gradually increase β-adrenoceptor blocker until haemodynamic goals* are met
Add calcium-channel antagonist when haemodynamic goals* are not met despite maximum α-adrenoreceptor-blockade
(e.g. nipedipine or amlodipine)
Administer a saline infusion (e.g. 2L NaCL 0.9% in 24 hours) 24 h before surgery

* Haemodynamic goals: supine systolic/diastolic blood pressure <130/80 mmHg, systolic blood pressure in the upright position between 90 and 110 mmHg, heart

prazosin, or terazosin may be used. These are all competitive and selective α1-adrenergic receptor blockers, with no effect on presynaptic α2-adrenergic receptors and therefore the negative feedback on catecholamine release is preserved, reducing the risk of reflex tachycardia. Doxazosin may need to be titrated up to 24 mg twice daily. Retrospective studies demonstrated that α1-selective adrenergic receptor blockers were associated with lower preoperative diastolic blood pressure, a lower intraoperative heart rate, better postoperative haemodynamic recovery and fewer adverse effects than non-selective α-adrenergic blockers [26]. Another study did not show any difference between the two classes of drugs [27]. Prospective trials investigating the effectiveness and safety of different α-adrenergic blocking therapies are under way.

B-adrenergic blocking agents such as propranolol, atenolol, and metoprolol are needed only when significant tachycardia occurs after α-blockade or for treatment of catecholamine-induced arrhythmia. Suggested targets for heart rate are below 80 beats per minute in the supine position and <100 beats per minute while standing. A (non-selective) β-blocker should never be used in the absence of sufficient α-adrenergic blockade because the former will exacerbate epinephrine-induced vasoconstriction by inhibiting β2-mediated vasodilation. This will make hypertensive episodes worse in subjects on a β-blocker alone. The use of labetalol is not recommended because of a fixed ratio of α- to β-antagonistic activity (1:5).

A-methyl-paratyrosine (metyrosine) is a competitive inhibitor of tyrosine hydroxylase, the rate-limiting step in catecholamine biosynthesis. It can also be used in the treatment of patients with metastatic PPGL. The drug is not generally available in all countries and institutions. Side effects such as sedation, depression, anxiety, and extrapyramidal manifestations relate to inhibition of catecholamine synthesis in the brain and can be severe. Alternatively, calcium-channel blockers such as nifedipine, amlodipine, and verapamil can be used or added, if maximum doses of α-adrenergic blockers are insufficient.

Usually, oral salt and fluid loading or intravenous fluids are given to expand blood volume to prevent preoperative orthostatic hypotension and severe postoperative hypotension. The rationale behind this recommendation is based on the notion that PPGL is associated with a decreased intravascular volume, which is restored under influence of treatment with α-adrenoceptor antagonists. It is common practice to administer a saline infusion (e.g. 2L NaCL 0.9% in 24 hours) during the 24 h before surgery [27]. Medications that can elicit a catecholamine surge should be avoided. See Table 5.5.2.3.

There is no consensus on the optimal anaesthetic management, as randomized controlled trials on this subject are not available. As a minimum requirement, anaesthesiologic management should be in experienced hands. Despite preoperative blockade, intraoperative blood pressure can vary widely, necessitating the use of short acting drugs such as phentolamine, nicardipine, and sodium nitroprusside. Perioperative glucocorticoid stress dosing to avoid Addison crisis should be applied in case of bilateral adrenalectomy, (partial) rest-adrenalectomy, and the rare event of preoperative Cushing syndrome due to mixed pheochromocytoma/adrenocortical adenoma or ectopic adrenocorticotrophic hormone (ACTH) production [28].

With regard to the surgical resection of both adrenal and extra-adrenal retroperitoneal PPGL, open surgery has been largely replaced by minimally invasive laparoscopic surgery via either the retroperitoneal or transperitoneal route. Open resection is recommended for large (e.g. >6 cm) or invasive PPGLs to ensure complete tumour resection, prevent tumour rupture and avoid local recurrence [3]. The optimal surgical approach for extra-adrenal paraganglioma depends on the tumour location, invasion of surrounding structures and size. In one of the largest surgical series reported so far, perioperative mortality and morbidity were 2.4% and 23.6%, respectively [29]. In the setting of bilateral adrenal PPGL or a high chance of developing contralateral disease and a low chance of metastases, for example in case of multiple endocrine neoplasia type 2, cortex-sparing partial adrenalectomy can be attempted. The latter approach particularly pertains to situations where contralateral adrenalectomy has already been performed previously and loss of adrenocortical function and subsequent hormone replacement could be prevented. However, this is at the cost of an increased risk of local recurrence.

Postoperatively, the patient is monitored in the ICU for at least 24 hours to manage potential complications such as rebound hypotension and hypoglycaemia. Hypotension can be overcome by volume loading and vasopressor therapy with noradrenaline under strict monitoring of haemodynamic parameters. Post-surgical hypertension on the other hand can occur as a consequence of non-radical resection, pain, or volume overload and should be treated accordingly.

Follow-up After Surgical Excision

In 2016, a European Society of Endocrinology clinical practice guideline on the follow-up of patients operated on for a PPGL was published [30]. These recommendations were based on a systematic review of the literature regarding the incidence of recurrence (local or metastatic) or new tumours in patients operated on for PPGL with apparently complete tumour resection. The 5-year incidence of recurrence was estimated at 4.7% (95% CI: 4.0, 6.1), distributed as follows: new tumours 22%, local recurrences 23% and metastatic recurrences 55%. The risk of new events persists in the long-term and is higher for patients with genetic or syndromic diseases. Plasma or urinary metanephrines should be determined between 2 and 6 weeks after recovery from surgery to establish biochemical cure. Subsequently, a minimum follow-up of 10 years by yearly clinical and biochemical investigations is recommended. In high-risk patients, i.e. young patients and those with a hereditary disease, a large tumour, and/or an extra-adrenal PPGL, lifelong annual follow-up should be offered. For patients with known genetic diseases, follow-up should be tailored to the specific condition. For patients with a familial paraganglioma syndrome due to succinate dehydrogenase mutation, the follow-up should also include periodic imaging, regardless of the results of metanephrines, to screen for biochemically silent PPGL and head and neck paraganglioma, as well as other associated tumours such as renal cell carcinoma, gastrointestinal stromal tumours, pituitary adenoma, carcinoid tumours and, rarely, neuroblastoma.

Metastatic PPGL

A minority of patients with PPGL (10–17%) develop metastatic disease. In around half of these patients metastases are already present at the initial diagnosis ('synchronous'), whereas metachronous metastases may develop in the course of years or decades after surgery. Predictors of a malignant course include large tumour size,

Box 5.5.2.4 TNM classification of malignant PPGL

Primary tumour size

T_x Primary tumour cannot be assessed
T_1 Tumour <5 cm in greatest dimension, no extra-adrenal invasion
T_2 Tumour ≥5 cm or extra-adrenal paraganglioma of any size, no extra-adrenal invasion
T_3 Tumour of any size with invasion into surrounding tissues (e.g. liver, pancreas, spleen, kidney)

Regional lymph nodes

N_x Regional lymph nodes cannot be assessed
N_0 No lymph node metastasis
N_1 Regional lymph node metastasis

Distant metastasis

M_0 No distal metastasis
M_1 Distant metastasis
M1a: to only bone
M1b: to only distant lymph nodes/liver or lung
M1c: to bone plus multiple other sites

extra-adrenal tumour location, and presence of a germline mutation in SDH subunit B. The TNM staging for PPGL has adopted a cut-off of 5 cm as well as extra-adrenal location as important determinants of the risk of metastasis [31]. See Box 5.5.2.4.

Reliable histological and molecular markers to predict a malignant course in individual patients are lacking. Distant metastases of mainly occur in the lymph nodes (80%), skeleton (72%), liver (50%), and lungs (50%) [32]. See Figure 5.5.2.4.

Local infiltration of the liver, pancreas, kidneys, gastrointestinal tract, and adipose tissue may also occur. Metastases to the brain, breasts, skin, and ovaries have rarely been described.

The natural course of the disease is highly heterogeneous. The overall 5-year survival rate varies between 34% and 60% [33]. Overall survival, progression-free survival, and clinical outcome are difficult to predict on an individual basis. Some patients have indolent disease, despite the presence of extensive distant metastases, especially when confined to the skeleton. These patients may have an excellent quality of life and may need little or no therapeutic intervention for a prolonged period of time. In a French series, half of therapy-naive patients with metastatic PPGL achieved stable disease at 1 year without treatment [34]. On the other hand, some patients exhibit very aggressive disease and lack of response to systemic therapy. Most patients exhibit intermediate outcomes with progressive disease that will require intervention at some point. Several factors have been associated with survival. This includes the presence of a germline mutation in *SDH subunit B* [35], with a prevalence of 30% in patients with metastatic PPGL and up to 90% if the tumour originates from an extra-adrenal location. Other negative predictors of survival are overall tumour burden, timing, and location of metastases, and the degree of catecholamine excess.

No official guidelines on the treatment of metastatic PPGL exist. In any case, successful management again requires a multidisciplinary approach, involving endocrinology, oncology, surgery, radiotherapy, interventional radiology, and pathology. The goals of treatment are to reduce tumour size, treat catecholamine-related adverse events, palliate symptoms related to tumour burden and prevent tumour progression. In case of limited metastatic disease

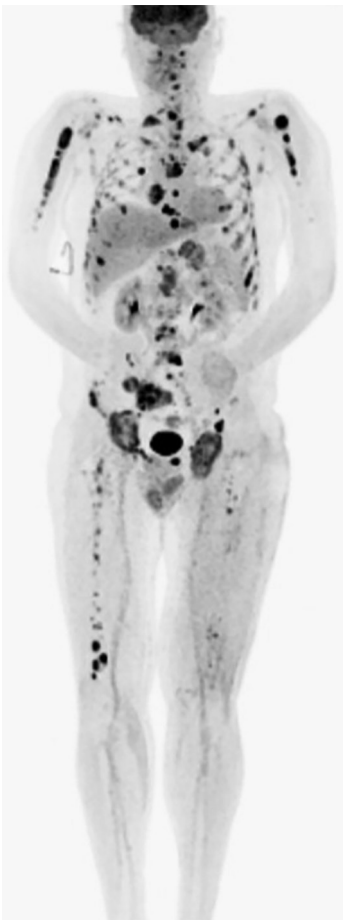

Figure 5.5.2.4 [^{18}F]-FDG PET in patient with widespread bone metastasis of extra-adrenal PPGL due to succinate dehydrogenase subunit B mutation.

such as local malignant lymphadenopathy, surgical metastasectomy can be undertaken with curative intent. Even in the presence of incurable disease, resection (or debulking) of the primary tumour has been shown to be of benefit for survival. Other local therapies include external beam irradiation, radiofrequency ablation, tumour embolization, cryotherapy, and percutaneous microwave coagulation, which can be applied for local symptom relief. Patients with epidural cord compression may benefit from spine surgery as well as external beam irradiation, or a combination of both. Stable compression fractures can be safely treated with percutaneous cement injection. Spinal instability can be treated only with surgery. Prior to these interventions, patients with hormonally active PPGL must be treated with α- and β-adrenergic blockers. Very importantly, these medications are also given to control symptoms of catecholamine excess. In some cases α-methyl-paratyrosine (metyrosine) might be added. Besides hypertension and other cardiovascular manifestations, patients with metastatic PPGL may suffer from severe constipation caused by the inhibitory effects of catecholamines on bowel movement, in particular noradrenaline. This requires vigorous treatment with laxatives.

In case of MIBG positive metastatic lesions on diagnostic scanning, targeted radiotherapy with [^{131}I]-MIBG can be applied. Both high-dose regimens and fractionated low-dose regimens have been shown to be effective in achieving a therapeutic response.

A meta-analysis on the effectiveness of different regimens of [^{131}I]-MIBG radiotherapy, yielded the following response data: a complete response in 3% of patients, a partial response in 27% of patients, and stable disease in 52% of patients [36]. Biochemical responses were as follows: 11% complete response, 40% partial response, and 21% stable disease. [^{131}I]-MIBG treatment is generally well-tolerated, although high-dose regimens may cause bone marrow toxicity. Recently, positive effects have also been reported for ultratrace iobenguane, a more efficiently radiolabelled form of [^{131}I]-MIBG. The use of radiolabelled somatostatin analogues for peptide receptor radionuclide therapy for patients with PPGL metastases that are positive on [^{68}Ga] DOTATATE, DOTANOC, or DOTATOC has not been systematically evaluated but may be effective in some cases.

Regarding chemotherapy, different agents have been used for metastatic PPGL, including mainly cyclophosphamide, doxorubicin, vincristine, dacarbazine, temozolomide, 5-fluorouracil, methotrexate, ifosfamide, streptozotocin, and platinum compounds. The best examined protocol, albeit in retrospective studies only, is a combination of cyclophosphamide, vincristine, and dacarbazine, usually administered in 21-day cycles. Complete and partial radiological response rates were 11% and 44%, respectively [37]. It was shown that besides yielding a potential survival benefit, this combination chemotherapy can facilitate control of blood pressure as well as symptoms [38]. On the other hand, the side effects may negatively impact the patient's quality of life. Patients likely to benefit from chemotherapy are those with rapidly progressive disease and tumour related symptoms that cannot be easily controlled by supportive therapies. The role of chemotherapy in a (neo)adjuvant setting of PPGL remains to be determined. As an oral alternative, temozolomide has been successfully applied to treat *SDH subunit B* related PPGL [39].

In a subset of patients, antiangiogenetic treatment with tyrosine kinase inhibitors such as sunitinib has been associated with partial response, disease stabilization and improved blood pressure control [40]. Prospective clinical trials are now ongoing (http://clinicaltrials.gov/). For future treatment, in the context of a tumour that is highly variable in its genotype, growth-rate, and prognosis, a multiomics approach is being investigated to better stratify PPGLs and guide tailor-made strategies [6]. A proposed algorithm for currently available treatments of metastatic PPGL is provided in Figure 5.5.2.5.

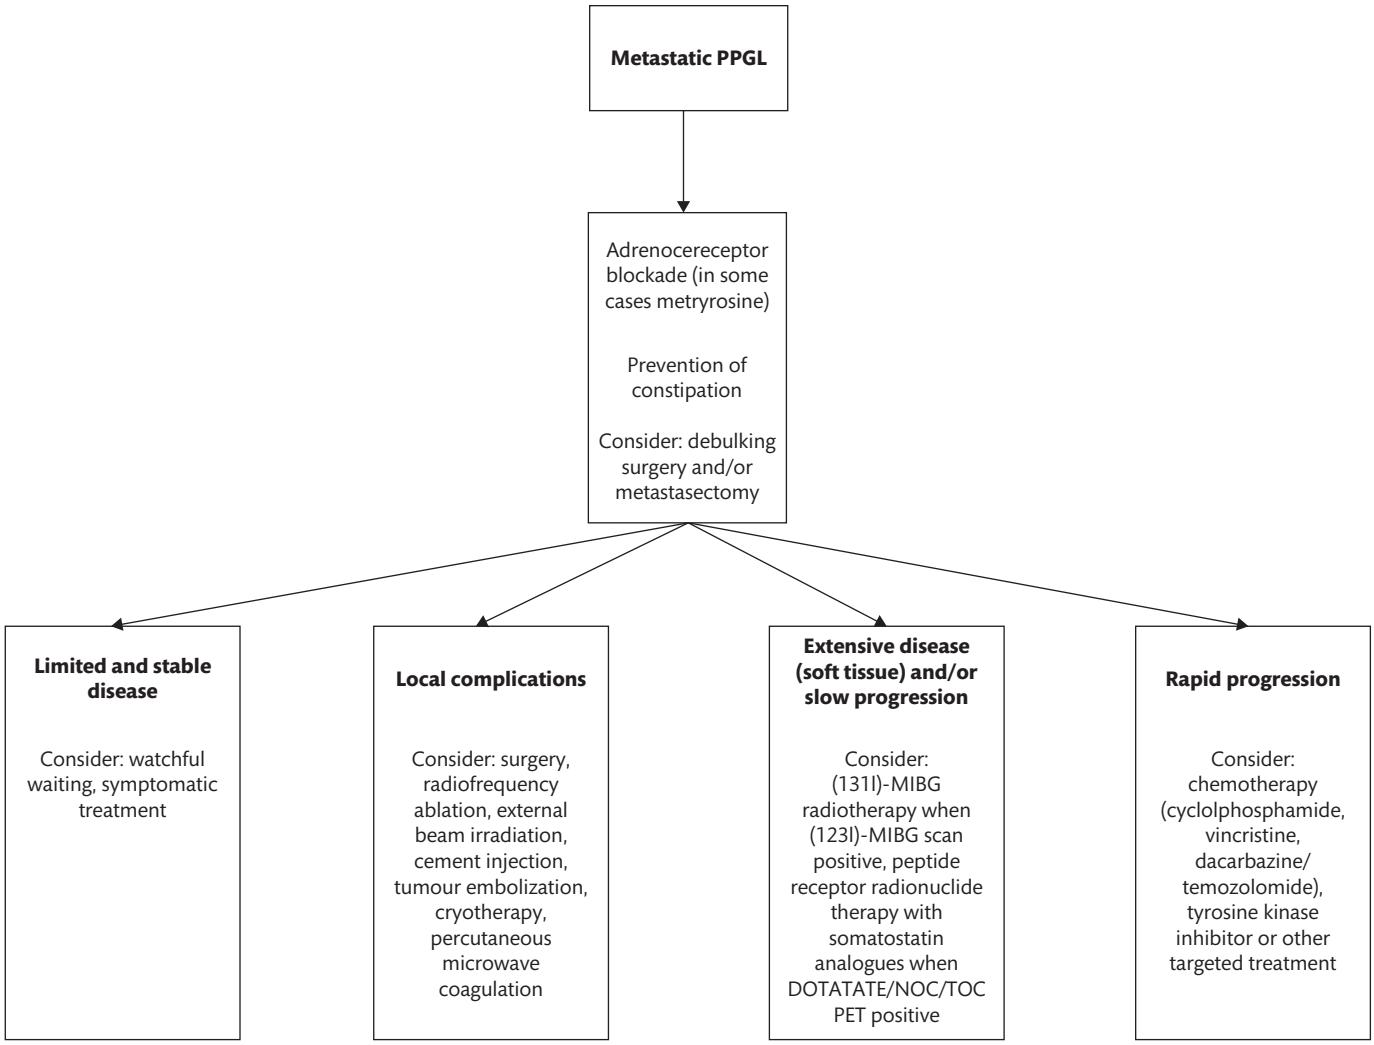

Figure 5.5.2.5 Proposed algorithm for the management of metastatic PPGL.

PPGL in Children

Considering the scarcity of PPGL in children, often in the context of hereditary disease, paediatricians face an even stronger challenge in diagnosing and treating this condition in an evidence-based way.

Although PPGLs are the most common endocrine tumours in children, they account for no more than 10% of all PPGLs, with an incidence of less than 2 per million per year [41]. As compared to adults, PPGLs in children are more commonly familial (80%), extra-adrenal (66%), multifocal (32%), and metastatic (49%) [42]. These features are probably interrelated. Childhood PPGLs peak at 10 to 13 years, with a male predominance (male vs. female, 2:1) before puberty. Regarding management, drug doses and haemodynamic treatment goals need to be adjusted according to age- and weight specific standards.

PPGL in Pregnancy

PPGL in pregnancy is extremely rare, occurring in around 0.002% of all pregnancies [43]. If undiagnosed, maternal and fetal mortality is around 50%. Confusion with the much more prevalent forms of pregnancy-related hypertension such as (pre)eclampsia is the main cause of overlooking the diagnosis. With early detection and proper treatment during pregnancy, mortality can be considerably decreased. For the biochemical diagnosis, plasma or urinary metanephrines can be used since they have a high negative predictive value. For localization, only MRI is suitable. When the diagnosis is made in the first 24 weeks of gestation, it should be (laparoscopically) removed after medical preparation. If the tumour is diagnosed in the third trimester, the patient should be managed using adrenoreceptor blockade until the fetus is viable and Caesarean section with tumour removal in the same session or at a later stage is then preferred.

5.6

Primary Aldosteronism

5.6.1 Genetics of Primary Aldosteronism and Other Steroid-Related Causes of Endocrine Hypertension

Maria Christina Zennaro, Fabio Fernandes-Rosa, and Sheerazed Boulkroun

Introduction

Arterial hypertension is a major cardiovascular risk factor. Identification of secondary forms of hypertension is key for targeted management and prevention of cardiovascular complications. Aldosterone plays a major role in regulating blood pressure and electrolyte homeostasis, and primary aldosteronism (PA) has been recognized as the most frequent form of secondary arterial hypertension. The prevalence of PA has been estimated to be around 4 to 6% of hypertensives in primary care [1, 2] and 10% in reference centres [1]. PA is associated with a suppressed renin-angiotensin system and often hypokalaemia; it is due mainly to unilateral aldosterone-producing adenoma (APA) or to bilateral adrenal hyperplasia. In addition to aldosterone excess, some rare disorders affecting corticosteroid production in the adrenal gland or their actions in the kidney also lead to steroid dependent hypertension. These include 11β-hydroxylase (*CYP11B1*) and 17α-hydroxylase (*CYP17A1*) deficiencies, as well as activating mineralocorticoid receptor mutations and the syndrome of apparent mineralocorticoid excess.

Aldosterone regulates blood pressure and electrolyte homeostasis by activating the mineralocorticoid receptor (MR) in the so-called aldosterone sensitive distal nephron (late distal convoluted tubule, connecting tubule and collecting duct), which plays an important role in fine-tuning renal sodium excretion by reabsorbing around 5–10% of the filtered sodium load [3]. The MR is a ligand dependent transcription factor, member of the nuclear receptor superfamily [4]. Following hormone binding, the MR activates transcription of a number of genes coding for proteins involved in regulating transepithelial sodium transport, including the epithelial sodium channel ENaC and the Na^+,K^+-ATPase [5]. Importantly, the MR binds aldosterone, 11-deoxycorticosterone (DOC), corticosterone and cortisol with very similar and high affinity [6], with certain differences in their efficiency of activating gene transcription [7]. Cortisol circulates in plasma at ≈1000-fold higher levels than aldosterone [8]. In epithelial aldosterone target tissues like the distal parts of the kidney, aldosterone selectivity of MR binding is made possible by the action of 11β-hydroxysteroid dehydrogenase type 2 (*HSD11B2*), an enzyme which converts cortisol to its inactive metabolite cortisone [9, 10]. In tissues not expressing 11β-HSD2, or in cases where the enzyme is inactive, the MR is mainly bound by cortisol and acts as a bona fide high affinity glucocorticoid receptor.

Aldosterone is synthetized from cholesterol through sequential enzymatic steps in the adrenal zona glomerulosa (ZG). The enzyme aldosterone synthase (*CYP11B2*), is the rate-limiting enzyme for aldosterone biosynthesis and is expressed exclusively in the ZG. It catalyses the three terminal reactions involving 11β-hydroxylation of DOC to corticosterone and its subsequent 18-hydroxylation and 18-oxidation to 18-hydroxy-corticosterone and aldosterone. Cortisol, the main glucocorticoid in human, is produced in the zona fasciculata (ZF) of the adrenal, where expression of 17α-hydroxylase mediates conversion of 17-deoxy-21-carbon steroids into 17-hydroxylated precursors of cortisol. In the ZF, 11β-hydroxylase (*CYP11B1*) catalyses 11-hydroxylation of 11-deoxycortisol to cortisol.

Aldosterone biosynthesis is tightly regulated to maintain sodium, potassium, and fluid homeostasis by the kidney. The principal regulators are the renin-angiotensin system (RAS), extracellular potassium concentration, and, to a lesser extent adrenocorticotrophic hormone (ACTH) [11]. The RAS responds to changes in renal perfusion and sodium concentrations; increased levels of angiotensin II (AngII) bind to AT1 receptors expressed in the ZG and activate aldosterone production via a Gαq-phospholipase C mediated pathway, increasing inositol 1,4,5-triphosphhate (IP3) and 1,2-diacylglycerol concentrations [12]. IP3 increases intracellular calcium concentrations by calcium release from intracellular stores. Extracellular potassium is a major regulator of aldosterone biosynthesis. Indeed,

the main ionic conductance of ZG cells is that of K^+ and their cell membrane potential closely follows the equilibrium potential of K^+ over a wide range of extracellular K^+ concentrations [13]. Increased extracellular K^+ leads to cell membrane depolarization and opening of voltage-dependent calcium channels, followed by increase of intracellular calcium concentrations. AngII also inhibits potassium channels and the Na^+,K^+-ATPase, inducing cell membrane depolarization and activation of voltage-gated calcium channels [12] (see online Figure 5.6.1.1, left panel). Increase in intracellular calcium induced by either AngII or potassium activates calcium signalling, the main trigger for aldosterone biosynthesis [12]. This mediates, in particular, activation of protein kinases regulating the phosphorylation and activity of different transcription factors, which increase *CYP11B2* transcription and aldosterone synthase expression [14].

Inherited Forms of Primary Aldosteronism

Although the majority of cases of PA is sporadic, in 1–5% of cases familial inheritance can be observed, which is due to different Mendelian forms of the disease (see online Table 5.6.1.1). Those diseases are essentially classified according to the underlying genetic defect as familial hyperaldosteronism (FH) type I to x, with additional numbers being used each time a new gene is identified. In particular, the most frequent group classified as FH-II most likely represents a genetically heterogeneous population, with patients sharing a similar phenotype but different genetic defects, many of which still remain to be identified. Genetic testing of inherited forms of PA is routinely performed in some genetic laboratories and family screening is useful for early diagnosis and targeted management.

Familial Hyperaldosteronism Type I

Familial hyperaldosteronism type I (FH-I), also called glucocorticoid-remediable aldosteronism (GRA), is an autosomal dominant disease characterized by severe hypertension typically occurring during childhood [15, 16]. Patients present with PA of variable severity, bilateral adrenal hyperplasia, with associated adrenal nodules in some cases, and high production of the hybrid steroids 18-hydroxycortisol and 18-oxocortisol [15–17]. The genetic abnormality underlying FH-I is a chimeric gene generated by an unequal crossing-over event, fusing the regulatory regions of *CYP11B1* to the coding sequence of *CYP11B2* [18, 19]. This leads to ectopic expression of *CYP11B2* throughout the adrenal cortex, with inappropriate regulation of aldosterone biosynthesis by ACTH, following the circadian rhythmicity of cortisol production [17, 20]. Patients respond well to treatment with exogenous glucocorticoids, which inhibit ACTH production [21]. The prevalence of FH-I has been estimated at around 0.6% of PA patients [22, 23]. However, the frequency seems to be higher in the hypertensive paediatric population, where a prevalence of the chimeric *CYP11B1*/*CYP11B2* gene of 3% has been reported [24]. Among the peculiar features of FH-I is the high morbidity and mortality at early age, due to the occurrence of early-onset haemorrhagic stroke and ruptured intracranial aneurysms [25].

Familial Hyperaldosteronism Type II

FH-II is the most common form of familiar hyperaldosteronism. It is clinically and biochemically indistinguishable from sporadic PA, not remediable by glucocorticoids, and diagnosis is based on the presence of two or more affected family members and autosomal dominant transmission [26, 27]. Patients show varying aldosterone responses on postural test and to AngII within a given family, and different PA subtypes (APA or bilateral adrenal hyperplasia) are found [23, 27]. Its prevalence is estimated to be 1.2% to 6% in adults with PA [23, 27–29]. The phenotypic variability of FH-II has suggested that FH-II may be associated with a variety of genetic defects [27]. Indeed, following the first description of *KCNJ5* mutations in FH-III [30], germline *KCNJ5* gene mutations were reported in patients with a moderate phenotype resembling FH-II [31]. In particular, affected members of three families carrying the *KCNJ5* p.Gly151Glu mutation and affected members from one family carrying the *KCNJ5* p.Tyr152Cys mutation exhibited a mild phenotype compatible with FH-II [32–34]. Somatic mutations of *KCNJ5* were also reported in APA in patients with familial hyperaldosteronism initially diagnosed as FH-II [33], suggesting that in some cases FH-II may represent familial aggregation of sporadic PA, given the high frequency of PA in patients with hypertension.

The large original family with FH-II described by Stowasser *et al.* [26] has been linked to a locus on chromosome 7p22 [35], although genetic heterogeneity had been shown subsequently [36]. It was only very recently that germline mutations in *CLCN2*, coding for the voltage-gated chloride channel ClC-2, have been identified in young onset PA and in the very same family with FH-II [37, 38]. *CLCN2* is expressed in the human and mouse adrenal cortex and is the main chloride conductor of resting glomerulosa cells [37]. The ClC-2 mutations affect different amino acids located in well conserved domains of the protein. In particular, the ClC-2 p.Gly24Asp mutation, found in a 9-year-old girl with PA, is located in a domain whose inactivation leads to 'open' ClC-2 channels. Functional analysis of the mutant channel indicated that the mutation abolished the voltage- and time-dependent gating of ClC-2, strongly increasing chloride currents at resting potential. In adrenocortical cells, this induced increased aldosterone production, which was mediated by plasma membrane depolarization, opening of voltage-gated calcium channels, increased intracellular Ca^{2+} concentrations and increased expression of *CYP11B2* [37] (see online Figure 5.6.1.1, right panel). The family described by Stowasser carried a p.Arg172Gln mutation, which was identified in four other cases; four additional mutations were identified in unrelated subjects with early-onset PA [38]. Again, the mechanism of autonomous aldosterone production involved gain-of-function mutations, promoting cell membrane depolarization, and opening of voltage-gated calcium channels [38]. These data identify a new genetic defect in patients with early-onset PA and a subset of FH-II and highlight the important role for chloride currents in regulating aldosterone biosynthesis.

Familial Hyperaldosteronism Type III

Patients with FH-III show severe early-onset hypertension, usually before age 20, resistant to medical treatment, and associated with severe hypokalaemia. Urinary concentrations of hybrid steroids 18-oxocortisol and 18-hydroxycortisol are elevated and aldosterone production is not suppressed by dexamethasone [39]. Hyperaldosteronism is typically due to massive bilateral adrenal hyperplasia and requires bilateral adrenalectomy to control blood pressure [39]. The genetic cause of FH-III are mutations in the *KCNJ5* gene, coding for the G protein-activated inward

rectifier potassium channel GIRK4 [30]. In particular, mutations p.Gly151Arg, p.Thr158Ala, p.Ile157Ser and p.Glu145Gln all are associated with a severe form of the disease [31]; other mutations are found in patients with moderate hyperaldosteronism resembling FH-II [32–34]. More recently, aldosterone and cortisol cosecretion has been observed in a patient carrying a germline p.Glu145Gln *KCNJ5* mutation [40]. The patient had shown severe hypertension and hypokalaemia at the age of 2 years and subsequently developed Cushing's syndrome at the age of 20 years, due to massive bilateral adrenal hyperplasia.

KCNJ5 mutations are located within or near the selectivity filter of the channel, which confers the K^+ selectivity to GIRK4. Functional studies have shown that mutations change its ion selectivity, leading to sodium influx into the cell and cell membrane depolarization. This leads to activation of voltage-dependent Ca^{2+} channels, increased intracellular Ca^{2+} concentrations, activation of calcium signalling promoting increased expression of steroidogenic enzymes and aldosterone production [30, 41] (see online Figure 5.6.1.1, right panel). Abnormal coexpression of steroidogenic enzymes, particularly aldosterone synthase (CYP11B2) and 17α-hydroxylase (CYP17A1), in the hyperplastic adrenal cortex of patients with FH-III may explain the abnormally high secretion rate of hybrid steroids in FH-III [42].

Familial Hyperaldosteronism Type IV

Whole exome sequencing in subjects with early-onset PA has identified a recurrent germline mutation p.Met1549Val in *CACNA1H* (coding for the pore-forming α1 subunit of the T-type voltage-dependent calcium channel Cav3.2) in five children with PA manifesting before the age of 10 years [43]. Analysis of their relatives showed that the mutation was inherited in an autosomal dominant manner in four cases, with an incomplete penetrance of the phenotype. In two *CACNA1H* mutation carriers, developmental delay or attention deficit disorder was subsequently observed. Affected patients had normal adrenal imaging findings, but in one case histological examination of the adrenal gland following adrenalectomy showed micronodular adrenal hyperplasia [43]. Functional studies showed that the mutation shifts the activation of the calcium channel towards more negative potentials with loss of normal inactivation, producing increased intracellular calcium entry into the cell due to prolonged opening of the channel [43] (see online Figure 5.6.1.1, right panel). Adrenocortical cells expressing the mutated channel had higher aldosterone production and increased *CYP11B2* mRNA expression, which were reduced by treatment with the T-type calcium channel blocker mibefradil, suggesting that T-type calcium channel inhibitors may be useful for treating patients with *CACNA1H* gain-of-function mutations [44].

Subsequently, four different germline *CACNA1H* mutations were identified in patients with different phenotypic presentations of PA [45]. They included a patient with early-onset hypertension and hyperaldosteronism associated with multiplex development disorder, who carried a *de novo* germline p.Met1549Ile *CACNA1H* mutation. A germline p.Ser196Leu and a p.Pro2083Leu mutation were identified in two kindreds diagnosed as FH-II, and a germline *CACNA1H* missense variant (p.Val1951Glu) was identified in a patient with APA [45]. In all cases, the electrophysiological properties of the channel were affected, with gain-of-function leading to increased calcium entry into the cell. Again, this was followed by increased expression of steroidogenic enzymes and aldosterone production in adrenocortical cells [45] (see online Figure 5.6.1.1, right panel). Identification of *CACNA1H* mutations in patients with different phenotypic presentations of PA, including FH-II, suggests that *CACNA1H* may be a susceptibility gene for different forms of the disease.

CACNA1D Mutations in a Rare Disease of PA, Seizures, and Neurological Abnormalities (PASNA)

De novo germline *CACNA1D* mutations were described in two children with a new form of hyperaldosteronism associated with a complex neurologic disorder (Primary Aldosteronism, Seizures and Neurologic Abnormalities, PASNA) [46]. The syndrome is characterized by early-onset PA, severe hypertension, and hypokalaemia in children showing a complex neurologic syndrome including cerebral palsy and epileptic seizures, with no adrenal hyperplasia visible on imaging. In one patient, treatment with a calcium channel blocker normalized blood pressure, with cure of hypertension and PA on follow up [47]. The *CACNA1D* gene codes for Cav1.3, the voltage-dependent L-type calcium channel subunit alpha-1D, which is commonly mutated in APA at the somatic level [46]. Mutations affect highly conserved residues located in domains responsible for channel opening. They modify channel voltage sensitivity, promoting L-type calcium channel opening at lower voltages. Activation at less depolarizing potentials increases intracellular calcium influx and activates calcium signalling, thereby enhancing aldosterone production (see online Figure 5.6.1.1, right panel).

Somatic Mutations in Aldosterone-Producing Adenoma

Sporadic forms of PA represent the majority of cases and are due either to bilateral adrenal hyperplasia or APA. APA are found in approximately one-third of patients, although frequency may vary depending on diagnostic criteria and thresholds used for subtype identification [2, 48, 49]. By applying whole exome sequencing to paired tumour and germline DNA samples, it has been possible to identify recurrent somatic mutations in different genes coding for ion channels (*KCNJ5* [30] and *CACNA1D* [46, 50]) and ATPases (*ATP1A1* and *ATP2B3*, [50, 51]) regulating intracellular ionic homeostasis and cell membrane potential (see online Figure 5.6.1.1, right panel). Mutations of *KCNJ5* and *CACNA1D* are similar to those identified in FH-III and PASNA and lead to increased intracellular calcium concentrations, which activate calcium signalling and aldosterone biosynthesis. Mutations in *ATP1A1*, coding for the α1 subunit of the Na^+,K^+-ATPase, lead to a loss of pump activity and inward proton or sodium leak, which increase aldosterone production through cell membrane depolarization and increased calcium influx [50, 51] or increased intracellular acidification [52]. *ATP2B3* codes for the plasma membrane calcium-transporting ATPase 3 (PMCA3). Mutations lead to loss of the physiological pump function and reduced Ca^{2+} export; they also lead to severely depolarized membrane potential [51], which is explained by a pathological sodium leak associated with or conducted by the mutant PMCA3 [53]. Finally, somatic mutations in

CTNNB1, coding for β-catenin which plays an important role in adrenal cortex development and tumorigenesis, are found in 2–5% of APA [46, 54, 55], and mutations in *PRKACA* (coding for the cAMP-dependent protein kinase catalytic subunit alpha) in rare cases [56]. Mutations in those genes are also found in cortisol-producing adenoma and adrenocortical cancer; the mechanisms whereby the same mutations lead to different hormonal phenotypes remain yet to be established [57].

KCNJ5 mutations are the most prevalent mutations found in ≈40% of APA, with a higher prevalence in Asian populations [58, 59]. Carriers of *KCNJ5* mutations are younger and more often women [58, 59]. Some studies also report larger tumour size, a ZF-like cellular phenotype, and higher plasma aldosterone levels when compared to non-carriers [59, 60], but these results, as well as other genotype-phenotype correlations, are not replicated in other studies [58, 61–64]. ATPase mutations were reported to be more frequent in men [51] and *CACNA1D* mutations are associated mainly with smaller tumours [46, 50, 51, 54, 58, 65, 66]. *CTNNB1* mutations seem to be more prevalent in women [46, 54, 55, 67].

Recent data indicate that the frequency of somatic mutations in APA might be much higher than previously described, due to tumour heterogeneity and the presence of multiple nodules, which do not all express aldosterone synthase. Indeed, aldosterone synthase immunohistochemistry-guided targeted sequencing on DNA extracted from formalin-fixed paraffin embedded adrenal samples revealed an overall frequency of somatic mutations of 88%, with a similar mutational spectrum then in previous studies [68, 69].

Genetic testing in patients with APA prior to surgery is challenged by the difficulty of detecting somatic mutations from peripheral blood. This could be circumvented by identifying surrogate biomarkers of the mutation status. Genotype-specific steroid profiles have been recently associated with APA, in particular a 7-steroid fingerprint able to correctly classify 92% of the APA according to genotype [70]. Future use of this type of screening could allow to select patients for adrenal vein sampling and to apply targeted treatments, once these approaches have been prospectively validated. Indeed, mutated KCNJ5 channels have peculiar pharmacological characteristics and are blocked by calcium-channel blockers, such as verapamil, and Na-channel blockers, such as amiloride at high therapeutic doses [71]. Macrolide antibiotics, including roxithromycin, potently inhibit mutant channels as well as *CYP11B2* expression and aldosterone production in adrenocortical cells [72] and in primary cell lines from APA [73]. Current studies are ongoing to test whether these compounds can be used to identify and treat patients with PA due to APA with *KCNJ5* mutations [74].

Hypertension Due to Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) is a group of autosomal recessive diseases of adrenal steroidogenesis caused by mutations in genes encoding enzymes or cofactors involved in cortisol biosynthesis. For a detailed description of CAH variants see Chapter 5.9, here we briefly describe those variants that are associated with increased mineralocorticoid receptor activation. While the most frequent form of CAH, 21-hydroxylase deficiency (21OHD), is characterized by salt wasting and hypotension, 11β-hydroxylase deficiency (11OHD) and 17α-hydroxylase deficiency (17OHD), are associated with hypertension (see online Table 5.6.1.1).

11β-Hydroxylase Deficiency

11OHD is the second most frequent cause of CAH, accounting for 2–5% of cases (overall incidence 1 in 100 000–200 000 live births) [75, 76]. The enzyme 11β-hydroxylase (CYP11B1) catalyses the conversion of 11-deoxycortisol to cortisol and DOC to corticosterone in the ZF. Defective cortisol biosynthesis results in ACTH secretion leading to accumulation of 11-deoxycortisol and DOC, which binds the MR with high affinity. Although a slightly less potent mineralocorticoid than aldosterone [7], the excessive production of DOC in 11OHD causes sodium retention, volume expansion and hypertension in 30–60% of cases [75, 77, 78]. Renin production is suppressed secondary to mineralocorticoid-induced sodium retention and volume expansion and aldosterone levels are decreased due to low serum potassium and low plasma renin (see online Table 5.6.1.1). Because newborns are relatively resistant to mineralocorticoids, hypertension might not become apparent during the neonatal period [79]. Increased ACTH secretion leads also to adrenal androgen excess resulting in fetal female virilization and precocious pseudopuberty in boys. 11OHD is caused by inactivating mutations in the *CYP11B1* gene located on chromosome 8q21 and is transmitted as an autosomal recessive trait [77]. *CYP11B1* is located in tandem with the highly homologous *CYP11B2* gene. Opposite to FH-I, unequal crossing-over between those genes, where the *CYP11B1* coding sequence is under the control of the *CYP11B2* promoter responding to angiotensin II and not ACTH, also results in a phenotype of classic 11OHD [80]. 11OHD treatment is based on cortisol replacement to normalize ACTH, which in turn removes the drive for overproduction of DOC, leading to remission of hypertension.

17α-hydroxylase Deficiency

17OHD is a rare form of CAH accounting for less than 1% of cases [81]. The enzyme 17α-hydroxylase (CYP17A1) is expressed in adrenal glands and gonads and catalyses 17α-hydroxylation of pregnenolone and progesterone as well as the 17,20 lyase reaction catalysing conversion of 17-hydroxypregnenolone to dehydroepiandrosterone (DHEA) and, with less efficiency, that of 17-hydroxyprogesterone to androstenedione. 17OHD shifts steroidogenesis towards the mineralocorticoid pathway, with accumulation of corticosterone and DOC. Patients exhibit hypokalaemic hypertension, male undervirilization at birth in affected 46,XY individuals, primary amenorrhea in 46,XX patients, and hypergonadotropic hypogonadism in both sexes [82]. 17OHD is caused by inactivating mutations in *CYP17A1*, located on the long arm of chromosome 10 [83]. To date, more than 100 mutations have been reported, 75% of which are missense mutations [84]. 17OHD treatment is based on partial glucocorticoid replacement to reduce DOC production, antihypertensive management, mainly with MR antagonists, and sex steroid replacement according to age and sex of rearing.

Apparent Mineralocorticoid Excess

Apparent mineralocorticoid excess (AME) is an autosomal recessive disease first described in a 3-years old boy with hypertension,

hypokalaemia, low plasma renin activity, and aldosterone concentration, and responsiveness to spironolactone [85], with a decreased rate of conversion of active cortisol to cortisone suggesting a defect in the oxidation of cortisol [86]. AME is caused by inactivating mutations in the *HSD11B2* gene encoding 11β-hydroxysteroid dehydrogenase type 2 (HSD11B2) [87]. Given that plasma free cortisol levels are ~1000-fold those of aldosterone and cortisol binds with high affinity to MR, lack of HSD11B2 is responsible for cortisol binding to MR in the distal nephron of the kidney and a phenotype of pseudohyperaldosteronism [88, 89].

In early life, AME is characterized by severe hypertension, suppressed renin and plasma aldosterone, and an elevated ratio of urinary cortisol to cortisone metabolites. Affected children may also exhibit lower birth weight, polydipsia, polyuria, failure to thrive, poor growth, hypokalaemia, and persistent metabolic alkalosis [90, 91]. AME is associated with variable organ damage, potentially affecting kidneys, retina, heart, and central nervous system [92]. A milder phenotype has been described in adults with hypertension and milder biochemical abnormalities [93]. The phenotypic variability is associated with different extents of impairment of HSD11B2 activity with distinct mutations [94, 95]. Differential diagnosis includes excessive ingestion of liquorice, which contains glycyrrhetinic and glycyrrhizic acid, both being potent competitive inhibitors of HSD11B2 activity [96]. Inadvertent overexposure to potent synthetic mineralocorticoids also mimics AME [97]. AME treatment is based on MR antagonism with spironolactone or eplerenone. Other antihypertensive drugs such as amiloride, calcium channel blockers, and thiazides, which can help to normalize blood pressure and lower hypercalciuria, may be associated [92]. The importance of early diagnosis and treatment was reinforced by the description of significant improvement in end-organ damage in patients who had undergone two to 13 years of treatment [90].

Activating Mutations of the Mineralocorticoid Receptor

A Mendelian form of human hypertension was described by Geller *et al.* in 2000, caused by an activating mutation of the *NR3C2* gene, coding for the MR. The heterozygous MR p.Ser810Leu mutation was identified in a 15-year-old boy with severe hypertension associated with suppressed plasma renin and low aldosterone levels [98]. Screening of his family showed that the p.Ser810Leu mutation was transmitted as an autosomal dominant trait and cosegregated with early-onset hypertension (before age 20) in 11 subjects. Two female carriers of the mutation had their pregnancies complicated by marked exacerbation of hypertension, accompanied by low serum potassium levels and undetectable aldosterone levels, but without signs of preeclampsia.

The MR p.Ser810Leu mutation is located in the MR ligand binding pocket, inducing a major change in its conformation and ligand specificity. While there is no difference in mutant or wild-type MR activity in response to aldosterone, both progesterone and spironolactone, two MR antagonists, are able to activate transcription via the p.Ser810Leu MR mutant. These findings suggest that progesterone may contribute to the exacerbation of hypertension during pregnancy [98]. The endogenous steroids responsible for hypertension in men and non-pregnant women carrying the p.Ser810Leu mutation were identified to be cortisone and 11-dehydrocorticosterone, the main cortisol and corticosterone metabolites produced by the action of HSD11B2 in the distal nephron, which bind with high affinity to the mutant MR and are potent activators of mutant MR-dependent transcription [98]. Given the much higher concentration of plasma cortisol than corticosterone, the authors suggested that cortisone is the endogenous steroid binding and activating the mutant MR [98]. While one study reported a high frequency of MR p.Ser810Leu in hypertensive pregnant women from Mexico [100], no further family carrying this mutation was described. Furthermore, the mutation is not listed in the large database of genetic variants ExAC (The Exome Aggregation Consortium, http://exac.broadinstitute.org) and its frequency is not described on the 1000 genomes project (http://www.internationalgenome.org). The use of MR antagonists such as spironolactone or eplerenone should be avoided in patients carrying the p.Ser810Leu mutation as they act as agonists on the mutant MR. In contrast, the third-generation MR antagonists BR-4628 and finerenone, both derived from dihydropyridines, are also antagonists on the mutant receptor [101, 102]. Finrenone, currently approved for clinical use, might be an option to treat carriers of the MR p.Ser810Leu mutation.

5.6.2 Management of Primary Aldosteronism

William M. Drake and Morris J. Brown

Introduction

The successful management of PA involves important contributions from primary, secondary, and tertiary physicians, clinical biochemists, cross-sectional and interventional radiologists, endocrine surgeons, specialist nurses experienced in conducting complex dynamic

testing and, increasingly, endocrine histopathologists who provide retrospective, molecular information as to the accuracy of the preceding clinical evaluation. Such collaborative, multidisciplinary working, involving mutual trust and shared learning over time, lends itself well to high-quality clinical care but complicates comparison of results between centres. Variations in assays for aldosterone and renin, subjective interpretation of adrenal imaging, and differences in the protocols for adrenal vein sampling (AVS), contrast with, for instance, evaluations of osteoporosis therapy. In PA, there is no equivalent to the strict, standardized bone mineral density scores used in osteoporosis as both entry criteria and outcome measures. The authors take the view that there is no 'perfect' way to manage PA, but we attempt to provide a balanced view of a fast-moving field. Where personal opinion is presented, it is done with appropriate caveats.

Evaluation of Published Evidence in PA

A decade after his original description [1], Conn published 145 cases of PA and suggested that the syndrome may account for up to 20% of patients with hypertension. He later revised this estimate down to 10% [2], which approximates to recent evidence suggesting a prevalence of 5–8% in unselected hypertensive populations. Allowing for inevitable variability between studies, the accepted prevalence of PA now stands on a par with type 1 diabetes and hepatitis B. In both of these examples, robust, prospective, outcome studies are plentiful and, indeed, mandated before any new intervention can receive approval for funding by most healthcare providers. Strikingly, the published long-term outcome data on PA are sparse and their quality substantially inferior to the two comparator conditions quoted. The vast majority of outcome data available for analysis are retrospective. To date, there exists only one published prospective intervention study in PA, discussed below [3], and it was only recently that international consensus data were produced defining what constitutes surgical 'cure' [4]. In contrast, the recent explosion of data on the molecular pathogenesis of PA [5–8] is incontrovertibly of high quality and provides an example of how such insights can re-energize an area of clinical research that had advanced only modestly in the preceding decades; and of how such findings can lead to the re-challenging of old 'dogmas' and 'rules'.

Suspicion of PA: Case Finding

Symptoms and physical signs (other than hypertension) are few in PA. Contrary to historical teaching, hypokalaemia occurs in only a minority of patients but, if present, may cause muscle weakness and cramps, palpitation, and, consequent upon an induced renal concentrating defect, symptoms of frequency and nocturia. Given that PA is most commonly diagnosed in middle age, these symptoms are often dismissed as consequent upon prostatic enlargement or childbirth. Transient hypokalaemia precipitated by the use of thiazide or other potassium-wasting diuretics is a common scenario, but this is often attributed to the drug alone, rather than raising suspicion that the diuretic is unmasking PA by increasing sodium delivery to the site of aldosterone action downstream in the nephron. When groups of patients with PA are compared with those with essential hypertension or other forms of endocrine-mediated hypertension, greater degrees of left ventricular hypertrophy (LVH), higher rates of atrial fibrillation and greater urinary albumin excretion are demonstrable, although none is diagnostically sensitive or specific. This bland clinical picture does not lend itself easily to diagnosis in the primary care setting, in which most cases of hypertension are seen, and mandates a more 'algorithmic' approach to case finding. Current consensus guidelines [9] recommend screening for PA in certain scenarios, shown in **Box 5.6.2.1**.

Box 5.6.2.1 Indications for testing for PA

Consensus guidance on when to test for primary aldosteronism (PA)

- Hypertension and spontaneous or diuretic-provoked hypokalaemia
- Hypertension resistant to three conventional antihypertensive drugs (including a diuretic)
- Hypertension controlled by the use of four conventional antihypertensive drugs (including a diuretic)
- Hypertension and an adrenal incidentaloma
- Hypertension and sleep apnoea
- Hypertension and a family history of early onset hypertension or stroke <40 years
- All hypertensive first-degree relatives of patients with diagnosed PA

Adapted with permission from Funder JW, Carey RM, Mantero F, *et al*. The Management of Primary Aldosteronism: Case Detection, Diagnosis, and Treatment: An Endocrine Society Clinical Practice Guideline. *J Clin Endocrinol Metab* 2016; 101(5): 1889–916; to which the reader is referred for a more detailed discussion.

These guidelines for screening are not underpinned by a published body of evidence indicating that they favourably impact on morbidity, mortality, or quality of life. To date, no prospective study exists to demonstrate that widespread testing for PA is cost effective. The 'targeted strategy' recommended by those experienced in the field, towards groups of patients 'enriched' with PA, represents a compromise between the cost and logistical challenge of screening huge numbers of patients and the consequences of a missed/delayed diagnosis on the development of hypertension that is more severe and/or resistant to medical or surgical treatment.

There is little dispute about the biochemical investigations with which to undertake case finding for PA. Like other areas of endocrinology, paired measurement of both limbs of the feedback system (in this case aldosterone and renin, with which to calculate an aldosterone:renin ratio, ARR) is needed; isolated measurements of potassium, aldosterone, and renin are demonstrably less accurate. Individual centres use different assays for both plasma aldosterone concentration (PAC) and renin (either plasma renin activity, PRA, or direct renin concentration, DRC) with slightly different reference ranges. Hence (like other endocrine conditions), implicit in the cut-off values for ARR given in **Table 5.6.2.1** [9] is advice to clinicians to be acquainted with their own institution's assay performance. The clinical use of the ARR grew out of recognition that many patients with PA do not have plasma aldosterone levels above earlier thresholds for diagnosis, and that a reduction in these would lead to false positives unless an elevated ARR was also required; and it has an intrinsic flaw due to the logarithmic distribution of plasma renin, but arithmetic distribution of aldosterone. The limitations of the use of a ratio as a screening tool are self-evident; when denominator (renin) levels are low the ARR may be high even if the PAC is also low and conceptually incompatible

Table 5.6.2.1 ARR cut-off values, depending on assay and based on whether PAC, PRA, and DRC are measured in conventional or SI units

	PRA (ng/ml/h)	PRA (pmol/L/min)	DRC (mU/L)	DRC (ng/L)
PAC (ng/dL)	20	1.6	2.4	3.8
	30	2.5	3.7	5.7
	40	3.1	4.9	7.7
PAC (pmol/L)	750	60	91	144
	1000	80	122	192

Adapted with permission from Funder JW, Carey RM, Mantero F, *et al*. The Management of Primary Aldosteronism: Case Detection, Diagnosis, and Treatment: An Endocrine Society Clinical Practice Guideline. *J Clin Endocrinol Metab* 2016; 101(5): 1889–916; to which the reader is referred for a more detailed discussion.

with a diagnosis of PA. To account for this issue, the concept of a 'minimum' PAC is advocated by some, although the precise value below which PA is excluded is not well defined.

The ARR test performs best when patients have been ambulant for at least 2 hours in the morning, with liberal salt intake in the preceding days and with hypokalaemia corrected if originally present. Blood is usually drawn with the patient seated for 10–15 minutes. The test should not be performed if a patient is taking spironolactone, epleronone, or high dose amiloride; discontinuation for a minimum of 4 weeks is mandatory for these drugs. However, in patients with difficult hypertension, safety is the first concern. Spironolactone has long-acting metabolites that have some activity even 6 weeks after discontinuation, whereas eplerenone and amiloride have shorter half-lives and no active metabolites. As a screening test, it is acceptable to measure the ARR on diuretics, angiotensin converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs), although the potential effect of these drugs to de-repress renin levels dictates that many patients will subsequently require further, confirmatory testing if PA is strongly suspected. Conversely, this generates a useful clinical practice point; the finding of a suppressed value during therapy with one of this class of drug is very suspicious of PA. β-adrenergic antagonists reduce renin levels, but aldosterone values also fall so the overall performance of the ARR as a screening tool is acceptably preserved.

It should be emphasized that the ARR is a 'case finding'/screening tool that is particularly effective at excluding PA in drug-naïve patients. It is accepted, in a substantial proportion of patients, that, because of indeterminate results and/or the effect of interfering medications, one of a choice of confirmatory tests will subsequently be required.

Confirmation of PA: Diagnostic Testing

The cut-off values for the ARR place a high priority on not missing a diagnosis of PA, so many patients will require a subsequent confirmatory test if the screening investigation does not confidently exclude autonomous aldosterone secretion. Conversely, for some patients the results will be sufficiently convincing not to require further testing. Published guidance on this is, perhaps, surprisingly strict (documented hypokalaemia, PAC>550 pmol/L and plasma renin below detection levels) [9] and many experienced clinicians adopt a more pragmatic approach.

Four confirmatory tests are in common use; each, in a slightly different way, seeks dynamically to interrogate the suspected abnormal prevailing physiology. None has been convincingly demonstrated to be superior to any other and individual choice is usually on the basis of pragmatic considerations such as local expertise and cost.

The oral sodium load and saline infusion tests are similar in concept; the provision of a surplus of sodium should, with a normally functioning renin–angiotensin–aldosterone feedback system, result in marked suppression of aldosterone production. In the former case, urinary aldosterone excretion is measured on day 3 of a diet that includes at least 200 mmol/day of sodium and during which correction of induced hypokalaemia is crucial. In the latter test, 2 L of 0.9% saline are infused over 4 hours into a fasted patient, with a single measurement of PAC at the conclusion of the infusion. Both tests have high reported sensitivities and specificities, and both carry the potential hazard, in patients with marked hypertension or cardiac failure, of precipitating clinical deterioration. The use of antihypertensive medications that do not interfere with the renin–angiotensin axis (e.g. doxazosin, verapamil, hydralazine) is therefore recommended to achieve blood pressure control prior to either of these confirmatory tests.

In the fludrocortisone suppression test, 0.1 mg fludrocortisone acetate is administered 6 hourly for 4 days, together with high doses of sodium and potassium supplements. In hypertensive patients without PA, PAC falls to below a generally agreed cut-off of 170 pmol/L; above this level, PA is highly likely. For precision and safety, many centres advocate conducting this test as an inpatient, which increases its cost considerably.

Where there is concern about tests that may exacerbate hypertension and/or precipitate cardiac failure, the captopril challenge test (CCT) is a potentially attractive alternative. Samples for PAC and renin are drawn at time zero and 1–2 hours after an oral dose of 25–50 mg captopril. PAC should fall by >30% during the test; failure to achieve this, in combination with a persistently suppressed renin value, is highly suggestive of PA. Head-to-head comparison of CCT with saline suppression testing suggests that failure to reduce plasma aldosterone to <230 pmol/L is a more accurate threshold. There are suspicions that the CCT may yield false positive results and, in clinical practice, the principle of the investigation is more commonly exploited by performing a screening ARR in a patient already treated with a longer-acting ACEI.

The issue arises as to what constitutes the 'gold standard' against which the performances of the ARR and confirmatory tests at detecting/diagnosing PA are compared. Many studies have compared the 'screening' ARR with the results obtained during

subsequent confirmatory testing, but, in turn, the thresholds applied during those confirmatory tests are often based on the lowest values of PAC recorded in patients subsequently shown to have had normal renin–angiotensin–aldosterone physiology restored after a unilateral adrenalectomy. Two problems arise from this (enforced) approach. First, if a patient with suspected PA has equivocal/indeterminate results from one of the confirmatory tests but does not undergo surgery, he/she can never contribute to the data set that gives rise to a diagnostic threshold. Second, in analysing data for a diagnostic threshold, the importance placed on data derived from patients who eventually undergo surgery (with histology and postoperative biochemical re-evaluation reasonably regarded as 'gold standard') assumes that the physiology of 'surgical' and 'non-surgical' PA is identical. This assumption may or may not be correct.

Subtyping of PA

Once the diagnosis of PA is securely established, the next stage of its management is accurate subtyping. Although rare causes of PA exist (adrenocortical carcinoma and various familial forms), the vast majority is accounted for by a benign, unilateral aldosterone-producing adenoma (APA) or bilateral adrenal hyperplasia (BAH). For this reason, the following discussion deals with the investigations and their interpretation that assist with the distinction between these two entities. This distinction is crucial because most patients with APA are managed by unilateral adrenalectomy, whereas patients with BAH should be treated medically. Unilateral adrenal hyperplasia (UAH) also exists and is grouped in with this discussion because, although much less common, the results from AVS and response to unilateral adrenalectomy are similar to APA.

Cross-Sectional Imaging

The role of adrenal imaging in the management of PA is to exclude a large, potentially malignant mass and provide anatomical information to the surgeon in the event of an adrenalectomy. By facilitating reconstruction of adrenal vein anatomy, it may also improve the success rates of AVS, although individual radiology opinion varies on this. No formal, prospective studies exist comparing computed tomography (CT) with magnetic resonance imaging (MRI), but most clinicians favour the former on account of its superior spatial resolution. MRI may be preferable in women of childbearing age; this may become more important once functional imaging (see below) becomes widely used in place of AVS. Thin slice, high-quality contrast-enhanced CT (and, crucially, interpretation) provides important information about the presence of nodules (macro ≥ 10 mm; micro <10 mm), adrenal limb thickening, or normal anatomy; all of which contribute to decision-making. A detailed description of radiological features and interpretation is beyond the scope of this chapter, but most patients will fall into one of the categories shown in Table 5.6.2.2, together with some important practice points. From the table, it can be seen that (other than concern about a malignant mass) the only scenario in which AVS can be avoided for accurate subtyping is the presence of a clear-cut, typical macronodule with unequivocally normal anatomy in a young person. Anecdotally, it is the authors' experience that it is the judgement of 'normality' in adrenal imaging that is often the most challenging issue. The detection of macronodules should be straightforward, but the molecular discoveries discussed in Chapter 5.6.1 have led to increasing recognition of 'scanning occult' microadenomas as important causes of PA (especially among African Caribbean patients), and of an inverse correlation between size of nodule and density of CYP11B2 (aldosterone synthase).

Table 5.6.2.2 Adrenal appearances on CT imaging and decision-making in PA

Imaging appearances	Interpretation/clinical management
Normal appearances	Does not imply BAH. Many APAs are small. AVS needed
Unilateral, typical macroadenoma and unequivocally normal contralateral gland	In young patients (<35 years), this is generally sufficient to avoid AVS and proceeding direct to unilateral adrenalectomy is reasonable. In patients ≥40 years, the presence of a macronodule cannot assumed to be an APA. AVS needed*
Bilateral micro and/or macronodules	Does not imply BAH. Some patients will have unilateral, surgically treatable, disease. AVS needed
Unilateral adrenal thickening	Implies neither UAH nor BAH. AVS needed.
Unilateral micronodule	May represent area of hyperplasia or be functionless. AVS needed
Unilateral nodule with ipsi- or contralateral thickening	AVS needed
Unilateral large (usually >4 cm), often heterogenous mass	Concern about malignancy highly likely to mandate surgery without recourse to AVS. Tests for other hormonal secretion (cortisol, androgens) also needed

* Opinion varies as to whether 35 or 40 represents the most appropriate 'threshold' for the avoidance of AVS with this anatomical scenario

It is important to appreciate the hazards of relying on imaging alone to guide clinical decision-making in PA. Errors occur in both directions: concluding that a nodule is the source of aldosterone excess may lead to erroneous adrenalectomy; whereas by relying on radiological appearances for a diagnosis of BAH patients may be denied potentially curative surgery. Rates of 'misdiagnosis by imaging alone' vary between studies but are consistently substantial [10].

AVS

AVS is widely accepted as the criterion standard to distinguish between unilateral and bilateral aldosterone production in patients with PA. The test involves the catheterization, via a femoral vein puncture, of both adrenal veins, guided by fluoroscopy and with confirmation of correct catheter placement by injection of contrast medium. Blood is obtained from both adrenal veins and the inferior vena cava (IVC) well below the renal veins (some advocate using an iliac vein), with all samples assayed for cortisol and aldosterone. The left adrenal vein is a tributary of the inferior phrenic vein and this sample is usually taken from close to the junction of the two. The right adrenal vein is the more difficult to cannulate on account of its

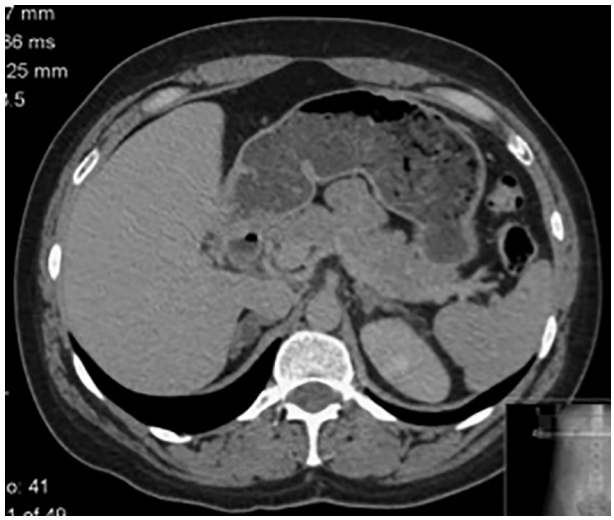

Figure 5.6.2.1 PA was diagnosed in a 38-year-old woman with severe hypertension who wished to conceive: PAC 780 pmol/L; PRA <0.01 pmol/ml/h. She was normokalaemic. CT confirmed a focal, hypodense nodule in the right adrenal, but concern about equivocal contralateral minor abnormal adrenal morphology mandated AVS, with results as shown in Table 5.4.4.3. The right adrenal vein was inadequately cannulated (SI 1.76), but the left adrenal vein: IVC cortisol-corrected aldosterone value was suppressed compared to that in the IVC (see Table 5.4.4.3). Together with the presence of the focal abnormality it was considered that this represented sufficient evidence, in a young patient, to offer a right adrenalectomy. She conceived shortly after surgery and remains normotensive several years later on no medication. In selected cases, careful interpretation of incomplete AVS may facilitate clinical decision-making.

length (approximately 2 mm), diameter (approximately 1 mm) and the fact that it enters the IVC posteriorly at an acute angle. It can sometimes be confused with adjacent small hepatic branches. With experience, repetition, persistence, and careful liaison with endocrine colleagues for feedback and audit, successful cannulation rates in the best centres rise above 90%. This process can be supported by intraprocedural rapid cortisol measurements, which provide the radiologists with additional information regarding correct catheter tip placement [11, 12]. Complication rates of AVS such as adrenal haemorrhage are low in high volume centres and are inversely correlated with radiological experience [13]. For clinical endocrinologists, the limited number of radiologists able to work to a high standard is a major contributor to the small proportion of patients with PA that are fully investigated.

Ideally, patients should be taking either no antihypertensive therapy at all, but in the majority of cases clinical safety dictates that non-renin/aldosterone interfering agents such as alpha$_1$ adrenoceptor antagonists (doxazosin, terazosin) and/or non-dihydropyridine calcium antagonists (verapamil) and/or hydralazine will be required for blood pressure control. Of note, a recent study showed good performance of AVS in differentiating APA from BAH irrespective of intake of mineralocorticoid receptor antagonists [14]. Potassium concentrations should be normal, as hypokalaemia restrains aldosterone secretion. Discontinuation of antiplatelet therapy is not necessary. Discontinuation of anticoagulants is at the discretion of the radiologist, although most experienced operators do not mandate it. In most centres, AVS is a day case procedure performed in the morning in order to allow sufficient time to elapse before safe discharge given the femoral vein puncture.

Variations and Refinements in AVS Protocols

The aforementioned is a 'generic' description of the principle of AVS, but different, very experienced, centres advocate various, subtle refinements for which controlled, prospective, comparative data are currently not available. Many units perform AVS under conditions of adrenocorticotrophic hormone (ACTH) stimulation, either continuously infused or administered as a bolus. Perceived advantages of this refinement include minimizing stress-associated fluctuations in cortisol and aldosterone; maximizing the gradient in cortisol from adrenal to peripheral (IVC or iliac) vein; and maximizing aldosterone secretion from an APA. The first of these is particularly relevant to the practice of sequential (as opposed to simultaneous) AVS, as a stress-induced surge of adrenal secretion has the potential to alter the results. Proponents of the unstimulated, bilateral simultaneous technique (a more challenging and prolonged protocol that slightly increases the risk of adrenal vein thrombosis if the catheters remain in position for long periods) point to the pulsatile nature of aldosterone secretion and the possibility of generating erroneous gradients between adrenals with sequential sampling. Bilateral, sequential, unstimulated sampling is probably the least practised technique. The authors (at whose centre sequential, ACTH-stimulated sampling is performed) take the pragmatic view that any subtle advantages of one variation over another are comfortably outstripped by the benefits of a single, experienced radiologist achieving bilateral cannulation rates in excess of 90% using a protocol with which he/she and the accompanying radiographer/nursing staff are comfortable and familiar.

Interpretation of AVS Data

The success of cannulation is determined using the selectivity index (SI), defined as the ratio of the cortisol concentrations in the adrenal veins to that in IVC/iliac vein. The 'cut-offs' used to determine successful AV catheterization are, inevitably, somewhat arbitrary. It is clearly appropriate to use a lower SI with unstimulated as opposed to stimulated AVS and, with both protocols, the more stringent the value used, the lower will be the proportion of patients judged to have had adequate AVS. A recent consensus statement recommended values of 3 and 2: 1 for stimulated and unstimulated protocols respectively [13]. In the authors' institution, a SI of 5:1 is used, but this is applied flexibly on a case-by-case basis.

The PAC at each of the sample sites (adrenal veins and IVC/iliac vein) is divided by the cortisol to generate a value termed the 'cortisol-corrected ratio', although a few centres refer to a 'normalized aldosterone'. 'Corrected' and 'normalized' denote the concept of correcting for the dilutional effect of non-adrenal blood (notably the inferior phrenic and accessory hepatic veins on the left and right, respectively). The cortisol-corrected ratios in each adrenal are then compared to produce a lateralization index (LI) and this is used to determine whether aldosterone excess is likely to be unilateral or bilateral. No prospective, randomized trials are available for determining the best LI cut-off to use for clinical decision-making; all published data come from retrospective, observational studies. Consensus criteria settle around LIs of 4.0 and 2.0 with and without ACTH stimulation, respectively, above which PA is highly likely to be unilateral and

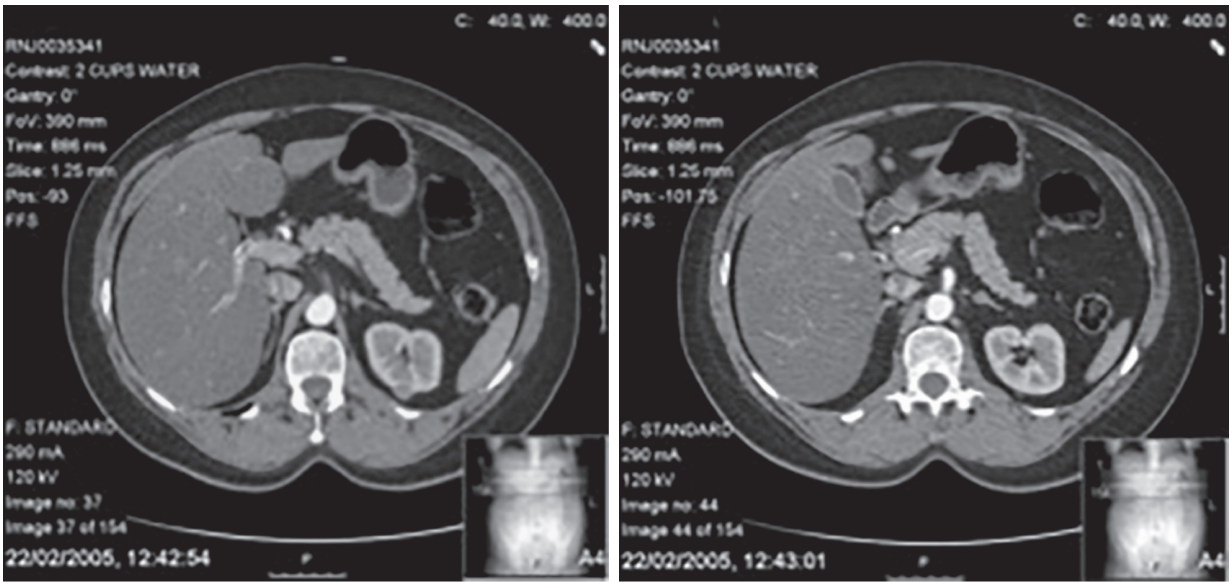

Figure 5.6.2.2 A 54-year-old woman with longstanding hypertension resistant to three agents was investigated for secondary causes. After withdrawal of interfering medication, PA was confirmed: serum potassium 3.1 mmol/L (normal 3.5–5.1), serum bicarbonate 31 mmol/L (normal 22–28), PRA <0.001 pmol/ml/hr, PAC 782 pmol/L. CT scanning showed normal appearances of the right adrenal with a small, hypodense nodule within the left adrenal. She underwent AVS, with results as shown. Lateralization was not confirmed (LI<4) and she was treated medically with spironolactone. This case highlights that, in PA patients over the age of 35–40, the presence of solitary, focal adrenal nodules cannot be assumed to imply a unilateral source of aldosterone excess.

Table 5.6.2.3 Data for Figure 5.6.2.1

Vein	Aldosterone (A), pmol/L	Cortisol (C), nmol/L	A/C	LI
Right adrenal vein	6620	1198	N/A	N/A
Left adrenal vein	9230	13470	0.7	N/A
Inferior vena cava	4148	682	6.2	

Table 5.6.2.4 Data for Figure 5.6.2.2

Vein	Aldosterone (A), pmol/L	Cortisol (C), nmol/L	A/C	Lateralization index
Right adrenal vein	76700	23830	3.7	2.2
Left adrenal vein	50500	29450	1.7	
Inferior vena cava	1368	1178	1.2	

Table 5.6.2.5 A 45-year-old man was referred to the authors' institution for a second opinion after a right adrenalectomy for PA was quickly followed by recurrent, hypokalaemic hypertension. He had presented 2 years earlier with hypertension resistant to three agents and thiazide-provoked mild hypokalaemia (serum potassium 3.4 mmol/L). PA was confirmed (PAC 1620 pmol/L; PRA undetectable) and adrenal imaging was reported as normal. The results from AVS are shown below. On the basis of the LI, the patient was advised to undergo a right adrenalectomy. Two months after the operation, the blood pressure was unchanged from its presenting value, identical biochemistry was recorded and he was referred to the authors' centre. Although the LI from right to left is >4, the contralateral (in this case left) adrenal vein A/C value is not suppressed compared to the peripheral (IVC) and the absolute aldosterone value is substantially greater than background. The authors' interpretation of this AVS is that there was bilateral aldosterone production, with predominance of the right over the left adrenal and that an adrenalectomy was unlikely to be curative. This case underscores the need to examine the raw data, in addition to calculating a LI. The patient continues MR antagonist therapy

Vein	Aldosterone (A), pmol/L	Cortisol (C), nmol/L	A/C	LI
Right adrenal vein	1445800	14559	99.3	4.8
Left adrenal vein	88 300	4317	20.5	
Inferior vena cava	3820	754	5.1	

patients should be considered for surgical treatment. With ACTH stimulation, a LI <3.0 is strongly indicative of bilateral disease; values between 3.0 and 4.0 represent an area of uncertainty. The authors, in general, work to the aforementioned consensus guidelines, but are mindful of the potential effects of cortisol cosecretion on AVS data and, in patients whose LI values fall close to the accepted cut-offs, also take into account, for any individual patient, the anatomy and other factors (age, PAC, severity of hypertension, marked hypokalaemia) that affect the *a priori* probability of PA being unilateral.

Controversies and Uncertainties in AVS

Common to all centres, at present, is the use of cortisol as the denominator for calculating a corrected ratio with which, subsequently, to determine a LI. This practice is increasingly being questioned, partly because of the growing recognition that cortisol cosecretion in PA affects a significant proportion of patients [15] and that this may influence AVS results. Low-grade autonomous cortisol secretion from one adrenal, sufficient to lower ACTH such that cortisol production by the contralateral gland is partially or completely suppressed, may result in the erroneous conclusion of failed cannulation in that adrenal vein. This issue applies to both stimulated and unstimulated AVS techniques. Even if, with ACTH stimulation, the SI is satisfied, it may still be the case that cortisol output is relatively restrained. By reducing the value of the denominator on the 'cortisol suppressed' side, the A/C value may be augmented, potentially leading to the erroneous conclusion that aldosterone production is bilateral. This has led to interest in the use of androstenedione and metanephrines in place of cortisol [16, 17], although at present this is not widely practised.

The requirement to discontinue mineralocorticoid receptor (MR) antagonists for 4–6 weeks prior to AVS poses problems for those patients whose severe hypertension is poorly responsive to other medications. This has led some groups to explore whether meaningful data may be derived from patients who, for safety reasons, cannot discontinue spironolactone or epleronone in preparation for AVS. In one small series, four patients underwent a unilateral adrenalectomy on the basis of AVS results obtained while taking spironolactone [18]. Importantly, the renin values were not derepressed by therapy and in all four patients the AVS correctly predicted the clinical and biochemical outcome after surgery. More, and larger, series will be needed before this practice can routinely be recommended and it represents a potential advantage of functional adrenal imaging, discussed next.

Given the technical difficulties of AVS, the question arises as to whether useful data for decision-making can be derived from studies in which only one vein (usually the left) is successfully cannulated. It has been suggested that suppression of the left adrenal vein A/C value ≤0.5 in comparison to the IVC value may imply that the source of aldosterone excess is the right adrenal and direct clinicians to recommend surgery [19]. Conversely, a left adrenal A/C value sufficiently greater than the IVC (≥5.5) may imply that a contribution from the right adrenal to aldosterone excess is improbable. It is hard to know if these thresholds can safely be applied to other centres using different protocols and their application does not address the underlying issue, for many patients, of lack of access to AVS.

Alternatives that Reduce the Requirement for AVS

Although the details and interpretation of AVS are debated, and some question its status as the 'criterion standard', most clinicians accept the need to divide PA patients into one of three groups: those with a high probability of unilateral disease, most of whom will be referred for surgery; those with a high probability of bilateral disease, treated medically; and those in whom there is sufficient uncertainty to require AVS. The discrepancy between the size of group 3 and the capacity for high-quality AVS has led to attempts to develop 'prediction scores' that can help move some extra patients into group 1. One scoring tool (a clinical prediction score, CPS) combined a clear-cut macroadenoma on CT with hypokalaemia and a threshold GFR, with a relative 'importance' weighting of radiology>severe hypokalaemia>mild hypokalaemia>GFR [20]. However, the reference standard against which the CPS was developed was AVS rather than surgical outcome. Given that glomerular filtration rate (GFR), for many patients, represents a surrogate for duration of hypertension (and, in turn, age of the patient), the CPS adds little to the *a priori* suspicion that a patient with a clear, unilateral nodule and normal contralateral adrenal morphology, marked hypokalaemia, and younger age has a high likelihood of unilateral PA. Other groups have found the CPS less accurate [21] and it is not widely used.

Nuclear Medicine Imaging in PA

The technical demands and lack of availability of AVS have, for many years, fuelled interest in the development of functional imaging in PA. The hazards of relying on CT imaging alone are discussed earlier, but combining anatomical detail with evidence of functional activity is an attractive concept and one that has the potential to allow more PA patients to be fully investigated. ^{131}I-iodomethyl norcholesterol and ^{75}Se-selenomethyl-19-norcholesterol have been used in past, but their overall accuracy and the requirement for prolonged use of high dose dexamethasone to suppress non-autonomous adrenal activity renders them unsatisfactory as an alternative to AVS.

More promising is the development of positron emission tomography (PET)-CT scanning, as it provides better spatial resolution than conventional planar scintigraphy. The most advanced tracer agent in use is metomidate, a methyl analogue of the anaesthetic agent etomidate. Metomidate is a potent inhibitor of CYP11B1 (11β-hydroxylase) and CYP11B2 (aldosterone synthase) and can be $C^{11}H_3$-labelled as a PET radiotracer (^{11}C-metomidate). The use of preparatory dexamethasone, to suppress non-adenomatous adrenal activity, appears to improve the diagnostic accuracy. In a non-randomized proof-of-concept study ^{11}C-metomidate PET-CT performed similar to AVS in distinguishing unilateral from bilateral PA [22]. Larger-scale, outcomes-based studies comparing metomidate PET-CT with AVS are awaited, but accumulated experience and published case reports suggest that a particular strength of the technique is its ability to identify small APAs, not easily visible on CT, whose histological architecture has a zona glomerulosa appearance and whose cells show high expression of CYP11B2 (aldosterone synthase). The requirement for an on-site cyclotron imposes limitations on the availability of this technique,

but newer tracers are in development and may be easier to deploy if published evidence supports their use. Alternatively, [^{123}I]-metomidate-SPECT-CT could be used, which has been evaluated for use in adrenal masses [23] but not yet systematically in primary aldosteronism; in this format local cyclotron facilities would not be required.

Other potential ligands for use in PET-CT scanning for PA include ^{68}Ga-pentixafor (which targets the CXC chemokine receptor-4) [24] and a compound with some structural homology to metomidate ^{8}F-CDP2230 [25]). To date, published experience with these ligands is confined to nine patients and rodents, respectively.

Steroid Metabolomics

Historically, pathological analysis of resected APAs was limited to size, colour (typical canary yellow), presence or absence of spironolactone inclusion bodies, and confirmation of benign histopathology, sometimes with a comment about surrounding hyperplasia. Recently, it has become apparent that APAs fall into one of two, broad, groups: those with cells that, paradoxically, resemble zona fasciculata (ZF) cells (often above the median for size) and those that resemble zona glomerulosa (ZG) cells. The latter type is often small and stains densely for CYP11B2 (aldosterone synthase). As described in Chapter 5.6.1, several somatic mutations have been described in APAs and there is an emerging consensus that KCNJ5 mutations are frequently associated with ZF-like histopathology, whereas mutations in certain calcium channels and ATPases tend to produce smaller tumours with ZG-like morphology. Interest has grown in the possibility that distinct steroid 'fingerprints' are associated with particular APA genotypes [26–29]. Increased concentrations of the hybrid steroids 18-hydroxycortisol and 18-oxocortisol have been documented in the adrenal and peripheral vein samples of patients carrying KCNJ5 mutated APAs [28, 30]. This has an attractive, plausible explanation: such tumours have increased expression of CYP11B1 (11β-hydroxylase) and CYP17A1, whereas these are absent from the ZG cells where aldosterone is physiologically produced. Increased availability of 11-deoxycortisol could result in its conversion by CYP11B2 to hybrid steroids, resulting in higher detected levels compared to other APAs. Evidence is beginning to point to KCNJ5-mutant adenomas as the group most likely to be solitary and unilateral, but these data will need to be robust before the finding of hybrid steroids reduces the requirement to perform AVS.

The use of liquid chromatography-tandem mass spectrometry (LC-MS/MS) to measure adrenal steroid levels including hybrid steroids in peripheral blood samples for the purpose of distinguishing APAs from BAH has been also tested. Statistically significant differences are demonstrable, although the degree of overlap is likely to limit the widespread use of this investigation. Again, such measurements, at best, can only provide information to suggest that BAH is likely (and therefore AVS is unnecessary) and it seems likely that advances in functional imaging will impact more on reducing AVS requirements and increasing the numbers of PA patients proceeding to surgery.

Surgical Treatment of PA

Laparoscopic adrenalectomy (see Chapter 5.2 for details) is now well-established as the treatment of choice for the majority of patients in whom it is possible to demonstrate a unilateral source of aldosterone excess. Morbidity is low in experienced hands and its development and subsequent refinement through the 1980s and 90s radically altered the threshold for surgical referral. (Prior to laparoscopic surgery, open adrenalectomy involved a large flank incision and sometimes resection of the twelfth rib; morbidity and mortality rates were substantial.) Various techniques are described: anterior or lateral transperitoneal, lateral or posterior retroperitoneal and (in selected centres) a single port retroperitoneal approach. The lateral transperitoneal route is the commonly used technique and involves insertion of three or four ports with the patient in a left or right lateral decubitus position for right- and left-sided operations, respectively. In both procedures the patient is flexed above the hip to open up the space between the iliac crest and rib cage. For a left adrenalectomy, ports are usually inserted below the rib cage along the anterior, posterior axillary, and mid-clavicular lines; for a right-sided procedure the ports are similarly sited, but with the addition of an extra subcostal midline port to facilitate liver retraction. Although cross-sectional imaging portrays the adrenal gland as being clearly distinct from the surrounding retroperitoneal fat, the reality is that, following mobilization of the surrounding structures (spleen, spleno-colic ligament, and tail of pancreas on the left; liver on the right) the adrenal gland may be challenging to identify, particularly if there is excess visceral fat. It is important to be aware of the surrounding structures and the planes which define the position of the adrenal gland, especially in patients with PA as the tumour may be too small to visualize and the adrenal gland is of normal dimensions. It is largely this 'judgement' aspect of adrenal surgery that dictates better results among more experienced surgeons, although no consensus exists as to what constitutes an appropriate minimum number of procedures per year to achieve good results. Unlike adrenal surgery for Cushing's syndrome or phaeochromocytoma, few, if any, anaesthetic issues arise over and above other laparoscopic (e.g. gall bladder) procedures, but close liaison regarding the possibility of cortisol cosecretion and postoperative contralateral adrenal suppression is important. Overt haemodynamic collapse due to postoperative adrenal insufficiency is rare, but described. Transient postoperative hyperkalaemia is well recognized and treated either with augmented sodium intake or temporary support with fludrocortisone.

Medical Therapy of PA

Medical treatment of PA is indicated for patients whose imaging and/or AVS results indicate that a unilateral adrenalectomy would be inappropriate or who, after careful discussion, are unfit/unwilling to undergo surgery. Given that aldosterone has deleterious effects on the heart and vasculature independent of blood pressure, the goals of pharmacological therapy of PA are not just control of hypertension, but also effective blockade of the MR.

General Measures

Although often overlooked and not formally studied, it is the authors' view that generic advice applicable to all patients with hypertension should be reinforced to patients with PA. This includes restriction of dietary sodium, maintenance of a healthy body weight, abstinence from tobacco and excessive alcohol intake, and regular aerobic exercise. All are likely to make useful contributions to making pharmacological therapy more effective.

Spironolactone

This is the drug for which most clinical experience exists in PA. Although no placebo-controlled trials of its use exist, there is sufficient consensus about its efficacy that most physicians would now consider such a study to be unethical. Its mechanism of action is competitive inhibition of cytosolic MRs, thereby modifying both transcription and translation of proteins that act to mediate sodium retention by the epithelial cells of the distal nephron. The drug is well absorbed and undergoes rapid hepatic metabolism to several metabolites including 7α-thiomethylspironolactone and canrenone. Both have a half-life substantially greater than the parent drug itself (1.4 hours) such that spironolactone is usually administered once daily. Oral canrenone is available in some countries but its use in PA is not widespread.

Individual physicians vary in their dosing strategies; the authors' practice is to start at modest doses (typically 25 mg daily), increasing slowly as tolerated and with frequent monitoring of blood potassium levels. An important clinical point is that the full hypotensive effects of spironolactone (typically 2 months or more) lag by several weeks behind the effect on potassium levels. An interesting, although not well studied, phenomenon is that, once blood pressure control is established, with time it is often possible to reduce the dose without loss of efficacy.

Various observational studies exist, some containing exclusively BAH patients and others a mixture of APA and BAH, to suggest excellent clinical efficacy either as monotherapy or by facilitating a reduction in other non-PA directed antihypertensive therapy. Dosing regimens vary markedly in the published series, from 25 to 400 mg daily, so rigid dosing protocols are hard to construct. Pragmatically, it is the blood potassium levels that govern dosing; once values approach the upper limit of the reference range further increments in dose are unlikely to be clinically beneficial without provoking problematic hyperkalaemia.

Spironolactone is not a 'pure' MR antagonist; its interaction with progesterone and androgen receptors explain its common, frequently dose-limiting, side effects of menstrual irregularity in premenopausal women and erectile dysfunction and painful gynaecomastia in men. The last of these is clearly dose-related, but such side effects tend to be under-reported in observational studies, so reports of an incidence of 50% at doses of 150 mg daily are, in the authors' view, improbably low. Other practical points about spironolactone usage include the need for regular monitoring of serum creatinine and potassium in patients with abnormal baseline renal function and/or diabetes mellitus, a reduction in efficacy with concomitant salicylate use and prolongation of its half-life with advanced liver disease or heart failure.

Inevitably, the relatively recent appreciation of adverse cardiometabolic consequences of aldosterone excess independent of blood pressure render historical observational reports of the efficacy of spironolactone somewhat incomplete. Although a systematic review suggested that regression of many of the adverse features of PA (LVH, proteinuria and renal function) were equivalent between medically and surgically treated patients [31], a recent, large, retrospective study suggested that current MR antagonist regimens do not restore the morbidity of PA to that of essential hypertension except (on subanalysis) in patients whose plasma renin was derepressed by an adequate dose of spironolactone [32]. This remains an area of uncertainty in the field.

Eplerenone

Developed and approved for the treatment of hypertension, this second-generation MR antagonist has fewer antiandrogen and antiprogesterone side effects than spironolactone consequent upon its 9.11-epoxide group which ensures more selective receptor affinity. It has few, if any, active metabolites and its half-life mandates twice daily dosing. Like spironolactone, no placebo-controlled studies for eplerenone exist in PA, but several trials have compared the two drugs against each other in this clinical setting [33]. Spironolactone appears consistently more effective at lowering blood pressure in PA, albeit at the expense of the side effects described earlier. One head-to-head study suggested a dose equivalence of 1:2 (spironolactone 50 mg = eplerenone 100 mg), but there was substantial crossover from spironolactone to eplerenone during the study [34]. Together with its greater cost, eplerenone should be considered second line medical therapy for PA and a good alternative when adverse symptoms limit the use of spironolactone. The maximum licensed dose is 100 mg daily, but this is often insufficient to achieve blood pressure control. The requirement to monitor blood potassium and creatinine levels is similar between the two MR antagonist drugs.

Non-MR Antagonist Medical Therapies

If adverse symptoms and/or cost and/or availability dictate that neither spironolactone nor epleronone can be used, high dose amiloride is an alternative. Although many of the mechanisms of action of aldosterone outside the kidney remain to be fully elucidated, at the distal tubule it is the amiloride-sensitive epithelial sodium channel (ENaC) that is the rate-limiting step on sodium reabsorption. Its perceived modest effect in PA may, in part, be due to historical underdosing and the authors consider the drug to be a useful adjunctive to a maximum tolerated dose of spironolactone in a patient with troublesome side effects and/or cost constraints on the use of MR antagonists. Sodium competes with amiloride for intraluminal binding to ENaC, such that the efficacy of amiloride can be improved by a reduction in sodium intake. The use of triamterene is uncommon, but, conceptually, is similar to amiloride.

Possible Future Medical Therapies

Finerenone is a non-steroidal MR antagonist that has shown promising results in patients with heart failure, but has yet to undergo clinical studies in PA. Aldosterone synthase (CYP11B2) inhibitors

represent an attractive concept for the treatment of PA. Older drugs in this class were compromised by their poor selectivity between the CYP11B2 and CYP11B1 enzymes involved in aldosterone and cortisol synthesis, respectively, whose structures are 93% identical. A few highly selective newer drugs are at the early stages of evaluation.

Decision-Making in PA: Medical or Surgical Management

An inevitable consequence of the way in which clinical trial and/or departmental audit/outcome data are presented is that decision-making can seem clear-cut to the point of 'rigidity'. The reality, for many patients, is that imaging and biochemical data can be equivocal and choices about medical or surgical treatment difficult. It has become commonplace in clinical teaching to state that 'decision-making should be within a multidisciplinary team (MDT)'. The authors subscribe to this practice, with some clarifying views. First, MDTs function best when constructive, robust audit programmes are embedded within the group culture, so that experience can be shared and augmented. Second, such audit and outcome data should be generously shared around the PA community, lowering the threshold for collaborative studies to improve practice. Last, although discussion among colleagues about imaging and AVS results is always helpful, individual knowledge of the case and personal clinician responsibility are paramount to good decision-making and clinical care.

It should be emphasized that the SI and LI values quoted earlier are guides rather than 'absolutes'. As with all endocrine testing (inferior petrosal sinus sampling and MRI scanning of the pituitary for ACTH-dependent Cushing's syndrome is another good example), results are always interpreted against a background of the *a priori* likelihood of a particular diagnosis. Careful review of the anatomy, results of AVS if performed, the presence or absence of cortisol cosecretion, patient age, severity of hypokalaemia (if present) and the diagnostic values of renin and aldosterone all contribute to an integrated decision-making process that improves with personal and shared experience.

Clinical Outcomes

The importance attached to distinguishing between unilateral and bilateral disease assumes that the former may be cured by adrenalectomy while the latter will not. However, the difference in outcomes is not as clear-cut as might be expected, and advances in molecular understanding of the pathogenesis also point to a blurring between the unilateral and bilateral subtypes. Immunohistochemistry with specific antisera against CYP11B2 shows most 'hyperplasia' to consist of discrete 'aldosterone-producing cell clusters', of which 30–60% have the same mutations as reported in the smaller, ZG-type APAs [35]. The frequency of these clusters, reported in at least 30% of post-mortem adrenals, and of the gene mutations they harbour, raises suspicion that fewer patients have unilateral disease than originally thought; and that apparently successful surgery may be due to 'debulking' rather than 'curing' disease. It is well known that only 30–60% of patients with rigorously proven unilateral PA are cured of hypertension, even though PA is biochemically cured in 90–95% of such patients. The likely explanation is the long duration of PA (usually decades) before diagnosis, resulting in irreversible vascular changes that sustain hypertension, even after the original cause is removed. This probably explains why younger patients, with less severe hypertension, have a greater likelihood of complete cure from hypertension.

The commonly agreed practice of integrating anatomical information and AVS results into clinical decision-making was recently challenged by the results of what is, to date, the only published prospective, randomized study in the field of PA and therefore worthy of particularly detailed discussion and analysis here. In SPARTACUS (Subtyping Primary Aldosteronism: A Randomized Trial Comparing Adrenal Vein Sampling and Computed Tomography Scanning), 200 patients were enrolled and randomized to have their clinical decision regarding medical or surgical management determined by AVS (preceded by CT, to exclude ACC and provide anatomical information for surgery, where relevant) or CT alone [3]. For those randomized to CT-based decision-making, surgery was undertaken only in the event of a unilateral radiological abnormality with unequivocally normal contralateral appearances. Patients with any other radiological findings (normal, bilaterally enlarged adrenal glands or a focal nodule with subtle contralateral thickening) were treated medically. The data from 184 patients who completed the protocol separated into four groups: CT-determined medical and surgical management; and AVS-determined medical and surgical management, with, neatly, 46 in each group. The primary endpoint of SPARTACUS was the burden of antihypertensive treatment required to achieve a predefined target blood pressure at 1 year.

There was no difference between the groups with regard to the intensity of antihypertensive drug treatment, mean blood pressure, proportion of patients reaching target blood pressure or quality of life at 1 year. The authors concluded that neither AVS nor CT scans should be considered as gold standard tests for identifying an APA and that the considerable expense of AVS could be jettisoned without compromising clinical outcomes.

The controversial nature of the reported findings has been associated with some criticism of the study design. First, the choice of primary endpoint is strikingly different from other reported outcome studies in PA and not in line with a recent international consensus statement on the definition of cure following adrenalectomy [4]. Second, the patients recruited into the study were at the more severe end of the PA spectrum; a group known to have more marked target organ damage, including LVH, renal damage, and vascular remodelling, each of which may contribute to persistence of hypertension after biochemically curative adrenalectomy. This, in turn, dictates that such patients would be less likely to be achieve satisfactory control of hypertension with either surgical or medical treatment, reducing the chances (with the size of study population) of detecting a difference between the randomized groups. Third, the perceived 'burden' of antihypertensive therapy depends, in part, on the choice of therapy for any residual, fixed hypertension as a consequence of longstanding PA or background essential hypertension, even if surgery leads to biochemical cure. In SPARTACUS, the antihypertensive medicines deployed in the study patients at 1 year was unusual. Fourth, the comparison of CT vs. AVS-determined medical therapy reduced the overall power

of the study and, given that APA patients respond perfectly satisfactorily to MR antagonists, did not provide significant clinical information.

With all those caveats, SPARTACUS is, to date, the only prospective, randomized study that has attempted to address/challenge the issue of whether AVS can justify its status as the 'criterion standard' for dictating clinical management. The investigators accept that CT scanning is associated with significant misclassification rates, but reasonably point out that, in their hands, AVS is flawed too and have re-energized the debate as to whether it is appropriate that a restricted, expensive investigation should continue severely to limit the access of PA patients to potentially curative surgery.

Cortisol Cosecretion in Primary Aldosteronism

Abnormal (non-ACTH mediated) cortisol secretion in PA has been known about for some time [35] but the availability of specific antisera to CYP11B1 has provided further insights. Total 24-h urinary glucocorticoid excretion in primary aldosteronism significantly correlates with immunohistochemical expression of CYP11B1 in the corresponding APA tissue [15]. Further, clinical surrogate parameters of metabolic risk, such as waist circumference and diastolic blood pressure, correlate significantly with cortisol, but not with aldosterone, production. This is potentially clinically relevant as studies in large cohorts of PA patients have demonstrated an increased risk of type 2 diabetes and osteoporosis compared to population-based controls [37, 38]; adverse outcomes usually associated with glucocorticoid rather than mineralocorticoid excess. It is conceivable, but not proven, that cortisol cosecretion in PA drives these adverse metabolic outcomes [39]. Of note, a recent study suggested that both LVH at diagnosis of PA and its reversibility correlated with cortisol co-secretion as assessed as total 24-h urinary glucocorticoid excretion [40].

In a separate report, 45 of 175 patients who underwent a postoperative short synacthen test after surgery for PA, 29% were shown to have a suboptimal response [15]; a figure supported by a separate study [42]. The clinical significance of this is uncertain and reports of overt post-operative hypadrenalism are very rare [43], but subtle abnormalities of cortisol requiring hydrocortisone supplementation may be more common and clinical awareness is paramount. This rate of adrenal insufficiency was confirmed in a recent prospective series carried out in 100 consecutive patients with primary aldosteronism due to unilateral APA; 27% of patients failed the postoperative synacthen test and required hydrocortisone replacement therapy for several months, with significant adrenal crisis risk [42]. The increasing awareness of the possible clinical implications for cortisol co-secretion are likely to feature more prominently in future iterations of consensus guidelines for the management of PA.

There is no doubt that these findings will be considered when the next American and European consensus guideline revisions will be undertaken and given the observed prevalence of postoperative adrenal insufficiency, the integration of an early postoperative short synacthen test in surgically treated primary aldosteronism patients may be prudent.

Rare Forms of PA

The previous discussion of APA and BAH applies to around 98% of cases of PA. Rare forms are recognized and briefly described here, but are dealt with in more detail elsewhere.

Aldosterone-Secreting Adrenocortical Carcinoma (ACC)

This diagnosis will be immediately apparent on cross-sectional imaging. Tumours are typically large (>4 cm) and often irregular, heterogeneous, and invasive. The only chance of cure is surgical resection. Other therapeutic options for non-curable ACC are covered in Chapter 5.4 and should be combined with MR antagonists and/or high dose amiloride therapy to control hypertension and hypokalaemia. Pure aldosterone-secreting ACCs are rare; more common is for an array of secreted steroids to include deoxycorticosterone (DOC), but the principles of management remain the same.

Familial Forms of PA

Various forms of inherited PA exist, distinguished by their clinical features and genetic causes; a detailed description of these conditions is provided in Chapter 5.6.1. The term is restricted to a small number of very rare conditions, in which germline mutation of a specific gene is identified. The current nomenclature, in which a different number is used for each genetic abnormality, is not practised in other areas of endocrinology and may not survive the discovery of further genes.

Special Situations in PA

As with many endocrine conditions, particular clinical situations arise for which few or no data exist to guide decision-making. Under these circumstances, physicians have to rely on judgement, backed up by collaborative discussion with experienced colleagues. Two such situations are the combination of PA and pregnancy and PA with advanced renal impairment.

PA in Pregnancy

The frequency with which PA occurs in pregnancy is not known. If the prevalence of hypertension in pregnancy (6–8%) is combined with the prevalence of PA in unselected hypertensive populations, then approximately 0.5–0.8% of pregnant women will have PA. One could argue that the majority of women with PA are diagnosed after childbearing years, making the aforementioned figure an overestimate, but most PA is diagnosed opportunistically and the chances of detecting asymptomatic hypertension are higher in pregnancy as blood pressure monitoring accompanies most obstetric/midwifery encounters. As discussed earlier, PA has few clinical features, so suspicion of PA arises in the context of hypokalaemia and/or severe hypertension before 20 weeks of gestation (after which the likelihood of pre-eclampsia as a cause rises). Supportive biochemical evidence for a diagnosis of PA is largely restricted to a suppressed

renin, as PAC rises in normal pregnancy. Standard confirmatory tests (SIT, CCT) should wait until after delivery. If PA is strongly suspected, then medical therapy with MR antagonists should be commenced. Classical teaching is that the antiandrogen properties of spironolactone dictate this drug is contraindicated in pregnancy, but in fact only one case report exists of ambiguous genitalia in a male infant associated with use of the drug in the first few weeks of gestation [44]. Eplerenone has no antiandrogenic action but published data on pregnancy outcomes are sparse. The authors recommend epleronone for use in pregnancy and breast feeding if PA is suspected or confirmed, but if this drug is unavailable or not tolerated, then given that sexual differentiation is largely complete by the end of the first trimester, and considering the context of the hazards of uncontrolled hypertension in pregnancy, the benefits of spironolactone on blood pressure and potassium control after this time probably outweigh any theoretical issue with male fetal development. If hypertension and/or hypokalaemia cannot be controlled medically and the diagnosis of PA is secured prepregnancy or strongly suspected during pregnancy on account of a suppressed renin measurement, then a mid-trimester adrenalectomy may be considered. Adrenal imaging should be with (non-ionizing) MRI; given the age of most pregnant women, incidental adrenal nodules are improbable, so the finding of a solitary nodule is usually sufficient evidence with which to proceed. AVS should not be performed in pregnancy.

PA and Renal Failure

The combination of PA and advanced renal failure presents particular diagnostic and therapeutic problems. Clinical suspicion is difficult, given that most patients with renal failure will have hypertension requiring therapy with more than one agent; the characteristic hypokalaemic alkalosis will be obscured by the renal disease; and secondary hyperaldosteronism is common as kidney function declines. Imaging quality may be compromised by the need to avoid iodinated contrast agents for CT scanning and some gadolinium containing agents are contraindicated in advanced renal disease because of the risk (albeit with repeated administration) of a characteristic dermopathy. Whereas some people may instinctively feel that, once renal failure is established, investigation and treatment of PA is too late and futile, the authors take the reverse view. It is the combination of hypertension and excess aldosterone exposure, in many cases, that has led to accelerated renal disease and correction of the latter almost invariably facilitates better treatment of the former, even in advanced cases. Further, in those patients who have progressed to end-stage renal disease (ESRD) requiring dialysis, it might be thought that the physician has a degree of control over salt and water balance and that the renal actions of aldosterone on sodium retention are irrelevant in an anuric patient. The fact that spironolactone improves blood pressure in patients with PA on dialysis provides compelling evidence for the extrarenal effects of aldosterone and that removing or pharmacologically blocking that excess will be clinically beneficial. In patients with ESRD contemplating transplantation, removal of an APA will prevent the scenario of a resumption of sodium and water retention and hypertensive damage to the grafted kidney. AVS requires the use of a modest volume of contrast agent and close nephrological liaison is advised.

Newer Techniques for Treating Unilateral Aldosterone Excess

Annual UK audit returns indicate that 250–300 adrenalectomies per year are performed for PA. Using even the most conservative estimates of the prevalence of PA (approximately 300 000) and assuming that 50% of cases are due to a unilateral APA, it is immediately apparent that, if case detection and access to accurate lateralization investigations were dramatically to improve, then endocrine surgical services would quickly become overwhelmed. This, together with a desire to avoid removing a whole gland as treatment for a small, benign tumour has led to a search for less invasive methods of removing the source of aldosterone excess. Radiofrequency ablation (RFA) is an established technique for the treatment of liver deposits from large bowel, neuroendocrine, and other malignant tumours and some centres have developed protocols to destroy functioning adrenal nodules. Slight variations are described, but, in general, patients are positioned prone in the lateral decubitus position either heavily sedated or under full general anaesthesia. Under CT guidance a monopolar radiofrequency electrode is introduced and, using a pulsed technique and generating a power of 50–150 W, RFA is applied for several minutes. Periadrenal fat stranding is observed and technical success judged by lack of enhancement on a follow-up CT scan. Interestingly, although the nodule being treated is steroid-producing, intraprocedural, urgent hypertensive episodes are not infrequent, necessitating continuous intra-arterial monitoring and appropriate pharmacological intervention.

No randomized studies are available that compare RFA with conventional adrenalectomy, but reports exist of extensive, accumulated single centre experience [45]; and a comparison of clinical outcomes between two neighbouring tertiary United States centres, one of which provides both surgery and RFA on the basis of patient choice [46]. The data are, at present, too preliminary to draw firm conclusions, but there is sufficient 'momentum' to justify a randomized study. Attractions of the technique include the possibility of shorter hospital stays and the potential to treat bilateral disease. With experience and refinement, the availability of RFA may, in time, lower the threshold for intervening in unilateral disease; at present, the scenario of a 'failed adrenalectomy' (one in which hopes for complete cure of hypertension are not met) often leads to caution in recommending abdominal surgery for a benign condition. If an intervention considered to be less invasive were available, it is possible that the threshold for that procedure would be lower than at present. Areas of uncertainty and controversy regarding RFA include the lack of histological proof and complete molecular diagnosis provided by surgery; and the long-term consequences of leaving untreated areas of hyperplasia that often surround the easily visible APA.

Conclusions

Conn's prediction of the number of hypertensive patients who would have the syndrome he described was uncannily accurate. The excess cardiometabolic morbidity associated with PA over and above essential hypertension is now widely accepted; as is the current shortfall in the rate of diagnosis, availability of subtyping investigations and access to potentially curative interventions. The

recent explosion in understanding of the molecular pathogenesis of the condition has fuelled a new wave of investigational protocols that promise to remove many of the barriers that currently block the management of patients with this condition. The authors predict that the next version of this chapter will look strikingly different.

Cushing's Syndrome

John Newell-Price

Introduction and Historical Perspective

> *I would like to see the day when somebody would be appointed surgeon somewhere who had no hands, for the operative part is the least part of the work.*
>
> Harvey Cushing: Letter to Dr Henry Christian, 20 November 1911

Harvey Cushing described the first case of Cushing's syndrome with a severe phenotype in 1912. Since that time, investigation and management of Cushing's syndrome has remained a significant clinical challenge [1–3] and patients suspected of this diagnosis warrant referral to major centres.

Endogenous Cushing's syndrome is due the chronic, excessive, and inappropriate secretion of cortisol. When presentation is florid, diagnosis is usually straightforward, but in modern practice Cushing's syndrome is frequently and increasingly considered in mild cases in the absence of the classical signs in the context of osteoporosis, diabetes, hypertension as well as in the context of gynaecological and psychiatric clinics. Achieving a diagnosis can be difficult. Appropriate management of Cushing's syndrome is dependent on correctly identifying the cause of excess cortisol. Separating ACTH-independent causes (adrenal tumours) from ACTH-dependent causes (pituitary or ectopic secretion of ACTH) is usually simple. However, many ectopic sources are occult and the identification of the source of ACTH secretion may require meticulous and repeated investigations.

In most circumstances the mainstay of therapy remains surgery to either an ACTH-secreting tumour or directly to the adrenal glands, but additional treatment with cortisol-lowering or opposing drugs and tumour-directed therapy is often needed.

Aetiology, Genetics, Pathogenesis, and Pathology

Endogenous Cushing's syndrome is usually sporadic and divided into ACTH-dependent, and ACTH-independent causes (Table 5.7.1). Overall, ACTH-dependent causes account for approximately 80% of cases, and of these 80% are due to corticotroph pituitary adenomas (Cushing's disease) with an excess female predominance, and the remaining 20% due to the ectopic ACTH syndrome with male predominance [1]. Cushing's disease, the ectopic ACTH syndrome, and adrenal adenomas may also be found in the context of multiple endocrine neoplasia 1 (MEN 1).

Cushing's Disease

Most cases of Cushing's disease are due to corticotroph microadenomas, a few millimetres in diameter, only being larger than 1 cm (macroadenoma) in 6% of cases [1, 3, 4]. These tumours express the proopiomelanocortin gene (*POMC* 176830), the peptide product of which is subsequently cleaved to ACTH. POMC-processing is usually efficient in corticotroph microadenomas,

Table 5.7.1 Aetiology of Cushing's syndrome

Cause of Cushing's syndrome	F:M	%
ACTH-dependent[a]		
Cushing's disease	3.5:1[b]	70%
Ectopic ACTH syndrome	1:1	10%
Unknown source of ACTH[c]	5:1	5%
ACTH-independent		
Adrenal adenoma	4:1	10%
Adrenal carcinoma	1:1%	5%
Other causes (PBMAH; PPNAD; McCune–Albright)		<2%

[a] In women 9:1 ratio of Cushing's disease to ectopic ACTH.
[b] Male preponderance in children.
[c] Patients may ultimately prove to have Cushing's disease.
PPNAD, primary pigmented nodular adrenal disease; AIMAH, ACTH-independent massive adrenal hyperplasia.

but less so in macroadenomas, which may secrete relatively large amounts of unprocessed POMC. Some pituitary macroadenomas are 'silent corticotroph adenomas', and may present with tumour mass effects (e.g. optic chiasm compression) alone; on follow-up, initial absence of cushingoid features may progress to overt clinical Cushing's syndrome. Approximately 90% of tumours express the corticotropin-releasing hormone (CRH)-1 receptor, as evidenced by the release of ACTH in response to exogenously administered CRH. Tumours also express the vasopressin-3 receptor, and respond to vasopressin and desmopressin.

Tumours causing Cushing's disease are relatively resistant to the effects of glucocorticoids, but *POMC* expression and ACTH secretion are reduced by higher doses of dexamethasone in 80% of cases [2, 5]. This may be caused by 'miss-expression' of the 'bridging protein' Brg1 (which is important for glucocorticoid inhibitory feedback on *POMC* expression) found in corticotroph tumours, and may be one event determining tumourigenesis [6]. Corticotroph tumours also show overexpression of cyclin E, low expression of the cyclin-dependent inhibitor, p27, and a high Ki-67 expression, all indicative of a relatively high proliferative activity [7]. The excess number of reproductive-aged women with Cushing's disease, and the fact that there is a male preponderance in prepubertal cases [8] suggest a potential aetiological role for oestrogens. Recent data has emphasized the role of epidermal growth factor (EGF) and its receptor (EGFR), which increases *POMC* mRNA transcription, cell proliferation and ACTH secretion [9–11]. Usually, EGFR is degraded by ubiquitination, but somatic missense mutations in ubiquitin-specific protease 8 (USP8), present in approximately 40% of patients with Cushing's disease, inhibits deubiquitinating activity and so EGFR is re-cycled and signalling is enhanced [9–11]. Antagonists of EGFR may have therapeutic potential in Cushing's disease.

Ectopic ACTH Secretion

Well differentiated neuroendocrine tumours from any source may cause the ectopic ACTH syndrome, and show a molecular phenotype close to that of pituitary corticotroph tumours. In contrast, data in small cell lung cancer cells have shown that *POMC* is activated by transcription factors distinct from those in the pituitary, including E2F factors [12], which are able to bind the promoter when it is in an unmethylated state [13], suggesting a different pathogenesis.

Adrenal Disease

Approximately 50% of adrenal adenomas causing overt Cushing syndrome exhibit hotspot mutations at L205R of *PRKACA*, which encodes the catalytic subunit of cAMP-dependent protein kinase A (PKA), and drives cortisol secretion [14–17].

In primary bilateral macronodular adrenal hyperplasia (PBMAH), previously also termed AIMAH (for ACTH-independent macronodular hyperplasia), excess cortisol secretion may be associated with either ectopically-expressed receptors or increased eutopic receptor expression [18], and activation by ligands not usually associated with adrenal steroidogenesis: gastric inhibitory peptide (food-dependent Cushing's); vasopressin; interleukin-1; luteinizing hormone; and serotonin. Activation of receptors increasing intracellular cAMP is thought to cause hyperplasia over many years, and hence Cushing's syndrome. Recently, it has been demonstrated that steroidogenic cell clusters in PBMAH adrenals produce corticotropin, which stimulates cortisol production by the adrenal in an intracrine/paracrine fashion. Therefore, in PBMAH, cortisol excess seems to mediated by ACTH, albeit of adrenal rather than pituitary or extra-adrenal ectopic origin; therefore, PBMAH is not truly ACTH-independent. For this reason, the term PBMAH is now preferred over AIMAH. The nodules can vary in size and may be massive. Germline inactivating mutations of Armadillo repeat 5 (*ARMC5*) [19] have now been identified as a common cause of PBMAH. ARMC5 is a cytosolic protein and little is known about its function; in rodent models a more complex phenotype ensued including compromised T-cell proliferation and differentiation; in humans, ARMC5 has also been reported to be associated with an increased incidence of meningioma alongside Cushing's syndrome. Characteristically, ARMC5 causes a mild Cushing's phenotype with onset over years and decades, often resulting in misdiagnosis as metabolic syndrome; family screening can reveal cases much earlier.

Primary pigmented nodular adrenal disease (PPNAD) causes small ACTH-secreting nodules on the adrenal, often not visualized on imaging. PPNAD can be sporadic or part of the Carney's complex and most cases occur in late childhood or in young adults, often with a mild or cyclical presentation [20, 21]. Germ line mutations of the regulatory subunit R1A of PKA (*PRKAR1A*) are present in approximately 45% of patients with Carney's complex [22, 23] and as well as in sporadic PPNAD. Another causative gene locus maps to chromosome 2p16. Interestingly, these patients show a paradoxical increase in cortisol secretion in response to dexamethasone.

McCune–Albright syndrome is due to a postzygotic activating mutation in the *GNAS1* gene. The resulting tissue mosaicism results in a varied phenotype, and the disease may present in the first few weeks of life. These mutations lead to constitutive steroidogenesis in the affected adrenal nodules [24]. Mutations of *GNAS1* have also been found in cases of PBMAH.

Epidemiology

The true prevalence of Cushing's syndrome is difficult to quantify. Earlier data suggest an incidence from 0.7 to 2.4/million population per year depending on the population studied. Biochemical Cushing's syndrome with no clear clinical features has, however, been shown to be common. Incidental adrenal lesions found on computed tomography (CT) scans are now a very common clinical problem and approximately 1–3% of the population aged 70 or more will have evidence of low-grade hypercortisolaemia from such a lesion. In addition, Cushing's syndrome has been reported in some series to be found in 1–5% of obese patients with type 2 diabetes, and up to 10.8% of older patients with osteoporosis and vertebral fracture [25]. The difficulty here, however, is whether detection of mild Cushing's syndrome in these populations is of clinical value as the outcomes of small and uncontrolled intervention studies are mixed. These data indicate that formal intervention trials are needed before widespread screening in these populations can be recommended, and there is a need for clinical decision-making tools to allow stratification for intervention on an individualized basis.

Clinical Features of Cushing's Syndrome

Glucocorticoid receptors are present in virtually all cells, reflecting the diverse actions of cortisol, and hence the symptoms and signs

of hypercortisolaemia encompass all organ systems. Many of the symptoms associated with hypercortisolaemia are common and of little specificity, such as weight gain, lethargy, weakness, menstrual irregularities, loss of libido, hirsutism, acne, depression, and psychosis (Table 5.7.2). While each symptom itself may be mild, the presence of a greater number of features in any given patient increases the likelihood of Cushing's syndrome. The signs most useful in differentiating Cushing's syndrome include the presence of proximal myopathy, and easy bruising, purplish striae, thinness, and fragility of the skin [1, 2, 25]. The sign of proximal weakness is most easily demonstrated by asking the patient to stand from sitting position without the use hands; an initial backwards movement of the buttocks is present in early myopathy, while in more severe cases rising from a chair may not be possible.

Presentation differs between genders, with purple striae, muscle atrophy, osteoporosis, and kidney stones being more common in men [26]. Gonadal dysfunction is common in both sexes. The adverse effects of glucocorticoids on bone metabolism are evidenced by decreased bone mineral density, especially of the axial skeleton. Over 70% of patients with Cushing's syndrome may present with psychiatric symptoms ranging from anxiety to frank psychosis; if present, depression is often agitated in nature, and some degree of psychiatric disturbance often persists following remission of Cushing's syndrome [3]. Impairment in short-term memory and cognition is common and can persist for at least a year following treatment. Cortisol excess predisposes to hypertension and glucose intolerance.

Classically, the ectopic ACTH syndrome due to small cell lung cancer may have a rapid onset with severe features: profound weakness, myopathy, hyperpigmentation, diabetes mellitus, and hypokalaemic alkalosis, while there is often neither weight gain nor the classical cushingoid appearance. In contrast, the clinical phenotype and biochemical features of neuroendocrine tumours (of any tissue origin) may be indistinguishable from that of Cushing's disease, causing diagnostic difficulty.

Clinical and biochemical features may commonly vary in a 'cyclical fashion', causing diagnostic difficulty. Signs and symptoms fluctuate with circulating cortisol, such as facial plethora, myopathy, mood, blood pressure, and blood glucose, and all investigations may be normal when hypercortisolaemia is absent. Great care is needed to seek for evidence of 'cyclicity' in the clinical history.

Table 5.7.2 Clinical features of Cushing's syndrome

Feature	%
Obesity or weight gain	95
Facial plethora	90
Rounded face	90
Decreased libido	90
Thin skin	85
Decrease linear growth in children	70–80
Menstrual irregularity	80
Hypertension	75
Hirsutism	75
Depression/emotional lability	70
Easy bruising	65
Glucose intolerance	60
Weakness	60
Acne	50
Osteopenia or fracture	50
Nephrolithiasis	50

Clinical Investigation and Diagnostic Criteria

Who to Test

Most patients initially suspected of possibly having Cushing's syndrome will not have this condition. The complete assessment of a patient known to have some form of Cushing's syndrome is complex, expensive, and often stressful for the patient, who is usually already significantly ill emotionally, psychologically, and physically. Thus efficient screening procedures are needed to identify the minority who will need intensive and expensive investigation leading to an accurate and precise differential diagnosis [1, 25].

It is recommended that clinical judgement is used to select patients for testing, which should be considered in: (1) patients with features that are unusual for age, such as hypertension and osteoporosis; (2) those with multiple and progressive features, especially if these include the signs that most reliably distinguish Cushing's syndrome: the presence of thin skin in the young, easy bruising, proximal myopathy, and purple striae; (3) in children with increasing weight percentile and decreased linear growth; and (4) patients with adrenocortical lesions consistent with an adenoma found on CT scans performed for other reasons, so-called adrenal 'incidentaloma' [25] (for details see Chapter 5.3).

It is essential that a careful drug history is taken prior to any biochemical testing seeking to exclude exogenous sources of glucocorticoids that may be present in prescribed oral, rectal, inhaled, topical, or parenteral medication as well as in many 'over the counter' preparations, including skin creams, 'skin-whitening' agents, and various 'tonics' and herbal preparations.

Biochemical Assessment

The biochemical hallmark of Cushing's syndrome is inappropriate cortisol secretion not subject to the normal negative feedback effects of circulating glucocorticoids on the regulatory centres, hypothalamus, and pituitary. The tests are based on demonstration of excessive cortisol secretion, loss of its circadian rhythm, and the abnormal feedback regulation of the hypothalamic–pituitary–adrenal (HPA) axis (Figure 5.7.1).

In florid cases of Cushing's syndrome the diagnosis may be obvious, but biochemical confirmation is still needed. Investigation of Cushing's syndrome is a two-step process. Hypercortisolaemia *must* be confirmed before *then* the cause is identified. Failure to follow this approach will result in inappropriate treatment and management.

Step 1: Diagnosis of Hypercortisolaemia

Several tests are usually needed. Investigation should be performed when there is no acute concurrent illness, such as infection or heart failure, as these may cause false-positive results. The three main tests in use are: 24-h urinary free cortisol; 'low-dose'

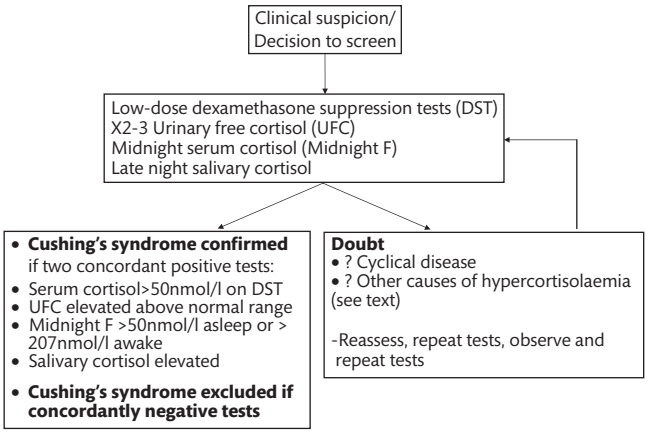

Figure 5.7.1 Biochemical diagnosis of Cushing's syndrome.

dexamethasone-suppression tests; and assessment of midnight plasma or late-night salivary cortisol. The best approach is to perform at least two different tests; if concordantly positive or negative, Cushing's syndrome is either likely or unlikely, respectively [1, 3, 25]. When there are discrepancies between tests, further evaluation and repeated testing is often required. Hypercortisolaemia is also found in some patients with depression, alcohol dependence, anorexia nervosa, and late pregnancy. However, in contrast to true endogenous Cushing's syndrome, the biochemistry of these pseudo-Cushing states improves when the underlying condition has resolved.

Urinary Free Cortisol

Urinary cortisol is a direct assessment of circulating free (biologically active) cortisol. Excess circulating cortisol saturates the binding proteins (cortisol-binding globulin, CBG) and is excreted in urine as free cortisol, and when collected for 24 h gives an integrated estimation of the level of hypercortisolaemia. A single measurement has low sensitivity, and three 24-h collections should be performed [2, 17]. There is a 50% day-to-day variability in urine-free cortisol (UFC) values in patients with Cushing's syndrome, reinforcing the need for multiple collections [27]. Values fourfold greater than the upper limit of normal are rare except in Cushing's syndrome. In contrast, if values are normal on repeated occasions, Cushing's syndrome is unlikely. Specificity is a common problem with antibody-based assays, but [1, 2, 25] high performance liquid chromatography (HPLC) and tandem mass spectrometry improves diagnostic accuracy, although substances such as digoxin and carbamazepine may produce peaks in the HPLC assay that give falsely high values [25]. Moreover, if there is renal impairment with a glomerular filtration rate (GFR) of less than 30.0 ml/min, or an incomplete collection, the urinary free cortisol may be falsely low [25]. Review of the collection volume and correction for creatinine concentration may be helpful in assessing whether the collection is complete. Use of urinary free cortisol is advised in the very rare situation of Cushing's syndrome being considered during pregnancy.

Low-Dose Dexamethasone-Suppression Tests

Two tests are in common use. In the overnight dexamethasone-suppression test, 1 mg of dexamethasone is administered at 23.00 hours and serum cortisol measured the next day at 08.00–09.00 hours. In the 48-h dexamethasone-suppression test, dexamethasone is administered at the dose of 0.5 mg every 6 hours for 2 days at 09.00, 15.00, 21.00, and 03.00 hours with measurements of serum cortisol at 09.00 hours at the start and end of the test. To exclude Cushing's syndrome the serum cortisol value should be less than 50 nmol/L following either test [1–3, 25]. The 48-h test, though more cumbersome, is more specific and with adequate regular instructions can easily be performed by outpatients. In both tests, caution needs to be exercised if there is potential malabsorption of dexamethasone or if patients are on drugs that increase hepatic clearance of dexamethasone, including carbamazepine, phenytoin, phenobarbital, or rifampicin. Simultaneous measurement of plasma dexamethasone may be useful to confirm compliance and adequate circulation levels, and a value of >3.3 nmol/L as measured by LC-MS/MS improves the accuracy of the test [28]. Patients taking oestrogen therapy, or who are pregnant, may have an increase in the cortisol-binding globulin. As commercial cortisol assays measure total cortisol, this may give a false-positive result on dexamethasone-suppression testing. Oral oestrogens need to be stopped for a period of 4–6 weeks so that cortisol-binding globulin may return to basal values. Even transdermal oestrogens may cause false-positive results, and tests should be repeated off transdermal oestrogens if positive results are obtained. In renal failure, suppression on dexamethasone testing is likely to exclude Cushing's syndrome. It is important to note that 3–8% of patients with proven Cushing's disease show suppression of serum cortisol to less than 50 nmol/L on either test. Thus, if clinical suspicion remains high, repeated tests and other investigations are indicated.

Late-Night Salivary Cortisol or Midnight Plasma Cortisol

The normal circadian rhythm of cortisol secretion is lost in patients with Cushing's syndrome. A single sleeping midnight plasma cortisol of less than 50 nmol/L effectively excludes Cushing's syndrome at the time of the test. This is one of the harder tests to perform as it requires hospitalization for at least 48 hours, and lack of intercurrent illness, but it can be of great utility to exclude Cushing's syndrome, especially when the patient is on drugs known to enhance metabolism of dexamethasone causing a false-positive on dexamethasone testing. Values above 50 nmol/L when asleep or above 207 nmol/L when awake are found in Cushing's syndrome, even in those who suppress on dexamethasone [29, 30]. An elevated midnight plasma cortisol does not provide additional information if clinical signs are florid and there is clear lack of suppression on dexamethasone testing.

Late-Night Salivary Cortisol

Salivary cortisol reflects free circulating cortisol and its ease of collection and stability at room temperature make it a highly suitable screening tool for outpatient assessment. The diagnostic ranges vary between reports due to the different assays and the comparison groups used to set cut-off points. The test has a sensitivity of between 95% and 98% [31, 32]. Comorbidities, such as poorly controlled diabetes and hypertension, as well as advancing age may cause false-positive results [33]. As the values of salivary cortisol are an order of magnitude lower than serum cortisol, it is essential that the performance of the local assay be known and that the appropriate cut-off point is utilized. The test is of particular use in the assessment of cyclical Cushing's syndrome, and in children.

Diagnostic Doubt

In cases of doubt the best option is to repeat the tests at a later date, or seek further opinion. The dexamethasone-suppressed CRH test, and the desmopressin test have been proposed as useful diagnostic tools but the dexamethasone-suppressed CRH test does not appear to be more accurate than the 48-h low-dose dexamethasone-suppression test [34–36].

Step 2: Establishing the Aetiology of Cushing's Syndrome: Differential Diagnosis

Once a diagnosis of Cushing's syndrome is established the next step is establish the cause. Investigation will vary depending upon the availability of the biochemical tests and imaging and expertise detailed next.

The first key procedure is to measure plasma ACTH. The plasma should be separated rapidly and stored at –40C to avoid degradation and a falsely low result. Levels consistently below 5 ng/L indicate ACTH-independent Cushing's syndrome and attention can be turned to imaging the adrenal with CT. Levels of ACTH persistently above 15 ng/L almost always reflect ACTH-dependent pathologies and require investigation, as detailed next. The values between these two need cautious interpretation as patients with Cushing's disease and adrenal pathologies may have intermediate values [1, 2]. A positive CRH test (see next) can identify an occasional patient with Cushing's disease with low baseline ACTH plasma levels.

Non-ACTH-Dependent Cushing's Syndrome

In established Cushing's syndrome, when plasma ACTH has been sampled and handled carefully, and levels are persistently undetectable, the cause is of adrenal origin. The next diagnostic procedure is to proceed to imaging with CT or MRI, which will most likely show an adrenocortical adenoma or carcinoma. If imaging is negative, the diagnosis may either be PPNAD, or due to surreptitious hydrocortisone absorption.

ACTH-Dependent Cushing's Syndrome

Localization of the source of ACTH secretion in ACTH-dependent Cushing's syndrome can constitute one of the most formidable challenges of clinical endocrinology. Neuroendocrine tumours may be clinically indistinguishable from Cushing's disease, and are frequently difficult to identify with imaging, especially if radiological (pituitary, thoracic, pancreatic) 'incidentalomas' complicate interpretation. As a result, biochemical evaluation rather than imaging is used to differentiate between pituitary and non-pituitary causes. In women with ACTH-dependent Cushing's syndrome, 9 out of 10 cases will be due to Cushing's disease. It is against this pre-test likelihood that the performance of any test needs to be judged. On occasion, despite all investigation, in some patients it may not be possible to locate the source of ACTH with confidence, and management of hypercortisolaemia may be needed without a precise diagnosis being reached.

Basal Testing: Plasma ACTH and Potassium

While very high levels of plasma ACTH may be seen in ectopic ACTH, the values frequently overlap those seen in Cushing's disease. High levels of cortisol of any aetiology may overwhelm the 11β-hydroxysteroid dehydrogenase type II enzyme in the kidney, allowing cortisol to act as a mineralocorticoid; approximately 70% of patients with ectopic ACTH syndrome due to carcinoid tumours have hypokalaemia, but it is also present in approximately 10% of patients with Cushing's disease with extremely high cortisol production [1, 2].

Dynamic Testing

The relative merits of each investigation will be discussed, but ultimately local experience of a given investigation, dependent on assays and radiological skill, will be an important determinant of the overall diagnostic success.

Dynamic Non-Invasive Tests

High-dose dexamethasone-suppression test: The high-dose dexamethasone-suppression test (2 mg given every 6 h for 48 h and serum cortisol measure at 09.00 h at the beginning and end, or a single 8 mg dose given at 23.00 h and serum cortisol measured the next day at 09.00 h) has been in widespread use for many years. The test relies upon the relative sensitivity of pituitary corticotroph adenomas to the effects of glucocorticoids, compared to the resistance exhibited by non-pituitary tumours. Approximately 80% of patients with Cushing's disease will demonstrate suppression of the serum cortisol to a value of less than 50% of the basal level [1, 2]. This is less than the pre-test likelihood of Cushing's disease and, thus, by itself the high-dose dexamethasone-suppression test has little diagnostic utility. Moreover, when utilizing the 48-h low-dose dexamethasone-suppression test, if there has already been the demonstration of suppression of serum cortisol by more than 30%, there is no further advantage to utilizing the high-dose dexamethasone-suppression test. Therefore, continued routine use of the high-dose dexamethasone-suppression test can no longer be recommended except when bilateral inferior petrosal sinus sampling (BIPSS) is not available. The positive predictive value for Cushing's disease is, however, high if there is a positive response (suppression of serum cortisol <50%) **and** a positive response on CRH testing (see next and Figure 5.7.2), but the negative predictive value for exclusion of Cushing's disease when both tests are negative, is low.

The corticotropin-releasing hormone (CRH) test: CRH was identified and sequenced in 1981, and is available for clinical practice as either the ovine (oCRH) or human sequence (hCRH) which differ by seven amino acid residues. oCRH has a longer duration of action and is the form available in North America, while the experience of hCRH dominates in Europe. In practice, the value of the test is the same [37, 38]. CRH is well tolerated, with side effects from systemic administration consisting of mild, short-lived facial flushing, a sensation of a metallic taste, and a transient sinus tachycardia. A single intravenous bolus of CRH (100 μg or 1 μg/kg) administered at 09.00 hours stimulates pituitary ACTH and cortisol release in healthy individuals, excessively in patients with pituitary-dependent Cushing's syndrome, but generally not in patients with ectopic ACTH secretion or adrenal tumours. A >35% rise above in mean plasma ACTH at 15 and 30 minutes when using oCRH [38], or a >14% rise in mean serum cortisol measured at these time points when using hCRH [37] give the best discrimination between pituitary and ectopic disease.

Desmopressin testing: Since the vasopressin-3 receptor is expressed in pituitary and many ectopic tumours secreting ACTH, the

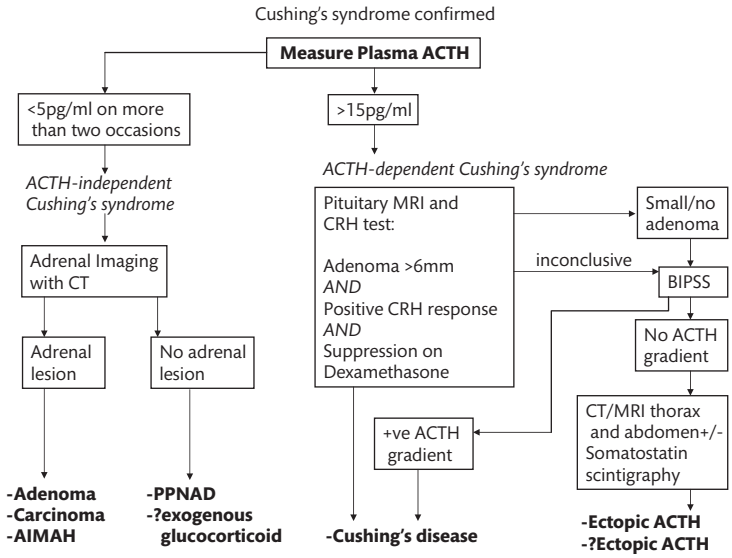

Figure 5.7.2 Diagnosis of cause of Cushing's syndrome. BIPSS, bilateral inferior petrosal sinus sampling; PPNAD, primary pigmented nodular adrenal disease; PBMAH, ACTH-independent macronodular hyperplasia.

desmopressin test is of limited utility in the differential diagnosis of ACTH-dependent Cushing's syndrome.

Dynamic Invasive Testing

Bilateral inferior petrosal sinus sampling (BIPSS): If a patient has ACTH-dependent Cushing's syndrome, with responses **both** on dexamethasone-suppression *and* CRH testing suggesting pituitary disease, and the pituitary MRI scan shows an isolated lesion of 6 mm or more, most will regard the diagnosis of Cushing's disease to have been made. A major problem is that up to 40% of patients with proven Cushing's disease have normal pituitary MRI scans [3]. In these cases, sampling of the gradient of ACTH from the pituitary to the periphery is the most reliable means for discriminating between pituitary and non-pituitary sources of ACTH, and is strongly recommended for most cases of ACTH-dependent Cushing's syndrome. Since the pituitary effluent drains via the cavernous sinuses to the petrosal sinuses and then jugular bulb, there is a gradient of the value of plasma ACTH compared to the simultaneous peripheral sample when there is a central source of ACTH. BIPSS is a highly skilled and invasive technique, requiring placement of catheters in both inferior petrosal sinuses. Plasma ACTH levels in peripheral blood fluctuate spontaneously by up to a factor of two, and hence a central to peripheral ratio greater than 2 is required to have confidence that ACTH secretion is pituitary and not the result of random variation from either a pituitary or ectopic source. Via a needle in a femoral vein, two catheters are passed up the inferior and superior vena cava into the neck. One each is then placed in a jugular vein and advanced into the inferior petrosal sinus. Catheter position and venous anatomy require confirmation by venography, as non-uniform drainage is not uncommon. The diagnostic accuracy of the test is improved with the administration of CRH. A basal central: peripheral ratio of more than 2:1 or a CRH-stimulated ratio of more than 3:1 is consistent with Cushing's disease. The combined data for many series indicate a sensitivity and a specificity of 94% [39]. Where CRH is unobtainable or too costly, desmopressin offers a reasonable alternative, but few patients with ectopic ACTH secretion have been studied in this way.

False-positive results may be caused by inadequate suppression of the normal corticotrophs; the duration and amount of hypercortisolism should be assessed prior to the test. For this reason pretreatment with cortisol-lowering agents prior to BIPSS is to be strongly discouraged as this increases the likelihood of a false-positive response in a patient with ectopic disease. ACTH secretion will always be localized to the pituitary in normal individuals and hence it is crucial to establish that all patients truly have ACTH-dependent Cushing's syndrome before undertaking this procedure. A false-negative result may be found in patients with cyclical Cushing's disease if the procedure is undertaken when the disease is inactive, and thus it is imperative to measure serum cortisol in the 24 hours prior to sampling to establish activity.

In adults, BIPSS is only 70% accurate for lateralization of the source of ACTH within the pituitary gland [1, 2], but in children it may have greater accuracy for this purpose than MRI [40]. False negatives may also occur if there is atrophic or plexiform venous drainage of the petrosal sinuses and this possibility should be checked for by venography at the time of BIPSS.

Imaging

Adrenal

CT gives the best resolution of adrenal anatomy (see Figure 5.7.3). Cortisol-secreting adenomas are typically less than 4 cm in diameter and associated with atrophy of the unaffected adrenal tissue, and the contralateral adrenal gland. Malignancy is more common with increasing tumour size, attenuation values of >10 on unenhanced CT and radiological evidence of vascular invasion, or cosecretion of sex steroids. In ACTH-dependent Cushing's syndrome, sustained stimulation of the adrenals may lead to the occurrence of adrenal nodules and adrenal hyperplasia that is not always symmetrical, causing diagnostic confusion with a unilateral primary adrenal cause if the biochemistry is not strictly assessed; in 30% of Cushing's disease the adrenal glands appear normal, while in ectopic ACTH the adrenals are virtually always homogeneously enlarged [41]. A recent report showed evidence for somatic mutations

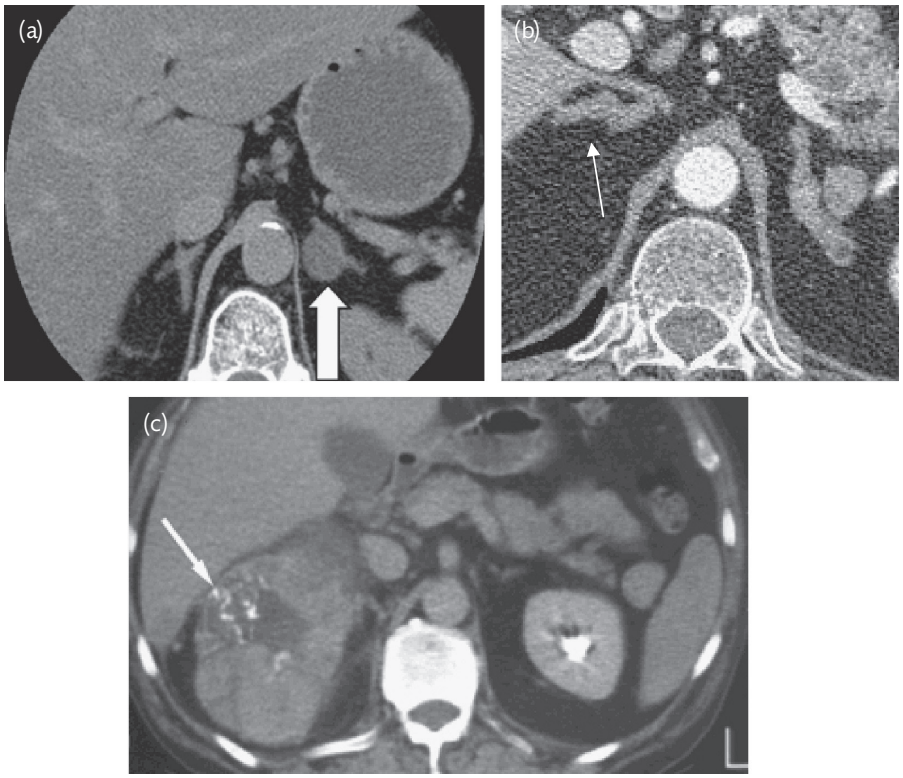

Figure 5.7.3 Adrenal imaging in Cushing's syndrome. (a) Non-contrast (= unenhanced) CT scan of left adrenal adenoma with low attenuation in the tumour area; (b) bilateral adrenal hyperplasia in ACTH-dependent Cushing's syndrome; (c) right-sided adrenocortical carcinoma.

in the PRKACA gene in nodular adrenal hyperplasia arising in two patients with long-standing adrenal stimulation due to long-standing Cushing's disease, demonstrating transition from pituitary to adrenal Cushing's.

Pituitary

Up to 40% of corticotroph adenomas causing Cushing's disease in adults are not visible on MRI scanning [3]. Those that are visible usually fail to enhance following gadolinium on T1-weighted imaging. The use of dynamic MRI, with the administration of intravenous contrast media and rapid sequence acquisition following this, does not improve the overall diagnostic rate. There is also a 10% rate of pituitary incidentalomas in the normal population [42], emphasizing the need for careful biochemical discrimination of pituitary from non-pituitary sources of ACTH. In the absence of a pituitary macroadenoma, an abnormal MRI alone is **not** conclusive evidence in favour of Cushing's disease.

Imaging in the Ectopic ACTH Syndrome

Small cell lung cancer may be obvious, but in most cases thoracic and abdominal imaging by high resolution CT with 1 mm 'cuts' with imaging early after intravenous contrast administration is needed to identify small neuroendocrine tumours, which may be extremely hard to localize, as a source of ACTH [43, 44]. Other than small cell lung cancer, bronchial neuroendocrine tumours are the most common sources of ectopic ACTH secretion, and are usually less than 1 cm in diameter. However, small, typically enhancing neuroendocrine tumours may be confused with pulmonary vascular shadows, but these tumours usually have high signal intensity on T_2-weighted and short-inversion-time inversion recovery on MRI. ACTH-secreting thymic neuroendocrine tumours are generally larger than 2 cm and readily visualized by CT. Although ectopic ACTH-secreting tumours often express somatostatin receptors and can be seen on radiolabelled octreotide scintigraphy, they are also almost always identified by CT. [^{68}Ga]-DOTATATE PET-CT is more sensitive and may detect tumours only a few millimetres in diameter, although even then the lesion is usually seen on CT The excess circulating cortisol in Cushing's syndrome may downregulate the sst2 receptor on the causative tumour and thus a period of medical therapy to lower cortisol, or offset the actions of cortisol, may result in a positive scan that had previously shown no uptake [45].

Treatment and Prognosis

The Endocrine Society has produced evidence-based clinical practice guidelines for the treatment of Cushing syndrome [46]. To deliver high-quality treatment to patients with Cushing's syndrome requires a team that includes specialized surgeons and physicians, radiologists, cytologists, histopathologists, and radiotherapists. The sustained hypercortisolaemia of Cushing's syndrome, of any aetiology, suppresses ACTH secretion from healthy corticotrophs and, hence, hypoadrenalism will be the consequence of complete excision of any tumour causing Cushing's syndrome, be it adrenal, pituitary, or an ectopic source of ACTH secretion, and this may be prolonged.

Management is aimed at lowering cortisol levels, removing tumour tissue, and, in the case of Cushing's disease, causing the least

harm to remaining pituitary function. Some centres use medical therapy to control hypercortisolaemia prior to surgery, and this makes intuitive sense, but there are no published data that this affects overall outcome. Hypertension and diabetes require treatment on their own merits, but both tend to improve, often dramatically, with control of hypercortisolaemia. Severe hypokalaemia secondary to Cushing's syndrome is extremely difficult to treat unless hypercortisolaemia is corrected. If it persists, or while cortisol control is being affected, triamterene or high-dose amiloride is helpful.

Medical Therapies

A potential side effect of all drugs used to control cortisol secretion is hypoadrenalism, particularly in patients with cyclical Cushing's syndrome, and hence all patients require close monitoring [47]. Although urinary free cortisol is easy to use for monitoring therapy, it has major limitations in that hypoadrenalism may be difficult to establish accurately, and failure to ensure a complete 24-h collection will result in spuriously low results. Calculation of the mean of five serum cortisol measurements across a single day, though cumbersome offers both the ability to identify transient hypoadrenalism and allows accurate monitoring, since a mean serum cortisol between 150 and 300 nmol/L has been demonstrated to equate to a normal cortisol production rate [48]. Measurement of salivary cortisol may offer and alternative at greater convenience [49], but this has not been formally assessed in clinical practice.

Adrenal Steroidogenesis Inhibitors

Hypercortisolaemia of any cause may be controlled by drugs that act on the adrenal glands to reversibly inhibit cortisol secretion [50]. Metyrapone and ketoconazole are currently licensed for this purpose. These drugs are not curative, and cortisol oversecretion will recur when they are discontinued. Steroidogenesis inhibitors are usually used to regulate cortisol secretion in very specific circumstances, namely: in preparation for surgery, in patients not cured by surgery, while waiting for radiotherapy to be effective, after chemotherapy, and to correct acute severe physical or psychiatric consequences of hypercortisolaemia. Cortisol-induced psychosis usually responds rapidly to lowering of circulating cortisol levels.

Metyrapone inhibits cortisol secretion by blocking the final step in cortisol synthesis, namely conversion from 11-deoxycortisol by the cytochrome P450 enzyme 11-hydroxylase (CYP11B1). Serum cortisol levels fall within 2 h of instigating therapy, but the effect is short-lived and metyrapone requires to be taken three times daily. Because 11-deoxycortisol levels are increased, it is best if LC-MS/MS assays are used for monitoring due the potential cross-reactivity of the accumulating 11-deoxycortisol with cortisol in immunoassays [46], where even a small amount of cross-reactivity of 11-deoxycortisol will produce artificially elevated apparent serum cortisol, potentially masking hypoadrenalism. The drug is usually given in doses ranging from 250 mg twice daily to 1.5 g every 6 hours, with lower doses for adrenal adenoma and higher for ectopic ACTH and overall, in clinical practice it is effective in around 50% of cases [51]. Nausea is a side effect that can be helped (if it is not caused by adrenal insufficiency) by giving the drug with milk.

Hypoadrenalism is the major unwanted effect of metyrapone and can occur for several reasons: overtreatment, inability to mount a cortisol response to intercurrent infection, and cyclical Cushing's syndrome, but this issue is circumvented by using an assay based on mass spectrometry [52]. Hirsutism and acne, if present in women patients before treatment, may worsen due to the accumulation of adrenal androgenic precursor steroids secondary to the blockade of cortisol synthesis.

Ketoconazole is an imidazole that was used as an antifungal agent, but because it blocks a variety of steroidogenic cytochrome P450–dependent enzymes it thus lowers plasma cortisol levels. In contrast to metyrapone, adrenal androgen concentrations fall with treatment. Treatment is usually initiated with 200 mg three times per day and adjusted depending on serum cortisol concentrations; with between 400 and 1200 mg/day required to normalize cortisol secretion rates in patients with Cushing's disease, and an acidic stomach is needed for absorption; in clinical practice the drug is effective in around 50% of patients [53]. An additional desirable characteristic is that ketoconazole lowers serum cholesterol concentrations, which are characteristically raised in Cushing's syndrome.

Ketoconazole is of slower onset of action than metyrapone, and dose adjustments should only be made every 2 to 3 weeks, although in patients with adrenal adenomas responsiveness is more rapid and hypoadrenalism has occurred within 24 h. Ketoconazole consistently induces a reversible rise in liver transaminase and γ-glutamyltransferase levels and increases by 2–3-fold are expected and should not preclude continuation of treatment, but rarely fulminant hepatic failure has been seen. Liver function must be monitored on initiation of treatment and closely thereafter [53]. Ketoconazole is teratogenic to male fetuses and is contraindicated in pregnancy.

Ketoconazole and metyrapone may be given in combination, allowing doses to be used that are lower than required as monotherapy, with ketoconazole lowering androgen levels and thereby greatly increases the acceptability of metyrapone in women. Combination therapy is also useful in cases of severe Cushing's [54].

Etomidate is an imidazole, and its principal clinical use is as an anaesthetic agent, however, already at low, subhypnotic doses intravenous etomidate is a potent inhibitor of cortisol secretion. The use of intravenous etomidate at subhypnotic doses is an option when oral adrenolytic therapy is not possible, also in the context of palliation (e.g. for metastatic cortisol-producing adrenocortical carcinoma). However, this usually requires ICU monitoring, though in some palliative situations cases of etomidate treatment via subcutaneous pump have been reported. Doses between 1.2 and 2.5 mg/h lower serum cortisol, sometimes to undetectable levels, when the patient needs to be maintained on a 'block and replace' regimen with the concomitant use of intravenous hydrocortisone (1–2 mg/h) [55, 56].

High-dose *o,p*'DDD (*ortho,para*' dichlorodiphenyl dichloroethane, mitotane) has been used widely for the treatment of cortisol excess due to inoperable adrenocortical carcinoma, but when given at a lower dose is effective in controlling cortisol secretion in Cushing's syndrome due to benign causes. It has a direct adrenolytic action, destroying adrenocortical cells, but also blocks cortisol synthesis by inhibiting 11β-hydroxylation and cholesterol side-chain cleavage. It is of slow onset of action; first effects are usually observed within 2 weeks but changes in dose usually require 6 weeks or more to be fully effective. Use of mitotane in adrenocortical cancer is addressed in Chapter 5.4. Low-dose treatment with mitotane for benign Cushing's syndrome, with a starting dose of 0.5 to 1 g/day, with gradual dose titration is well

tolerated with rare gastrointestinal upset and few neurological side effects, and is used more frequently for this purpose in mainland Europe [57]. Currently, it is mainly used for Cushing's disease only when metyrapone and ketoconazole cannot be used effectively. The major limitation of treatment is that it consistently causes hypercholesterolaemia, but if mitotane therapy is necessary, then the hypercholesterolaemia can be reversed by the use of a statin or ketoconazole.

Osilodrostat is a newer inhibitor of 11β-hydroxylase (CYP11B1) with greater potency and longer duration of action compared to metyrapone, that shows promise for the treatment of Cushing's disease. Phase 2 data indicates control, as assessed by UFC, in 80% of patients [58]. A large multinational phase 3 study is complete, but is yet to be formally reported.

Glucocorticoid Receptor Blockade

RU 486 (mifepristone) is a potent glucocorticoid receptor antagonist (GRA) that blocks cortisol action and reverses the consequences of hypercortisolaemia. It is licensed in the US for the treatment of hyperglycaemia associated with active endogenous Cushing's syndrome [59]. Efficacy of action is determined by clinical assessment because levels of cortisol remain high, and this may result in hypokalaemia through the action of cortisol binding to the mineralocorticoid receptor [59]. Antagonism of the progesterone receptor can cause endometrial hyperplasia. Newer GRAs are in development that lack progesterone activity.

Therapies to Lower ACTH and Thus Cortisol in Cushing's Disease

Somatostatin analogues such as octreotide and lanreotide that bind predominantly somatostatin receptor (sstr) subtype 2, are generally ineffective in Cushing's disease. However, the multireceptor somatostatin analogue, pasireotide, which demonstrates high-affinity binding to sstr subtypes 1, 2, 3, and 5, normalizes urinary free cortisol in 17–40% of patients with Cushing's disease depending on the severity of disease, with hyperglycaemia being a common side effect [60, 61].

Cabergoline has been assessed in Cushing's disease, and lowers cortisol and hence ACTH and in the recent largest series 20–25% of patients achieved good control of UFC using modest doses (1 mg per week) [62].

Surgery

Transsphenoidal Surgery

Transsphenoidal selective microadenectomy, by an experienced pituitary surgeon, is the treatment of choice for Cushing's disease, as it offers the prospect of a dramatic, rapid, and long-lasting cure without other hormonal deficiency (Figure 5.7.4a, b) [46, 63].

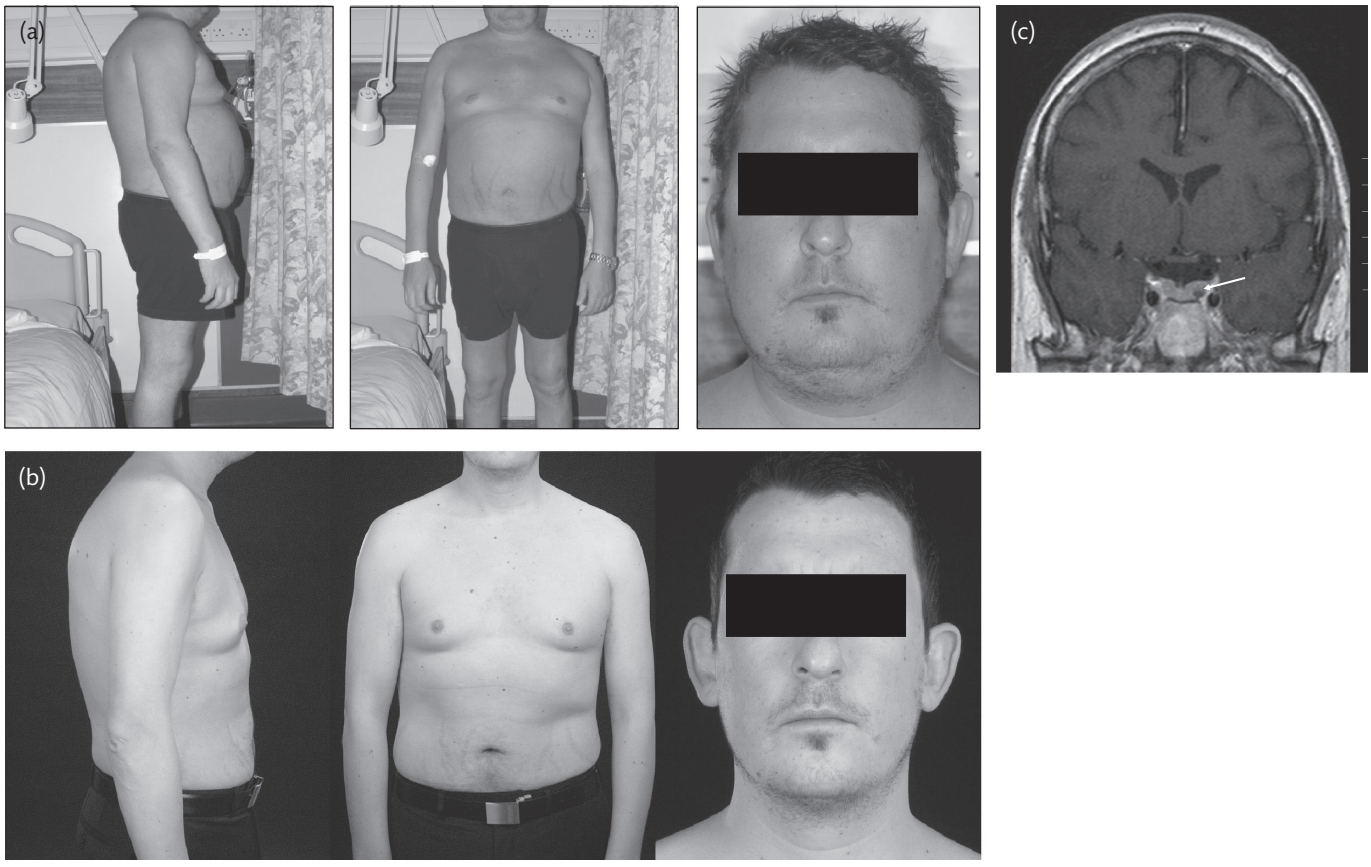

Figure 5.7.4 Resolution of clinical features following selective trans-sphenoidal microadenomectomy. (a) A 33-year-old man with florid Cushing's syndrome; note truncal obesity, striae, proximal muscle wasting, and facial plethora. (b) Dramatic resolution of clinical features 4 months after selective removal of ACTH-secreting microadenoma. (c) T_1-weighted gadolinium-enhanced MRI scan from the same patient showing 2.3 mm pituitary microadenoma causing Cushing's disease. Note non-enhancement (arrow). Patient underwent bilateral inferior petrosal sinus sampling to confirm pituitary source of ACTH. (See also Plate 27.)

In most cases, control of tumour volume is not a priority as the majority have either microadenomas (Figure 5.7.4c) or no visible tumour on MRI. Numerous series have reported the results and long-term follow-up following transsphenoidal surgery for Cushing's disease. Taking all series in the world literature together, the initial remission rate is 70% to 90% for microadenomas and 50% for macroadenomas but with a relapse rate of up to 20% when followed for many years, emphasizing the need for lifelong follow-up (Figure 5.7.5) [46, 63]. Rates for postoperative hypopituitarism and permanent diabetes insipidus depend on how aggressive the surgeon was in removing pituitary tissue.

It is likely that the variations in outcomes reflect surgical skill as well as the controversy regarding the characterization of remission or continuing disease in the postoperative period. Overall, with careful and prolonged follow-up (10 years) the long-term remission rate is approximately 60%; series suggesting rates higher than this usually either have shorter follow-up or less stringent criteria for remission. Patients who are hypocortisolaemic (low 09.00 h serum cortisol) in the immediate postoperative period require glucocorticoid therapy until the HPA axis recovers, usually 6–18 months postoperatively. While long-term remission is most likely when postoperative serum cortisol is low (<50 nmol/L), there is no threshold value that fully excludes possible recurrence [46, 63]. Care needs to be taken in the interpretation of postoperative serum cortisol in those patients who have received high-dose perioperative glucocorticoids, as these may suppress the level of cortisol in any remaining corticotroph tumour cells, with the patient appearing to be in remission, but then for the tumour cells to grow slowly and relapse appear years later. Similarly, suppression of normal serum cortisol levels on dexamethasone testing in the postoperative period is a poor indicator of long-term remission. Levels of basal 09.00 h postoperative serum cortisol of 100–200 nmol/L do not necessarily indicate failure of surgery, as some patients may remain in long-term remission [46]. On the other hand levels above 200 nmol/L will almost always indicate failure of surgery, although in some patients levels fall to very low levels 4–6 weeks after surgery Prompt postoperative assessment of the HPA axis is important, as in patients in whom hypercortisolaemia persists after an initial operation, repeat surgery, within 10 days, will allow remission in a further 50% of patients having a second operation. Care is needed in assessment of patients who have been taking cortisol-lowering therapy in the preoperative period as this may 'derepress' the suppressed normal corticotrophs and confound interpretation [64]. There is no agreement as to whether the presence or absence of a microadenoma on MRI makes remission more likely.

Complications of pituitary surgery include cerebrospinal fluid leakage (less than 5%) or meningitis (under 2%), but are unusual in experienced hands. Hypopituitarism may occur, but successful microadenectomy will leave pituitary function intact in more than 50%. Pituitary function needs to be tested in full, pre-, and postoperatively. The importance of preserving pituitary function has to be balanced against fitness for surgery and the consequences of deficiency, such as future fertility plans. It is important to note that functional deficiencies of growth hormone secondary to hypercortisolaemia may remain for 2 years after achieving remission by surgery. Thus the frail elderly patient, in whom a second operation would not be possible, might need an attempted total hypophysectomy at first operation, whereas in a fit young patient the tumour may be treated by a more limited procedure to attempt selective removal of the apparent local microadenoma, on the understanding that a second operation may be necessary if cure does not follow the first attempt, with almost inevitable hypopituitarism afterwards.

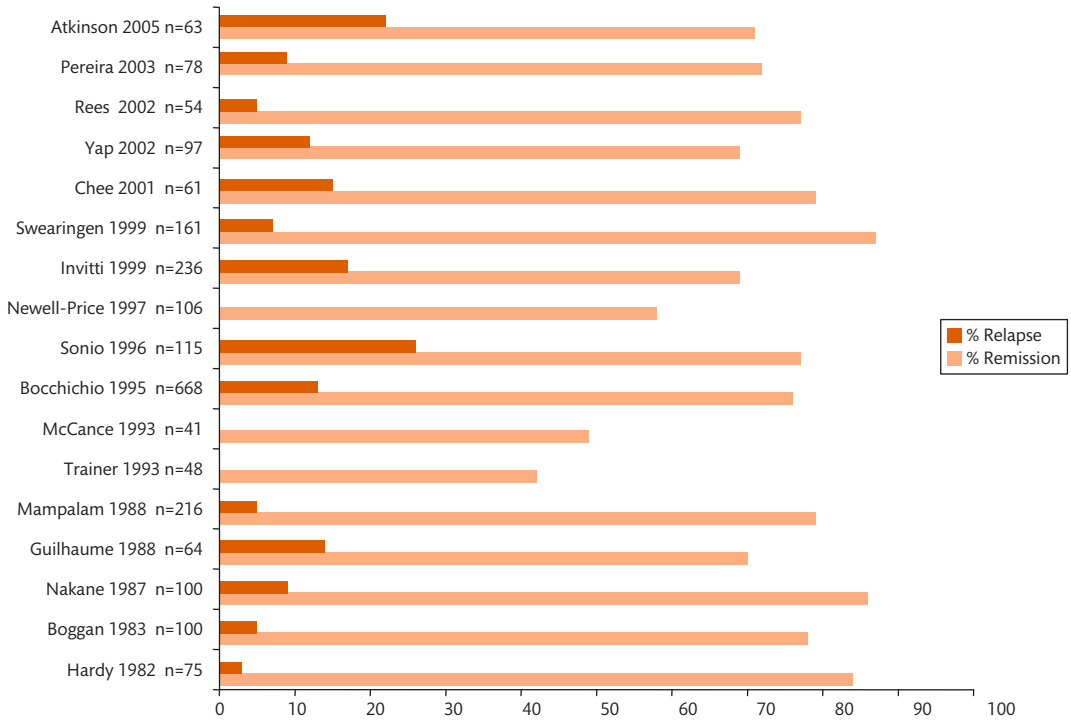

Figure 5.7.5 Modified from long-term outcome of transsphenoidal surgery for Cushing's disease. Initial remission rates in grey, relapse in black. Note that the lower initial remission rates are frequently associated with less relapse on follow-up.

Adrenal Surgery

For patients with an adrenocortical adenoma causing Cushing's syndrome the treatment of choice is a laparoscopic adrenalectomy by an experienced surgeon, as this is a safe and well-tolerated procedure [46]. Higher volume surgeons have better outcomes with fewer complications [65] (for details on adrenal surgery see Chapter 5.2).

The adrenal contralateral to a cortisol-secreting adrenal tumour will be atrophic, and glucocorticoid, but not mineralocorticoid, replacement therapy may be required for months or sometimes years, in rare cases permanently. In any cause of ACTH-dependent Cushing's syndrome, total bilateral adrenalectomy induces a rapid resolution of the clinical features. Following bilateral surgery, patients require lifelong treatment with glucocorticoid and mineralocorticoid replacement. With the low morbidity associated with laparoscopic adrenal surgery, this approach is being considered more frequently, and possibly even as primary therapy in some patients with Cushing's disease, especially when disease is severe or because of patient preference, and also in ectopic Cushing's due to an occult tumour; long-term outcomes are good [66, 67]. A major concern following bilateral adrenalectomy in patients with Cushing's disease is the development of Nelson's syndrome, a locally aggressive pituitary tumour that secretes high levels of ACTH, resulting in pigmentation. It remains controversial as to whether the tumour progression is a result of the lack of cortisol feedback following adrenalectomy, or whether the progression reflects corticotroph tumours that were always programmed to behave in an aggressive manner [68, 69]. If no tumour is visible on pituitary MRI at the time of adrenalectomy the likelihood of Nelson's syndrome is much less. Monitoring is by MRI and measurement of plasma ACTH. The tumour itself may be treated with further surgery or radiotherapy. Some advocate pituitary radiotherapy at the time of adrenalectomy to reduce the risk of this syndrome, but others have not confirmed this [69]. In contrast to adrenal adenomas most adrenal carcinomas have a very poor prognosis.

Fractionated External Pituitary Radiotherapy

Conventional external-beam radiotherapy has been available for 40 years, with large amounts of data demonstrating it to be safe and effective at controlling tumour growth and hormone secretion [46]. In Cushing's disease, its use is reserved for patients not cured by surgery, those in whom surgery is deemed inappropriate, and in the treatment of Nelson's syndrome. While waiting for the effect of radiotherapy to happen, which appears to be quicker in children, patients will usually require continued treatment with cortisol-lowering drugs, and regular biochemical assessment. Long-term hypopituitarism is likely in most cases, and fewer patients undergo radiotherapy than in previous decades [46].

Stereotactic Radiosurgery

Stereotactic radiotherapy, the most widely used variety being the 'Gamma Knife', is a means of delivering a high dose of radiation to a small volume in a single session without surrounding tissues being exposed to significant radiation. The main advantages of stereotactic over conventional radiotherapy are the convenience of a single session, more rapid correction of hypersecretion, and preservation of the function of surrounding healthy pituitary tissue. Rare, larger tumours are less easily treated, and the dose to the optic chiasm limited to less than 6–8 Gy. Gamma knife radiosurgery is effective [70, 71] but there is a relapse rate that is not apparent after remission following fractionated radiotherapy. It is likely that this outcome reflects case selection. In some circumstances Gamma Knife radiotherapy can be extremely effective, even as primary therapy, and may be more rapid in onset and in efficacy. This depends on absolute confidence in diagnosis, and an anatomically favourable lesion, especially if not approachable by surgery (Figure 5.7.6).

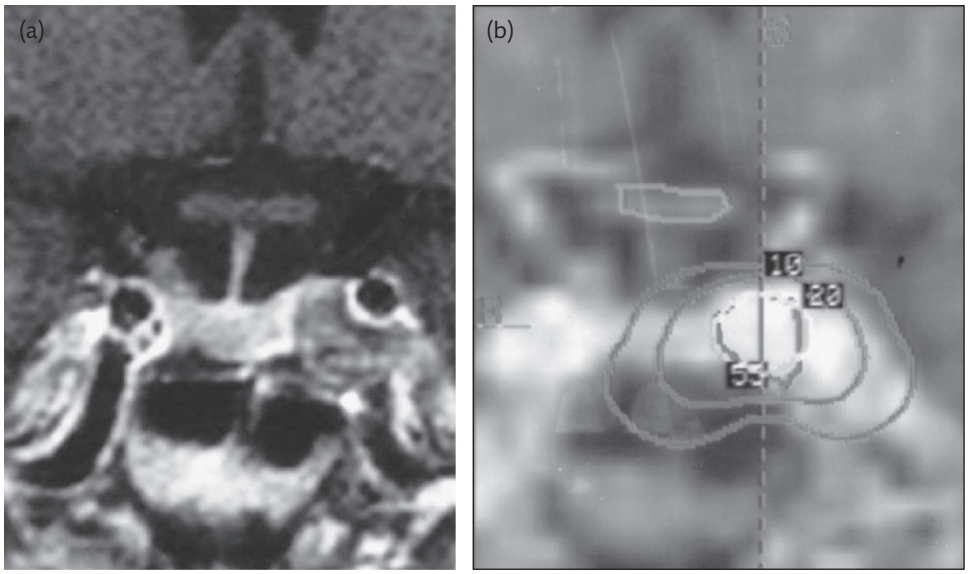

Figure 5.7.6 Gamma knife stereotactic radiosurgery for Cushing's disease. Figure shows diagnostic and planning MRI images of a patient with severe Cushing's disease treated by Gamma Knife radiosurgery as the primary and only definitive therapy at the author's institution, and who remains in remission with no pituitary deficit 10 years later. (a) Pretreatment the laterally placed tumour (arrow) was inaccessible to surgical approaches. (b) Tumour targeting with Gamma Knife 50% isodose to the tumour margin is shown; note the margin of safety from the 10% isodose to optic chiasm (outlined). (See also Plate 28.)

Prognosis

Uncontrolled and severe Cushing's syndrome has a 5-year survival of just 50%, with death due mainly to vascular and infective complications. Despite modern management, cardiovascular risk persists for many years after an apparent remission, but if remission is achieved at the first pituitary surgery the standardized mortality rate approaches the normal population, emphasizing the need for expert surgeons [72, 73].

Patients should be warned that they will often feel worse on correction of the hypercortisolism, with skin desquamation, profound lethargy, steroid-withdrawal arthropathy, and mood changes that may take several weeks or months to resolve [46]. These features can be ameliorated by a short-term increase in glucocorticoid replacement therapy. Patients are invariably growth hormone (GH) deficient, and GH replacement therapy may produce clinical benefit. Following pituitary surgery for a microadenoma the HPA axis is often suppressed for 9–12 months, with gradual recovery as evidenced by measuring 09.00 h serum cortisol every 3 months; once this is greater than 200 nmol/L it is reasonable to perform a synacthen test to assess the HPA axis. Once glucocorticoids are no longer needed patients need clinical and biochemical follow-up and surveillance for potential relapse. Even in remission, quality of life remains impaired and patients require careful counselling about this [74, 75].

Childhood Cushing's Syndrome

Cushing's syndrome should be considered in any child with obesity in combination with short stature, as children with simple obesity tend to be tall whereas hypercortisolaemia stunts growth. The elevated circulating androgens seen in Cushing's syndrome, particularly in adrenal adenomas, can result in apparent puberty and virilization without gonadal enlargement (pseudoprecocious puberty). Contrary to earlier reports, bone age is normal in 80% of children with Cushing's syndrome as although androgens accelerate bone maturation, with a consequent loss of linear growth potential, hypercortisolaemia appears to delay maturation.

The specific features that may be present on examination include inappropriate axillary or pubic hair, penile enlargement, scrotal pigmentation, and clitoral hypertrophy. Acne vulgaris can develop in children of any age. These features of hyperandrogenism are likely to be more pronounced with androgen-secreting adrenal tumours, but also occur with ACTH-dependent Cushing's syndrome. Primary or secondary amenorrhoea may be a feature in girls. Blood pressure is often mildly or moderately elevated, but diabetes mellitus is very unusual. School performance can suffer and psychiatric and emotional symptoms may occur.

Aetiology

The distribution of causes in childhood is different from that encountered in adults; there is a male predominance in Cushing's disease [8]. Fetal- and neonatal-onset Cushing's syndrome have been described, but the diagnosis remains exceptionally rare until approximately 8 years of age. Under 2 years of age, adrenal carcinoma accounts for 80% of cases of Cushing's syndrome, of which 80% occur in females [76].

Investigation in Childhood

Cushing's syndrome presenting in childhood is rare. Any child with weight gain and growth failure should be investigated but, as described earlier, the presenting symptoms may vary. The investigative algorithm is as described for adults, and experience shows that it is not necessary to alter the dose of dexamethasone or CRH used in

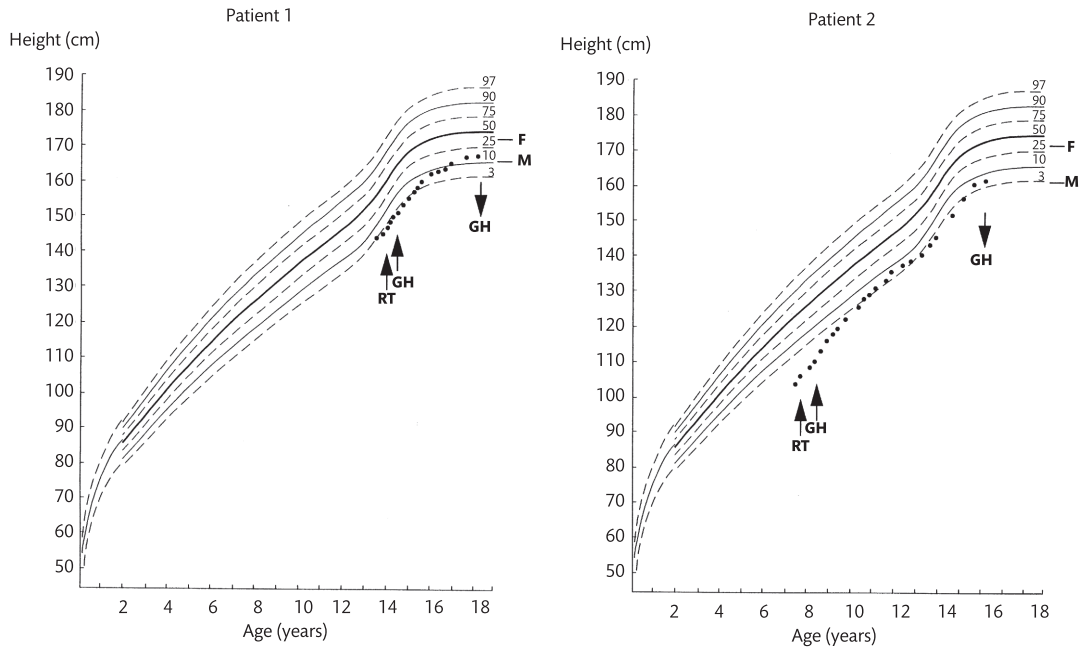

Figure 5.7.7 Growth charts of two children with Cushing's disease treated with pituitary irradiation. GHT, growth hormone therapy; RT, radiotherapy; M, mother's height; F, father's height.

adults. Although more technically challenging in children, inferior petrosal sinus sampling is, as in adults, vital for localizing the source of ACTH secretion [40].

Treatment

The principles of treatment of hypercortisolaemia are the same in children as in adults. Ketoconazole is preferable to metyrapone in children, as the former lowers, rather than increases, circulating androgen levels, but both are safe. Transsphenoidal surgery achieves remission in the majority of children with Cushing's disease. Pituitary radiotherapy is reserved for surgical failures, or those whose surgery is impossible because of the small size of the pituitary fossa; however, when required it controls ACTH secretion more promptly in children than in adults with Cushing's disease, but residual pituitary function requires close monitoring to ensure normal pubertal development and growth. Growth hormone deficiency occurs early after radiotherapy in children, but may recover in some [77].

Once hypercortisolaemia has been controlled, the management of growth and puberty is a major challenge. Glucocorticoids both inhibit growth hormone secretion and induce epiphyseal insensitivity to growth hormone action, and correction of hypercortisolaemia is a prerequisite to re-establishing linear growth. Adrenal androgen-induced pseudoprecocious puberty causes premature true gonadotropin-dependent puberty, and hence, even once adrenal androgen secretion has been controlled, bone age will continue to advance and potential for linear growth to diminish. These factors can be regulated by the combined use of gonadotropin-releasing hormone analogues to inhibit gonadotropin secretion and control puberty, and growth hormone treatment to induce linear growth. With effective treatment of hypercortisolaemia and careful management of puberty and growth, children with Cushing's syndrome will achieve a normal final height [78] (**Figure 5.7.7**).

Likely Developments Over the Next 5–10 Years

There remains a clear need for novel approaches to medical therapy. Antisense approaches to the GR that inhibit in the periphery, but do not cross the blood-brain barrier and so still allow GR-mediated feedback, and antibody approaches to lower ACTH are in development. Improved radiotracer ligands are likely to enhance the ability to discover occult sources of ACTH secretion.

Adrenal Insufficiency

5.8.1 Genetics of Adrenal Insufficiency

Li F. Chan and Shwetha Ramachandrappa

Introduction

Adrenal insufficiency refers to the inadequate secretion of glucocorticoids from the adrenal cortex, with or without mineralocorticoid deficiency. The production of glucocorticoid, cortisol in humans, and corticosterone in rodents, is regulated by circulating levels of adrenocorticotropic hormone (ACTH) which is secreted by the anterior pituitary gland in response to hypothalamic signals. The hypothalamic–pituitary–adrenal (HPA) axis is under negative feedback control with cortisol acting to inhibit the secretion of corticotropin-releasing hormone (CRH) and ACTH from the hypothalamus and pituitary, respectively.

Primary adrenal insufficiency is used to describe situations where the causal defect in glucocorticoid production lies within the adrenal gland, while in secondary adrenal insufficiency defects in the pituitary gland or hypothalamus lead to inadequate ACTH levels, with lack of adrenocortical stimulation resulting in secondary loss of cortisol production.

Causes of adrenal insufficiency can be genetic or non-genetic. Non-genetic causes are the most common (listed in Table 5.8.1.1) and include, autoimmune, infective, neoplastic, traumatic, and iatrogenic causes presenting at any age. Genetic causes, which are inherited or sporadic, as part of a syndrome or restricted to isolated adrenal insufficiency, generally present early in life although presentation in adolescence and adulthood has been described.

The incidence of primary adrenal insufficiency is reported to be 4 per million in Caucasian populations with a prevalence of 100–140 cases per million [1]. The most common cause of primary adrenal insufficiency in Western society is autoimmune adrenalitis while infective causes, especially tuberculous adenalitis, remain a leading cause of adrenal insufficiency worldwide. In comparison secondary adrenal insufficiency has an estimated prevalence of 150 to 280 per million [2, 3]. The most common cause of secondary adrenal insufficiency is suggested to be iatrogenic due to glucocorticoid therapy that leads to suppression of ACTH secretion and adrenal atrophy.

In this chapter we will focus on the causes of monogenic adrenal insufficiency. As expected, alterations in genes that play a direct role in the development and function of the HPA axis give rise to monogenic causes of adrenal insufficiency. More recently, defects in a number of ubiquitously expressed genes involved in a wide range of cellular processes have also been shown to cause adrenal insufficiency, providing novel insights into adrenal steroid regulation.

Genetics of Secondary Adrenal Insufficiency

There are many genetic causes of secondary adrenal insufficiency broadly categorized into those involved in pituitary development and genes involved in pro-opiomelanocortin (POMC) cell maturation and POMC synthesis and processing (Table 5.8.1.2). Defects in genes involved in pituitary development give rise to combined pituitary hormone deficiency. Often there is relative sparing of corticotroph function in these disorders, which are described in more detail in Chapter 2.3.1 ('Development of the Pituitary and Genetic Forms of Hypopituitarism'). Here we will focus on the few genes, in which alterations give rise to isolated ACTH deficiency.

Disorders of POMC Synthesis and Processing

The paraventricular nucleus of the hypothalamus secretes vasopressin and CRH, which regulate the synthesis of the precursor protein pro-opiomelanocortin (POMC) in the corticotropic cells of the anterior pituitary gland. POMC is then cleaved to produce ACTH, which binds to its unique receptor the ACTH receptor (also known as the melanocortin 2 receptor, MC2R) on the surface of adrenocortical cells to stimulate glucocorticoid secretion. POMC is also expressed in the arcuate nucleus of the hypothalamus where it is processed to generate melanocortin peptides, most importantly α-MSH. Central melanocortin signalling through the melanocortin 3 and 4 receptors (MC3R and MC4R) regulates energy balance and satiety [4]. Peripheral melanocortin signalling through the melanocortin 1 receptor (MC1R) is involved in pigment production in melanocytes [5]. Biallelic loss-of-function mutations in POMC in humans have been

Table 5.8.1.1 Non-genetic causes of adrenal insufficiency

Secondary adrenal insufficiency	
Iatrogenic	Adrenal suppression following exogenous steroid treatment
	Adrenal suppression following treatment of endogenous hypercortisolaemia due to Cushing's syndrome
	Following transsphenoidal surgery for ACTH-producing adenoma
	Pituitary irradiation and radiotherapy for brain tumours and craniospinal irradiation for other tumours
Tumours	Pituitary tumours (mostly adenomas, rarely carcinomas)
	Tumours affecting the hypothalamic–pituitary region (craniopharyngioma, meningioma, ependymoma, intra/suprasellar metastasis)
Infiltration/deposition	Tuberculosis, actinomycosis, sarcoidosis, histiocytosis X, Wegener's granulomatosis, Hemochromatosis
Autoimmune	Autoimmune hypophysitis; most frequently in relation to pregnancy; commonly associated with panhypopituitarism, but also presenting with isolated ACTH deficiency
Infarction/haemorrhage	Pituitary apoplexy/necrosis
	Postpartum pituitary infarction (Sheehan's syndrome)
Trauma	Pituitary stalk lesions
	Traumatic brain injury
Primary adrenal insufficiency	
Infections leading to adrenalitis	Tuberculosis
	HIV, CMV
	Cryptococcosis, histoplasmosis, coccidiomycosis, candidiasis, African trypanomiasis
	Treponema pallidum
Bilateral adrenal haemorrhage	Septic shock, specifically meningococcal sepsis (Waterhouse–Friderichsen syndrome)
	Anticoagulants
	Trauma
Adrenal infarction	Primary antiphospholipid syndrome
	Anticardiolipin syndrome
	Lupus anticoagulant syndrome
Adrenal infiltration	Adrenal metastases
	Primary adrenal lymphoma
	Sarcoidosis
	Amyloidosis
	Hemochromatosis
Bilateral adrenalectomy	Management of intractable Cushing's disease or ectopic ACTH secretion
	Following nephrectomy for tumour
	Treatment for bilateral pheochromocytoma
Drug-induced AI	Mitotane (steroid synthesis inhibitor/adrenolytic agent)
	Mifepristone (Glucocorticoid Receptor Antagonist antagonist)
	Abiraterone acetate (steroid synthesis inhibitor)
	Trilostane (steroid synthesis inhibitor)
	Etomidate (inhibits cortisol synthesis)
	Ketaconazole/fluconazole (inhibits cortisol synthesis)
	Suramin (steroid synthesis inhibitor/adrenolytic agent)
	Aminoglutethiamide (inhibits cortisol synthesis)
	Phenytoin (increased cortisol metabolism)
	Phenobarbital (increased cortisol metabolism)
	Rifampicin (enhanced autoimmunity)
	St John's wort (increased cortisol metabolism)
	CTLA-4 inhibitors (enhanced autoimmunity)
	Thyroxine (accelerated cortisol metabolism and stimulation of 11-beta-hydroxysteroid dehydrogenase)

Genetic SAI

Table 5.8.1.2 Genetic causes of secondary adrenal insufficiency

Disorder	Gene	OMIM	Mechanism of action	Inheritance	Additional phenotypic features
Pituitary development					
Combined pituitary hormone deficiency	Prophet of Pit-1 (PROP1)	601538	Loss of function	AR	Progressive development of combined pituitary hormone deficiency (CPHD) in the order GH, PRL, TSH, LH/FSH, (ACTH—late onset); anterior pituitary may be hypoplastic, normal, or enlarged
	Homeobox gene 1 (HESX1)	601802	Loss of function	AR/AD	CPHD + optic nerve hypoplasia and midline brain defects/ agenesis of corpus callosum (septo-optic dysplasia); anterior pituitary hypoplastic or ectopic;
	LIM homeobox 3 (LHX3)	600577	Loss of function	AR	CPHD with involvement of GH, TSH, gonadotrophins, PRL; ACTH may be deficient; limited neck rotation, short cervical spine, sensorineural deafness; anterior pituitary hypoplastic, normal, or enlarged
	LIM homeobox 4 (LHX4)	602146	Loss of function	AD	CPHD with involvement of GH, thyrotropin, and ACTH secretion, cerebellar abnormalities; anterior pituitary hypoplastic or ectopic
	SRY-box 3 (SOX3)	313430	Loss of function	XLR	Infundibular hypoplasia, CPHD, variable mental retardation
POMC synthesis and processing					
POMC deficiency	Pro-opiomelanocortin (POMC)	176830	Loss of function	AR	Hyperphagia, early onset obesity, cholestasis, pigmentary defect, central hypothyroidism, GH deficiency, hypogonadotropic hypogonadism
Proprotein convertase 1/3 deficiency	Proprotein convertase Subtilisin/Kexin type 1(PCSK1)	162150	Loss of function	AR	Obesity, gastrointestinal disturbance, other pituitary deficiencies possible, elevated proinsulin, low insulin
POMC lineage differentiation and transcription defects					
Congenital isolated ACTH deficiency	T-box transcription factor 19 (TBX19)	604614	Loss of function	AR	Neonatal presentation
Other syndromes associated with secondary adrenal insufficiency					
Prader–Willi syndrome	Imprinted gene cluster 15q11.2 (Including genes SNRPN, NDN)	-	Loss of function	IC	Syndrome of hypotonia, short stature, hyperphagia, obesity, hypogonadism, psychomotor delay, and sleep-related breathing disorders
Pallister-Hall syndrome	GLI3	165240	Loss of function	AD	Hypothalamic hamartomas, hypopituitarism, imperforate anus, and postaxial polydactyly

Genetic PAI

demonstrated to lead to adrenal deficiency in the first few months of life. Hyperphagia, early onset obesity and hypopigmentation of skin and hair are invariably also present [6–8]. Mutations in proprotein convertase 1 (PC1), a subtilisin-like enzyme responsible for the cleavage of POMC, gives rise to a related phenotype of secondary adrenal insufficiency associated with obesity [9].

POMC Lineage Differentiation and Transcription Defects

Autosomal recessive genetic variants in the gene T-box 19 (TBX19), which encodes a transcription factor, which is involved in the development of the POMC expressing cells of the anterior pituitary and the transcription of POMC, have been identified in patients with isolated ACTH deficiency, typically presenting with hypoglycaemia, seizures and prolonged jaundice in the neonatal period [10, 11].

Genetics of Primary Adrenal Insufficiency

The number of genes known to be involved in primary adrenal insufficiency has been steadily growing in light of recent breakthroughs in genetic techniques. These genes include those that affect adrenocortical cell function from ACTH signalling to defects in steroidogenesis. Other pathways such as redox and antioxidant mechanisms, and DNA replication and repair have more recently been shown to be important in the development of primary adrenal insufficiency. We have summarized the genes involved in primary adrenal insufficiency in Table 5.8.1.3 and selected those that affect specific pathways to discuss further here.

Defects in ACTH Signalling

Familial glucocorticoid deficiency (FGD), also known as isolated glucocorticoid deficiency or hereditary unresponsiveness to ACTH, is a subtype of primary adrenal insufficiency characterized by adrenal resistance to ACTH. The hallmark of FGD is low to absent serum cortisol in the presence of preserved mineralocorticoid production and extremely high levels of plasma ACTH. FGD classically presents in the neonatal period or infancy with symptoms of hypocortisolaemia leading to hypoglycaemia, failure to thrive, coma, susceptibility to infections, and death if untreated. Intense hyperpigmentation is a feature of FGD due to the action of ACTH on MC1R in skin.

Table 5.8.1.3 Genetic causes of primary adrenal insufficiency

Disorder	Gene	OMIM	Mechanism of action	Inheritance	Additional phenotypic features
Defects in ACTH signalling					
Familial glucocorticoid deficiency 1	MC2R	607397	Loss of function	AR	Isolated GC deficiency, occasionally mild MC deficiency, absent adrenarche, and tall stature
Familial glucocorticoid deficiency 2	MRAP	609196	Loss of function	AR	Isolated GC deficiency occasionally mild derangement of RAA
Defects affecting the steroidogenic pathways					
Congenital lipoid adrenal hyperplasia	StAR	600617	Loss of function	AR	46,XY sex reversal, partial or complete, gonadal insufficiency
Congenital lipoid adrenal hyperplasia due to cytochrome P450 SCC deficiency	CYP11A1	118485	Loss of function	AR	46,XY sex reversal, partial or complete, gonadal insufficiency
Congenital adrenal hyperplasia due to 3beta-HSD deficiency	HSD3B2	613890	Loss of function	AR	46,XY DSD, 46,XX DSD,
Congenital adrenal hyperplasia due to 21-hydroxylase deficiency	CYP21A2	613815	Loss of function	AR	46,XX DSD, androgen excess
Congenital adrenal hyperplasia due to 11beta hydroxylase deficiency	CYP11B1	610613	Loss of function	AR	46,XX DSD, androgen excess, hypertension
Congenital adrenal hyperplasia due to 17α-hydroxylase deficiency	CYP17A1	609300	Loss of function	AR	46,XY DSD, gonadal insufficiency, hypertension
Congenital adrenal hyperplasia due to cytochrome P450 oxidoreductase deficiency	POR	124015	Loss of function	AR	46,XY DSD, 46,XX DSD, gonadal insufficiency, dysmorphisms skeletal malformation, disorder of drug metabolism, developmental delay
Alterations in antioxidant mechanisms					
Familial glucocorticoid deficiency 4, with or without mineralocorticoid deficiency	NNT	607878	Loss of function	AR	Variable presentation with or without mineralocorticoid deficiency
Familial glucocorticoid deficiency	GPX1	138320	Loss of function	AR or digenic	
Familial glucocorticoid deficiency	PRDX3	604769	Loss of function	Possible Digenic	
Familial glucocorticoid deficiency, type 5	TXNRD2	606448	Loss of function	AR	Possible structural cardiac abnormalities
Defects in metabolic pathways					
Wolman disease and cholesteryl ester storage disease	LIPA	613497	Loss of function	AR	Malabsorption, gastrointestinal symptoms, liver dysfunction, atherosclerosis, serum lipid abnormalities, hypersplenism, xanthelasma, hypercholesterolemia, steatorrhea, enlarged adrenal glands with punctate calcifications
Smith–Lemi–Opitz disease	DHCR7	602858	Loss of function	AR	Mental retardation, craniofacial malformations, growth failure, polydactyly, 46,XY DSD, renal hypoplasia, genital abnormalities
Abetalipoproteinemia	MTP	157147	Loss of function	AR	Hypocholesterolaemia and malabsorption of lipid-soluble vitamins leading to retinal degeneration, neuropathy, and coagulopathy. Hepatic steatosis
Familial hypercholesterolaemia	LDLR	606945	Loss of function	AD	Tendinous xanthomas, corneal arcus, and coronary artery disease
Sitosterolemia (phytosterolemia)	ABCG5, ABCG8	605459, 605460	Loss of function	AR	Very high levels of plant sterols in the plasma and develop tendon and tuberous xanthomas, accelerated atherosclerosis, and premature coronary artery disease, short stature, gonadal failure
Adrenoleukodystrophy	ABCD1	300371	Loss of function	XLR	Cognitive and behavioural problems, motor problems, visual impairment, headache, seizures, bowel and bladder disturbance, sexual dysfunction, elevated VLCFA's

(*continued*)

Table 5.8.1.3 *Continued*

Disorder	Gene	OMIM	Mechanism of action	Inheritance	Additional phenotypic features
Peroxisome biogenesis disorder 1A (Zellweger)	PEX1	602136	Loss of function	AR	Congenital malformations, developmental delay, corneal clouding, retinal dystrophy, sensorineural hearing loss, neurological deficits, liver dysfunction, renal oxalate stones, failure to thrive, skeletal abnormalities, urogenital anomalies, liver dysfunction,
Sphingosine-1-phosphate lyase deficiency	SGPL1	603729	Loss of function	AR	Steroid-resistant nephrotic syndrome, Ichthyosis, primary hypothyroidism, hypogonadism, cryptorchidism, and immune and neurological abnormalities
Kearns–Sayre syndrome	mtDNA deletion	530000	Loss of function	Maternal	Ophthalmoplegia, pigmented retinopathy, cardiomyopathy, cerebellar ataxia, endocrinopathies, hypoparathyroidism, type 1 diabetes, rarely AI
Refsum disease	PHYH	602026	Loss of function	AR	Retinitis pigmentosa, peripheral neuropathy, cerebellar ataxia, ichthyosis, and elevated protein levels in the cerebrospinal fluid (CSF) without an increase in the number of cells
DNA replication and repair disorders					
Immunodeficiency 54,	MCM4	602638	Loss of function	AR	Severe intra and extrauterine growth retardation, microcephaly, decreased numbers of natural killer cells, and recurrent viral infections, hepatosplenomegaly, hyperpigmentation, increased susceptibility to lymphoproliferative disorders, chromosomal breakage
Achalasia–Addisonian–alacrimia syndrome	AAAS	605378	Loss of function	AR	Microcephaly, short stature, neurological symptoms, alacrimia, autonomic dysfunction, developmental delay, hyperkeratosis, achalasia, optic atrophy
Monogenic causes of autoimmune adrenalitis					
Autoimmune polyendocrinopathy syndrome, type I	AIRE	607358	Loss of function/ Dominant negative	AR/AD	Candidiasis, hypoparathyroidism, insulin dependent diabetes, alopecia, vitiligo, gastrointestinal complaints, eye abnormalities
Conditions associated with adrenal dysgenesis					
Congenital adrenal hypoplasia	NR0B1 (DAX1)	300473	Loss of function	XLR	Genital abnormalities, hypogonadotropic hypogonadism, occasionally gonadotrophin independent precocious puberty, Duchenne muscular dystrophy + glycerol kinase deficiency (psychomotor retardation) for Xp21.2 contiguous gene syndrome
IMAGe syndrome	CDKN1C	600856	Gain of function	AD—maternal transmission only	Intrauterine growth restriction, metaphyseal dysplasia, adrenal hypoplasia congenita, hypogonadotropic hypogonadism, and genitourinary abnormalities in males, facial dysmorphism
MIRAGE syndrome	SAMD9	610456	Gain of function	AD	Myelodysplasia, infection, restriction of growth, adrenal hypoplasia, genital phenotypes, and enteropathy, cognitive impairment, hypoplastic thymus, hyperpigmentation, skeletal anomalies, gastrointestinal problems,
Steroidogenic factor 1 deficiency	NR5A1	184757	Loss of function	AD	46,XY DSD, gonadal insufficiency, 46,XX Sex Reversal, Premature ovarian failure, Spermatogenic failure

FGD is a rare autosomal recessive disorder, first described by Shepherd *et al.* in 1959 [12], who reported siblings with 'familial Addison's disease'. This prompted subsequent reports of individuals with isolated glucocorticoid deficiency and normal aldosterone production [13–15]. The first inactivating mutation in the ACTH receptor was described some 30 years later [16, 17], made possible by the cloning of the receptor, the second melanocortin receptor to be cloned—hence the alternative name MC2R [18]. Since 1993 over 40 variants have been described, predominantly missense mutations spread throughout the length of the receptor [19]. Nonsense MC2R variants are less frequent and have been associated mild disturbance of the renin-angiotensin-aldosterone system [20, 21]. Mutations in MC2R account for approximately 25% of cases of FGD (FGD type 1). Tall stature has been associated with FGD type 1; it is unclear whether this is due to ACTH action on bone or to hypocortisolaemia, it is not seen in all FGD type 1 individuals. Absent adrenarche, i.e. loss of accelerating adrenal androgen production at age 6–9 years, has also been described, demonstrating the importance of ACTH in this process [22].

In 2005, homozygosity mapping using SNP arrays in consanguineous FGD families without causative mutations in MC2R enabled the identification of MRAP, melanocortin 2 receptor accessory protein [23]. It had long been suggested that the MC2R required an adrenal specific factor to enable expression at the cell surface. MRAP proved to be this factor. A small single transmembrane domain protein expressed in adrenal cells, MRAP was shown to be essential for the functional expression of the MC2R at the cell surface. Intriguingly, it has now been shown that this protein adopts an antiparallel dimer conformation—the only eukaryotic protein, except for its paralogue MRAP2, to do this [19]. Approximately 20% of cases of FGD are now known to be due to mutations in MRAP (FGD type 2). Unlike mutations in MC2R, MRAP mutations are usually nonsense or splice-site variations resulting in truncation or complete absence of the protein. As such, individuals with mutations in MRAP present earlier than those with defects in MC2R [24]. Rare MRAP missense mutations have been described and are associated with milder, late onset disease [25].

Studying FGD type 3 and beyond, i.e. those individuals without mutations MC2R and MRAP, has identified novel genes and pathways in adrenal gland physiology (described next). Such genetic discoveries have highlighted great phenotypic heterogeneity, prompting increased awareness of overlap in classical categorizations of primary adrenal insufficiency disorders.

Defects Affecting the Steroidogenic Pathways

The synthesis of steroid hormones in the adrenal cortex is dependent on the coordinated action of numerous enzymes [26]. Congenital adrenal hyperplasia (CAH) is a group of recessive conditions in which genetic alterations in the enzymes involved in steroid synthesis result in impaired glucocorticoid production. Depending on the enzyme involved and the point at which steroidogenesis is disrupted this is associated with excess or inadequate androgen production, accompanied by varying degrees of mineralocorticoid deficiency.

CAH is the most common genetic cause of primary adrenal insufficiency in childhood with mutations in *CYP21A2* accounting for 95% of cases of CAH [27]. The carrier rate of 21-hydroxylase deficiency (21OHD) is estimated to be around 1 in 50, but is higher in certain ethnicities. *CYP21A2* is located in a tandemly duplicated sequence within the human leukocyte antigen (HLA) cluster on chromosome 6 [28]. The region contains the C4A and C4B genes, which encode complement factor 4 as well as *CYP21A2* and its pseudogene *CYP21A1P* [29]. The tandem arrangement of these genes with a high degree of sequence similarity makes this region susceptible to misalignment during meiosis which can result in deletions and duplications as well as gene conversion events. The tenascin X gene, *TNXB*, which encodes an important constituent of the connective tissue, is located next to *CYP21A2*. Deletions of *CYP21A2* together with part or all of TNXB lead to connective tissue disease [30]. The high sequence similarly between *CYP21A2* and its pseudogene precludes the use of direct sequencing approaches in cell-free DNA analysis as part of non-invasive prenatal diagnosis for CAH. Relative haplotype dosage analysis has now been successfully developed for this purpose.

The genetics of CAH is covered in detail in Chapter 5.9.1, here we will focus on those genes that have been identified in studies of FGD.

The first step in steroid synthesis in the adrenal gland involves the rate-limiting step of cholesterol transport from the outer mitochondrial membrane to the inner mitochondrial membrane by the steroidogenic acute regulatory protein (StAR). Defects in the *STAR* gene have long been known to cause lipoid CAH, whereby both glucocorticoid and mineralocorticoid deficiency are present together with defective gonadal steroidogenesis, the latter presenting as 46,XY DSD or gonadal insufficiency. In 46,XX females, lipiod CAH can present as progressive hypogonadism. However, it is now clear that 5–10% of FGD patients harbour partial loss-of-function mutations in StAR which result in non-classical lipoid CAH and isolated glucocorticoid deficiency [31].

Once transported, cholesterol is converted to pregnenolone by the P450 side-chain cleavage enzyme (CYP11A1). Recessive genetic defects in the *CYP11A1* gene are known to cause a similar phenotype to lipoid CAH. Partial loss-of-function mutations, with retention of up to 20% of wild type function can lead to delayed onset adrenal insufficiency with minor malformations of the external genitalia such as hypospadias [32–34]. A relatively common variant in *CYP11A1* among European populations, traditionally characterized as a benign variant, has recently been shown to affect splicing, thus demonstrating the difficulties in assigning pathogenicity to variants and the limited utility in using population frequencies to inform pathogenicity in recessive disease.

Alterations in Antioxidant Mechanisms

The redox milieu of a cell is maintained by a tissue specific range of antioxidant mechanisms. There is growing evidence that adrenocortical cells are particularly susceptible to oxidative stress. Steroid production not only generates substantial levels of reactive oxygen species (ROS) but is also itself exquisitely sensitive to the intracellular redox environment. ROS have been shown to supress the synthesis of StAR protein and the steroidogenic enzymes *CYP11A1* and *CYP11B2* utilize the reducing power of NADPH [35]. Under normal physiological conditions, this negative feedback mechanism may have a role in the regulation of glucocorticoid secretion, however, a number of disease states illustrate that glucocorticoid secretion can be compromised when the redox state of the adrenal tissue is disturbed.

Examples of this include the discovery that mutations in the gene encoding Nicotinamide nucleotide transhydrogenase (NNT) account for 10% of FGD [36]. NNT is ubiquitously expressed in human tissues and is responsible for generation of NADPH, a reducing agent for the glutathione and thioredoxin systems as well as the ferredoxin system to remove ROS. The discovery of a homozygous truncating mutation in thioredoxin reductase 2 (TXNRD2) as a cause of FGD in a consanguineous family of Kashimiri origin suggests that individual components of these networks provide a rich source of putative candidate genes for FGD [37]. Alterations in glutathione peroxidase 1 (GPX1) and peroxiredoxin 3 (PRDX3) [38] have been described in a family with FGD, where they are hypothesized to have a synergistic effect. Furthermore, several observations suggest that oxidative stress may play a role in the pathogenesis of Triple A syndrome [39]. Seen in the context of the ubiquitous nature of these antioxidant pathways the narrow phenotype of FGD suggests that these antioxidant pathways are redundant/less important in most other tissue types.

Genes Affecting Metabolic Pathways That Are Essential for Steroid Synthesis

Esterified cholesterol and triglycerides are degraded by lysosomal acid lipase in lysosomes. The resulting non-esterified cholesterol can be used as a substrate for steroidogenesis. Lysosomal acid lipase (LAL) deficiency caused by biallelic genetic alterations in the gene *LIPA* leads to the accumulation of esterified cholesterol and triglycerides in the lysosomes [40, 41]. The deficiency of intracellular cholesterol can lead to impaired steroidogenesis affecting glucocorticoid and mineralocorticoid production. A wide range of phenotypes are seen in LAL deficiency. The infantile onset form known as Wolman disease is characterized by malabsorption, hepatomegaly, and adrenal insufficiency [42]. The later onset forms collectively known as cholesteryl ester storage disease (CESD) may present in childhood in a similar manner to Wolman disease or in later life with lipid abnormalities, hepatosplenomegaly, and elevated liver enzymes. Adrenal insufficiency can occasionally be seen in CESD [43].

Peroxisomes are found in virtually all eukaryotic cells. Their principal function is the β-oxidation of very long chain fatty acids (VLCFAs), amino acids, and uric acid. They are also important in producing cholesterol and plasmalogens, a distinct class of glycerophospholipids. Disruption of peroxisome function results in adrenal insufficiency, ostensibly as a result of the accumulation of VLCFAs initiating apoptotic mechanisms and resulting in the generation of reactive oxidative species.

X-linked adrenoleukodystrophy (ALD), caused by alterations in the gene *ABCD1* which mediates transport of VLCFA across the peroxisome membrane, manifests as a spectrum of different phenotypes affecting the adrenal gland and the nervous system [44]. There are three main patterns of involvement seen in affected males. In the childhood cerebral form, inflammatory cerebral demyelination often presents with mild learning disability or behavioural problems that are progressive. In the adrenomyeloneuropathy form loss of axons and demyelination in the gracile and corticospinal tracts leads to progressive spasticity and leg weakness presenting in adulthood. In both of these forms of X-linked ALD, affected individuals generally have adrenocortical dysfunction by the time their neurological problems are apparent. The third common presentation of X-linked ALD is isolated adrenal insufficiency, which can present in childhood or adulthood. A significant proportion of heterozygote females manifest adrenomyeloneuropathy symptoms, but adrenal function appears to be preserved. There is no correlation between the molecular insult in the *ABCD1* gene and the age of onset or severity of the resulting phenotype. The most common disease-causing alteration in *ABCD1* is c.1415_1416delAG, which leads to a frameshift and premature truncation of the resultant protein.

Zellweger spectrum disorder (ZSD) caused by mutations in the *PEX* genes leads to a range of phenotypes [45]. The *PEX* genes encode peroxin proteins required for the assembly and maintenance of peroxisome membranes and the import of peroxisome matrix proteins. In severe disease infants are born with congenital malformations, make poor developmental progress, and typically die in the first year of life. In milder disease progressive peroxisome dysfunction leads to retinal dystrophy, sensorineural hearing loss, neurological deficits, liver dysfunction, and renal oxalate stones. There is a high prevalence of adrenal insufficiency in ZSD [46]. The majority of cases of ZSD are related to alterations in PEX1. Two common variants in PEX1 have been identified p.Ile700TyrfsTer42 and p.Gly843Asp [47, 48]. These variants are found within specific haplotypes implying that they have arisen as a result of the dissemination of specific founder mutations [49].

DNA Replication and Repair Disorders Associated with Primary Adrenal Insufficiency

An autosomal recessive disorder characterized by adrenal insufficiency, severe intra- and extrauterine growth retardation, microcephaly, decreased numbers of natural killer cells, and recurrent viral infections has been described in a genetically isolated Irish population. This disorder is caused by genetic alterations in the gene *MCM4* (minichromosome maintenance complex component 4), which forms part of a helicase complex that is involved in DNA replication in the S phase of the cell cycle [50]. Affected individuals show increased chromosome breakage suggesting that DNA repair is compromised. To date, only one variant in MCM4 (c.71-1insG, p.Pro24ArgfsTer4) has been shown to cause FGD, identified in the Irish traveller community. In some individuals, adrenal insufficiency has been shown to develop over time.

Monogenic Causes of Autoimmune Adrenalitis

Autoimmune primary adrenal insufficiency also known as Addison's disease accounts for almost 90% of cases of primary adrenal insufficiency. This can be isolated or can be found together with other autoimmune conditions associated with genetic factors such as the HLA-DR3 haplotype or common polymorphisms in CTLA-4 (Chapter 1.7).

Monogenic causes of autoimmune adrenalitis are seen in polyglandular syndromes. Classical cases of autoimmune polyglandular syndrome type 1 (APS-1) characterized by hypoparathyroidism, adrenal insufficiency and chronic mucocutaneous candidiasis, are caused by genetic alterations in the autoimmune regulator gene *AIRE* [51, 52]. *AIRE* encodes a transcription factor, which is expressed in a subset of medullary T cells, where it mediates the expression of antigens leading to centrally mediated T cell tolerance. *AIRE* also appears to play a role in regulating the central and peripheral tolerance of B cells. Absence of functional *AIRE* resulting in APS-1 was first described as a recessive condition. However, dominant forms of the condition have now emerged, which are thought to be due to dominant negative mutations in the SAND and PHD domains.

Autoimmune polyglandular syndrome type 2 is characterized by adrenal insufficiency, hypothyroidism, and diabetes. Other endocrine glands may also be involved. APS-2 seems to be inherited within families in a dominant fashion with incomplete penetrance. The genetic basis of APS-2 is not yet known.

Disorders Associated with Adrenal Dysgenesis

Alterations in several genes can cause adrenal dysgenesis. Among these conditions, alterations in *CDKN1C* are notable for their unusual pattern of inheritance which derives from the location of *CDKN1C* within an imprinted region of the genome.

There are two imprinted clusters of genes at chromosome 11p15 which are known to regulate growth and development. Imprinting centre 1 regulates the expression of *IGF2* which is a fetal growth factor, and *H19*, a non-translated RNA. Imprinting centre 2 regulates the expression of *CDKN1C, KCNQ1OT1* a non-coding RNA, and *KCNQ1*. Differential methylation of the imprinting centres on the maternal and paternal chromosomes results in expression of *H19, CDKN1C*, and *KCNQ1* from the maternal chromosome and *IGF2* and *KCNQ1OT1* from the paternal chromosome. A number of growth disorders including Russell–Silver syndrome, Beckwith–Wiedemann syndrome (BWS) and hemihypertrophy are caused by perturbations of gene expression with this region.

CDKN1C is a cyclin dependent kinase inhibitor which plays a role in cell–cycle regulation, DNA replication and repair, and activation of apoptosis and is expressed in the developing adrenal gland. The CDKN1C protein has three functional domains, the cyclin-dependent kinase (CDK) inhibitor domain, the PAPA domain, and the PCNA domain. Approximately 5% of cases of BWS are caused by loss-of-function genetic alterations in the maternal copy of *CDKN1C* which are distributed throughout the gene. A broad spectrum of adrenal phenotypes are seen in BWS including cystic changes, adenomas, hyperplasia, and neuroendocrine tumours. In direct contrast, gain-of-function genetic alterations in the maternal copy of *CDKN1C* give rise to IMAGE syndrome characterized by intrauterine growth retardation, skeletal abnormalities, adrenal hypoplasia, and genital abnormalities in males [53, 54]. Adrenal insufficiency can be of variable severity, presenting soon after birth with adrenal crisis or in infancy with mild, non-specific symptoms. Gain-of-function alterations are clustered tightly in the PCNA domain where they have been shown in *in-vitro* expression models to disrupt PCNA binding and its subsequent ubiquitination.

The gene *NR0B1*, also known as *DAX1*, is situated at position Xp21.2. The gene encodes a nuclear receptor protein which plays a role in the development and physiological function of several endocrine tissues including the adrenal gland, the pituitary gland, the hypothalamus, and the gonads. Alterations in *NR0B1* are associated with X-linked adrenal hypoplasia congenita (AHC) a form of primary adrenal insufficiency resulting from the agenesis or underdevelopment of the adrenal gland [55, 56]. The condition classically presents in boys in early infancy or childhood with adrenal failure affecting both glucocorticoid and mineralocorticoid production. Absent or delayed pubertal development becomes apparent at adolescence due to combined hypothalamic and pituitary dysfunction. A subgroup of patients with AHC with precocious puberty have been described in whom a degree of sexual maturation may precede signs of adrenal insufficiency. Variants in *NR0B1* which are located in the ligand like binding region around the hydrophobic core and around the repression helix domain can result in late onset forms of AHC [57, 58]. It has also been observed that nonsense variants in the amino terminal region of the protein can be bypassed by translational initiation from codon 83, leading to a protein with some residual function resulting in late onset disease [59]. Deletions and duplications of Xp21.2 have been described in human disease. Deletions involving *NR0B1* lead to X-linked adrenal hypoplasia (AHC). When the neighbouring genes dystrophin and glycerol kinase are also involved contiguous gene deletion syndromes where features of AHC are compounded by the presence of muscular dystrophy, neurobehavioral features and the metabolic sequelae of glycerol kinase deficiency are seen [60]. Duplications encompassing *NR0B1* lead to 46,XY disorders of sexual development, indicating that *NR0B1* plays a dosage sensitive role in sex determination [61].

The gene *NR5A1* encodes the transcription factor SF1, which is involved in the development of the gonads and the adrenal glands [62]. Genetic alterations in SF1 cause a spectrum of reproductive phenotypes ranging from 46,XY disorders of sexual development and hypospadias to male factor infertility or primary ovarian insufficiency. Disruption of SF1 causing adrenal insufficiency has been described [63], but this is very rare.

Advances in Gene Discovery in Adrenal Insufficiency

The traditional approach to gene discovery in adrenal insufficiency centred on the sequencing of candidate genes implicated in adrenal development and/or function. Subsequent use of gene arrays and linkage analysis in informative families helped narrow down a region of interest in which selected candidate genes could then be studied. However, more recently, the increased accessibility of whole exome sequencing has led to the identification of several genes in novel pathways which may not have been implicated in adrenal insufficiency using candidate gene approaches.

An example of recent success includes the study of syndromic forms of adrenal hypoplasia, defined as MIRAGE syndrome (myelodysplasia, infection, restriction of growth, adrenal hypoplasia, genital phenotypes, and enteropathy), which has been shown to be caused by heterozygous variants in the gene *SAMD9* which is involved in endosome fusion [64, 65]. Although the majority of reported individuals with variants in *SAMD9* have primary adrenal insufficiency, the adrenal phenotype of MIRAGE syndrome is emerging as being more variable than early reports would suggest [66].

Another example is the discovery of sphingosine-1-phosphate (SGPL1), an intracellular and extracellular signalling molecule, which is involved in several fundamental cellular processes including differentiation, migration, and survival as well as in angiogenesis. SGPL1 is responsible for the breakdown of sphingosine-1-phosphate [67]. Recessive alterations in the *SGPL1* gene result in steroid-resistant nephrotic syndrome. Adrenal development and steroidogenesis are also commonly affected leading to adrenal insufficiency [68, 69]. Ichthyosis, primary hypothyroidism, hypogonadism, cryptorchidism, and immune and neurological abnormalities have also been described in these patients. Recessive alterations in *SGPL1* have recently been described in individuals with isolated adrenal insufficiency, and it remains to be seen whether these individuals will develop renal manifestations later in life [70].

Despite the list of genes associated with adrenal insufficiency continuing to grow, a significant proportion of cases of adrenal

insufficiency remain unsolved. This was illustrated by a recent study in which a molecular diagnosis was reached in approximately 80% of a large cohort of children with PAI recruited across multiple endocrine centres in Turkey [71]. As the challenge of novel gene discovery moves from the generation of sequence data to its accurate interpretation, it is important to appreciate that large scale databases of benign genetic variation may be subject to poor phenotyping for mild adrenal phenotypes. Furthermore, our understanding of how to use frequency data in the clinical interpretation of genetic variants is predominantly derived from models of dominant conditions in outbred populations, neither of which may be appropriate assumptions in primary adrenal insufficiency.

Conclusion

Our understanding of the genetic causes of adrenal insufficiency has greatly increased in recent years due to advances in sequencing techniques. Despite this, there are still a significant proportion of patients where causative mutations have not been found. Novel mechanisms of inheritance, genetic variation in non-coding portions of the genome as well as oligogenic and synergistic mechanisms are likely to contribute. Ultimately, future advances in our understanding of the genetics of adrenal insufficiency, and rare disease as a whole, are likely to depend heavily on the careful, precise and purposeful integration of patient cohorts/data and the coordinated mobilization of international resources and expertise to deal with the vast amount of data generated from advances in genetic technologies.

5.8.2 Management of Adrenal Insufficiency

Wiebke Arlt

Introduction

In 1855, Thomas Addison identified a clinical syndrome characterized by wasting and hyperpigmentation as the result of adrenal gland destruction [1]. This landmark observation paved the way for progress in understanding and treating adrenal insufficiency, with the introduction of adrenal extracts for treatment of Addison's disease by the groups of Hartman and Pfiffner in 1929. However, long-term survival of patients with adrenal insufficiency only became possible after the seminal work of Edward Kendall, Philip Hench, and Tadeus Reichstein on the characterization and therapeutic use of cortisone. In 1946, Lewis Sarrett, a Merck scientist, achieved a partial synthesis of cortisone, which marked the beginning of industrial-scale production of cortisone. In 1948, in a fundamental clinical experiment at the Mayo Clinic, the first patient with Addison's received intravenous injections of Kendall's Compound E, cortisone, resulting in 'notable improvement of his condition'. This was followed by the ground-breaking trials on the use of cortisone in rheumatoid arthritis, yielding unanticipated clinical improvements, which quickly led to the labelling of cortisone as 'the wonder drug'. In November 1950, cortisone was made available to all physicians in the United States, a rapid translational development process, which culminated in the award of the 1950 Nobel Prize in Medicine to Kendall, Hench, and Reichstein. This progress reached other countries with variable delay and widespread availability of cortisone in the United Kingdom was achieved by joint efforts of Glaxo and the Medical Research Council. Though almost 150 years have passed since Addison's landmark observations and 60 years since the introduction of life-saving cortisone, there are still advances and challenges in the management of adrenal insufficiency, summarized in this chapter.

Physiology of Adrenal Steroid Synthesis

Adrenal Steroids and Steroidogenesis

When extracting steroids from the adrenal Kendall and Reichstein identified 28 separate steroids and today we classify the steroids produced by the adrenal glands, the corticosteroids, in three major classes—glucocorticoids (cortisol, corticosterone), mineralocorticoids (aldosterone, deoxycorticosterone), and adrenal sex steroid precursors (dehydroepiandrosterone (DHEA), androstenedione).

Cholesterol is the precursor for all adrenal steroidogenesis. The principal source of cholesterol is provided from the circulation in the form of low-density lipoprotein (LDL) cholesterol. Uptake is by specific cell-surface LDL receptors present on adrenal tissue; LDL is then internalized via receptor-mediated endocytosis, the resulting vesicles fuse with lysozymes, and free cholesterol is produced following hydrolysis. However, it is clear that this cannot be the sole source of adrenal cholesterol as patients with abetalipoproteinaemia, who have undetectable circulating LDL, and patients with defective LDL receptors in the setting of familial hypercholesterolaemia still have normal basal adrenal steroidogenesis. Cholesterol can be generated *de novo* within the adrenal cortex from acetyl coenzyme A. In addition, there is evidence that the adrenal can utilize high-density lipoprotein (HDL) cholesterol following uptake through the HDL receptor, scavenger receptor.

The biochemical pathways involved in adrenal steroidogenesis start with the rate-limiting step of the transport of intracellular cholesterol from the outer to the inner mitochondrial membrane. Within the mitochondrion cholesterol is then converted to pregnenolone by the cholesterol side chain cleavage enzyme, cytochrome P450scc (CYP11A1). The rapid transport of cholesterol into the mitochondria is importantly facilitated by steroidogenic acute regulatory protein, which is induced by an increase in intracellular cAMP following binding of adrenocorticotrophic hormone (ACTH) to its receptor.

Steroidogenesis involves the concerted action of several enzymes, including a series of cytochrome P450 (CYP) enzymes (for schematic overview, see Chapter 5.9). CYP11A1 and the CYP11B1 and CYP11B2 enzymes are localized to the mitochondria and require an electron shuttle system—provided through adrenodoxin/adrenodoxin reductase—for functional activity. Other CYP enzymes involved in steroidogenesis, namely 17α-hydroxylase (CYP17A1) and 21-hydroxylase (CYP21A2), are localized to the microsomal/endoplasmic reticulum fraction and depend on electron transfer from nicotinamide adenine dinucleotide phosphate (NADPH) via the electron donor enzyme P450 oxidoreductase (POR).

After the uptake of cholesterol to the mitochondrion, side chain cleavage of cholesterol by CYP11A1 forms pregnenolone, which is converted in the cytoplasm to progesterone by the type 2 isoenzyme of 3β-hydroxysteroid dehydrogenase. Progesterone is hydroxylated to 17-hydroxyprogesterone (17OHP) through the activity of 17α-hydroxylase. 17-hydroxylation is an essential prerequisite for glucocorticoid synthesis. CYP17A1 also possesses 17,20 lyase activity, which crucially facilitates the synthesis of the sex steroid precursor DHEA, a reaction that also requires allosteric interaction of the flavoprotein cytochrome b5 with both CYP17A1 and POR. In humans, 17OHP is not an efficient substrate for CYP17A1, and there is negligible conversion of 17-OH progesterone to androstenedione. Adrenal androstenedione secretion is dependent upon the conversion of dehydroepiandrosterone to androstenedione by 3β-hydroxysteroid dehydrogenase (3β-HSD). 21-hydroxylation of either progesterone (zona glomerulosa) or 17OHP (zona fasciculata) is carried out by 21-hydroxylase (CYP21A2) to yield deoxycorticosterone or 11-deoxycortisol, respectively. The final step in cortisol biosynthesis takes place in the mitochondria and involves the conversion of 11-deoxycortisol to cortisol by 11β-hydroxylase activity of the enzyme CYP11B1. In the zona glomerulosa, 11β-hydroxylase may also convert deoxycorticosterone to corticosterone. However, the enzyme CYP11B2, or aldosterone synthase, may also carry out this reaction and, in addition, is required for the conversion of corticosterone to aldosterone via the intermediate 18-OH corticosterone. Thus, CYP11B2 can carry out 11β-hydroxylation, 18-hydroxylation, and 18-methyl oxidation to yield the characteristic C11–18 hemiacetal structure of aldosterone.

Cortisol is inactivated to cortisone by action of the enzyme 11β-hydroxysteroid dehydrogenase type 2 (HSD11B2) mainly in the kidney, while the opposite reaction, activation of cortisone to cortisol, is carried out by the type 1 isoenzyme, HSD3B1, mainly in the liver (**Figure 5.8.2.1**). Recent years have highlighted the important role of this system in the tissue-specific activation and inactivation of glucocorticoids. Without the action of hepatic HSD11B1, Kendall would have observed no activity of his 'Compound E', as cortisone does not bind the glucocorticoid receptor and conversion to cortisol by HSD11B1 is a mandatory requirement for its biological activity.

Glucocorticoids are secreted in relatively high amounts (cortisol 10–20 mg/day) from the zona fasciculata, while mineralocorticoids are secreted in low amounts (aldosterone 100–150 μg/day) from the zona glomerulosa. The adrenal androgen precursors DHEA, its sulphate ester dehydroepiandrosterone sulphate (DHEAS), and androstenedione are produced in the adrenal zona reticularis and represent the most abundant steroids secreted by the adult adrenal gland (>20 mg/day). Recent work has shown that androstenedione is effectively converted to 11-hydroxyandrostenedione (11OHA4) by CYP11B1 and 11OHA4 is a major product of adrenal steroidogenesis, as measured in adrenal vein blood [2]. Adrenal zonal-specific steroidogenesis of the three different corticosteroid

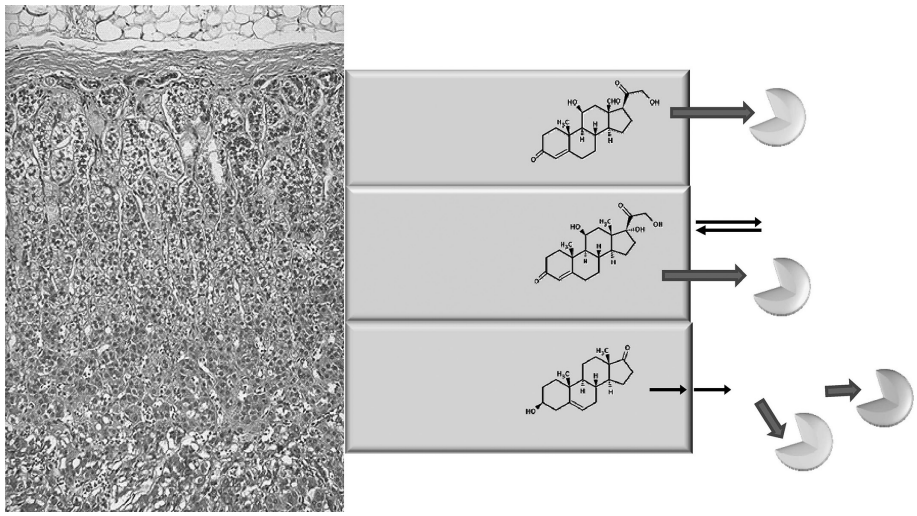

Figure 5.8.2.1 Schematic representation of adrenal zonation and steroidogenesis, depicting histology of the three adrenocortical and the major corticosteroids and the receptors mediating their action. While cortisol and aldosterone can bind and activate the glucocorticoid and mineralocorticoid receptor, respectively, DHEA requires conversion to active androgens and further aromatization to oestrogens prior to exerting sex steroid action. (See also Plate 29.)

classes is facilitated by tissue-specific expression of the required steroidogenic enzymes. The zona glomerulosa generally does not synthesize cortisol because it does not express 17α-hydroxylase. In contrast, aldosterone secretion is largely confined to the outer zona glomerulosa through the restricted expression of CYP11B2. Although CYP11B1 and CYP11B2 share 95% homology, the 5′ promoter sequences differ and permit regulation of the final steps in glucocorticoid and mineralocorticoid biosynthesis by ACTH and angiotensin II, respectively. DHEA is sulphated in the zona reticularis by the DHEA sulphotransferase (SULT2A1) to form DHEAS.

Regulation of Adrenal Corticosteroid Synthesis

Classical endocrine feedback loops are in place to control the secretion of both cortisol and aldosterone. Cortisol inhibits the secretion of both hypothalamic corticotrophin-releasing factor and pituitary ACTH, and the aldosterone-mediated increase in sodium retention inhibits renin secretion by the juxta-glomerular cells of the kidney (Figure 5.8.2.2).

Glucocorticoid synthesis is under negative feedback control of the hypothalamic–pituitary–adrenal (HPA) axis (Figure 5.8.2.2a). Adrenocorticotropic hormone (ACTH) secretion from the anterior pituitary is stimulated by hypothalamic corticotrophin-releasing hormone (CRH) following a circadian rhythm, with a peak around 03.00h to 04.00h. Other major effectors on CRH secretions are various forms of stress, including hypoglycaemia, hypotension, fever, trauma, and surgery. ACTH binds to its receptor (melanocortin receptor 2, MC2R) on the adrenocortical cell surface and stimulates import of cholesterol into the mitochondrion by steroidogenic acute regulatory protein. In parallel, transcription of genes encoding steroidogenic enzymes and proteins of the electron transfer shuttle is increased.

Mineralocorticoid synthesis is mainly under the control of the renin–angiotensin–aldosterone system (RAAS) and a potassium feedback loop (Figure 5.8.2.2b). A variety of factors stimulate renin secretion from renal juxtaglomerular cells, with renal perfusion being the most important regulator. Several other stimulators (β-adrenergic stimulation, prostaglandins) and inhibitors (α-adrenergic stimulation, dopamine, atrial natriuretic peptides, angiotensin II) are known. Angiotensinogen is an α_2-globulin synthesized within the liver which is cleaved by renin to form angiotensin I. Angiotensin I is converted to angiotensin II by angiotensin-converting enzyme in the lung and many other peripheral tissues. Angiotensin I has no apparent biological activity but angiotensin II is a potent stimulator of aldosterone secretion. In addition, angiotensin II acts as a potent vasoconstrictor. The rate-limiting step in the RAAS is the secretion of renin, which is also controlled through a negative feedback loop. Renin is secreted from juxtaglomerular epithelial cells within the macula densa of the renal tubule in response to underlying renal arteriolar pressure, oncotic pressure, and sympathetic drive. Thus, low perfusion pressure and/or low tubular fluid sodium content, as seen in haemorrhage, renal artery stenosis, dehydration, or salt loss, increase renin secretion. Conversely, secretion is suppressed following a high salt diet and by factors that increase blood pressure. Hypokalaemia increases and hyperkalaemia decreases renin secretion; in addition, potassium exerts a direct effect upon the adrenal cortex to increase aldosterone secretion. Angiotensin II and potassium stimulate aldosterone secretion principally by increasing the

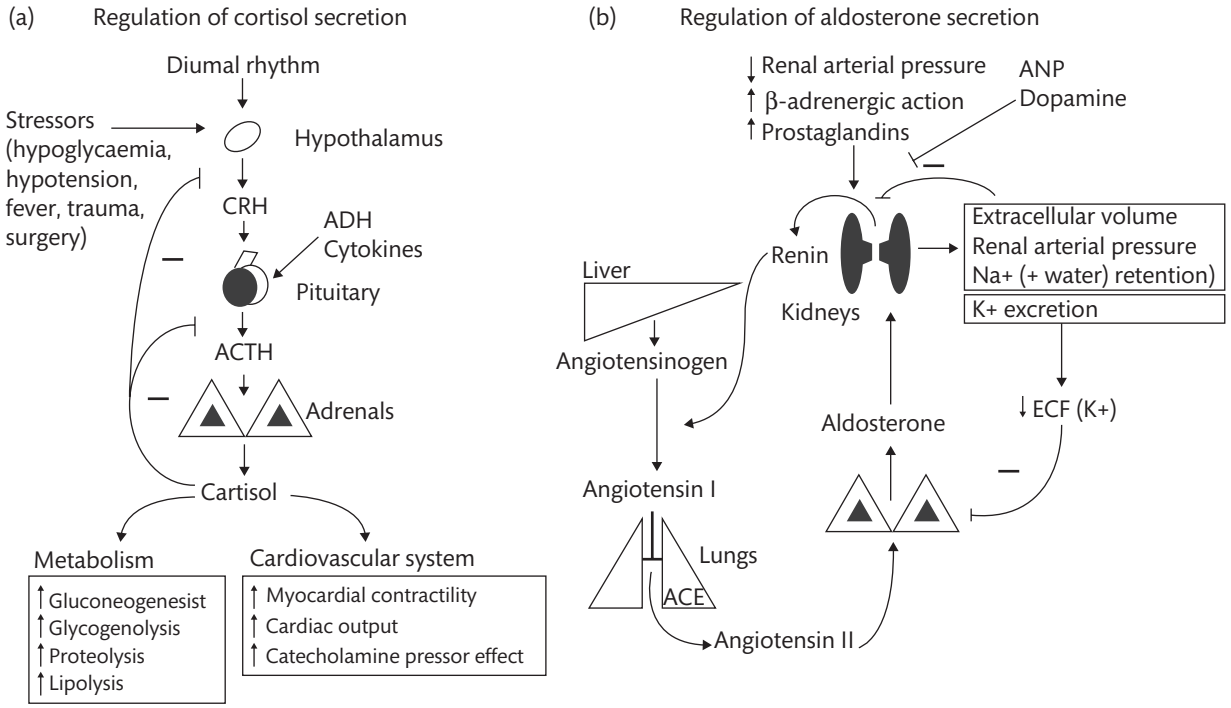

Figure 5.8.2.2 Negative feedback regulation of cortisol and aldosterone secretion. (a) Glucocorticoid feedback regulation by the hypothalamic–pituitary–adrenal (HPA) axis. CRH, corticotropin-releasing hormone; ACTH, adrenocorticotropic hormone; ADH, antidiuretic hormone.
(b) Mineralocorticoid regulation by the renin–angiotensin–aldosterone system (RAAS). The extracellular fraction (ECF) of potassium has an important direct influence on aldosterone secretion. ACE, angiotensin-converting enzyme; ANP, atrial natriuretic peptide.

transcription of *CYP11B2* through common intracellular signalling pathways. The potassium effect is mediated through membrane depolarization and opening of calcium channels, and the angiotensin II effect following binding of angiotensin II to the surface AT_1 receptor and activation of phospholipase C.

The separate control of glucocorticoid biosynthesis through the HPA axis and mineralocorticoid synthesis via the renin–angiotensin system has important clinical consequences. The overwhelming majority of patients with primary adrenal failure have both cortisol and aldosterone deficiency, whereas patients with ACTH deficiency due to pituitary disease have glucocorticoid deficiency only, as the intact renin–angiotensin system maintains normal aldosterone levels.

Corticosteroid Hormone Action

Both cortisol and aldosterone exert their effects following uptake of free hormone from the circulation and binding to intracellular receptors, termed the glucocorticoid and mineralocorticoid receptors (GR, MR). These are both members of the thyroid/steroid hormone–receptor superfamily of transcription factors, comprising a C-terminal ligand binding domain, a central DNA binding domain, interacting with specific DNA sequences on target genes, and an N-terminal hypervariable region. In both cases, although there is only a single gene encoding the GR and MR, splice variants have been described resulting in α and β variants.

The binding of glucocorticoid to the GR-α in the cytosol results in activation of the steroid–receptor complex through a process which involves the dissociation of heat-shock proteins HSP 90 and HSP 70. Following translocation to the nucleus, gene transcription is stimulated or repressed following binding of dimerized GR–ligand complexes to specific DNA sequences (glucocorticoid-response element) in the promoter regions of target genes. The GR-β variant may act as a dominant negative regulator of GR-α transactivation.

In contrast to the diverse actions of glucocorticoids, mineralocorticoids have a more restricted role, principally to stimulate epithelial sodium transport in the distal nephron, distal colon, and salivary glands. This is mediated through the induction of the apical sodium channel (comprising three subunits α, β, and γ) and the α_1 and β_1 subunits of the basolateral Na^+K^+-ATPase through transcriptional regulation of a specific aldosterone-induced gene that encodes serum and glucocorticoid-induced kinase. Aldosterone binds to the MR, principally in the cytosol (though there is evidence for expression of the unoccupied MR in the nucleus) followed by translocation of the hormone–receptor complex to the nucleus.

The MR and GR share considerable homology—57% in the steroid binding domain and 94% in the DNA binding domain. Therefore, it is perhaps not surprising therefore that there is promiscuity of ligand binding with aldosterone binding to the GR and cortisol binding to the MR. For the MR this is particularly impressive—*in vitro* the MR has the same inherent affinity for aldosterone, corticosterone, and cortisol. Specificity upon the MR is conferred through the 'prereceptor' metabolism of cortisol via the enzyme HSD11B2 in the kidney, which inactivates cortisol and corticosterone to 11-keto metabolites that do not activate the MR, thereby enabling aldosterone to bind to the MR.

For both glucocorticoids and mineralocorticoids, there is accumulating evidence for so-called non-genomic effects involving hormone response obviating the genomic GR or MR effects. A series of responses have been reported within seconds/minutes of exposure to corticosteroids and are thought to be mediated by, as yet uncharacterized, membrane-coupled receptors.

Cortisol-Binding Globulin and Corticosteroid Hormone Metabolism

Over 90% of circulating cortisol is bound, predominantly to the α_2-globulin cortisol-binding globulin (CBG). This 383-amino acid protein is synthesized in the liver and binds cortisol with high affinity. Affinity for synthetic corticosteroids (except prednisolone, which has an affinity for CBG of approximately 50% of that of cortisol) is negligible. Circulating CBG concentrations are approximately 700 nmol/L; levels are increased by oestrogens and in some patients with chronic active hepatitis but generally reduced in patients with cirrhosis, nephrosis, and hyperthyroidism. The oestrogen effect can be marked, with levels increasing two- to threefold across pregnancy, and this should also be taken into account when measuring plasma 'total' cortisol in pregnancy and in women taking oestrogens. Inherited abnormalities in CBG synthesis are much rarer than those described for thyroid-binding globulin but include patients with elevated CBG, partial and complete deficiency of CBG, or CBG variants with reduced affinity for cortisol. In each case, alterations in CBG concentrations change total circulating cortisol concentrations accordingly but 'free' cortisol concentrations are normal. Only this free circulating fraction is available for transport into tissues for biological activity. The excretion of 'free' cortisol through the kidneys is termed urinary-free cortisol and represents only 1% of the total cortisol secretion rate. Approximately 50% of secreted cortisol appears in the urine as tetrahydrocortisol (THF), 5alpha-tetrahydrocortisol (allo-THF), and tetrahydrocortisone (THE), 25% as cortols/cortolones, 10% as C19 steroids, and 10% as cortolic/cortolonic acids.

Aldosterone is also metabolized in the liver and kidneys. In the liver it undergoes tetrahydro reduction, followed by its excretion in the urine as a 3-glucuronide tetrahydroaldosterone derivative. However, glucuronide conjugation at the 18 position occurs directly in the kidney, as does 3α and 5α/5β metabolism of the free steroid. Because of the aldehyde group at the C18 position, aldosterone is not metabolized by HSD11B2. Hepatic aldosterone clearance is reduced in patients with cirrhosis, ascites, and severe congestive heart failure.

Epidemiology of Adrenal Insufficiency

The prevalence of Addison's disease, mostly due to primary adrenal failure due to autoimmune adrenalitis, is 93–140 per million while secondary insufficiency, mostly due to hypothalamic–pituitary tumours, has a prevalence of 125–280 per million [3]. The overall prevalence of adrenal insufficiency is 5 in 10 000 population; on average, three of those suffer from secondary adrenal insufficiency, one from primary adrenal insufficiency due to autoimmune adrenalitis, and one from congenital adrenal hyperplasia (see Chapter 5.9).

Primary Adrenal Insufficiency

According to recent studies, chronic primary adrenal insufficiency has a prevalence of 93 to 140 per million and an incidence of 4.7

to 6.2 per million in Caucasian populations [3, 4]. These numbers are considerably higher than reported earlier, despite a continuous decline in tuberculous adrenalitis in the developed world, and suggest an increasing incidence of autoimmune adrenalitis. The age at diagnosis peaks in the fourth decade of life, with women more frequently affected. For details on the rare inborn causes of primary adrenal insufficiency, please see Chapters 5.8.1 and 5.9.1.

Secondary Adrenal Insufficiency

Secondary adrenal insufficiency has an estimated prevalence of 150 to 280 per million [3, 4]. Again, women are more frequently affected and age at diagnosis peaks in the sixth decade.

It has been suggested that therapeutic glucocorticoid administration is the most common cause of adrenal insufficiency, as exogenous glucocorticoids induce atrophy of both pituitary corticotroph and adrenocortical cells. However, iatrogenic adrenal insufficiency only becomes potentially relevant during or after glucocorticoid withdrawal. As iatrogenic adrenal insufficiency is transient in the majority of cases it can be suspected that the prevalence of permanent iatrogenic adrenal insufficiency is clearly lower than that of endogenous adrenal insufficiency.

Causes of Adrenal Insufficiency

A large number of frequent and rare causes of adrenal insufficiency are summarized in Tables 5.8.2.1 and 5.8.2.2, and in the following sections more detailed information on some of the more frequent causes is provided. Two reviews have given an excellent overview of causes of adrenal insufficiency including citation of all original literature which cannot be provided here because of space constraints [3, 4].

Causes of Primary Adrenal Insufficiency

During the times of Thomas Addison, tuberculous adrenalitis was by far the most prevalent cause of adrenal insufficiency. In the developing world, tuberculosis still remains a major cause of adrenal insufficiency. In active tuberculosis, the incidence of adrenal involvement is 5%.

In North American and European countries, autoimmune adrenalitis accounts for more than 90% of cases with primary adrenal insufficiency; in 40% adrenal insufficiency is isolated while in 60% it arises as part of an autoimmune polyendocrine syndrome (APS) [3, 5]. APS type 1, also termed autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy, accounts for 15% of cases and is characterized by adrenal insufficiency, hypoparathyroidism, and chronic mucocutaneous candidiasis, the latter being the primary manifestation in most cases and already apparent in childhood [6]. APS 1 is caused by mutations in the autoimmune regulator gene (*AIRE*) [7–9] while APS 2 is thought to be inherited as a complex trait, associated with loci within the major histocompatibility complex [5] and distinct susceptibility genes [10–12]. APS 2 is much more common than APS 1 and in addition to adrenal insufficiency most frequently comprises

Table 5.8.2.1 Causes of primary adrenal insufficiency

Diagnosis	Clinical features	Pathogenesis/genetics
Autoimmune adrenalitis (AA)		
Isolated AA	AI	Associations with HLA-DR3, CTLA-4
AA as part of autoimmune polyendocrine syndromes (APS)		
APS 1 (=APECED) APS 2	AI + hypoparathyroidism + chronic mucocutaneous candidiasis ± other autoimmune disorders AI + thyroid disease (= Schmidt's syndrome) + type 1 diabetes mellitus (= Carpenter's syndrome) ± other autoimmune diseases	*AIRE* gene mutations (21q22.3) Associations with HLA-DR3, CTLA-4
Infectious adrenalitis		
Tuberculous adrenalitis	AI + other organ manifestations of tuberculosis	Tuberculosis
AIDS	AI +other AIDS-associated diseases	HIV, CMV
Fungal adrenalitis	AI + mostly immunosuppressed patients	Cryptococcosis, histoplasmosis, coccidioidomycosis
Genetic disorders leading to AI		
Adrenoleukodystrophy (ALD) Adrenomyeloneuropathy (AMN)	AI + demyelination of CNS (cerebral ALD) or spinal cord/peripheral nerves (AMN)	Mutation of the *X-ALD* gene encoding for the peroxisomal adrenoleukodystrophy protein (ALDP)
Congenital adrenal hyperplasia (CAH)		
21-hydroxylase deficiency 11β-hydroxylase deficiency 3β-HSD type 2 deficiency 17α-hydroxylase deficiency P450 oxidoreductase deficiency	AI + ambiguous genitalia in females AI + ambiguous genitalia in females + hypertension AI + ambiguous genitalia in males + postnatal virilization in females AI + ambiguous genitalia in males + lack of puberty in both sexes + hypertension AI + ambiguous genitalia in both sexes + skeletal malformations	*CYP21A2* mutation *CYP11B1* mutation *HSD3B2* mutation *CYP17A1* mutation *POR* mutation
Congenital lipoid adrenal hypoplasia (lipoid CAH)	AI + XY sex reversal	Mutations in the steroidogenic acute regulatory protein (*STAR*) gene Mutations in *CYP11A1* (encoding P450scc)
Smith–Lemli–Opitz syndrome (SLOS)	AI, mental retardation, craniofacial malformations, growth failure	Sterol delta-7-reductase gene (*DHCR7*) mutations

(*continued*)

Table 5.8.2.1 *Continued*

Diagnosis	Clinical features	Pathogenesis/genetics
Adrenal hypoplasia congenita (AHC)		
X-linked AHC Xp21 contiguous gene syndrome SF-1 linked AHC	AI + hypogonadotropic hypogonadism AI + Duchenne muscular dystrophy + glycerol kinase deficiency (psychomotor retardation) AI + XY sex reversal	Mutation in *NROB1* (encoding DAX1) Deletion of the Duchenne muscular dystrophy, glycerol kinase, and *DAX1* genes Mutation in *NR5A1* (encoding SF-1)
IMAGe syndrome	Intrauterine growth retardation + metaphyseal dysplasia + AI + genital anomalies	?
Kearns–Sayre syndrome	Progressive external ophthalmoplegia, pigmentary retinal degeneration and cardiac conduction defects; endocrinopathies include gonadal failure, hypoparathyroidism, type 1 diabetes, only rarely AI	Mitochondrial DNA deletions
ACTH insensitivity syndromes = familial glucocorticoid deficiency (FGD)	Glucocorticoid deficiency, excess plasma ACTH; no (or only very mild) impairment of mineralocorticoid synthesis; lack of adrenarche	
FGD 1 FGD 2 FGD 3 Triple A syndrome (=Allgrove's syndrome)	AI, tall stature AI AI AI + alacrimia + achalasia; additional symptoms (neurological impairment, deafness, mental retardation, hyperkeratosis)	Mutations in melanocortin-2-receptor (*MC2R*) encoding the ACTH receptor Mutations in MC2R accessory protein (*MRAP*) ? Mutations in the triple A gene (*AAAS*) encoding a WD repeat protein
Bilateral adrenal haemorrhage	AI + symptoms of underlying disease	Septic shock, specifically meningococcal sepsis (Waterhouse–Friderichsen syndrome) Primary antiphospholipid syndrome
Diagnosis	Clinical features	Pathogenesis/genetics
Adrenal infiltration	AI + symptoms of underlying disease	Adrenal metastases primary adrenal lymphoma sarcoidosis, amyloidosis, haemochromatosis
Bilateral adrenalectomy	AI + symptoms of underlying disease	e.g. in the management of Cushing's due to ectopic ACTH secretion of unknown source or following tumour nephrectomy
Drug-induced AI	AI	Treatment with mitotane, aminoglutethimide, arbiraterone, trilostane, etomidate, ketoconazole, suramin, RU486

AI, adrenal insufficiency; APECED, autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy.

autoimmune thyroid disease, albeit more often autoimmune hypothyroidism than Graves' disease.

X-linked adrenoleukodystrophy (ALD) is caused by a mutation in the *X-ALD* gene, which encodes a peroxisomal membrane protein (adrenoleukodystrophy protein), leading to accumulation of very long chain fatty acids (>24 carbon atoms). The clinical picture comprises adrenal insufficiency and neurological impairment due to white matter demyelination. The two major forms are cerebral ALD (50% of cases; early childhood manifestation, rapid progression) and adrenomyeloneuropathy (35% of cases; onset in early adulthood, slow progression) with restriction of demyelination to spinal cord and peripheral nerves. Adrenal insufficiency may precede the onset of neurological symptoms and is the sole manifestation of disease in 15% of cases.

Other causes of primary adrenal insufficiency (Table 5.8.2.1), e.g. adrenal infiltration or haemorrhage, are rare. Congenital or neonatal primary adrenal insufficiency accounts for only 1% of all cases. However, the recent elucidation of the genetic basis of underlying diseases has highlighted the importance of specific genes for adrenal development and steroidogenesis (see Chapter 5.8.1).

Causes of Secondary Adrenal Insufficiency

The most common cause of secondary adrenal insufficiency is a tumour of the hypothalamic–pituitary region, usually associated with panhypopituitarism as a result of tumour growth or treatment with surgery and/or irradiation (Table 5.8.2.2). Autoimmune lymphocytic hypophysitis is less frequent, mostly affecting women during or shortly after pregnancy. Isolated ACTH deficiency may also be of autoimmune origin as some patients concurrently suffer from other autoimmune disorders, most frequently thyroid disease. The differential diagnosis of postpartal autoimmune hypophysitis includes Sheehan's syndrome, which results from pituitary apoplexy, mostly due to pronounced blood loss during delivery. Very rarely mutations of genes important for pituitary development or for synthesis and processing of the corticotropin precursor proopiomelanocortin cause secondary adrenal insufficiency (Table 5.8.2.2).

Table 5.5.2.2 Causes of secondary adrenal insufficiency

Diagnosis	Comment
AI as the consequence of growth or therapeutic management of hypothalamic–pituitary mass lesions	
Pituitary tumours	Generally adenomas, carcinomas very rare Additional signs and symptoms consequent to impairment of other pituitary axes (thyroid, gonads, PRL, GH), visual field impairment due to compression of the optic chiasm
Other tumours of the hypothalamic–pituitary region	Craniopharyngioma, meningioma, ependymoma, intra-/suprasellar metastases
Pituitary irradiation	Radiation therapy for pituitary tumours, brain tumours outside the HPA axis and craniospinal irradiation in leukaemia and other cancers
Non-tumoural causes	
Lymphocytic hypophysitis isolated	Autoimmune hypophysitis; most frequently in relation to pregnancy; commonly associated with panhypopituitarism, but also presenting with isolated ACTH deficiency only
as part of autoimmune polyendocrine syndromes (APS)	associated with autoimmune thyroid disease, less frequently also with vitiligo, primary gonadal failure, type 1 diabetes, and pernicious anaemia
Genetic disorders leading to secondary AI	
Congenital isolated ACTH deficiency	Tpit or T-box 19 (*TBX19*) mutations; neonatal presentation; autosomal recessive
Combined pituitary hormone deficiency (CPHD)	Prophet of Pit-1 (*PROP1*) mutations: progressive development of CPHD in the order GH, PRL, TSH, LH/FSH, (ACTH– late onset); anterior pituitary may be hypoplastic, normal, or enlarged; autosomal recessive Homeobox gene 1 (*HESX1*) mutations: CPHD + optic nerve hypoplasia and midline brain defects/ agenesis of corpus callosum (=septo-optic dysplasia); anterior pituitary hypoplastic or ectopic; autosomal recessive, autosomal dominant Lim homeobox 3 (*LHX3*) mutations: CPHD with involvement of GH, TSH, gonadotrophins, PRLs; ACTH may be deficient; limited neck rotation, short cervical spine, sensorineural deafness; anterior pituitary hypoplastic, normal, or enlarged; autosomal recessive LIM homeobox 4 (*LHX4*) mutations: CPHD with involvement of GH, thyrotropin, and ACTH secretion, cerebellar abnormalities; anterior pituitary hypoplastic or ectopic; autosomal dominant SRY-box 3 (*SOX3*) mutations: infundibular hypoplasia, CPHD, variable: mental retardation
Proopiomelanocortin (POMC) deficiency syndrome	*POMC* gene mutations; clinical triad AI + early-onset obesity + red hair pigmentation
Prader–Willi syndrome	Imprinting disorder, manifests with AI, obesity, hypogonadism, variable learning difficulties, and hypotonia
Pituitary apoplexy—Sheehan's syndrome	Onset mainly with abrupt severe headache, visual disturbance, nausea/vomiting Pituitary apoplexy/necrosis with peripartal onset (e.g. due to high blood loss and/or hypotension)
Pituitary infiltration/ granuloma	Tuberculosis, actinomycosis, sarcoidosis, histiocytosis X, Wegener's granulomatosis
Trauma	Pituitary stalk lesions, traumatic brain injury
Drugs	Chronic glucocorticoid excess: exogenous glucocorticoid administration for more than 4 weeks endogenous glucocorticoid hypersecretion due to Cushing's syndrome

GH, growth hormone; LH/FSH, luteinizing hormone/follicle-stimulating hormone; PRL, prolactin; TSH, thyroid-stimulating hormone.

Clinical Presentation of Adrenal Insufficiency

The clinical signs and symptoms of both acute and chronic adrenal insufficiency are a logical consequence of the underlying pathology, i.e. mostly the deficiency of adrenal corticosteroid production arising from primary or secondary adrenal failure (Table 5.8.2.3).

Acute adrenal insufficiency (i.e. life-threatening adrenal crisis) typically presents with severe hypotension or hypovolaemic shock, acute abdominal pain, vomiting, and often with fever, and, therefore, is sometimes mistaken for acute abdomen. In a series of 91 patients with Addison's disease, adrenal crisis led to the initial diagnosis of adrenal insufficiency in half of the patients. In children, acute adrenal insufficiency often presents as hypoglycaemic seizures. Deterioration of glycaemic control with recurrent hypoglycaemia may be the presenting sign of adrenal insufficiency in patients with pre-existing type 1 diabetes. In APS 2, onset of autoimmune hyperthyroidism (or thyroxine replacement for newly diagnosed hypothyroidism) may precipitate adrenal crisis due to enhanced cortisol clearance.

The leading symptom of chronic adrenal insufficiency is fatigue, accompanied by lack of stamina, loss of energy, reduced muscle strength, and increased irritability. In addition, chronic glucocorticoid deficiency leads to weight loss, nausea, and anorexia (in children, failure to thrive) and may account for muscle and joint pain. Unfortunately, most of these symptoms are non-specific. Thus, every second patient suffers from signs and symptoms of Addison's disease for more than 1 year before diagnosis is established. In secondary adrenal insufficiency, diagnosis is mostly prompted by a history of pituitary disease, but may also be delayed (e.g. in isolated ACTH deficiency). A more specific sign for primary adrenal failure is hyperpigmentation (Figure 5.8.2.3), which is most pronounced in areas of the skin exposed to increased friction (e.g. hand lines, knuckles, scars, oral mucosa). Hyperpigmentation is due to enhanced stimulation of skin MC1-receptor by ACTH and other pro-opiomelanocortin-related peptides. Accordingly, patients with secondary adrenal insufficiency often present with pale, alabaster-coloured skin. Laboratory

Table 5.8.2.3 Clinical manifestations of adrenal insufficiency

Manifestations	Explained by deficiency of
Symptoms	
Fatigue, lack of energy/stamina, reduced strength	Glucocorticoids (adrenal androgens)
Anorexia, weight loss (in children: failure to thrive)	Glucocorticoids
Abdominal pain, nausea, vomiting (more frequent in primary AI)	Mineralocorticoids, glucocorticoids
Myalgia, joint pain	Glucocorticoids
Dizziness, postural hypotension	Mineralocorticoids
Salt craving (primary AI only)	Mineralocorticoids
Dry and itchy skin (in women)	Adrenal androgens
Loss/impairment of libido (in women)	Adrenal androgens
Signs	
Skin hyperpigmentation (primary AI only)	*Excess* of pro-opiomelanocortin (POMC) derived peptides (primary AI)
Alabaster-coloured pale skin (secondary AI only)	Deficiency of POMC derived peptides (secondary AI)
Loss of axillary/pubic hair (in women)	Adrenal androgens
Fever	Glucocorticoids
Low blood pressure (systolic RR <100 mm Hg), postural hypotension (pronounced in primary AI)	Mineralocorticoids, glucocorticoids
Anaemia, lymphocytosis, eosinophilia	Glucocorticoids
Serum creatinine ↑ (primary AI only)	Mineralocorticoids
Hyponatraemia	Mineralocorticoids, (glucocorticoids = SIADH)
hyperkalaemia (primary AI only)	mineralocorticoids
TSH ↑ (primary AI only)	Glucocorticoids (or autoimmune hypothyroidism)
Hypercalcaemia (primary AI only)	Glucocorticoids (rare, mostly observed if concurrent hyperthyroidism)
Hypoglycaemia	Glucocorticoids, (epinephrine deficiency?) (more frequent in children)

SIADH, syndrome of inappropriate antidiuretic hormone secretion; TSH, thyroid-stimulating hormone.

findings in glucocorticoid deficiency may include mild anaemia, lymphocytosis, and eosinophilia. Cortisol physiologically inhibits thyrotropin (TSH) release. Thus, TSH is often increased at initial diagnosis of primary adrenal insufficiency, but returns to normal during glucocorticoid replacement, unless there is coincident autoimmune thyroid failure. In rare cases, glucocorticoid deficiency may result in hypercalcaemia, which is due to increased intestinal absorption and decreased renal excretion of calcium and usually coincides with autoimmune hyperthyroidism, facilitating calcium release from bone.

Mineralocorticoid deficiency, which is only present in primary adrenal insufficiency, leads to dehydration and hypovolaemia, resulting in low blood pressure, postural hypotension, and sometimes even in prerenal failure. Deterioration may be sudden and is often due to exogenous stress such as infection or trauma. Combined mineralocorticoid and glucocorticoid replacement in primary adrenal insufficiency reconstitutes the diurnal rhythm of blood pressure and reverses cardiac dysfunction. Glucocorticoids contribute to this amelioration not only by mineralocorticoid receptor binding, but also by permissive effects on catecholamine action. The latter may account for the relative unresponsiveness to catecholamines in patients with unrecognized adrenal crisis. Mineralocorticoid deficiency accounts for hyponatraemia (90%), hyperkalaemia (65%), and salt craving (15%). Low serum sodium may also be present in secondary adrenal insufficiency due to the syndrome of inappropriate antidiuretic hormone secretion, which results from the loss of physiological inhibition of pituitary vasopressin release by glucocorticoids.

Adrenal insufficiency inevitably leads to DHEA deficiency. DHEA is the major precursor of sex steroid synthesis and loss of its synthesis results in pronounced androgen deficiency in women. As a consequence, women with adrenal insufficiency frequently show loss of axillary and pubic hair (absence of pubarche in children), dry skin, and reduced libido. DHEA also exerts direct action as a neurosteroid with potential antidepressant properties. Thus, DHEA deficiency may contribute to the impairment of well-being that is observed in patients with adrenal insufficiency despite adequate glucocorticoid and mineralocorticoid replacement.

Diagnostic Laboratory Evaluation of Adrenal Insufficiency

Presentation with acute adrenal insufficiency (i.e. life-threatening adrenal crisis), requires an immediate, combined diagnostic and therapeutic approach (Figure 5.8.2.4). Haemodynamically stable patients may undergo a cosyntropin stimulation test (also termed short synacthen test, as synacthen, i.e. $ACTH_{1-24}$, is used, rather than the full-length $ACTH_{1-39}$ peptide. In a severely unwell patient, baseline bloods for serum cortisol and plasma ACTH will suffice and if cortisol is less than 100 nmol/L while ACTH is considerably elevated, there is no doubt about the diagnosis of primary adrenal insufficiency. Formal confirmation of diagnosis can be performed via the short synacthen test following clinical improvement. Diagnostic measures must never delay treatment of a suspected adrenal crisis; therefore, treatment should be initiated upon strong clinical suspicion of adrenal insufficiency without awaiting biochemical results. It is of negligible risk to start hydrocortisone and stop it after adrenal insufficiency has been safely excluded; withholding potentially life-saving treatment, however, could have fatal consequences.

Adrenal insufficiency is readily diagnosed by the short synacthen test, a safe and reliable diagnostic tool with excellent long-term predictive value [13, 14]; it is important to be aware of the considerable variability between results of different cortisol assays [15] and when defining the cut-off for failure, commonly set at 500 nmol/L but with the use of newer, mass spectrometry-based assays now often at 400–450 nmol/L, one should ideally refer to results from a local reference cohort obtained with the same assay. The diagnostic value of the short synacthen test is compromised within the first 4 weeks following a pituitary insult [14, 16], as during this period the adrenals

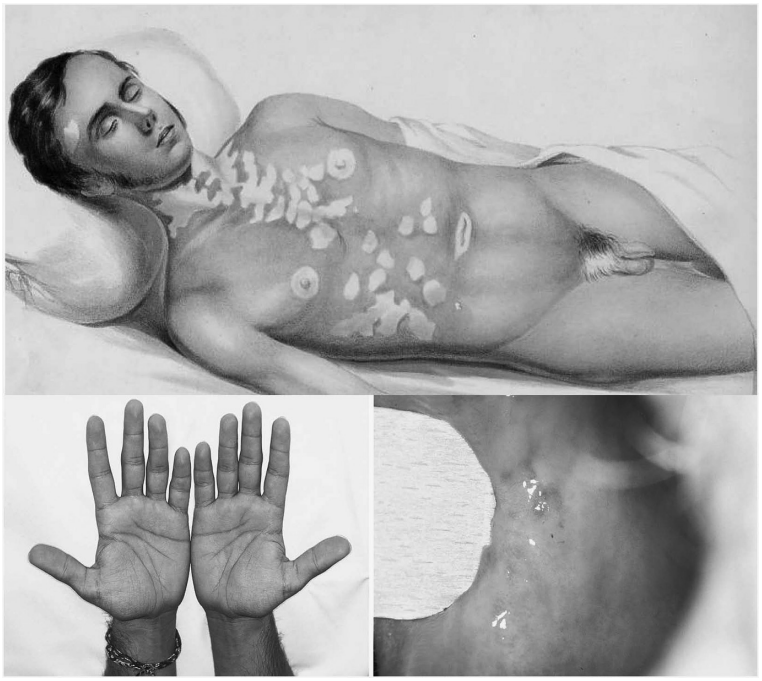

Figure 5.8.2.3 Skin changes observed in primary adrenal insufficiency (Addison's disease). (a) Panel drawn by Thomas Addison (1855) of a patient with Addison's disease, depicting generalized hyperpigmentation, in particular in areas of increased friction, and patchy vitiligo, indicative of autoimmune polyendocrine syndrome. (b) Hyperpigmentation of the palmar creases in a patient with acute primary adrenal insufficiency. (c) Patchy hyperpigmentation of the oral mucosa in a patient with acute primary adrenal insufficiency. (See also Plate 30.)

will still respond to exogenous ACTH stimulation despite the loss of endogenous ACTH drive. When suspecting secondary adrenal insufficiency, the insulin tolerance test is an alternative choice for diagnostic confirmation, considered by many as the gold standard, however it is associated with side effects and requires exclusion of cardiovascular disease and history of seizures. Again, hydrocortisone treatment could be initiated, with formal confirmation of the diagnosis of secondary adrenal insufficiency once the patient is clinically better and time since a suspected pituitary insult is more than 4 weeks. Formal confirmation of diagnosis by the short synacthen stimulation test should include blood samples for plasma ACTH, which will guide the way for further diagnostic assessment, by reliably differentiating primary from secondary adrenal insufficiency, i.e. adrenal from hypothalamic–pituitary disease (Figure 5.8.2.4).

Possible glucocorticoid deficiency is also indicated by normocytic anaemia as sufficient levels of cortisol are required for maturation of blood progenitor cells; other blood count changes may include lymphocytosis and eosinophilia. Sometimes mild metabolic acidosis or hypercalcaemia can be observed in affected patients, the latter mostly in the context of coincident hyperthyroidism. Serum glucose may be low; however, significant hypoglycaemia as a presenting sign plays a more important role in childhood adrenal insufficiency where it can result in significant brain damage. However, in a patient with pre-existing type 1 diabetes onset of recurrent hypoglycaemic episodes despite unchanged insulin regimen should raise the suspicion of adrenal insufficiency.

Mineralocorticoid deficiency is present in primary adrenal insufficiency only; the renin–angiotensin–aldosterone system in patients with hypothalamic–pituitary disease and intact adrenals is usually preserved. Mineralocorticoid deficiency is not only reflected by the arterial hypotension and deranged potassium and sodium but intravascular volume depletion is also indicated by the slightly raised creatinine, a common finding in Addison patients. Hyponatraemia is observed in about 80% of acute cases while less than half present with hyperkalaemia. In the first instance, baseline bloods for serum aldosterone and plasma renin should be taken.

Diagnosis of Primary Adrenal Insufficiency

The combined measurement of early morning serum cortisol and plasma ACTH separates patients with primary adrenal insufficiency from normal subjects and patients with secondary adrenal insufficiency. Plasma ACTH is usually grossly elevated and invariably higher than 22 pmol/L, with baseline serum cortisol usually below the lower end of the reference range (<150 nmol/L), sometimes also in the lower reference range. Establishment of the diagnosis of primary adrenal insufficiency always depends on the **combined** measurement of ACTH and cortisol at the same time. Serum aldosterone concentrations are subnormal or within the lower normal range with plasma renin activity concurrently increased above the normal range. In patients with adrenal insufficiency, serum DHEAS is invariably low, in women often below the limit of detection.

The impaired ability of the adrenal cortex to respond to ACTH is readily demonstrated by the short synacthen test (SST), employing serum cortisol measurements before and 30 min after IV injection of 250 µg $ACTH_{1-24}$ (= synacthen). In some areas, IM injections are used and others use a 60 min timepoint for analysing the adequacy of the cortisol response. However, there are no studies showing superiority of either administration or timepoint; hence, IV injection and the 30 min interval are generally preferred, as more convenient for the patients. In normal subjects, this leads to a physiological increase in serum cortisol to peak concentrations above 500 nmol/L. In primary adrenal insufficiency, the adrenal cortex is already

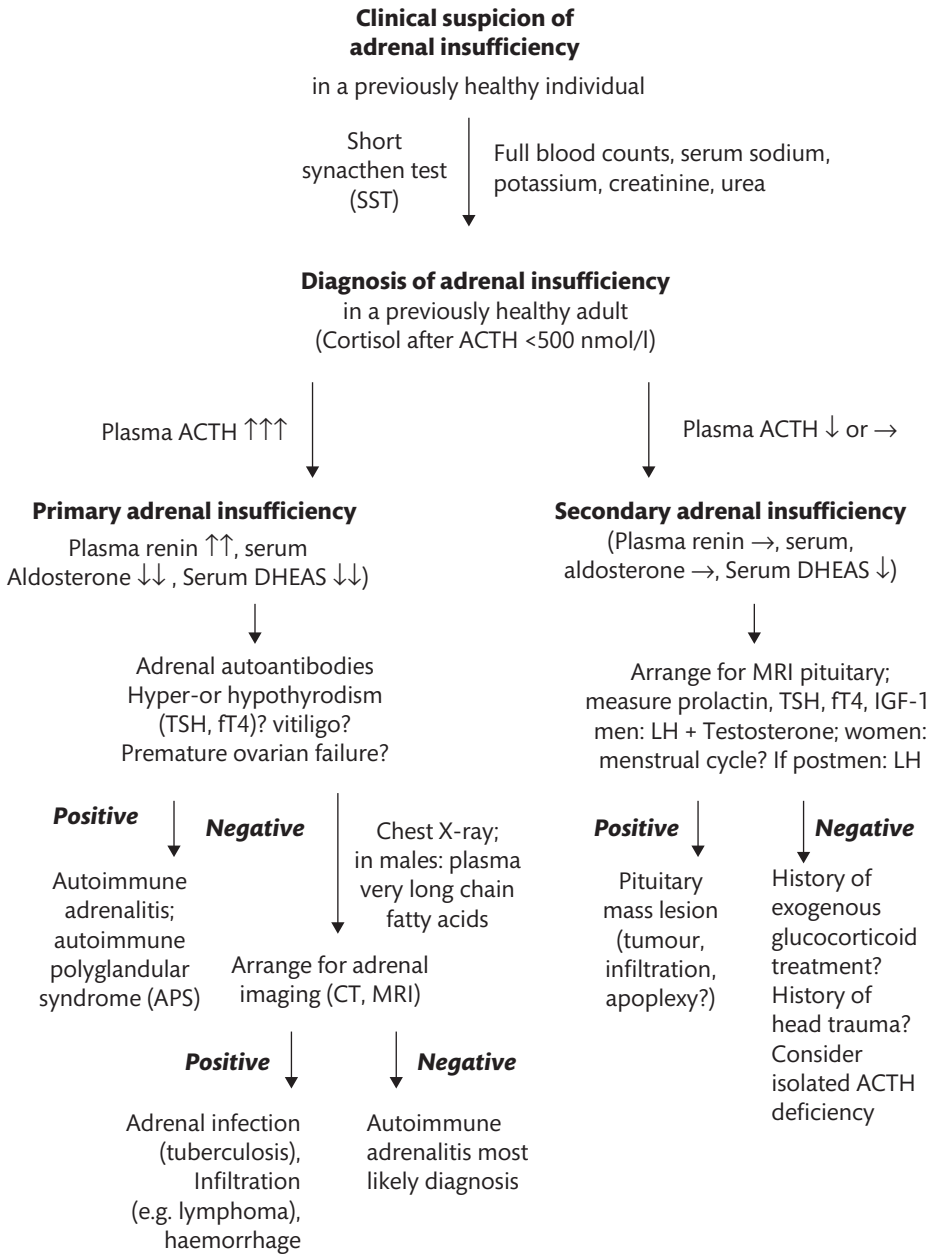

Figure 5.8.2.4 Flowchart outlining the steps to be taken for the diagnostic management of adults with newly diagnosed adrenal insufficiency. DHEAS, dehydroepiandrosterone sulphate ester; IGF-1, insulin-like growth factor 1; LH, luteinizing hormone; TSH, thyroid-stimulating hormone.

maximally stimulated by endogenous ACTH, exogenous ACTH administration therefore usually does not evoke any further increase in serum cortisol.

Adrenal cortex autoantibodies and/or antibodies against 21-hydroxylase are found in more than 80% of patients with recent-onset autoimmune adrenalitis. While 21-hydroxylase has been identified as the major autoantigen in autoimmune adrenalitis, autoantibodies against other steroidogenic enzymes (CYP11A1, CYP17A1) and steroid-producing cell antibodies are present in a lower percentage of patients. Measurement of autoantibodies is particularly helpful in patients with isolated primary adrenal insufficiency and no family history of autoimmune disease. In APS 2, autoimmune adrenalitis may be associated with autoimmune thyroid disease or type 1 diabetes and screening for concomitant disease should involve measurements of thyrotropin and fasting glucose but not of other organ-related antibodies. (For a state-of-the-art review of adrenal insufficiency in the context of APS, please see reference [17]).

In male patients with isolated primary adrenal insufficiency without unequivocal evidence of autoimmune adrenalitis, serum very long chain fatty acids (chain length of 24 carbons and more; C26, C26/C22, and C24/C22 ratios) should be measured to exclude adrenoleukodystrophy/adrenomyeloneuropathy.

Diagnosis of Secondary Adrenal Insufficiency

Baseline hormone measurements only poorly separate patients with secondary adrenal insufficiency from normal subjects. However, a morning cortisol below 100 nmol/L indicates adrenal insufficiency,

whereas a serum cortisol greater than 500 mmol/L is consistent with an intact HPA axis, unless the patient is clinically severely unwell and treated in the ICU. Thus, in most cases, dynamic tests of the HPA axis are required to establish the diagnosis of secondary adrenal insufficiency.

In addition to the widely used SST, the insulin tolerance test (ITT) is still regarded as a 'gold standard' in the evaluation of suspected secondary adrenal insufficiency, as hypoglycaemia (blood glucose <2.2 mmol/L) is a powerful stressor resulting in rapid activation of the HPA axis. An intact HPA axis is demonstrated by a peak cortisol above 500 nmol/L at any time during the test. The occasional patient will pass the ITT while exhibiting clinical evidence for adrenal insufficiency responding to hydrocortisone substitution and a higher cut-off value (550 nmol/L) may help to reduce misclassification. During ITT close supervision is mandatory and cardiovascular disease and history of seizures represent contraindications.

Another test for the diagnosis of secondary adrenal insufficiency, which is no longer widely used, is the overnight metyrapone test (30 mg metyrapone/kg (maximum 3 g) with a snack at midnight). Metyrapone inhibits the adrenal 11β-hydroxylase enzyme CYP11B1, thereby blocking the conversion of 11-deoxycortisol to cortisol. In normal subjects, HPA feedback activation will increase serum 11-deoxycortisol, while serum cortisol remains less than 230 nmol/L. In patients with secondary adrenal insufficiency, 11-deoxycortisol does not exceed 200 nmol/L at 8.00 hours after metyrapone. Shortcomings of the test are limited availability of reliable 11-deoxycortisol assays and of the drug itself, which cannot be obtained in all countries though it is readily available in the United Kingdom. As metyrapone may precipitate adrenal crisis in severe cortisol deficiency, a morning cortisol above 200 nmol/L should be documented prior to performing the test on an outpatient basis.

As both the ITT and the metyrapone test pose a significant burden to patients and physicians, there have been continuing efforts to replace these tests by more convenient tools. Sustained secondary adrenal insufficiency leads to adrenal atrophy and also to reduced adrenal ACTH receptor expression, as ACTH up-regulates its own receptor. Thus adrenal responsiveness to an acute exogenous ACTH challenge is impaired also in secondary adrenal insufficiency facilitating the use of the SST for the evaluation of HPA axis integrity (Figure 5.5.2.4). Several studies have reported excellent agreement between peak cortisol values in the short synacthen test and the ITT [14] and a definitive study has convincingly demonstrated the long-term predictive accuracy of the SST [13]. However, there is some evidence that some patients with secondary adrenal insufficiency will pass the SST while failing the ITT. The use of a higher cut-off value for passing the SST may minimize the risk of overlooking secondary adrenal insufficiency but this is largely assay dependent as different radioimmunoassays and now more widely mass spectrometry-based assays have different cut-offs [18] and it is now more important than ever to ascertain locally derived reference ranges with the cortisol assay used.

There are other tests that have been used in the diagnostic assessment of adrenal insufficiency but their use is not recommended as a routine procedure. As the administration of 250 μg 1–24 ACTH represents a massive supraphysiological challenge, a low-dose corticotropin test (LDT) employing only 1 μg ACTH has been proposed as a more sensitive test for the diagnosis of secondary adrenal insufficiency. The LDT has been successfully used to monitor recovery of adrenal function after withdrawal of oral glucocorticoids and to detect subtle impairment of adrenal reserve during inhalative steroid therapy. However, the administration of 1 μg ACTH IV still results in ACTH levels above those required for maximum cortisol release. Accordingly, in normal subjects serum cortisol concentrations measured 30 min after the ACTH challenge do not differ between the 250 μg SST and LDT. Thus it is currently a matter of debate whether employing the LDT represents any advantage [19, 20], which would be further offset by handling problems due to the necessity of dilution from the commercially available 250 μg ACTH 1–24 ampoule and due to the potential binding of ACTH to the surface of injection devices.

CRH has been used to differentiate hypothalamic from pituitary disease in secondary adrenal insufficiency. However, CRH stimulation is not of great help in actually diagnosing secondary adrenal insufficiency as individual responses to exogenous CRH are highly variable and cut-off values or even normal ranges are still not well defined.

Finally, a word of caution: none of the tests, including the ITT, will classify all patients correctly. Mild secondary adrenal insufficiency may pass as intact HPA axis and some healthy subjects may fail any single test by a small margin. Thus clinical judgement remains important. Persisting symptoms such as fatigue, myalgia, or reduced vitality should lead to reassessment.

Special Diagnostic Situations

Adrenal Insufficiency After Pituitary Surgery

Screening for adrenal insufficiency by SST should not be performed immediately after pituitary surgery, but only 4 to 6 weeks later, as adrenal atrophy may develop only gradually after onset of ACTH deficiency. Until then, patients with a morning cortisol not excluding secondary adrenal insufficiency (<450 nmol/L at 3 days and <350 nmol/L at 7 days after surgery, with cut-offs varying according to locally used cortisol assays) should receive hydrocortisone replacement paused 24 h prior to scheduled adrenal function testing. The impairment of other hormonal axes after pituitary surgery increases the likelihood of ACTH deficiency, whereas isolated corticotropin deficiency is uncommon.

Adrenal Insufficiency in Critically Ill Patients

In critically ill patients, the corticotropic axis is markedly activated [21, 22]. Moreover, patients in intensive care units are less sensitive to dexamethasone suppression and achieve higher peak ACTH and cortisol concentrations after CRH. In addition, patients with critical illness show relatively low serum aldosterone levels with concurrently elevated plasma renin activity. Cortisol concentrations correlate with illness-severity scores and are highest in patients with the highest mortality. On the other hand, cytokine activation may induce relative secondary adrenal insufficiency in some patients with severe illness, thus putting them at risk of dying from adrenal crisis. Chronic inhibition of cortisol production by etomidate has been associated with increased mortality in intensive care unit patients. Unfortunately, no consensus exists how to diagnose adrenal insufficiency in critically ill patients. In patients with primary adrenal insufficiency or severe secondary adrenal insufficiency the SST will establish the diagnosis by demonstrating

a low baseline cortisol (<150 nmol/L) not responding to corticotropin (peak cortisol <500 nmol/L). However, it has been suggested that 'relative' adrenal insufficiency may be present in a number of critically ill patients, characterized by a poor cortisol response (increment <248 nmol/L) to ACTH despite normal baseline cortisol. These patients often present with catecholamine-dependent hypodynamic shock responding to hydrocortisone administration. One study has reported decreased mortality in patients with septic shock and abnormal cortisol response in the SST (increment <248 nmol/L) after treatment with hydrocortisone [23] but a prospective study did not support this finding [24]. At present it seems prudent to collect a random sample of serum cortisol and plasma ACTH in critically ill patients with suspected adrenal insufficiency followed by immediate hydrocortisone administration. Depending on the results of these hormone determinations (it is agreed that serum cortisol >700 nmol/L rules out adrenal insufficiency) hydrocortisone therapy is terminated or a more detailed evaluation employing the SST is performed. For more details, please review the recently published, updated consensus statement of the American and European critical care societies [25].

Imaging Requirements in Adrenal Insufficiency

If there is no coexisting autoimmune disease and adrenal and steroid autoantibodies are negative, imaging of the adrenals, preferably by computed tomography (CT), is warranted (Figure 5.8.2.4). Tuberculosis should be considered, which is frequent in developing countries and, therefore, also in migrant populations. Chest radiography is helpful and imaging of the adrenals typically shows hyperplastic organs in the early phase and spotty calcifications in the late phase of tuberculous adrenalitis. Much rarer causes are bilateral infiltration by bilateral primary adrenal lymphoma, (predominantly lung cancer) metastases [26, 27], sarcoidosis, haemochromatosis, or amyloidosis. Bilateral adrenal haemorrhage is usually only seen during septic shock or in very rare instances in primary antiphospholipid syndrome [28]. In male patients with isolated Addison's and negative autoantibodies, imaging should be preceded by measurement of plasma very long chain fatty acids to safely exclude X-linked adrenoleukodystrophy which affects 1 in 20 000 males [29]. *ABCD1* gene mutations encoding for the peroxisomal ALD protein involved in cross-membrane transport manifest in 50% of cases in early childhood and primarily with central nervous system (CNS) symptoms. However, the adrenomyeloneuropathy variant, accounting for 35% of cases, can manifest with adrenal insufficiency prior to the development of spinal paraparesis during early adulthood [29].

If ACTH is inappropriately low in the presence of cortisol deficiency, imaging of the hypothalamic–pituitary region by MRI is the first diagnostic measure that should be arranged for, alongside an endocrine pituitary baseline profile (Figure 5.8.2.4). Pituitary adenomas are most common, craniopharyngiomas are much rarer and may present at any age; very rare causes include meningioma, metastases, and infiltration by sarcoidosis, Langerhans' cell histiocytosis, or other granulomatous disease. Careful history-taking should ask for previous head trauma [30, 31], surgery, radiotherapy, and for clinical indicators of pituitary apoplexy [32], i.e. the sudden onset of high-impact headache [33]. The latter may occur spontaneously in larger pituitary adenomas or may result from sudden hypocirculation during surgery or as a consequence of complicated deliveries with significant blood loss, the classical cause of Sheehan's syndrome. Lymphocytic hypophysitis of autoimmune origin [34] commonly presents with panhypopituitarism including diabetes insipidus and a pituitary mass effect. However, it may present with isolated ACTH deficiency, in some cases coinciding with autoimmune thyroid disease [35, 36].

Importantly, the most obvious should not be forgotten— suppression of the hypothalamic–pituitary axis by exogenous glucocorticoid treatment. This should always be excluded, considering not only oral steroid intake but also glucocorticoid inhalers, creams, or intra-articular injections.

Treatment of Adrenal Insufficiency

Glucocorticoid Replacement

A patient with suspected acute adrenal insufficiency needs immediate therapeutic attention. Symptoms such as fatigue and weight are non-specific; more specific signs and symptoms, and therefore more suggestive of adrenal insufficiency include generalized hyperpigmentation including patchy hyperpigmentation of the oral mucosa (sometimes the only visible hyperpigmentation in dark-skinned individuals) and the presence of severe hypovolaemic hypotension. If peripheral veins are collapsed, a central line for IV fluid resuscitation may be required, administered at an initial rate of 1 L/h and with continuous cardiac monitoring. In addition, hydrocortisone replacement should be immediately commenced upon suspicion of acute adrenal insufficiency, by intravenous bolus injection of 100 mg hydrocortisone followed by continuous infusion of 200 mg hydrocortisone per 24 h [37]. Mineralocorticoid replacement does not need to be added in the acute setting as long as the total daily hydrocortisone dose is greater than 50 mg, as such a dose will ensure sufficient mineralocorticoid receptor activation by cortisol.

Chronic glucocorticoid replacement requires additional considerations. Physiological daily cortisol production rates vary between 5 and 10 mg/m^2 [38], which is equivalent to the oral administration of 15 to 25 mg hydrocortisone (i.e. cortisol). After oral ingestion cortisol produces highly variable peak concentrations within the supraphysiological range followed by a rapid decline to below 100 nmol/L 5 to 7 h after ingestion (Figure 5.8.2.5). It is recommended to administer hydrocortisone in two to three divided doses (e.g. 15 mg in the morning upon awakening followed by 5 mg 6 h later, or 10 mg upon awakening followed by 5 mg 4 h and 8 h later). It is important to let the patient experiment with different timings to find the most suitable regimen for their individual needs. Importantly, patients who work shifts have to adjust the timing of the glucocorticoid doses to their working times and consequent sleep–wake cycle. Whether a thrice daily glucocorticoid regimen should be preferred over twice daily administration is not clear as well-designed and appropriately powered studies are lacking. As Figure 5.8.2.5 illustrates, neither of the two regimens will be able to achieve cortisol availability similar to that of physiological diurnal secretion. Some groups advocate weight-related dosing [39]

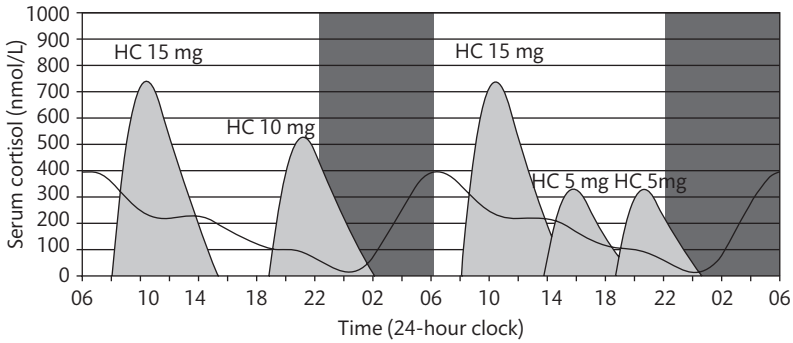

Figure 5.8.2.5 Schematic graph depicting the physiological diurnal rhythm of cortisol secretion and typical mean serum cortisol concentrations observed after different doses of oral hydrocortisone (HC) in patients with adrenal insufficiency.

and this appears to generate a smoother pharmacokinetic profile but data demonstrating superiority of such a regimen are lacking. However, body surface area adjusted glucocorticoid dosing is commonly used for guiding glucocorticoid replacement in children.

The oral administration of currently available cortisol preparations is not able to mimic the physiological pattern of cortisol secretion, which follows a distinct circadian rhythm. Physiologically, cortisol secretion begins to rise between 02.00 and 04.00 hours, peaks within an hour of waking and then declines gradually to low levels during the evening and nadir levels at and after midnight [40]. There is evidence for a diurnal variability in glucocorticoid sensitivity. Plat *et al.* [41] have demonstrated that a more unfavourable metabolic response occurs to evening administration of glucocorticoids. Also, high levels of glucocorticoids may disrupt sleep, thus late evening hydrocortisone administration should be avoided; sleep disturbances contributing to increased fatigue are a common feature in chronic adrenal insufficiency [42, 43]. The delivery of cortisol by intravenous infusion [44] or subcutaneous pump [45] can closely mirror diurnal secretion, but these administration modes are obviously not suited for routine delivery. Recently developed modified and delayed release hydrocortisone preparations mimicking physiological cortisol secretion represent a very promising therapeutic approach [46, 47].

Cortisone acetate requires intrahepatic activation to cortisol by HSD11B1, which contributes to a higher pharmacokinetic variability compared to hydrocortisone; 25 mg cortisone acetate are equivalent to 15 mg hydrocortisone [48, 49]. Long-acting glucocorticoids are also used for replacement (e.g. in 20% of respondents to the 2002 survey of the North American Addison Disease Foundation). Some countries do not have access to hydrocortisone or cortisone acetate and therefore have to resort to long-acting synthetic glucocorticoids. However, prednisolone and dexamethasone have considerably longer biological half-lives, likely to result in unfavourably high night-time glucocorticoid activity with potentially detrimental effects on insulin sensitivity and bone mineral density [50]. In addition, available preparations offer limited options for dose titration. Therefore, synthetic glucocorticoids should generally be avoided in the replacement therapy for adrenal insufficiency; the only exception are patients with concurrent insulin-dependent diabetes in whom the use of longer-acting prednisolone may help to avoid the peaks and troughs of hydrocortisone pharmacokinetics and thus also subsequent rapid changes in glucose control. For clinical purposes, one can assume equipotency to 1 mg hydrocortisone for 1.6 mg cortisone acetate, 0.2 mg prednisolone, 0.25 mg prednisone, and 0.025 mg dexamethasone, respectively. While equipotency doses of hydrocortisone and cortisone acetate are based on pharmacokinetic studies [48, 49], suggested doses for synthetic steroids are based on estimates from very old studies comparing the relative anti-inflammatory properties of various glucocorticoids based on rodent *in vivo* experiments.

Recent work has highlighted the potential of modified and delayed release hydrocortisone in delivering cortisol to mimic its physiological, diurnal secretion pattern in patients with congenital adrenal hyperplasia [50], with the outcomes of a phase 3 study currently awaited. Another hydrocortisone preparation, which is already approved by regulators, offers delayed release, which might be a good option in particular for elderly patients with secondary and partial adrenal insufficiency, who could then rely on the intake of a single glucocorticoid morning dose; however, current studies have been undertaken exclusively in primary rather than secondary adrenal insufficiency patients [51, 52]. Another option for modified hydrocortisone delivery to yield physiological, diurnal cortisol delivery is subcutaneous hydrocortisone administration via pump, for which encouraging results have been described [53, 54]. This option is particularly suitable for patients with impaired gastrointestinal absorption of hydrocortisone, but obviously require much more intense monitoring than oral hydrocortisone replacement.

Monitoring of glucocorticoid replacement is mainly based on clinical grounds as a reliable biomarker for glucocorticoid activity has yet to be identified (Table 5.8.2.4). Plasma ACTH cannot be used as a criterion for glucocorticoid dose adjustment. In primary adrenal insufficiency, ACTH is invariably high before the morning dose and rapidly declines with increasing cortisol levels after glucocorticoid ingestion [55, 56] (Figure 5.8.2.6a). Therefore, aiming at ACTH levels within the normal range would result in overreplacement. In secondary adrenal insufficiency, plasma ACTH is anyway low and thus not informative. Urinary 24-h free cortisol excretion has been advocated for monitoring of replacement quality by some [57]. However, after exogenous glucocorticoid administration, urinary cortisol excretion shows considerable interindividual variability. Also, following glucocorticoid absorption by the gut, CBG is rapidly saturated, resulting in transient but pronounced increases in renal cortisol excretion. Thus, one cannot refer to normal ranges for healthy subjects when judging urinary cortisol excretion during replacement therapy for adrenal insufficiency. Some authors have suggested regular measurements of

Table 5.8.2.4 Treatment and monitoring in chronic adrenal insufficiency

Chronic adrenal insufficiency	
Glucocorticoid replacement	Primary adrenal insufficiency: 20–25 mg hydrocortisone per 24 h
	Secondary adrenal insufficiency: 15–20 mg hydrocortisone per 24 h; if borderline fail in cosyntropin test consider 10 mg or stress dose cover only
	Administer in 2–3 divided doses with two-thirds and half of the dose, respectively, administered immediately after awakening
	Monitoring: • Check body weight, calculate body mass index • Check for signs of under-replacement (weight loss, fatigue, nausea, myalgia, lack of energy) • Check for signs of overreplacement (weight gain, central obesity, stretch marks, osteopenia/osteoporosis, impaired glucose tolerance, hypertension) • Take a detailed account of stress-related glucocorticoid dose self-adjustments since last visit, potential adverse events including emergency treatment and/or hospitalization
Mineralocorticoid replacement	Only required in primary adrenal insufficiency
	Not required as long as hydrocortisone dose >50 mg per 24 h
	Start on 100 µg fludrocortisone (doses vary between 50 and 250 µg per 24 h) administered as a single dose in the morning immediately after waking up
	Monitoring: • Blood pressure sitting and erect (postural drop ≥15 mm Hg indicative of under-replacement, high blood pressure may indicate overreplacement) • Check for peripheral oedema (indicative of overreplacement) • Check serum sodium and potassium • Check plasma renin activity (annually, upon clinical suspicion of over- and under-replacement and after significant changes in the hydrocortisone dose (40 mg hydrocortisone = 100 µg fludrocortisone)
Adrenal androgen replacement	Consider in patients with impaired well-being and mood despite apparently optimized glucocorticoid and mineralocorticoid replacement and in women with symptoms and signs of androgen deficiency (dry, itchy skin; reduced libido)
	DHEA 25–50 mg as a single morning dose
	If no perceived benefit after 6 months, consider stopping
	Monitoring: • In women, serum testosterone and SHBG (to calculate free androgen index) • In people on DHEA replacement, serum DHEAS and androstenedione levels • Blood should be sampled at steady state, i.e. ideally 24 h after the preceding DHEA dose
Additional monitoring requirements	Regular follow-up in specialist centre every 6–12 months
	In primary adrenal insufficiency of autoimmune origin (isolated Addison or autoimmune polyendocrine syndrome) serum TSH every 12 months
	In female patients: check regularity of menstrual cycle, consider measurement of ovarian autoantibodies if family planning not finalized
	Check emergency bracelet/steroid card, update as required
	Check knowledge of 'sick day rules' and reinforce emergency guidelines involving partner/family members
	Consider prescription of a hydrocortisone emergency self-injection kit, in particular if delayed access to acute medical care is likely (rural areas, travel)
	Check if other medication includes drugs known to induce (e.g. rifampicin, mitotane, anticonvulsants such as phenytoin, carbamazepine, oxcarbazepine, phenobarbital, topiramate) or inhibit (e.g. antiretroviral agents) hepatic cortisol inactivation by CYP3A4, which may require glucocorticoid dose adjustment

DHEA, dehydroepiandrosterone; SHBG, sex hormone-binding hormone; TSH, thyroid-stimulating hormone.

serum cortisol day curves to monitor replacement therapy [57, 58]. However, the efficacy of this approach is not supported by data that indicate a poor correlation between clinical assessment and cortisol levels [59]. Timed serum cortisol measurements can be of some value in selected patients (e.g. in case of suspected non-compliance or gastrointestinal malabsorption); however, random serum cortisol measurements without information on the timing of the hydrocortisone dose intake and without referring to a locally generated time course reference range are not informative.

Thus, in the absence of objective parameters, the physician has to rely primarily on clinical judgement, carefully taking into account signs and symptoms potentially suggestive of glucocorticoid over- or under-replacement, recognizing their relative lack of specificity. Glucocorticoid under-replacement bears the risk of incipient crisis and significant impairment of well-being. Conversely, chronic overreplacement may lead to substantial morbidity including impaired glucose tolerance, obesity, and osteoporosis. An increased incidence of osteoporosis has only been reported in patients receiving daily replacement doses of 30 mg hydrocortisone or higher [60–62] or 7.5 mg prednisone [60] whereas appropriate replacement doses of 15–25 mg hydrocortisone do not affect bone mineral density [59, 63]. Therefore, bone mineral density measurements are not routinely required in patients with adrenal insufficiency receiving recommended glucocorticoid replacement doses.

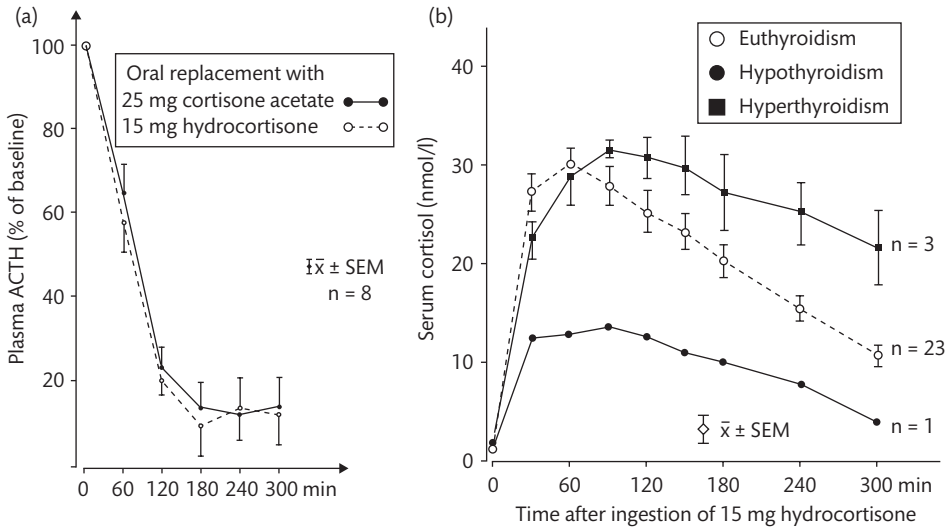

Figure 5.8.2.6 (a) Plasma ACTH concentrations before and after administration of the hydrocortisone morning dose in patients with primary adrenal insufficiency (n = 8). (b) Serum cortisol and thyroid function. Serum cortisol concentrations after administration of 15 mg hydrocortisone orally in 27 patients with primary adrenal insufficiency. Patients with concurrent overt hypothyroidism (n = 3) or hyperthyroidism (n = 1) differ from euthyroid patients (n = 23), which has to be considered when choosing appropriate glucocorticoid replacement doses.

Mineralocorticoid Replacement

Patients with primary adrenal insufficiency require mineralocorticoid replacement, which usually consists of the oral administration of 9α-fludrocortisone; fluorination at the 9α position ensures selective binding to the MR and thus exclusive mineralocorticoid action. By contrast, cortisol binds with equal affinity to both the GR and MR. However, excessive MR binding of cortisol in the kidney is prevented by 11β-hydroxysteroid dehydrogenase type 2, which inactivates cortisol to cortisone. Oelkers has coined the term 'mineralocorticoid unit' (MCU), determining that 100 MCU are equivalent to 100 µg fludrocortisone and 40 mg hydrocortisone, respectively [64]. By contrast, prednisolone exerts only reduced mineralocorticoid activity and dexamethasone none at all; therefore, patients treated with synthetic glucocorticoids need particularly careful monitoring of their mineralocorticoid replacement requirements.

In the newly diagnosed patient, mineralocorticoid replacement should be initiated at 100 µg once daily; optimized doses may vary between 50 and 250 µg. Children, in particular neonates and infants, have considerably higher mineralocorticoid dose requirements and often need additional salt supplementation. However, also among adults there is a good degree of interindividual variability. A high dietary salt intake may slightly reduce mineralocorticoid requirements. An important additional factor is temperature and humidity (e.g. individuals living in Mediterranean summer or tropical climates will require a 50% increase in fludrocortisone dose due to increased salt loss through perspiration). Monitoring (Table 5.8.2.4) includes supine and erect blood pressure and serum sodium and potassium; plasma renin activity should be checked regularly, aiming at the upper normal range [64]. If essential hypertension develops, mineralocorticoid dose may be slightly reduced, accompanied by monitoring of serum sodium and potassium, but complete cessation of mineralocorticoid replacement should be avoided. It is important to recognize that plasma renin physiologically increases during pregnancy; therefore, monitoring in pregnancy should not rely on renin measurement, but comprise blood pressure, serum sodium and potassium, and, if required, urinary sodium excretion. During the last term of pregnancy fludrocortisone dose may require adjustment, also due to increased progesterone levels exerting antimineralocorticoid activity [65].

Prevention of Adrenal Crisis

Risk of adrenal crisis is higher in primary adrenal insufficiency and several factors such as coincident APS or age have been suggested as additional modifiers [2, 66]. Many crises are due to glucocorticoid dose reduction or lack of stress-related glucocorticoid dose adjustment by patients or general practitioners [3]. A survey in 526 patients found that 42% of patients (47% in primary adrenal insufficiency, 35% in secondary adrenal insufficiency) had experienced at least one adrenal crisis during the course of their disease. Precipitating causes were mainly gastrointestinal infections and fever but also several other causes, including major pain, surgery, psychological distress, heat, and pregnancy. This was corroborated by data from a large patient survey (n = 841) [67] that also highlighted gastrointestinal infections as the single most important cause of crisis. Importantly, a prospective study in 423 patients with primary and secondary adrenal insufficiency, respectively, showed a high incidence of adrenal crises, occurring at a rate of 8.3 crises and 0.5 deaths per 100 patient-years [68]. Thus, adrenal crisis is a predictable and frequent, but still undermanaged event that regularly leads to loss of life [69]. Crisis prevention and better education of patients and healthcare professionals is a key strategy that needs to be pursued to avoid morbidity and mortality. Currently, prompt initiation of glucocorticoid therapy is delayed in nearly half of adrenal insufficiency experiencing an adrenal crisis [70].

All patients and their partners should receive regular crisis prevention training, including verification of steroid emergency card/

bracelet and instruction on stress-related glucocorticoid dose adjustment (Table 5.8.2.4). Generally, hydrocortisone should be doubled during intercurrent illness, such as a respiratory infection with fever, until clinical recovery. Gastrointestinal infections, a frequent cause of crisis, may require parenteral hydrocortisone administration,. Preferably all patients, but at least patients travelling or living in areas with limited access to acute medical care should receive a hydrocortisone emergency self-injection kit (e.g. 100 mg for IM injection). In case of serious illness and trauma, major surgery, or if intensive care unit treatment is required, patients should receive major stress dose cover with an immediate bolus injection of 100 mg hydrocortisone, followed by 200 mg hydrocortisone per 24 h via perfuser; if IV access is lost, patients should receive 50 mg hydrocortisone per intramuscular injection immediately and every 6 hours until IV access is re-established [37, 71]. This recommendation is based on recently published experimental evidence [72] that has clarified the exact dose requirements for the prevention of adrenal crisis for the first time since the seminal observation that glucocorticoid replacement needs to be increased during periods of major stress to avoid adrenal crisis and death [73]. Recent work has also highlighted the feasibility of subcutaneous hydrocortisone emergency injections [74], albeit pharmacokinetic data were obtained in unstressed adrenal insufficiency patients, while in impending shock subcutaneous might be hypoperfused, possibly preventing good uptake of hydrocortisone; however, subcutaneous self-administration would certainly be better than no self-administration of hydrocortisone at all. The development of a 'Corti-Pen' (as an Epi-Pen equivalent for adrenal insufficiency) or similar easy-to-use devices or delivery modes for hydrocortisone self-administration would certainly be game changing, but are still awaited.

DHEA Replacement

The introduction of DHEA, the third major steroid produced by the adrenal gland, into the replacement regimen for adrenal insufficiency [75] represents a major advance, in particular for women who are invariably androgen deficient [75, 76]. DHEA has been shown to significantly enhance well-being, mood, and subjective health status in women with primary and secondary adrenal insufficiency [75, 77–80] and also recently in children and adolescents with adrenal failure [81]. Similar effects have been described for testosterone replacement in hypopituitarism [82], however, no study has yet directly compared DHEA to testosterone. In addition to acting as an androgen precursor, DHEA has neurosteroidal properties, exerting a primarily antidepressive effect, and also shows immunomodulatory properties [83]. Of note, DHEA has been shown to exert beneficial effects on subjective health status and energy levels not only in women but also in men with primary adrenal insufficiency [78, 79] including significant beneficial effects on bone mineral density and truncal lean mass [78].

Currently, DHEA replacement is hampered by the lack of pharmaceutically controlled preparations, with questionable quality and content of several over-the-counter preparations [84]. At present, DHEA should be reserved for patients with adrenal insufficiency suffering from significant impairment in well-being despite otherwise optimized replacement, in particular women with signs of androgen deficiency such as dry and itchy skin and loss of libido. DHEA should be taken as a single dose (25–50 mg) in the morning. Treatment monitoring (Table 5.8.2.4) should include blood sampling 24 h after the last preceding morning dose for measurement of serum DHEAS (in women also androstenedione, testosterone, sex hormone-binding hormone) aiming at the middle normal range for healthy young subjects. I usually start patients on 25 mg and increase to 50 mg after 2 to 4 weeks, advising them to halve the dose if androgenic skin side effects (greasy skin, spots) persist for more than a week. Transdermal testosterone represents an alternative androgen replacement tool in women with adrenal failure.

Special Therapeutic Situations Impacting on Corticosteroid Replacement

Thyroid Dysfunction

Hyperthyroidism results in increased cortisol metabolism and clearance and hypothyroidism the converse, principally due to an effect of thyroid hormone upon hepatic 11β-HSD1 and 5α/5β-reductases. Insulin-like growth factor 1 (IGF-1) increases cortisol clearance by inhibiting hepatic HSD11B1 (conversion of cortisone to cortisol). In patients with adrenal insufficiency and unresolved hyperthyroidism, glucocorticoid replacement should be doubled to tripled. To avoid adrenal crisis, thyroxine replacement for hypothyroidism should only be initiated after concomitant glucocorticoid deficiency has either been excluded or treated. Obviously overt endogenous hyperthyroidism will also increase hydrocortisone metabolism (Figure 5.8.2.6b). Therefore, the initiation of glucocorticoid replacement in patients with newly diagnosed hypopituitarism should always precede the initiation of thyroxine replacement as the reverse might precipitate adrenal crisis.

Pregnancy

Pregnancy is physiologically associated with a gradual increase in CBG and during the last term of pregnancy also with an increase in free cortisol. In addition, serum progesterone increases, exerting antimineralocorticoid action. Therefore, during the third trimester, hydrocortisone replacement should be increased by 50%. Plasma renin activity cannot serve as a monitoring tool because it physiologically increases during pregnancy. Peripartal hydrocortisone replacement should follow the requirements for major surgery, with 100 mg hydrocortisone per bolus injection at the onset of active labour, followed by administration of 200 mg hydrocortisone per 24 h [37]. After delivery, the dose can be immediately tapered back to normal replacement doses, unless there are clinical complications.

Concomitant Drug Therapy and Interactions

When deciding on the glucocorticoid dose, it is important to consider concurrent medication, in particular drugs known to increase hepatic glucocorticoid metabolism by CYP3A4 induction, which results in increased 6β-hydroxylation and hence cortisol inactivation [3, 4]. 6β-hydroxylation by CYP3A4 is normally a minor pathway but cortisol itself induces CYP3A4 so that 6β-hydroxycortisol excretion is markedly increased in patients with Cushing's syndrome. A multitude of drugs are known to induce CYP3A4 (Table 5.8.2.1), which require a two- to threefold increase in glucocorticoid dose. Conversely, the intake of drugs inhibiting CYP3A4 would require reduction of glucocorticoid replacement dose.

Of note, treatment of tuberculosis with rifampicin increases cortisol clearance but does not influence aldosterone clearance. Thus, glucocorticoid replacement should be doubled during rifampicin treatment. Mitotane (o,p′DDD, *ortho, para′*, dichlorodiphenyldichloroethane) decreases bioavailable glucocorticoid levels due to an increase in CBG and concurrently enhanced glucocorticoid metabolism following induction of CYP3A4. During chronic mitotane treatment, e.g. in adrenal carcinoma [85], usual glucocorticoid replacement doses should therefore be at least tripled.

Quality of Life, Disablement, and Prognosis in Adrenal Insufficiency

Studies demonstrate that current standard corticosteroid replacement fails to restore quality of life, which is significantly impaired in both patients with primary and secondary adrenal insufficiency [42, 86], with no apparent difference between prednisolone and hydrocortisone-treated patients [87]. Predominant complaints are fatigue, lack of energy, depression, anxiety, and reduced ability to cope with daily demands; the degree of impairment is comparable to that observed in congestive heart failure and chronic haemodialysis patients [42, 86]. Subjective health status is most reduced in younger patients but all age groups are significantly impaired [86], a persistent finding even if only analysing patients without any comorbidity [86]. This also has a socioeconomic perspective as patients with Addison's disease have a two- to threefold higher likelihood of receiving disablement pensions [42, 86].

In addition, large cohort studies have demonstrated an increased mortality not only in patients with secondary adrenal insufficiency due to hypopituitarism [88] but also in primary adrenal insufficiency, i.e. Addison's disease [89, 90], a finding still valid when the influence of comorbidities is excluded. The causes underlying this increased mortality remain unclear. However, a recent study demonstrated that patients on conventional, immediate release hydrocortisone replacement have considerably impaired natural killer cell function [91], an immune cell critically involved in protection from respiratory infections. Another study [92, 93] indicated that natural killer cell numbers increase after switching adrenal insufficiency patients from conventional to modified-release hydrocortisone. We certainly need to consider the possible impact of current replacement regimens on the observed increase in mortality from cardiovascular and cerebrovascular disease and respiratory infections.

Conclusions

More than 150 years after Thomas Addison first described a disease characterized by salt wasting and hyperpigmentation as the result of adrenal gland destruction [1], adrenal insufficiency is no longer an invariably fatal condition. The landmark achievement of the synthesis of cortisone in the late 1940s and its introduction into therapy in the early 1950s quickly lead to widespread availability of life-saving glucocorticoid replacement therapy. However, while initial survival is routinely achieved nowadays, current replacement regimens may not be able to achieve normal quality of life and the reliable prevention of adrenal crisis as a cause for the observed increased mortality is an important issue. Future research has to uncover the causes underlying the increased mortality in adrenal insufficiency and should further establish the role of novel glucocorticoid replacement modalities to more reliably mimic physiological diurnal cortisol delivery.

Congenital Adrenal Hyperplasia

5.9.1 Genetics of Congenital Adrenal Hyperplasia

Nils P. Krone

Introduction

Congenital Adrenal Hyperplasia (CAH) represents a group of autosomal recessive conditions caused by the deficiency of one of the steroidogenic enzymes involved in cortisol biosynthesis or in the electron donor enzyme P450 oxidoreductase (POR) [1]. Steroidogenic enzymes belong to two major groups: cytochrome P450 (CYP) enzymes and hydroxysteroid dehydrogenases (HSD). CYP enzymes are subdivided in type I and type II enzymes. Steroidogenic CYP type I enzymes include P450 side-chain cleavage (CYP11A1) and 11β-hydroxylase (CYP11B1) enzymes. They are localized to the mitochondrion where they receive electrons from reduced nicotinamide dinucleotide phosphate (NADPH) via ferredoxin reductase and ferredoxin. Microsomal CYP type II enzymes include 21-hydroxylase (CYP21A2) and 17α-hydroxylase (CYP17A1) enzymes. These enzymes are localized to the endoplasmic reticulum and receive electrons from POR [1, 2] (**Figure 5.9.1.1**).

Commonly, three additional conditions are categorized as CAH. Inactivating mutations in the mitochondrial cholesterol transporter steroidogenic acute regulatory protein (StAR) cause congenital lipoid adrenal hyperplasia (CLAH) compromising all three steroidogenic pathways. CLAH is clinically indistinguishable from deficiency of CYP11A1 that catalyses the first step in steroidogenesis, the generation of pregnenolone from cortisol [1, 2]. Aldosterone synthase (CYP11B2) is a mitochondrial CYP enzyme facilitating aldosterone biosynthesis. CYP11B2 deficiency is associated with isolated aldosterone deficiency [3].

All genes causing CAH are well characterized and mutation analysis is widely available (**Table 5.9.1.1**). An overall strong genotype-phenotype correlation exists in these conditions. Molecular genetic diagnosis confirms the clinical and biochemical diagnosis and provides important information for clinical and genetic counselling.

21-Hydroxylase (CYP21A2) Deficiency

The most common cause of CAH is 21-hydroxylase deficiency (21OHD, MIM +201910), accounting for 90–95% of cases. 21OHD is caused by inactivating mutations in the 21-hydroxylase gene (*CYP21A2*, GeneID 1589) leading to impaired conversion of progesterone to 11-deoxycorticosterone and 17-hydroxyprogesterone (17OHP) to 11-deoxycortisol. Commonly, 21OHD is classified into severe classic CAH and the milder non-classic (NC) form. Classic CAH is clinically subdivided into simple virilizing (SV) and salt-wasting (SW) 21OHD, which both lead to glucocorticoid deficiency. SVCAH is characterized by hyperandrogenism resulting in 46,XX DSD and precocious pseudopuberty in both sexes. This is also observed in SWCAH, but affected patients present with additional severe renal salt loss due to impaired aldosterone synthesis, which leads to life-threatening salt-wasting crisis during the first weeks of life. NCCAH manifests later in life with precocious pseudopuberty due to androgen excess, or with clinical features resembling polycystic ovary syndrome comprising hirsutism, oligomenorrhea and anovulation [4]. In some cases, individuals with NCCAH are asymptomatic [2, 5]. Classic 21OHD affects about 1 in 9800 to 18 000 live births in most Caucasian populations [6]. However, the incidence varies depending on ethnicity and geographical area, with the highest frequency detected in isolated populations such as Yupik Eskimos (1 in 282) and on the island of La Reunion (1 in 2100). Significant lower incidences are reported in the Japanese (1 in 21 000) and Taiwanese (1 in 28 000) population

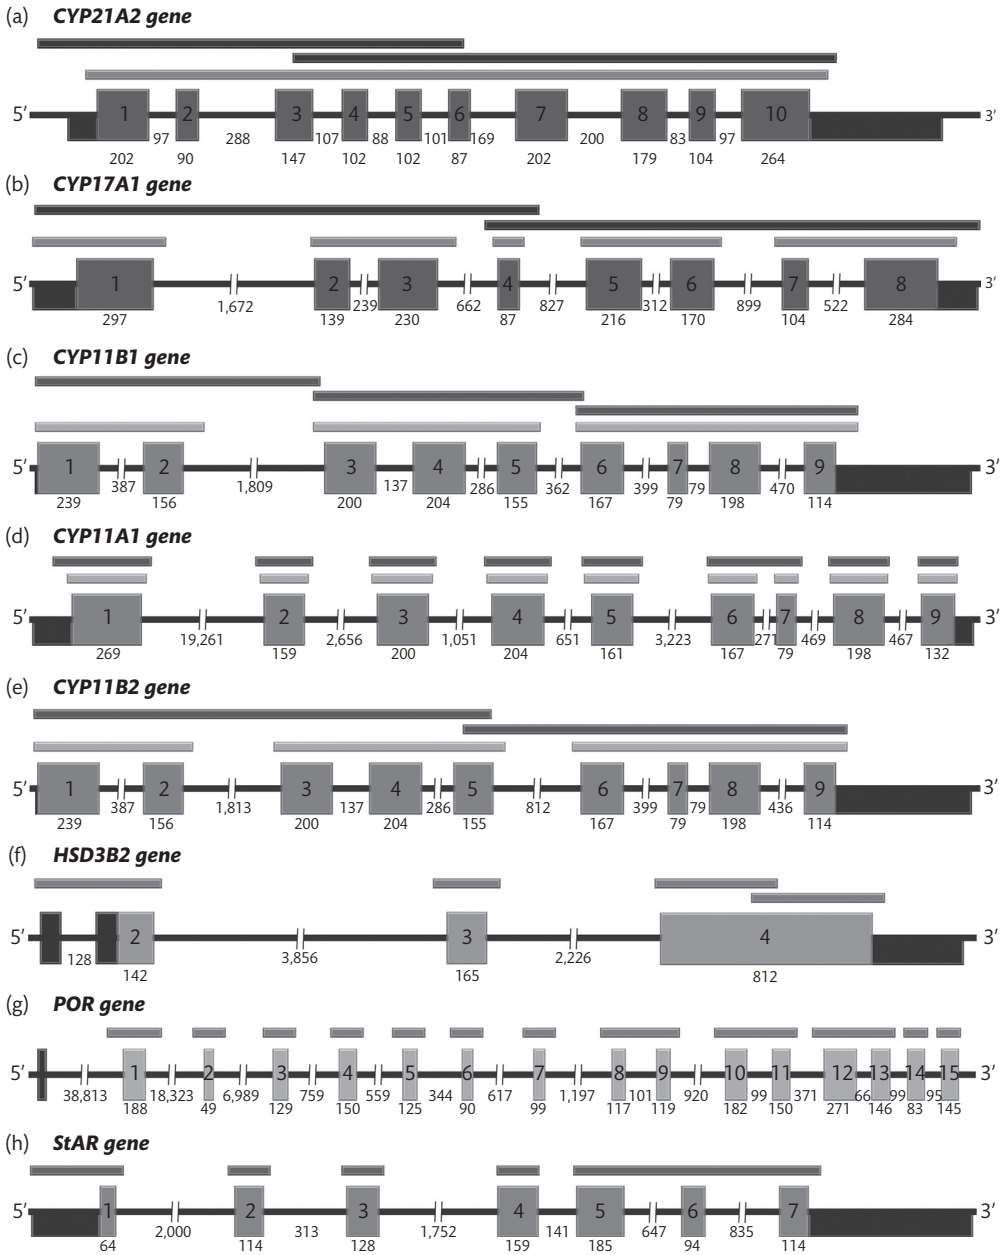

Figure 5.9.1.1 Genomic organization of genes causing different forms of congenital adrenal hyperplasia. (1) Genes encoding steroidogenic Cytochrome P450 type II enzymes: (a) The 21-hydroxylase (*CYP21A2*) gene consists of 10 exons and it is typically amplified in two overlapping fragments. (b) The 17-hydroxylase (*CYP17A1*) gene consists of 8 exons and different strategies have been employed either amplifying the gene in five or in two fragments. (2) Genes encoding steroidogenic Cytochrome P450 type I enzymes: (c) The 11-hydroxylase (*CYP11B1*) gene consists of 9 exons and is usually amplified in three overlapping fragments, although non-overlapping strategies have been described. (d) The P450 side chain cleavage (*CYP11A1*) gene consists of 9 exons and it is usually amplified in small non-overlapping fragments, although different PCR strategies have been described. (e) The aldosterone synthase (*CYP11B2*) gene consists of 9 exons normally amplified in either two overlapping fragments or three non-overlapping fragments. (3) Genes encoding hydroxysteroid dehydrogenases: (f) The hydroxysteroid dehydrogenase type 2 (*HSD3B2*) gene has 4 exons; exon 1 and the 5-prime part of exon 2 are not translated. (4) Gene encoding the electron donor of steroidogenic cytochrome P450 type II: (g) The P450 oxidoreductase (*POR*) gene has 15 translated exons and an untranslated exon (1U). PCR amplification is performed in several small fragments. (5) Gene encoding for a cholesterol transporter: (h) The steroid acute regulatory protein (*StAR*) gene consists of 7 exons commonly amplified in five fragments.

and in African Americans (1 in 42 000) [6]. NCCAH occurs with an estimated prevalence of about 1 in 200 to 1 in 1000 in Caucasian populations [7–10]. However, the incidence of NCCAH varies depending on ethnicity and geographical area ranging from 1 in 27 of Ashkenazi Jews and 1 in 50 to 1 in 100 of Hispanics and Yugoslavs (Table 5.9.1.2).

21-Hydroxylase Gene and Gene Locus

The *CYP21A2* gene encodes for the microsomal enzyme 21-hydroxylase of 495 amino acids. *CYP21A2* is localized in the HLA III region on the short arm of chromosome 6 (6p21.3), approximately 30-kilobases apart from its non-functional *CYP21A1P* pseudogene. The *CYP21A2* and *CYP21A1P* genes share a high nucleotide

homology, of about 98% and 96% at exon and intron level, and consist of 10 exons [6]. Both genes are arranged in tandem repeat with the *C4A* and *C4B* genes encoding the fourth complement factor. The *C4/CYP21A2* unit is flanked by the *RP1* (*STK19*) gene on the telomeric side and by the *TNXB* gene on the centromeric side, and their truncated pseudogenes, *RP2* and *TNXA*, forming the RCCX module (*RP-C4-CYP21-TNX*). The highly variable RCCX module spans about 30 kb. Most chromosomes harbour two copies of the modules with a *CYP21A1P* pseudogene in the telomeric module and a *CYP21A2* gene in the centromeric module. However, monomodular, trimodular, or even quadrimodular haplotypes have been described [11] (Figure 5.9.1.2). The reverse DNA strand from the *C4* and *CYP21A* genes encodes for the *TNXA* and *TNXB* genes with opposite transcriptional orientation. *TNXB* is a very large gene consisting of 43 exons and spans 68.2 kb of DNA encoding the extracellular matrix protein, tenascin (TNX). The *TNXA* pseudogene was truncated during the duplication of the ancestral RCCX module. The last exon of *TNXA* and *TNXB* is located in the 3-prime untranslated region of exon 10 of *CYP21A1P* and *CYP21A2*, respectively [11, 12].

Mutations Causing 21-Hydroxylase Deficiency

The majority of mutations causing 21OHD are the consequence of intergenic recombination within the RCCX module. The high recombination rate in the HLA III region along with the nucleotide identity shared across the RCCX locus promote unequal crossing-over and

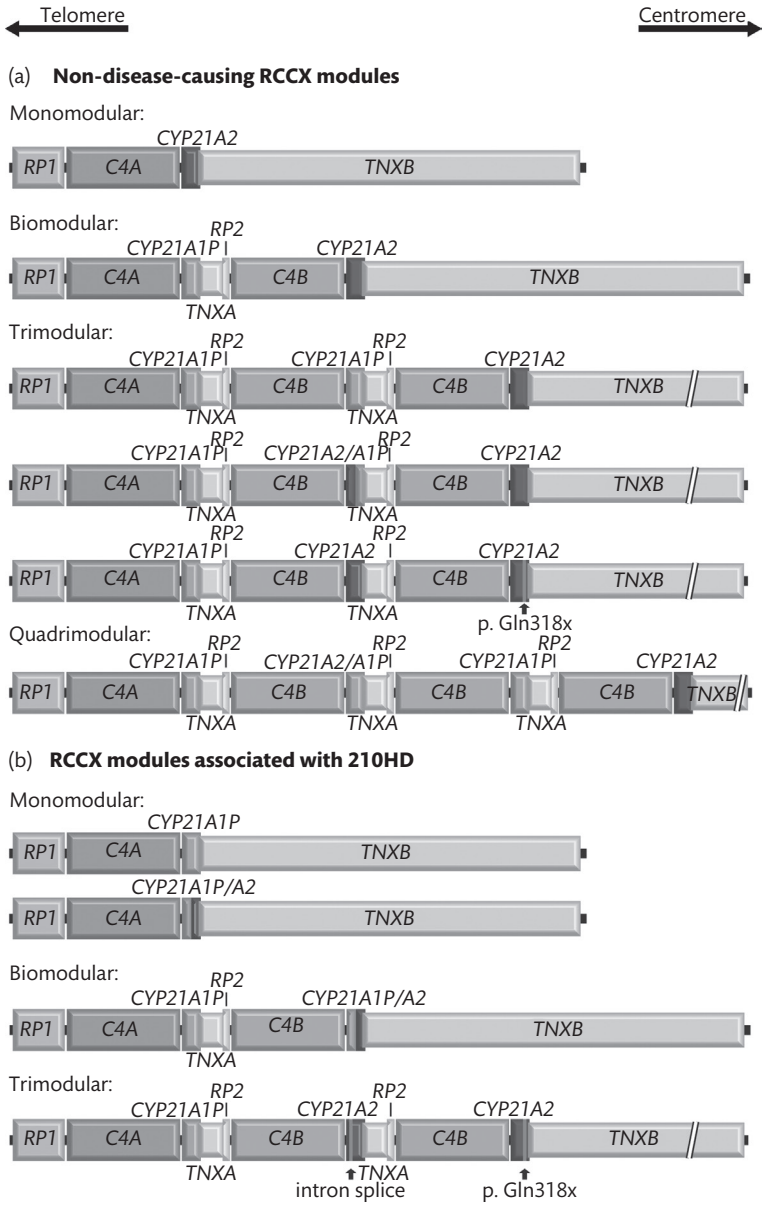

Figure 5.9.1.2 Organization of the RCCX module at chromosome 6p21. Representative Copy Number Variants at the RCCX locus (a) non-disease variants; (b) Configurations associated with 21-hydroxylase deficiency. *C4A* and *C4B*: complement component C4A and C4B genes; *CYP21A1P*: steroid 21-hydroxylase pseudogene; *CYP21A2:* steroid 21-hydroxylase gene; *TNXB:* tenascin-X gene. *TNXA*: tenascin-X pseudogene; *RP1*: serine/threonine kinase 19 gene (other names: *STK19*); *RP2*: serine/threonine kinase 19 pseudogene (other names: *STK19P*); intron splice, I2G, c.293-13A/C>G.

gene conversions between *CYP21A2* and its pseudogene. Unequal crossing overs with break points outside the *CYP21A* locus cause deletions of the *CYP21A2* gene. Chromosomes lacking the *CYP21A2* gene frequently carry a *TNXB/TNXA* chimeric gene. Misalignment of chromosomes carrying different RCCX copy numbers promote unequal crossing overs within the *CYP21A* locus leading to the formation of *CYP21A1P/CYP21A2* chimeric genes, which have in the past been regarded as large gene conversions. Deletions and chimeric genes account for approximately 20–25% of mutant alleles in 21OHD [6]. *CYP21A2* gene duplications are relatively frequent in some populations [8, 13]. The majority of these alleles carrying a *CYP21A2* gene duplication have a p.Gln318X mutation in the duplicated *CYP21A2* gene next to the *TNXB* gene, and a wild-type *CYP21A2* gene next to the *TNXA* pseudogene [8] (Figure 5.9.1.2a). Such alleles are non-disease-causing.

Approximately 75% of *CYP21A2* disease-causing mutations, including seven point mutations, a deletion of 8 base pairs in exon 3 and a cluster of three point mutations in exon 6 originate from the transfer of genetic material from the *CYP21A1P* pseudogene to the *CYP21A2* gene [6, 11] (Figure 5.9.1.3b). In addition, over 200 pseudogene-independent mutations are listed in the Human Gene Mutation Database (HGMD, http://www.hgmd.cf.ac.uk; August 2018) and the Pharmacogene Variation Consortium (https://www.pharmvar.org/gene/CYP21A2). Most of these rare mutations are sporadic. However, due to founder effects increased frequencies of some pseudogene-independent mutations are observed in some populations [11].

Pseudogene-derived mutations occur with similar frequencies in most populations (Table 5.9.1.2) [11]. Deletions and chimeric genes along with the splice site mutation in intron 2 (c.293-13A/C>G) and p.Ile172Asn are the most common mutations in most Caucasian populations [1, 14–19]. The p.Val281Leu is by far the most common mutation detected in NCCAH patients [6, 11]. Novel or rare mutations account for about 3–5% of detected mutations in large cohorts. The vast majority of these rare mutations has been identified in single families or small populations. Approximately 1–2% of *CYP21A2*-inactivating mutations arise *de novo* [6, 17]. If possible, carrier testing should be performed in the parents to confirm compound heterozygosity or homozygosity in the index case and estimate the reoccurrence risk.

Genotype-Phenotype Correlation in 21-Hydroxylase Deficiency

Mutation groups have been established based on the basis of the residual 21-hydroxylase activity of the mutant proteins as observed *in vitro* (Figure 5.9.1.3c). CYP21A2 deficiency is an autosomal recessive condition. About 65–75% of the CAH patients are compound heterozygous (e.g. they are affected), but carry different mutations on each chromosome. The clinical phenotype of CAH correlates well with the less severely mutated allele, and consequently with the allele encoding for the higher residual *in vitro* activity of 21-hydroxylase. This has major implications for genetic counselling in patients with NCCAH. If a patient with NCCAH is compound heterozygous for a mild and a severe mutation, the risk of having a child with classic CAH increases significantly to about 1 in 400 ($1/50 \times 1/2 \times 1/4$), assuming a heterozygous rate of 1/50 for classic mutations in the general population. The correlation with glucocorticoid and mineralocorticoid deficiency is strong (Figure 5.9.1.3c). However, divergence between genotype and phenotype occurs in some cases. Although a trend exists, the correlation between the genotype and degree of 46,XX DSD classified assessed by Prader genital stage is less pronounced (Figure 5.9.1.3c). This implies the importance of factors modifying clinical androgen effects. Several potential modifiers have been studied. However, no analysed candidate has sufficiently explained the phenotypic variability in 21OHD. Long-term health outcomes in adults do not necessarily show a good correlation with the genotype [20]. However, girls and women with CAH with more severe genotypes appear to have an increased risk for psychiatric disorders [21].

CYP21A2 gene deletions extending into *TNXB* lead to a contiguous gene syndrome consisting of CAH and Ehlers–Danlos syndrome, which is rarely observed in patients with severe SWCAH. Up to 10% of patients with SWCAH show haploinsufficiency of *TNX* and heterozygosity for *TNXB* mutations. This extended phenotype has been termed as CAH-X syndrome. CAH-X is associated with joint hypermobility, chronic arthralgia, joint subluxations, hernias, and cardiac defects [12]. Further investigations in patients with CAH-X should be considered.

Novel insights into the underlying molecular pathology have been gained by the analysis of the CYP21A2 protein crystal structure. Null and A mutations commonly disrupt haeme- and/or substrate-binding domains, the anchoring of the protein to the membrane, or impair protein stability. Mutations categorized as group B partially impair membrane anchoring or affect conserved hydrophobic clusters within the protein. Milder mutation (group C) results in less severe alterations, often interfering with electron transfer from POR, salt-bridge and hydrogen-bonding networks, and non-conserved hydrophobic clusters [22].

Molecular Genetic Testing for *CYP21A2* Gene Mutations

Southern blot analysis has been the gold standard for the detection of *CYP21A2* gene deletions and *CYP21A1P*/*CYP21A2* chimeric genes. However, Southern Blot analysis requires relatively large amounts of high-quality DNA, is labour intensive and time consuming. In addition, *CYP21A1P* duplications and certain rare rearrangements at this locus may impede the detection of *CYP21A2* gene deletions or duplications [6, 11]. Several approaches for gene dosage detection have been developed to overcome the disadvantages of Southern Blot analysis [6]. The most widely used approach in current practice is multiplex ligation-dependent probe amplification (MLPA). MPLA requires only small amounts of DNA for detection of gene deletions, rearrangements and fusion genes [13, 23–25].

The design of *CYP21A2*-specific primers for PCR-based amplification of *CYP21A* is crucial to avoid amplification of the pseudogene and allele dropout by non-amplifying PCR fragments. This is challenging due to the high number of polymorphisms found across *CYP21A2* and the high homology with its pseudogene. A variety of targeted molecular genetic strategies for detecting mutations have been published. Direct sequencing of the amplified PCR products combined with a method for the detection of gene deletions and chimeric genes are the only available strategies that allow for the detection of 100% of *CYP21A2* mutated alleles and due to decreasing costs represents the method of choice in most routine laboratories.

Figure 5.9.1.3 *CYP21A2* gene locus, most common *CYP21A2* gene mutations and genotype-phenotype correlation. (a) Organization of the functional *CYP21A2* gene and its non-functional *CYP21A1P* pseudogene in the RCCX module Grey arrows indicate for the approximate position of MLPA probes. (b) Nine out of 10 common mutations are transferred by microconversions from the *CYP21A1P* gene into *CYP21A2*. Grey arrows show the five MLPA probes specific for the *CYP21A2* gene and the three probes specific for the *CYP21A1P* pseudogene. (c) Genotype-phenotype correlations in CAH due to 21-hydroxylase deficiency based on *in vitro* CYP21A2 activity. Mutation groups Null and A are associated with the salt-wasting (SW) form of 21-hydroxylase deficiency (21OHD), group B with the simple virilizing (SV) form, and group C with the non-classic (NC) form. Positive predictive values are calculated from the cited publications. The variability in the degree of virilization of the female external genitalia in the different mutation groups (grading according to Prader genital stages) is shown in the lower panel. Modal values are provided in brackets where possible. E6 cluster refers to the p.Ile236Asn, p.Val237Glu and p.Met239Leu mutation cluster at exon 6; intron splice refers to the c.293-13A/C>G mutation (other names: i2G, I2G, IVS2-13A/C>G): Δ8bp refers to the p.Gly110Val*fs*X21 mutation.

11β-Hydroxylase (CYP11B1) Deficiency

Approximately 5% of CAH cases are caused by 11β-hydroxylase (CYP11B1) deficiency (11OHD, OMIM + 202010) leading to impaired cortisol biosynthesis. Accumulation of the mineralocorticoid precursor 11-deoxycorticosterone leads to transactivation of the mineralocorticoid receptor resulting in arterial hypertension. Excess steroid hormone precursors are shunted into androgen synthesis and cause hyperandrogenism. Classic 11OHD occurs 1 in 100 000 to 1 in 200 000 live births.

A higher incidence has been reported in Israel (1 in 30 000 to 1 in 40 000 live births), in particular in Israeli Jews of Moroccan origin (1 in 5000 to 1 in 7000 live births) [26, 27]. The clinical presentation of classic 11OHD includes glucocorticoid deficiency, severe virilization of external genitalia in 46,XX neonates, precocious pseudopuberty in both sexes, and, in two-thirds of patients, hypertension [26, 27]. Non-classic 11OHD (NC11OHD) is much rarer than NC21OHD, but appears to be more frequent than previously thought [28] (Table 5.9.1.1). Patients with NC11OHD present with signs and symptoms of androgen excess during childhood [27, 28].

Mutations in the 11β-hydroxylase gene (*CYP11B1*; GeneID: 1584, GenbankID NC_000008.9) are the underlying cause of 11OHD [29]. *CYP11B1* is localized on chromosome 8q21, approximately 40 kb apart from the highly homologous aldosterone synthase gene (*CYP11B2*) [26]. The *CYP11B1* gene consists of nine exons (Figure 5.9.1.1) and encodes for a protein of 503 amino acids. CYP11B1-inactivating mutations are distributed over the entire coding region consisting of 9 exons. A cluster is reported in exons 2, 6, 7, and 8, but real hot spots do not exist. A broad variety of mutations have been reported to cause either classic or non-classic 11OHD. Most molecular analysis approaches amplify the *CYP11B1* gene in 3 fragments avoiding amplification of the highly homologous *CYP11B2* gene (Figure 5.9.1.1). Since no hotspots exist in the general population, direct DNA sequencing is the most suitable approach for molecular genetic analysis. Large rearrangements, such as large gene deletions and chimeric genes can be detected by Southern Blot analysis or MLPA [6, 26].

17α-Hydroxylase (CYP17A1) Deficiency

Steroid 17α-hydroxylase (CYP17A1) deficiency (17OHD, OMIM #202110) accounts for about 1% of all CAH cases. CYP17A1 facilitates two distinct enzymatic reactions, 17α-hydroxylase and 17,20-lyase, relying on electron transfer facilitated by the enzyme P450 oxidoreductase (POR) for its catalytic activity. Cytochrome b_5 (CYB5A) is required as an additional allosteric factor for an efficient 17,20-lyase reaction [1]. 17OHD results in both cortisol and sex steroid deficiency. In addition, the mineralocorticoid precursors DOC and corticosterone accumulate. The accumulation of the weak glucocorticoid corticosterone prevents adrenal crisis in the majority of 17OHD patients. Increased DOC concentrations lead to severe hypokalaemic hypertension. Deficient sex steroid synthesis results in male undervirlization (46,XY DSD) and in primary amenorrhea in 46,XX individuals. Absent pubertal development is observed in both sexes, with biochemical signs of hypergonadotropic hypogonadism [30] (Table 5.9.1.1). Isolated 17,20-lyase deficiency is a rare variant with largely preserved 17α-hydroxylase activity. This variant manifests with impaired sex steroid biosynthesis only, but neither with evidence of mineralocorticoid excess nor glucocorticoid deficiency [6, 30]. The *CYP17A1* gene (GeneID 1586; GenbankID NC_000010.9) is located on chromosome 10 (10q24.3) and consists of 8 exons (Figure 5.9.1.1) encoding a 508 amino acid protein. Over 70 *CYP17A1*-inactivating mutations exist. There is no mutational a hot spot in most large populations. Therefore, sequencing of the entire coding region is commonly necessary for molecular genetic diagnosis. Exceptions have been described (i.e. in Brazil) where the p.Met1Thr and p.Tyr329X mutations account for 82% of mutant alleles, in Canadian Mennonites and Dutch Frieslanders, as well as in Japan and in East Asia [1, 6, 30]. Mutations causing isolated 17,20-lyase deficiency result in amino acid substitutions located within the area of the CYP17A1 molecule interacting with the cofactor cytochrome b_5 [6, 30]. However, urine steroid metabolome analysis from patients carrying such CYP17A1 mutations provided evidence for impaired 17α-hydroxylation, which means that this condition does not represent true but apparent isolated 17,20 lyase deficiency. Apparently isolated 17,20-lyase deficiency might be mimicked by POR deficiency due to mutations in the *POR* gene [6] while mutations in CYB5A represent true 17,20 lyase deficiency [31].

3β-Hydroxysteroid Dehydrogenase Type 2 (HSD3B2) Deficiency

Two 3β-hydroxysteroid dehydrogenase isoforms, type 1 (HSD3B1) and type 2 (HSD3B2), exist. HSD3B2 is mainly expressed in adrenals and gonads while HSD3B1 is expressed in the placenta and peripheral tissues [32]. HSD3B2 deficiency (OMIM +201810) is a rare cause of CAH.

HSD3B2 is a nicotinamide adenine dinucleotide (NAD^+)-dependent enzyme anchored to the membrane of the endoplasmic reticulum and mitochondria. HSD3B2 catalyses the conversion of Δ5 to Δ4 steroids and HSD3B2 deficiency affects all three steroidogenic pathways (mineralocorticoids, glucocorticoids, and androgens). A broad phenotypic spectrum has been reported. Classic HSD3B2 deficiency presents with either salt-wasting or non-salt-wasting. Affected males show a variable impairment of gonadal steroidogenesis leading to different degrees of 46,XY DSD. Affected 46,XX individuals manifest only with adrenal symptoms and normal or mildly virilized external genitalia. Isolated premature pubarche and primary hypogonadism has been reported in infants and children of both sexes. A non-classic variant has also been described, manifesting with hirsutism and menstrual irregularities [32–34] (Table 5.9.1.1). The 3β-hydroxysteroid dehydrogenase type 1 and 2 isoforms, are encoded by the *HSD3B1* and *HSD3B2* genes, respectively. Mutations in the *HSD3B2* (GeneID 3284, GenbankID NC_000001.9) gene cause 3β-hydroxysteroid dehydrogenase deficiency. *HSD3B2* is located on chromosome 1p13.1, in close proximity to the highly homologous *HSD3B1* gene. It consists of one untranslated and 3 translated exons. Mutation analysis is performed by PCR amplification of *HSD3B2* of exons 2 to 4 covering intron-exon boundaries followed by direct DNA sequencing of the PCR products (Figure 5.9.1.1). Over 40 mutations have been reported so far, which are distributed over the entire genomic region. An overall good genotype-phenotype correlation has been described for the salt-loss phenotype, with completely inactivating mutations associated with the salt-wasting form and partly inactivating mutations allowing for some residual aldosterone synthesis. A poor correlation with gonadal steroidogenesis has been observed [32].

P450 Oxidoreductase (POR) Deficiency

P450 oxidoreductase (POR; OMIM *124015) deficiency (PORD; OMIM #201750) presents biochemically and clinically as apparent combined CYP17A1-CYP21A2 deficiency and with a malformation phenotype resembling the Antley–Bixler syndrome (ABS, OMIM #207410) [35, 36]. The incidence of PORD remains unclear, but it is likely the third most common CAH variant, after 21OHD and 11OHD. POR serves as an electron donor enzyme to CYP21A2, CYP17A1, and CYP19A1 (P450 aromatase). PORD impacts on both glucocorticoid and sex steroid synthesis and can result in mineralocorticoid excess with hypertension, albeit milder than in other CAH variants and often only manifesting in adulthood. The PORD phenotype usually consists of adrenal insufficiency, DSD or normal sex development in both sexes and presentations with or without skeletal and other malformations [35]. In contrast to other hyperandrogenic CAH forms, virilization does not progress after birth. Primary hypogonadism and lack or delayed pubertal development has been reported in both sexes. PORD is a multisystem disorders as it affects all microsomal CYP enzymes relying on POR for their enzymatic function (Table 5.9.1.1). The *POR* gene (GeneID 5447; GenbankID NC_000007.12) spans 32.9 kb and located on 7q11.2. It consists of 15 translated exons encoding for a 680 amino acid protein. An untranslated exon is located approximately 30.5 kb upstream of the first translated exon (Figure 5.9.1.1). *POR* is highly polymorphic with 140 genetic variants identified in a large cohort of healthy individuals [37] and over 60 disease-causing mutations have been described. No clear mutational hot spot exists for *POR*-inactivating mutations apart from two frequently detected mutations. The p.Ala287Pro mutation accounts for approximately 50% of mutated alleles in Caucasians, whereas the p.Arg457His mutation is the most common mutation (50–70% of alleles) in the Japanese population [35, 36]. Some studies have explored the genotype-phenotype correlation in PORD [38]. The phenotypic expression of a specific genotype is variable. Carriers of two mild mutations commonly present with a milder phenotype than compound heterozygotes for a mild and a severe mutation. Generally, mutations causing 46,XY DSD present with normal female external genitalia in 46,XX individuals and variants associated with 46,XX DSD lead to normal external male genitalia in 46,XY individuals. In carriers of severe genotypes, more severe skeletal and other complex malformation can be found [39]. The variable genotype-phenotype correlation is likely to be caused by the differential impact of POR mutations on the catalytic activity of different microsomal CYP enzymes; the malformation phenotype is explained by impairment of POR-dependent CYP enzymes involved in sterol biosynthesis and retinoic acid metabolism.

Steroid Acute Regulatory Protein (stAR) Deficiency–Congenital Lipoid Adrenal Hyperplasia

StAR actively transports cholesterol into the mitochondrion, where cholesterol is converted to pregnenolone by P450 side-chain cleavage enzyme (CYP11A1). Loss of StAR-dependent cholesterol transport causes CLAH, OMIM #201710), leading to an impairment of all three steroidogenic pathways. Classic CLAH is associated with salt-wasting and adrenal failure manifesting within the first month of life, female external genitalia irrespective of karyotype, and hypergonadotropic hypogonadism in both sexes. Non-classic Lipoid CAH may manifest later in life with primary adrenal insufficiency and mild 46,XY DSD or normal male genital development [1]. In some patients, hypocortisolism is the only clinical manifestation and non-classic CLAH might be misdiagnosed as familial glucocorticoid deficiency [40, 41] (Table 5.9.1.1).

The *StAR* gene (GeneID: 6770, NC_000008.10) is localized on chromosome 8p11.23 and consists of 7 exons (Figure 5.9.1.1) encoding for a protein of 285 amino acids. The N-terminus of the protein contains a mitochondrial signal and the C-terminus is involved in the interaction with cholesterol. Over 40 StAR mutations have been reported (HGMD, August 2018), nine of which are associated with non-classic CLAH. The majority of StAR-inactivating mutations are located in exons 5 to 7 encoding for the C-terminal protein. Recurrent mutations are detected in some populations. The p.Gln258X is found in over 80% of the CLAH-causing alleles in Korean and Japanese patients [1]. The p.Arg182Leu and the c.201_202delCT mutations are the most common mutations in Palestinian patients and the p.Arg182His is most frequently found in patients of Saudi Arabian origin [1]. In classic CLAH the genotype-phenotype correlation is good, whereas non-classic CLAH presents with phenotypic variability [1].

P450 Side-Chain Cleavage Enzyme (CYP11A1) Deficiency

CYP11A1 is a mitochondrial CYP type I enzyme and catalyses the first and rate-limiting step of steroidogenesis, the generation of pregnenolone from cholesterol. CYP11A1 deficiency (OMIM *118485) is rare and similar to CLAH impairs all three steroidogenic pathways in the adrenal and gonadal sex steroid synthesis. Its presentation resembles the CLAH phenotype. Affected patients present soon after birth or later in infancy with adrenal insufficiency and normal female external genitalia in both sexes [42]. A milder form has been described, presenting with different degrees of 46,XY DSD [42] or normal male genital development [43], and in some cases isolated adrenal insufficiency. In contrast to CLAH, all patients with CYP11A1 deficiency have small or normal-sized adrenals [42] (Table 5.9.1.1).

The *CYP11A1* gene (GeneID 1583, NC_000015.9) is located on chromosome 15q24.1 and consists of 9 exons (Figure 5.9.1.1). An overall good correlation of the genotype and onset and severity of adrenal phenotype has been reported. Severe mutations are invariably associated with female external genitalia irrespective of chromosomal sex. Current data suggest that the genotype in partially inactivating mutations cannot be used to predict DSD. In some populations, milder CYP11A1 deficiency appears to be a significant underlying cause for the clinical presentation of clinically diagnosed 'isolated' adrenal insufficiency.

Aldosterone Synthase (CYP11B2) Deficiency

Aldosterone synthase (CYP11B2) is a mitochondrial enzyme expressed in the zona glomerulosa. CYP11B2 deficiency causes isolated impairment of aldosterone synthesis in the context of normal cortisol and sex steroid production. Affected individuals present with salt-wasting crisis during the first days or weeks of life. Adults are usually asymptomatic, but might be more sensitive to episodes of severe salt loss than non-affected individuals [3]. Two biochemically distinct forms have been described, ASD1 (OMIM # 203400) and ASD2 (OMIM # 610600), which are both caused by CYP11B2 deficiency (**Table 5.9.1.1**). The *CYP11B2* gene (GeneID 1585, GenbankID NC_000008.10) lies on chromosome 18q24.3 approximately 40 kb apart from the highly homologous *CYP11B1* gene (**Figure 5.9.1.1**). More than 30 mutations have been described so far (HGMD August 2018). The p.[Arg181Trp+Val385Ala] double mutant is the most common ASD2 allele found in Iranian Jewish [3]. Homozygosity for only one of these mutants is not sufficient to cause the disease. The underlying molecular mechanism distinguishing the two ASD forms is not well understood. *In vitro* data suggests that mutations completely abolishing CYP11B2 activity are associated with ASD1, while mutations allowing for 11- and 18-hydroxylase activities appear to be associated with ASD2 [3].

5.9.2 Modern Management of Congenital Adrenal Hyperplasia and Prospects for the Future

Richard J. Auchus

Introduction to Congenital Adrenal Hyperplasias

Genetic defects in the enzymes and cofactor proteins essential for cortisol production (Figure 5.9.2.1) lead to congenital adrenal hyperplasia (CAH). As the name implies, the defects are inborn errors, which typically lead to overgrowth of the adrenal glands. The lack of negative feedback from cortisol increases adrenocorticotropin (ACTH) secretion, adrenal growth, and the futile drive to produce the deficient cortisol. Importantly, these defects span the spectrum from complete or very severe ('classic CAH') to partial or mild ('non-classic CAH'). For the purposes of this chapter, classic CAH is defined as those patients with clinically manifest cortisol deficiency, imperative glucocorticoid replacement, and risk of adrenal crisis—with the exception of 17-hydroxylase deficiency (17OHD), as will be explained subsequently.

In addition to cortisol deficiency, cortisol precursors accumulate behind the enzymatic block—not only the substrate(s) for the deficient enzyme but also further upstream steroids. Often, one or more of these steroids and/or their peripheral metabolites has biologic activity, primarily mineralocorticoids or androgens. The loss of enzyme activity forces the shunting of steroids around the block and into alternative and ordinarily minor pathways, leading to a characteristic pattern of steroids for each defect. Corticosterone is the only alternative endogenous steroid to cortisol with glucocorticoid activity, and corticosterone substitutes for cortisol in 17OHD but no other form of CAH. Consequently, the goals of CAH treatment can be divided into replacing the deficient cortisol and other steroids decreased by CAH and reducing the production or attenuating the action of unwanted, CAH-related steroid excess particular for each form of CAH. In 17OHD and non-classic CAH, only the second goal is germane.

21-Hydroxylase Deficiency

Biochemistry of 21-Hydroxylase Deficiency

By far, 21-hydroxylase deficiency (21OHD) is the most common form of CAH, both classic at ~1:16 000 worldwide and non-classic, ~1:1000 or more prevalent in certain populations [1]. The genetics and diagnosis of 21OHD is reviewed in detail in

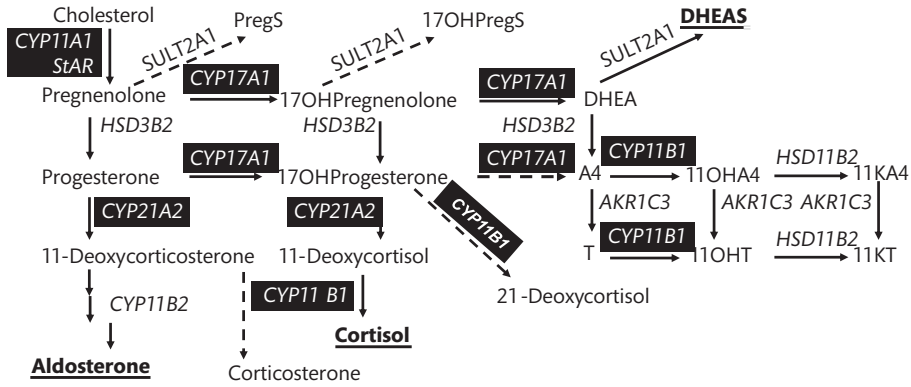

Figure 5.9.2.1. Composite diagram of adrenal steroid biosynthesis, highlighting the genetic defects causing the congenital adrenal hyperplasias (enzyme names in white on black boxes). Underlined steroid names in large font indicate major adrenal products: aldosterone, cortisol, and DHEAS. Minor pathways, either due to poor enzyme activity or limited substrate availability, are shown with dashed arrows. The 11-oxyandrogen pathways, which in part are due to conversions in peripheral tissues, are indicated at right.

Chapter 5.9.1. Upstream of the defective CYP21A2 enzyme, 17-hydroxyprogesterone (17OHP), progesterone, and other cortisol precursors accumulate, and some of these steroids are metabolized to androgens (Figure 5.9.2.2). Patients with classic 21OHD require cortisol replacement, and most also benefit from mineralocorticoid therapy, even those who make some aldosterone. In addition, treatment must also control the androgen excess to the extent that is clinically indicated. In non-classic 21OHD, treatment is employed to control androgen excess and reproductive dysfunction in children and women with these clinical manifestations. Based on conservative estimates from population studies, <10% of females and <1% of males with non-classic 21OHD are ever diagnosed with the condition, and of these roughly 70% are compound heterozygotes for classic and non-classic 21OHD alleles and thus carriers for classic 21OHD [2].

While 17OHP, androstenedione (A4), and testosterone (T) measurements have been traditionally used to diagnose and monitor therapy for 21OHD, these steroids also derive from the gonads, limiting their specificity. For example, diagnostic testing for non-classic 21OHD must be performed in the follicular phase avoid the contribution of ovarian 17OHP, and men with 21OHD in very poor control or very good control can both have a 'normal' male-range T. In addition, dehydroepiandrosterone sulphate (DHEAS), the most abundant steroid in the circulation through most of life, is elevated in non-classic 21OHD but normal or low in classic 21OHD, contrary to simple predictions by inspection of Figure 5.9.2.1.

The adrenals of patients with 21OHD, however, still contain the enzyme 11-hydroxylase (CYP11B1), and most of the 3-keto-Δ^4-steroids that accumulate in 21OHD are substrates for CYP11B1. For example, CYP11B1 converts 17OHP to the 11-oxygenated steroid 21-deoxycortisol (21dF), and 21dF is more specific than 17OHP for diagnosis of non-classic 21OHD [3] and for determination of carrier status [4]. The 3β-hydroxy-Δ^5-steroids pregnenolone and 17-hydroxypregnenolone, which also accumulate in 21OHD, are substrates for the sulfotransferase SULT2A1, and pregnenolone sulphate rises in classic 21OHD to about 40% the abundance of DHEAS [5]. More importantly, A4 is an excellent substrate for CYP11B1, and circulating concentrations of 11β-hydroxyandrostenedione (11OHA4) exceed those of A4 in treated patients with classic 21OHD by twofold [5]. Via two consecutive intra-adrenal and/or peripheral enzymatic steps, 11OHA4 is converted to 11-ketotestosterone (11KT), which is a

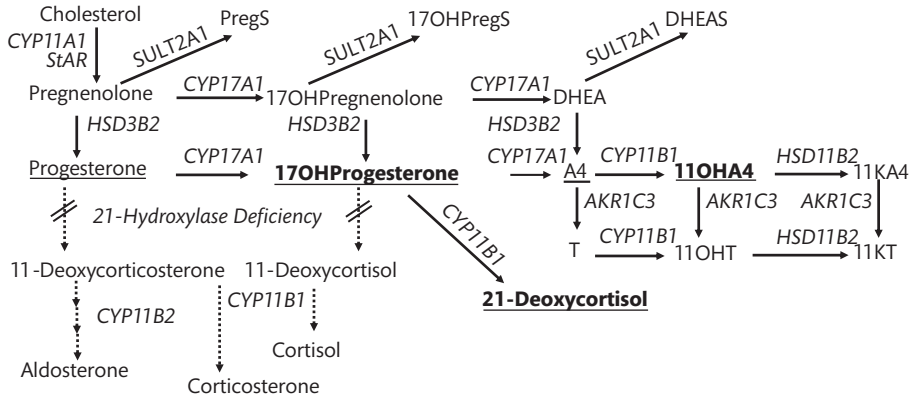

Figure 5.9.2.2. Altered steroidogenesis in classic 21OHD. The block at P450 21A2 (double crossed lines on dotted arrows) causes deficient synthesis of aldosterone and cortisol. Underlined steroid names in large font indicate major adrenal products in 21OHD: 17OHP, 21-deoxycortisol, and 11OHA4. Lack of substrate production also precludes downstream conversions, also indicated with dotted arrows. Note that pregnenolone sulphate (PregS) accumulates comparably to DHEAS in classic 21OHD, and progesterone (underlined in normal size font) is also elevated.

biologically relevant androgen, particularly in 21OHD. In teleost (bony) fishes and some reptiles, 11KT is the major gonadal androgen, and 11KT activates the human androgen receptor nearly as potently and effectively as T [6], depending on model system used. Furthermore, serum 11KT is roughly twice as high as T in treated patients with classic 21OHD, suggesting that 11KT is the dominant androgen in most patients with classic 21OHD [5, 7]. The 11KT correlates directly with T in women with classic 21OHD, as both steroids derive entirely or mostly from the adrenals. Conversely, 11KT correlates inversely with T in men with classic 21OHD, reflecting the testicular origin of T in well-controlled men and primarily adrenal origin of both T and 11KT in those with poor disease control.

Paediatric Care of Classic 21-Hydroxylase Deficiency

The diagnosis of a neonate with classic 21OHD is a medical emergency, whether the diagnosis is derived from newborn screening, clinical symptoms, or presence of genital ambiguity. Newborns with adrenal insufficiency of any cause are very vulnerable to crises due to several factors, including small body size and high surface-to-volume ratio (and propensity to fluid loss), resistance of the infant kidney to the action of mineralocorticoids, and low sodium content of the diet, particularly breast milk with 7 meq/L. Intentional yet modest overtreatment with glucocorticoid is common practice at first, to gain control of the de-repressed hypothalamic–pituitary–adrenal (HPA) axis and to begin to reverse the adrenal hyperplasia. If the dose is not excessive, the child will gradually 'grow into the dose', whereas growth suppression indicates overzealous treatment and mandates gradual dose reduction until growth normalizes. A typical dose of hydrocortisone will be about 25 mg/m^2/d in three divided doses [8]. Fludrocortisone acetate, used to replace aldosterone, is dosed at 0.1–0.4 mg/d—the same dose used in adults, to account for the poorly responsive infant kidney and tenuous volume status. Sometime in the first year of life, the hydrocortisone dose should be reduced to <17 mg/m^2/d, as higher doses impair growth [9].

During childhood, control of androgen excess is important to limit bone age advancement, which will compromise adult height. Most clinical androgen and oestrogen assays lack the accuracy to quantify the minute amounts needed to advance bone age, and 17OHP values are used as a surrogate for sex steroid measurements to gauge disease control. Growth rate, bone age, and weight are used with measurement of steroids, electrolytes, and plasma renin to adjust therapy. Controlled studies comparing various dosage regimens and monitoring schemes are lacking, which leads to considerable variations in practice style.

For girls with masculinized genitalia, clitoral reduction and vaginoplasty surgeries have been performed in the first year of life after stabilization of the medical condition. The purpose of the surgery is to establish functional anatomy for menses, voiding, and intercourse. For example, a urogenital sinus can cause vaginal voiding, the pooling of urine in the vaginal component, which leaks out upon standing. In recent years, patients, advocacy groups, and the medical community have broadly considered the factors that determine the optimal timing of reconstructive surgeries [10]. Evidence supporting early versus late timing are limited to retrospective studies. Many women who have had early surgeries endorse their parents' decision [11], while others report dissatisfaction and regret [12, 13]. Sexual activity and satisfaction are reduced women with classic 21OHD, and genital anatomy with or without reconstructive surgery is only one of many factors contributing to outcomes. Regardless of whether the child has surgery or not, control of androgen excess is important to limit further masculinization, and good control can lead to substantial clitoral regression during early childhood [14].

Adult Care for Classic 21-Hydroxylase Deficiency and Transitioning from Childhood

This chapter will focus on the management of adults with 21OHD, and adult care begins with the transition from paediatric care. For patients with 21OHD and many other chronic conditions, the transition process should be an organized series of step with the acquisition of skills and knowledge for greater self-management [15]. Unfortunately, the process is abrupt and haphazard for many patients. For example, a centre of excellence for CAH in Germany reported that less than half of young adults with 21OHD attended more than one appointment in the adult endocrinology clinic [16] and that many choose to discontinue therapy until suffering an adrenal crisis [17]. Guidance for coordinated care transition has been described [18, 19], yet logistic and financial barriers limit the widespread implementation of these strategies. Low income and lack of strong support structure are two documented risk factors for poor outcomes following transition to adult care for other chronic diseases arising in childhood [20]. At a minimum, adolescent should demonstrate a basic understanding of their disease and the reasons for treatment, the procedures to access medical care, and emergency protocols prior to transitioning to the adult clinic.

The natural history study of 21OHD from the National Institutes of Health [21], the CaHASE study from the United Kingdom [22], and other cohort studies from Europe [23] demonstrate that more adults with 21OHD suffer complications from supraphysiologic glucocorticoid exposure than from undertreatment. Common features include striae, obesity [22], adverse cardiovascular risk profiles [21, 23, 24], and reduced bone mineral density [25, 26] or occasionally osteoporosis [21, 22]. Consequently, unlike the child for whom normal growth and puberty are high priorities, the care for the adult with 21OHD must strongly consider strategies to mitigate the long-term health consequences of chronic glucocorticoid therapy.

Glucocorticoid Therapy

For motivated patients who have been consistently adherent to prescribed therapy with hydrocortisone during adolescence and show good disease control, there is no reason to significantly change treatment. Although surprisingly low doses of hydrocortisone such 10 mg BID sometimes achieves good control of adrenal androgens [27], most patients require more aggressive regimens of 5–10 mg TID with meals. The major advantages of hydrocortisone include the capacity to deliver a high peak morning glucocorticoid exposure as occurs in normal physiology and the low risk of serious complications from overtreatment, due to short half-life of about 1 hour. The short half-life of hydrocortisone is also its main disadvantage, as ACTH-driven adrenal steroid production tends to rise prior to the first morning dose when drug exposure and negative feedback are waning [28–30]. Consequently, the strategy when using hydrocortisone is to somewhat overtreat during the daytime in order to limit the ACTH rise in the early morning when exposure is poor.

For many adults, particularly those with compromised fertility or those whose schedules make midday dosing difficult, hydrocortisone therapy restores well-being without side effects but fails to control adrenal androgen production sufficiently to meet the patient's goals. One option is to continue the hydrocortisone dosing similar to conventional regimens for adrenal insufficiency—to replace the cortisol deficiency—and then add a small dose of a long-acting glucocorticoid at bedtime, to keep the ACTH suppressed until the first morning hydrocortisone dose. Although the use of two different glucocorticoids might seem paradoxical, the analogy would be a bedtime dose of long-acting insulin to control the fasting glucose rise from the dawn phenomenon. For example, a regimen might consist of hydrocortisone, 15 mg on arising and 5 mg in the early afternoon, plus 0.5–2 mg prednisolone, or 0.1–0.25 mg dexamethasone at bedtime. Prednisone, which is popular in the United States for its immunosuppressant properties, should be avoided, as prednisone is a prodrug that must be metabolized in the liver by 11β-hydroxysteroid dehydrogenase type 1 to prednisolone, yielding delayed and variable exposure to the active agent. 'Inverse diurnal rhythm' schedules, where the largest glucocorticoid dose is given at bedtime, should be avoided as well. These regimens do not replace the cortisol deficiency well and overtreat during the nighttime, when glucocorticoids are most likely to cause adverse effects such as weight gain and poor sleep. Instead, the dose of evening glucocorticoid should be smaller than those provided during the day and the minimum amount to maintain drug exposure until the first-morning dose [31].

Should the two-drug regimen be too complicated or insufficient to maintain adrenal androgens at goal, prednisolone as a single morning dose sometimes suffices to replace cortisol deficiency and control androgen production [32]. If disease control deteriorates, a second small bedtime dose of the same drug might be added, maintaining the larger dose in the morning for adrenal replacement. While dexamethasone is a potent, inexpensive, widely available, and long-acting glucocorticoid, its potency and duration of action render patients at high risk of adverse metabolic consequences during chronic therapy, and morning dexamethasone, due to its kinetics, does not replace the cortisol deficiency as well as other glucocorticoids. Dexamethasone also does not have any mineralocorticoid activity, which needs to be taken into account. Dexamethasone therapy is best limited to cautious combination with hydrocortisone and for androgen excess refractory to all other approaches. Doses of 0.25–0.75 mg once daily or rarely divided BID are typical, but even apparently modest doses can cause severe cushingoid manifestations when used over months to years. Whereas liquid or suspension preparations of hydrocortisone are no longer manufactured on an industrial scale due to poor consistency [33], liquid prednisolone and dexamethasone are generally available. Although in some ways inconvenient and messy, the liquid preparations when delivered precisely using syringes allow for continuous and careful dose titration to avoid overtreatment. A new multiparticulate granule preparation of hydrocortisone is in advanced stages of development [34]. Table 5.9.2.1 summarizes glucocorticoid options.

Regardless of glucocorticoid choice, patients are instructed to increase doses for significant physical stress and illness. For states of greater fluid loss than replacement, such as high fever, diarrhoea, and vomiting, the patient should double the dose until well for a full day.

Table 5.9.2.1 Glucocorticoid treatment options for CAH

Drug(s)	Advantages	Disadvantages
Hydrocortisone monotherapy or + bedtime prednisolone/ dexamethasone	Well tolerated Ideal cortisol replacement	Multiple daily doses Limited potency
Prednisolone/ methylprednisolone	Once/twice daily Good androgen control	Modest side effects Fair cortisol replacement
Dexamethasone	Once/twice daily Best androgen control Crosses placenta	High side effects Titration difficult Poor cortisol replacement

If the patient is too sick to take pills or to stand without assistance, the patient should receive 100 mg hydrocortisone hemisuccinate intramuscularly and taken to the hospital immediately. Patients who are vomiting are particularly vulnerable to adrenal crisis, and such illness should be approached with a low threshold for parenteral hydrocortisone and hospital transport (also see Chapter 5.8.2 regarding management of adrenal crisis).

Mineralocorticoid Replacement

Perhaps the most common error in treating all forms of adrenal insufficiency is inattention to mineralocorticoid replacement and volume status [35]. Most adults with 21OHD benefit from 9α-fludrocortisone acetate regardless of whether they were described as 'salt wasting' during childhood. The dose is typically 0.05–0.2 mg once daily, but some patients require 0.4–0.6 mg daily as a single dose or divided BID. Persistent fatigue unresponsive to higher glucocorticoid dosing often represents chronic volume depletion as a result of mineralocorticoid deficiency. Hydrocortisone provides some mineralocorticoid activity, particularly at higher doses, but prednisolone, methylprednisolone, and dexamethasone have little to no mineralocorticoid activity. Consequently, any patients converted from hydrocortisone to another glucocorticoid might need to increase their dose of 9α-fludrocortisone acetate to maintain euvolemia.

Special Considerations for Infertility in Women with 21OHD

Because classic 21OHD causes 46,XX disorders of sex development (DSD) and androgen excess in women, attention has been focused on infertility in women with this disease. A major impediment to fertility is simply the paucity of women with classic 21OHD who ever attempt pregnancy, estimated to be 25% overall and 10% of women with null alleles [36]. The fecundity rates for the minority who do attempt pregnancy, however, is more than 90%, equivalent to that of the general population—with proper treatment [37]. Glucocorticoid regimens that are adequate for replacing the cortisol deficiency, maintaining regular menses, and preventing unwanted acne and facial hair might require intensification to restore fertility. In particular, increased adrenal-derived progesterone, which accumulates upstream of 17OHP, is a major mechanism of impaired fertility in women with 21OHD. Sustained progesterone production through the follicular phase of the cycle causes changes in cervical mucus and thinning of the endometrial lining, similar to oral contraceptive pills. Thus, attention to suppression of

follicular-phase progesterone is critical for managing women with 21OHD attempting to conceive, and a bedtime dose of a long-acting glucocorticoid (but not dexamethasone, as it passes the placenta in pregnant women) is often necessary [37].

Special Considerations for Infertility in Men with 21OHD

Paradoxically, although men with classic 21OHD do not have 46,XY DSD, men appear to have greater problems with fertility than women with 21OHD [38–40]. One major mechanism of decreased sperm production is that high production of adrenal-derived androgens suppresses gonadotropin secretion [41, 42]. similar to exogenous androgens. The other major cause of infertility is testicular adrenal rest tumours (TART), which develop in 30–50% of adolescent and adult males with 21OHD when ultrasound is used for sensitive detection [21, 38]. TART appear in the posterior aspect of the testes and tend to be firm, irregular bilateral masses. The origin of TART and their mechanisms of formation are not known. Although most men with large TART have poor control of adrenal androgen synthesis, one study found no correlation of TART development with traditional laboratory parameters of disease control [43]. Originally, TART were thought to form from adrenal cortex cells, which migrated to the testis during embryonic development and later underwent hyperplasia under robust ACTH stimulation. Subsequently, TART cells were shown *in vitro* to produce the same pattern of steroids as the adrenal cortex of patients with 21OHD [44] and to express an overlapping set of enzymes unique to adrenal cortex and Leydig cells [45]. These data suggest that TART derive from Leydig progenitor cells, which have become partially transdifferentiated under the influence of elevated ACTH [38, 39, 46].

Because the testis is confined to a capsule, the growth of any testicular mass impairs blood flow to the normal cells of the testicular tubules. The chronically impaired perfusion leads to dysfunction and fibrosis of the normal testis. A high serum follicle-stimulating hormone (FSH) heralds the permanent loss of Sertoli cells and indicates chronic damage. As TARTs grow, the normal testis tissue suffers from compression, impaired blood flow, functional impairment, and fibrosis. To induce regression of TART, either dexamethasone (once or twice daily) or divided doses of hydrocortisone plus bedtime dexamethasone are required to keep ACTH suppressed all day long for weeks to months [47]. Sperm production and fertility are often restored with intensified therapy, but some TART do not regress with medical therapy, particularly when longstanding and already associated with fibrotic transformation [48]. Testis-sparing surgery effectively and usually permanently removes the TARTs, but fertility and testicular T production are rarely restored [38, 49]. Hence, testis surgery is usually employed only after the patient accepts the permanent loss of fertility in order to remove the mass effect. The presence of TART and an FSH >35 IU/L are poor prognostic signs for fertility in men with 21OHD [50]. One case report [51] describes TART regression and restoration of fertility in a man with 21OHD after 2 years of treatment with mitotane, an adrenolytic drug otherwise used in the context of adrenocortical carcinoma. Because the presence of TART is so common and its consequences so grave, boys with 21OHD should have a baseline testicular ultrasound upon reaching adulthood and periodically thereafter [52], as well as testicular exams at least annually.

Additional Treatment Options

Bilateral adrenalectomy for 21OHD patients was previously advocated as a means to eliminate adrenal-derived androgens without the use of supraphysiologic glucocorticoid therapy. Although short-term results appear successful [53] and fertility might even be restored [54, 55], long-term outcomes are not durable. One study found recurrent hyperandrogenaemia in 8 of 18 patients following bilateral adrenalectomy [56]. TART may subsequently develop in men [56] or adrenal rest tumours in the ovaries and pelvis in women [57, 58]. A pituitary corticotrope adenoma has been described in one patient with 21OHD following adrenalectomy [59], and patients appear to be more vulnerable to potentially fatal adrenal crises following bilateral adrenalectomy [55, 56]. For these reasons, bilateral adrenalectomy is rarely recommended any longer.

As with any form of androgen excess, mechanical epilation methods, including shaving, waxing, plucking, electrolysis, and laser hair removal, reduce the dependence on pharmacotherapy and thus might spare some glucocorticoid exposure. Topical application of 13.9% eflornithine cream is also a useful adjunct for controlling hirsutism, particularly for small areas of skin, but the cost can be prohibitive. The ethinyl oestradiol component of oral contraceptive pills increases circulating sex-hormone binding globulin concentrations and thus lowers the free and bioavailable fractions of T even without lowering total T. Androgen receptor antagonists might be employed as well, but spironolactone, which is commonly used for this purpose, is also a diuretic and mineralocorticoid receptor antagonist (MRA), which can cause serious volume depletion in women with classic 21OHD; its interference with the progesterone receptor can cause additional menstrual cycle irregularities. Terminal hairs never revert back to vellus hairs, and hair follicles cycle between growing, resting, and shedding phases. Medical treatments of androgen excess lead to thinner terminal hairs and more time in the resting phase. Electrolysis and laser epilation permanently destroy hair follicles, but only those in the growing phase, which are visible at the time of treatment.

Non-classic 21-Hydroxylase Deficiency

Patients with non-classic 21OHD generally do not have manifest cortisol (or aldosterone) deficiency but only androgen excess. However, partial adrenal insufficiency manifesting in times of stress has been described, as cortisol deficiency depends on the degree of enzymatic impairment, which is by definition on a continuous spectrum. When ascertained as children for premature androgen exposure and/or advanced bone age, hydrocortisone therapy is conventionally employed to attenuate the ACTH-mediated excess of adrenal-derived androgens. Logically, non-classic 21OHD is easier to manage than classic 21OHD, and lower doses of glucocorticoids can be used than in classic 21OHD. Upon reaching adulthood, treatment in boys is normally discontinued [8], except in some patients with genotypes at the more severe end of the non-classic 21OHD spectrum. In women diagnosed with non-classic 21OHD due to irregular menses and/or androgen excess and those diagnosed as children with persistent symptoms upon reaching adulthood, hydrocortisone treatment might be continued. More potent glucocorticoids are rarely necessary but can be used instead of hydrocortisone but sparingly, such as dexamethasone 0.25 mg at bedtime 3 days per week [60]. Similarly, mechanical epilation, oral

contraceptive pills, and antiandrogens including spironolactone are adjuncts or alternatives to glucocorticoids for these patients.

One area of confusion relates to pregnancy in women with non-classic 21OHD. The notion that women with non-classic CAH commonly suffer from reduced fecundity largely derives from ascertainment bias, as infertile women are more commonly tested for non-classic 21OHD than fertile women. Given that the prevalence of non-classic 21OHD based on allele frequencies is at least 1:1000 in the general population, most women with the disease are never diagnosed, and those who come to medical attention tend to have more severe disease, with 70% being compound heterozygotes for classic and non-classic 21OHD alleles [2]. In a French study, 83% of women with non-classic 21OHD became pregnant in 1 year with or without glucocorticoid therapy [61]. Of 139 pregnancies in a cohort from Israel of non-classic 21OHD women without male factor infertility, the mean time to conception was 4.0 months without and 3.3 months with glucocorticoid therapy, and only 17 pregnancies occurred after starting glucocorticoids following failure to conceive after an average of 10.2 months [62]. In contrast, the miscarriage rate in these women is as high as 26% in untreated women and, in retrospective series, is closer to that of the normal population (6%) in those treated with hydrocortisone therapy [61]. A more recent study showed a 23% rate of miscarriage without and 14% with glucocorticoid therapy, but the latter group included only six cases [62]. Conclusions should be drawn with caution, as the data are retrospective and not reproduced in other series. If hydrocortisone is used during pregnancy, the dose should be physiologic or slightly lower (10–20 mg/d) to prevent iatrogenic adrenal axis suppression.

Monitoring and Adjusting Treatment of 21OHD

The history taking in the adult with classic 21OHD includes prior therapy—changes, lapses in medication adherence, and frequency of adrenal crises. The patient should be asked about weight changes, salt craving, easy bruising, and orthostasis. For women, menstrual regularity and androgen excess features are important parameters, and women should be asked if they use epilation or other measures to control hirsutism and acne. Men should be asked about testicular pain and masses. The desire for current or future fertility should be explored, and it is alarming how many patients have been incorrectly counseled that fertility is not possible in 21OHD.

Physical examination should include sitting and standing blood pressure and heart rate to probe volume status and adequacy of mineralocorticoid replacement. Although physical exam findings are not very helpful for demonstrating adequacy of cortisol replacement, cushingoid features consistently develop with months of overtreatment. Weight gain frequently occurs with glucocorticoid therapy, yet weight gain is also common in untreated adults and difficult to ascribe to the glucocorticoids. Dermal atrophy is a very specific finding for glucocorticoid excess. For example, most adult treated with long-term dexamethasone develop dermal atrophy even in the absence of other cushingoid features. Dermal atrophy and capillary fragility lead to the easy bruising and purple, non-blanching striae in the abdomen but also flanks, thighs, and upper arms. Moon facies and plethora, proximal muscle weakness, and disproportionate fat accumulation in the head and neck area (supraclavicular and dorsocervical fat pads) are also quite specific for glucocorticoid excess. Women receive an assessment of acne and hirsutism, interpreted in the context of recent epilation, and annual gynaecologic exams. Men have at least annual testicular exams for atrophy and TART development.

Plasma renin activity (or mass concentration) correlates inversely with plasma volume, and reflects the adequacy of mineralocorticoid replacement. Low standing blood pressure, high serum potassium, and high plasma renin indicate inadequate fludrocortisone acetate dosing, and excessive dosing yields the opposite results. 17OHP is commonly used to titrate therapy in children, as normal 17OHP values assure that even small amounts of sex steroids capable of advancing bone age are not being produced. The utility of 17OHP in adults is limited, primarily because values fluctuate dramatically with time after each glucocorticoid dose, and adults do not experience detrimental consequences of small, brief rises in androgens relative to gonadal production. DHEAS is not elevated in classic 21OHD patients [63], and the only utility of DHEAS is to gauge adherence and exposure to glucocorticoid therapy, as treated patients should have suppressed DHEAS. A4, which is one step from T, is perhaps the best commonly available biomarker of adrenal androgen production, even though 11OHA4 is more abundant in 21OHD patients. A4 values fluctuate less than 17OHP throughout the day, and T values fluctuate even less than A4. For these reasons, A4 and T values are the primary laboratory parameters used for evaluating disease control and for titrating glucocorticoid dosing, but with some caution. Given that 11KT is typically more abundant than T in patients with classic 21OHD, T values tend to underestimate the production of adrenal-derived androgens.

For women with classic 21OHD who are not currently attempting to conceive, the main parameters of disease control are clinical assessments: regular menses, androgen excess features at goal, and absence of cushingoid features [64]. It is inappropriate to define goal values for A4 and T, but trends and correlates to good clinical features are valuable information. For example, if a woman with classic 21OHD suddenly develops amenorrhea, the question arises whether the reason is deterioration in disease control. If the A4 and T values are significantly increased from previous measurements when menses were regular, then poor control of 21OHD is likely the reason. If the laboratory data are unchanged, other reasons for amenorrhea should be sought.

On the other hand, regular menses alone does not necessarily indicate adequate disease control for women who desire to conceive. Upstream of 17OHP, progesterone (P4) accumulates as well in 21OHD, and chronically elevated P4 is a major cause of irregular menses and amenorrhea in women with 21OHD, because P4 withdrawal does not occurs [28]. Chronic elevation of P4 into luteal-phase values (>2 ng/ml or 6 nmol/L) thins the endometrial lining, alters cervical mucus, and interferes with menses, similar to progestin-only contraceptives. For women with 21OHD attempting to conceive, glucocorticoid therapy should be titrated to maintain the follicular-phase serum progesterone <0.6 ng/ml (<2 nmol/L) [37].

A quandary in managing men with 21OHD is that T can be in the normal male range for men in good control as well as those in poor control; the difference is whether the androgens derive from the adrenal or the testes [64]. Simultaneous A4 and luteinizing hormone (LH) values allow one to sort out the origin of most T. The Leydig cells of the testes are the only cells in postnatal human beings that normally contain the enzyme 17β-hydroxysteroid dehydrogenase type 3, which efficiently converts A4 to T. Thus, when T is produced

from the testes, the A4/T ratio is <0.5 and often <0.2. When the T is primarily of adrenal origin, the A4 exceeds T, and the A4/T ratio is >1 [31]. In addition, a suppressed LH is consistent with high adrenal androgen production. For example, a 20-year-old man with classic 21OHD and poor adherence through adolescence can have full secondary sexual characteristics, a T in the normal male range (~300 ng/dl or 10 nmol/L) yet have atrophic testes, undetectable LH, and A4 four times the T value. This man has never progressed through puberty and has been exposed only to adrenal-derived androgens. For post-pubertal men who later lapse into poor control, the LH can be suppressed with a T near the low end of normal (200 ng/dl or 7 nmol/L). One reason for this discrepancy between LH and T is that men with 21OHD in poor control have high 11KT. In men with 21OHD, 11KT correlates roughly inversely with T [5]. For men in poor control, the adrenal-derived 11KT is higher than T, and testicular T synthesis is negligible. For men in good control, testicular T production is normal, and little 11KT derives from the adrenal. As in women, a sex-hormone binding globulin measurement allows determination of free and bioavailable T. A high FSH value indicates severe testicular damage, and a semen analysis is indicated when evaluating for infertility.

Other Forms of Congenital Adrenal Hyperplasia

3β-Hydroxysteroid Dehydrogenase Deficiency (HSD3B2D)

This disease is the form of CAH most similar physiologically to 21OHD. Patients with classic HSD3B2D have cortisol and aldosterone deficiency and are vulnerable to adrenal crises as infants. The major difference is that the androgen excess is milder than 21OHD, such that girls have modest clitoral enlargement but generally little or no labioscrotal fusion [65]. Because the testicular Leydig cells and ovarian theca cells employ the enzyme in the A4 and T biosynthetic pathway, boys with HSD3B2D have undervirilization and often gynaecomastia. Thus, HSD3B2D is one of two forms of CAH that cause DSD in both 46,XX and 46,XY babies [66]. Boys often require T supplementation at the time of normal puberty and throughout adulthood. Nevertheless, one young man with severe deficiency was found to have a normal semen analysis, possibly due to aberrant compensation via up-regulation of the HSD3B1 enzyme in the Leydig cells [67]. There are no reports of fertility in women with HSD3B2D.

The diagnosis of HSD3B2D is best made from the 17-hydroxypregnenolone/cortisol ratio, which must be at least 6 (and typically >300) standard deviations above normal [68, 69]: typical values are a cortisol <5 μg/dl (<140 nmol/L) and a 17-hydroxypregnenolone of more than 6000 ng/dl (>160 nmol/L). Non-classic HSD3B2D was once thought to be common, but most women with mildly elevated delta-5 steroids such as DHEAS have polycystic ovary syndrome and no mutations in the *HSD3B2* gene [70]. One hypothesis is that these women have functional impairment of the enzyme due to high intra-adrenal delta-4 steroids, which also bind to the enzyme and reduce activity via product inhibition [71].

Monitoring for mineralocorticoid replacement in HSD3B2D is the same as for 21OHD. Glucocorticoid replacement goals in children and adults is likewise similar, and the androgen excess is milder than in classic 21OHD. Laboratory monitoring should not focus on delta-5 steroids, as some patients have persistently high DHEA despite adequate therapy [72]. The adrenal-derived delta-5 steroids are metabolized in the liver, skin, and other tissues one step beyond the enzymatic block to P4, 17OHP, and A4 (Figure 5.9.2.3). These delta-4 steroids do not significantly re-enter the adrenal steroidogenic pathways and progress to final steroid products (cortisol) but represent useful biomarkers for titrating therapy. Some A4 is converted to T via AKR1C3, and limited data suggest that 11OHA4 is low in patients with HSD3B2D [67].

17-Hydroxylase/17,20-lyase Deficiency (17OHD)

In many respects, 17OHD is the orthogonal disorder to 21OHD. Patients with 17OHD cannot produce androgens and oestrogens,

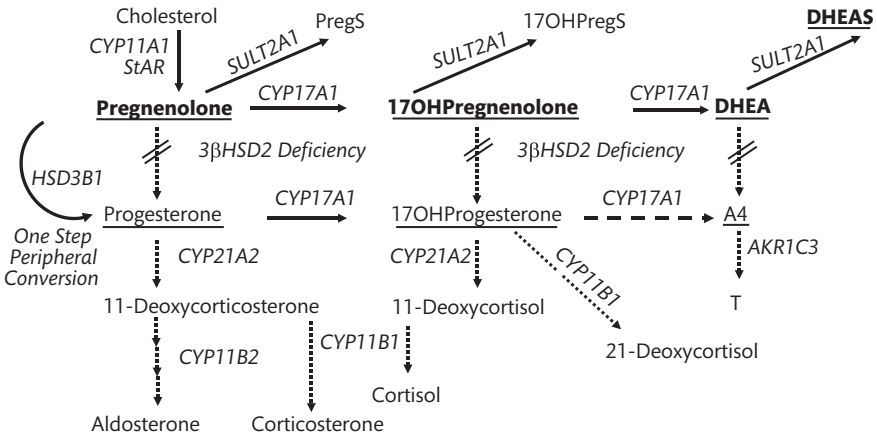

Figure 5.9.2.3. Altered steroidogenesis in classic HSD3B2 deficiency. The block at HSD3B2 (double crossed lines on dotted arrows) causes deficient synthesis of all delta-4 steroids in the adrenals and gonads; however, peripheral conversion via HSD3B1 affords increased circulating concentrations of the steroids one step past the block but not further (underlined steroid names in normal size font). Underlined steroid names in large font indicate major adrenal products in HSD3B2D: pregnenolone, 17-hydroxypregnenolone, and DHEA. Lack of substrate production also precludes downstream conversions, also indicated with dotted arrows. DHEAS is elevated in HSD3B2, and other delta-5 steroid sulphates might also be elevated (data are lacking). Limited data indicate that 11-oxyandrogens are not produced in HSD3B2.

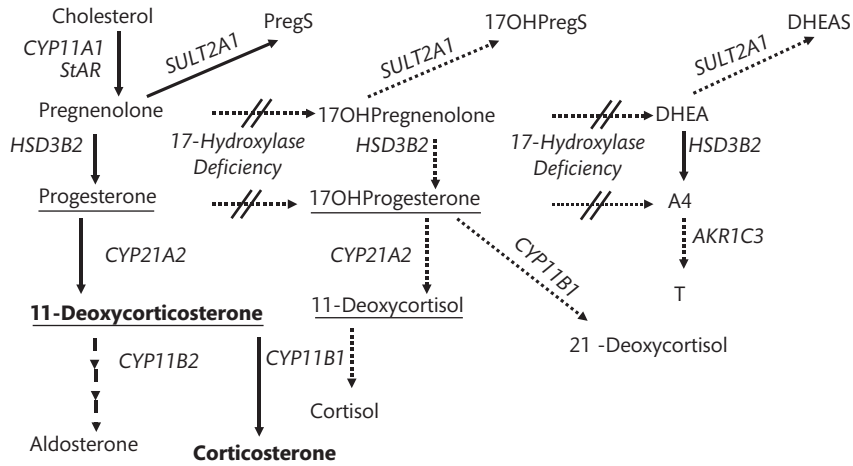

Figure 5.9.2.4. Altered steroidogenesis in 17OHD. The block at P450 17A1 (double crossed lines on dotted arrows) causes deficient synthesis of 17-hydroxysteroids and 19-carbon steroids. Underlined steroid names in large font indicate major adrenal products in 17OHD: 11-deoxycorticosterone and corticosterone. Lack of substrate production also precludes downstream conversions, also indicated with dotted arrows. Note that progesterone is also elevated in 17OHD (underlined in normal size font), and pregnenolone sulphate (PregS) might also be elevated (data are lacking). Aldosterone production (dashed arrows) is low due to renin suppression.

because the same *CYP17A1* gene, which encodes the CYP17A1 enzyme, is expressed in the adrenal and gonads [73] and is required for both cortisol and sex steroid synthesis. As previously mentioned, 17OHD is the only form of CAH without adrenal insufficiency, because the 17-deoxysteroid corticosterone, which is also a glucocorticoid, accumulates and compensates for the lack of cortisol [74]. Patients with 17OHD are rarely diagnosed as infants, unless an inguinal hernia or discordant prenatal 46,XY karyotype in a phenotypically female newborn is discovered. Upstream of corticosterone, 11-deoxycorticosterone (DOC) and P4 also accumulate (Figure 5.9.2.4), and DOC has mineralocorticoid activity. Consequently, hypertension and hypokalaemia often but not always develop during adolescence or early adulthood [75]. Thus, the typical presentation of 17OHD is pubertal failure in a phenotypic female with early-onset hypertension [66]. There is considerable variation in the clinical spectrum depending on the severity of the enzymatic defect. Because androgen biosynthesis requires the sequential 17-hydroxylase and 17,20-lyase activities of CYP17A1—two conversions catalysed by the same enzyme—the mutations necessarily impair androgen production greater than cortisol, and some elevation of 17-deoxysteroids is always present even in the absence of clinical manifestations. A non-classic form of 17OHD has not been described, but missense mutations that preferentially impair 17,20-lyase activity and cause isolated 17,20-lyase deficiency are known [76–78].

The diagnosis of 17OHD is established when cortisol and sex steroids are low and the steroids above the enzymatic block (P4, DOC, corticosterone) are all elevated. Infants and children with normal blood pressure and serum potassium for age do not require treatment, even when the diagnosis is established early in life, because corticosterone provides glucocorticoid activity. If and when hypertension and/or hypokalaemia develop, glucocorticoid therapy the suppress DOC formation is the traditional therapy. The dose is titrated primarily on the basis of blood pressure, serum potassium, and plasma renin, although renin can remain low for years after normalization of blood pressure. When using glucocorticoids, the patient should not be rendered cushingoid or treated with supraphysiologic doses, as alternatives to glucocorticoids are available. MRA, including spironolactone and eplerenone, are effective alternatives to glucocorticoids and act by blocking the action of DOC at the receptor [79]. Combination therapy with a small dose of hydrocortisone and as much MRA as necessary to normalize blood pressure and serum potassium is also a good option [74].

Sex steroid replacement is needed at the time of puberty or upon diagnosis if delayed until adulthood. Most patients are phenotypic females, and oestrogen replacement alone is sufficient in patients with 46,XY karyotype who lack a uterus. Gonadectomy should be considered in 46,XY patients with intra-abdominal testes, as gonadoblastoma may develop, although the absolute risk is not known. Patients with 46,XX karyotype have a uterus and therefore require periodic withdrawal bleeding with a progestin. A single case of term pregnancy has been reported in a patient with incomplete but classic 17OHD [80]. The treatment strategy was to suppress P4 with dexamethasone, prepare the uterine lining with oestradiol valerate, induce ovulation with gonadotropins, and implant embryos in a subsequent cycle after intracytoplasmic sperm injection. The amount of enzyme activity needed to enable pharmacologic induction of ovulation is not known, and gonadotropins should be used with extreme caution. Most women with 17OHD already have chronically elevated gonadotropins and chronic anovulation, which tends to cause the development of large ovarian cysts [81]. Undervirilized males with partial 17OHD or isolated 17,20-lyase deficiency with male gender identity require testosterone therapy and sometimes surgical correction of hypospadias. Fertility in men with 17OHD has not been described.

11β-Hydroxylase Deficiency (11OHD)

In 11OHD, the defect in CYP11B1 disrupts the final step of cortisol biosynthesis (Figure 5.9.2.5), and the phenotype is somewhat a combination of 17OHD and 21OHD. Similar to 17OHD, DOC but not corticosterone accumulates upstream of the enzymatic

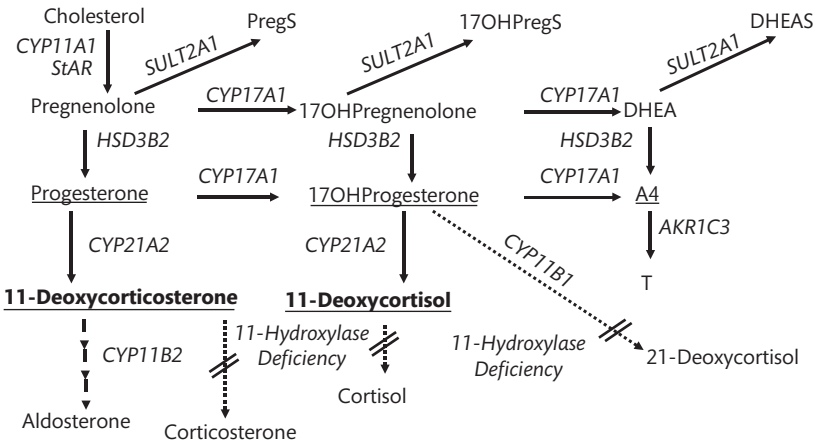

Figure 5.9.2.5. Altered steroidogenesis in classic 11OHD. The block at P450 11B1 (double crossed lines on dotted arrows) causes deficient synthesis of corticosterone, 21-deoxycortisol, and cortisol. Underlined steroid names in large font indicate major adrenal products in 11OHD: 11-deoxycorticosterone and 11-deoxycortisol. Progesterone, 17OHP, and A4 (underlined in normal size font) are also elevated in 11OHD, and aldosterone production (dashed arrows) is low due to renin suppression.

block, and patients with 11OHD tend to develop hypertension and/or hypokalaemia during adolescence—yet blood pressure does not correlate well with serum DOC [82]. Unlike 17OHD and similar to 21OHD, the steroid diversion leads to androgen excess as well, and girls are born with variable virilization of the external genitalia, which can be severe. Also like 21OHD, infants with 11OHD produce neither cortisol nor corticosterone and are prone to develop adrenal crises during illness if not treated. Thus, glucocorticoid therapy to replace the cortisol deficiency is required at birth or upon diagnosis.

Also like 21OHD, androgens, P4, and 17OHP are all elevated in 11OHD, but 17OHP is not elevated as much as in 21OHD. The diagnostic steroid is 11-deoxycortisol, which is the steroid immediately above the enzymatic block and is typically >10 000 ng/dL (>3000 nmol/L) in classic 11OHD [83]. Non-classic 11OHD is very rare, and the diagnosis should be considered when androgen excess presents in childhood and the 17OHP is elevated but not sufficient to diagnose non-classic 21OHD [84, 85]. Typically, the cortisol is normal, but the 11-deoxycortisol is >1800 ng/dl (>500 nmol/L).

The treatment of 11OHD throughout childhood and adulthood is similar to that of 21OHD, with divided doses of hydrocortisone but without the need for fludrocortisone acetate. More potent glucocorticoids such as prednisolone and dexamethasone are rarely necessary. In fact, MRA can be added to limit the dose of glucocorticoid used and still control blood pressure and serum potassium [66]. For 46,XX patients with 11OHD, spironolactone at doses of 50–200 mg/d functions as both an MRA and an antiandrogen, which compensates for mild residual elevations of DOC and T when physiologic doses of hydrocortisone are used. For 46,XY patients with 11OHD, eplerenone is a specific MRA that will not interfere with T action. Also like 21OHD, men are prone to developing TART and infertility [86], which would require intensification of glucocorticoid therapy. Women require glucocorticoid intensification to lower follicular-phase P4 when attempting to conceive. Only two cases of term pregnancies have been described in women with classic 11OHD [87].

P450 Oxidoreductase Deficiency (PORD)

PORD is the last form of CAH for which the molecular genetics and pathophysiology was determined [88, 89], although patients with this condition were first described clinically many years previously [90]. PORD is the most complex and variable form of CAH, in part because all patients thus far identified have incomplete deficiencies of POR function. POR mutations can alter the activities of any microsomal cytochrome P450 (CYP) enzyme, including the steroidogenic enzymes CYP21A2, CYP17A1, and CYP19A1 (aromatase); however, the influence on each enzymatic reaction is uniquely different for each missense mutation with some retained activity. Consequently, generalized statements about diagnosis, treatment, and outcomes are difficult to develop. The genetics and biochemistry of PORD is reviewed in detail elsewhere [91].

In general, P4, the only steroid upstream of all potential enzymatic defects, is always and often markedly elevated in PORD (Figure 5.9.2.6). Steroids past one impaired enzymatic step—including 17OHP and corticosterone—can be high or normal. Steroids past two impaired enzymatic steps—including cortisol, A4, and T—will be low and often very low. Oestrogen biosynthesis requires three enzymatic steps that utilize POR, and oestrogens are always very low, including maternal estriol in mothers carrying a fetus affected with PORD. Although androgen biosynthesis is always impaired, girls are born with genital virilization due to small but biologically significant amounts of 5α-reduced androgens of adrenal origin produced via the alternative pathway [88, 92]. With such complex and variable biochemical manifestations, PORD is best diagnosed with mass spectrometry profiling of urinary steroids [91].

Most patients with PORD have clinically meaningful cortisol deficiency and are prone to adrenal crises. These patients should be given replacement doses of hydrocortisone upon diagnosis and continued throughout life, and the dose is clinically titrated solely for cortisol replacement as in patients with absent adrenal function. Other patients might require stress dose hydrocortisone coverage only. Mineralocorticoid replacement is rarely required, even though CYP21A2 is required for aldosterone biosynthesis. In fact, the production of DOC and corticosterone is often increased in patients

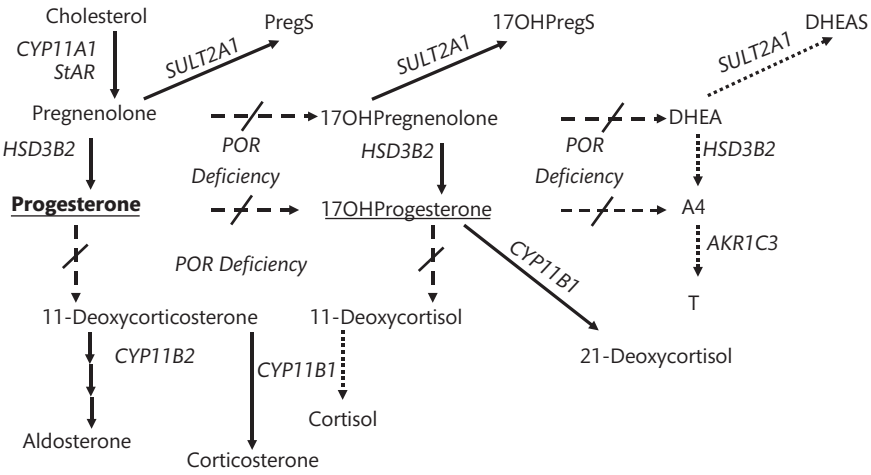

Figure 5.9.2.6. Altered steroidogenesis in PORD. The multiple and variable partial blocks at P450 21A2 and P450 17A1 (single crossed lines on dashed arrows) causes deficient synthesis of cortisol and androgens, which require two impeded transformations. Progesterone (underlined in large font) is upstream of all blocks and always accumulates in PORD; 17OHP and corticosterone (underlined in normal size font) variably accumulate depending on the specific mutation(s). Lack of substrate production precludes downstream conversions (dotted arrows).

with PORD but not to the same extent as in 17OHD. Patients with PORD rarely if ever develop early-onset hypertension despite DOC elevations, so adjunctive therapy with MRA is not required, either; however, in adulthood, hypertension regularly manifests in PORD patients. Both male and female patients require sex steroid replacement at the time of puberty and throughout adulthood, concordant with gender identity. PORD might be underdiagnosed in women with infertility, and one example of term pregnancy using ovulation induction and *in vitro* fertilization has been described [93].

Lipoid Congenital Adrenal Hyperplasia (LCAH)

LCAH derives from mutations in the *STAR* gene encoding the steroidogenic acute regulatory protein (StAR). StAR delivers cholesterol from the outer mitochondrial membrane to the cholesterol side-chain-cleavage enzyme (CYP11A1) on the inner mitochondrial membrane, where its conversion to pregnenolone occurs. Patients with classic LCAH are born with cholesterol ester-laden adrenals and make no steroids. Thus, similar to 21OHD and HSD3B2D, treatment with glucocorticoid and mineralocorticoid therapy at birth is critical for survival. More akin to PORD, these treatments are purely to replace the deficiencies, as misdirection of steroidogenesis and adrenal-derived hormone excess does not occur. Monitoring and dose titration is limited to adequacy of cortisol replacement, absence of cushingoid features, serum electrolytes, plasma renin, and standing blood pressure. StAR is also essential for normal gonadal androgen and oestrogen biosynthesis, so LCAH patients are all are phenotypically female and raised as girls. Intra-abdominal testes in 46,XY patients are non-functional and at risk for developing malignancies, and surgical orchiectomy is therefore prudent.

LCAH patients with 46,XX karyotype might have some ovulatory cycles and breast development at puberty [94], but ovarian failure typically ensues as cholesterol esters accumulate [95]. Consequently, oestrogen replacement therapy with or without progestin cycling depending on presence of a uterus is commenced in adolescence and continued throughout adulthood. Despite the severe adrenal insufficiency and pubertal failure, a few remarkable cases of pregnancy in 46,XX women with classic LCAH have been reported [96]. The first case conceived with clomiphene citrate and maintained two pregnancies to term with progesterone support. The second case involved gonadotropin stimulation, *in vitro* fertilization, and implantation of frozen embryos following uterine preparation with oestrogen [97].

Non-classic LCAH is well described, and these patients primarily show cortisol deficiency, simply because a higher circulating cortisol concentration is required to meet physiologic needs than for all other classes of steroid hormones [98, 99]. Thus, treatment of these patients is largely limited to cortisol replacement, although T supplementation is sometimes need in affected boys starting at puberty. A similar biochemical pattern to classic LCAH is observed in rare patients with P450 11A1 deficiency due to *CYP11A1* mutations, but the latter patients do not have cholesterol ester-filled adrenals [100]. Patients with P450 11A1 deficiency are managed similar as patients with classic LCAH, and limited information about long-term outcomes is available.

Experimental Therapies

In recent years, interest in improved treatment for classic 21OHD has grown [101–109]. These treatments can be grouped as improved glucocorticoid delivery approaches and glucocorticoid-sparing therapies to mitigate androgen excess. Small series of patients treated with continuous subcutaneous hydrocortisone infusion have been reported [101, 102], using an insulin pump with hydrocortisone hemisuccinate. This approach appears to be most useful for patients with rapid hydrocortisone metabolism [103] or patients with impaired absorption via the gut, but is labour-intensive and costly. Alternatively, modified-release oral hydrocortisone has been tested in once daily [104] and twice daily regimens [105], the latter yielding significantly better lowering of adrenal-derived androgens compared to conventional therapy [109]. A phase III trial of one preparation (Chronocort) has been completed primarily in Europe (NCT03062280), and one is planned for the United States (NCT03532022).

Conceptually, glucocorticoid-sparing regimens for 21OHD could add drugs to block androgen action, inhibit androgen biosynthetic enzymes, or reduce ACTH stimulation of steroidogenesis. The first such approach employed the antiandrogen flutamide and the first-generation aromatase inhibitor testolactone to reduce hydrocortisone exposure and to optimize adult height in children [106]. Subsequently, the potent CYP17A1 inhibitor abiraterone acetate, which is FDA-approved for the treatment of prostate cancer (at 1000 mg/d), was studied in six adult women with classic 21OHD. This short-term study demonstrated robust reductions is adrenal-derived androgens with 100–250 mg/d of abiraterone acetate when added to 20 mg/d hydrocortisone [27]. A phase I clinical trial of abiraterone acetate in children with 21OHD is now in progress (NCT 02574910).

Alternatively, direct suppression of ACTH secretion might be possible using small-molecule inhibitors of the corticotropin-releasing hormone type 1 receptor (CRHR1). A single-dose, dose-escalation study in eight women with classic 21OHD demonstrated significant reductions in first morning ACTH and 17OHP in half of patients with the CRHR1 antagonist NBI-77860 given at bedtime [107]. Currently, two short-term multiple-dose phase II clinical trials of CRHR1 antagonists are ongoing, crinecerfont (NCT 03525886) and tildacerfont (NCT03257462). The sterol-O-acyltransferase inhibitor ATR-101 was also studied in a dose-escalation trial that included eight men and women with classic 21OHD (NCT02804178), and an extended trial is now planned in Europe.

SECTION 6

Neuroendocrine Tumours and Inherited Endocrine Tumour Syndromes

6.1

Overview and Pathophysiology of Neuroendocrine Neoplasms

Rajaventhan Srirajaskanthan and Guido Rindi

Introduction

The first description of a neuroendocrine tumour was in 1867 by T. Langhans, who described a submucosal tumour that resembled poorly differentiated glandular tissue arranged in 'nests' with a rich, thick fibrous stroma [1]. Thereafter in 1888, O. Lubarsch reported the post-mortem identification of multiple ileal tumours, which he was reluctant to classify as 'carcinomas' due to a benign growth pattern appearance [2]. However, it was Siegfried Oberndorfer who published his seminal paper *Carcinoid Tumours of the Small Intestine* in 1907 and recognized their unique nature; finally defining the lesions as a neoplasm distinct from carcinoma. The term 'karzinoide' (meaning carcinoma-like) was initially introduced by Oberndorfer in 1907 [3]. Although, the term 'carcinoid tumour' has historically been used, with advances in the understanding of the tumour biology, and the recent World Health Organization (WHO) classifications, the term neuroendocrine tumour (NET) is considered more appropriate. In consideration of the current classification terminology, the definition of neuroendocrine neoplasm (NEN) is now adopted to embrace well and poorly differentiated types. Originally, Pearse proposed that tumours develop from migration of cells from the neural crest; however, it is now thought that the tumour cells are derived from multipotent stem cells [4]. NENs are believed to originate from neuroendocrine or neuroendocrine-committed cells, which are present in organs throughout the body.

Incidence and Prevalence

Over the last 10 years there has been a number of studies investigating the true incidence and prevalence [5, 6]. SEER data demonstrated the incidence of 5–7 per 100 000 population. Further studies have demonstrated similar prevalence in Europe [7, 8]. Interestingly, however, while the overall incidence is around 7 per 100 000 population [6, 9], there is an ethnic variation with a higher incidence rectal NENs seen in African-Caribbean and Asian populations [10]. In addition, there is an ethnic variation in different countries [11]. Gender difference between male or female varies according to the anatomical site of neoplasm occurrence.

The prevalence of NENs in a recent study from the USA, using the SEER database is reported at 48 per 100 000 population, this excludes the appendiceal NETs [9]. The incidence in Europe and the rest of the world is reported between 4 and 6 cases per 100 000 [7, 8, 12, 13].

There is a significant increase in incidence of NENs over the last 40 years. This may represent with increasing incidence of these NENs in addition to increase detection with endoscopic screening and use of cross-sectional imaging [8, 10]. This trend has been demonstrated worldwide and affecting both low- and high-grade neuroendocrine neoplasms [14]. Incidence of carcinoid syndrome has been reported at 19% of all NENs and this give an overall incidence of 1: 100 000 population [5]. Little information is available as for risk factors for NEN. A recent metanalysis of published information indicated several variables including family history of cancer, alcohol consumption, smoking habits, and diabetes mellitus as potential risk factors with variable significance at different anatomical places [14].

Clinical Features and Diagnostic Investigations

Signs and symptoms of neuroendocrine neoplasms can be separated into non-functional and functional. Approximately 60% of neoplasms are non-functional and therefore, these often present as incidental findings, or as result of mass effect of the tumour. The

Table 6.1.1 The clinical features of neuroendocrine tumours

Site	Clinical features	Main cell type	MEN 1
Pancreas			
Non-functional	Symptoms related to mass effect	various	60%
Insulinoma	Hypoglycaemia, Whipple's triad, clammy, sweating, weight gain	B cell	5–10%
Gastrinoma	Zollinger–Ellison syndrome	G cells	25%
VIPoma	Werner–Morrison syndrome, watery diarrhoea	VIP	10%
Glucagonoma	Diabetes mellitus, necrolytic migratory erythema	A cell	5–10%
Somatostatinoma	Gallstones, diabetes mellitus, steatorrhoea	D cells	5–10%
Bronchial	Majority non-functional, 8% carcinoid syndrome, 'atypical' flushing		
Stomach	Majority non-functional, associated with chronic atrophic gastritis; rare 'atypical' carcinoid syndrome		
Duodenum	Majority non-functional; rare gastrinoma syndrome	G cells	20%
Small bowel	Majority non-functional, 40% develop carcinoid syndrome	Serotonin-producing Enterochromaffin EC cells	
Colorectal	Usually non-functional, however tumours may secrete somatostatin, other peptides, and occasionally carcinoid syndrome may occur	PYY/glicentin-producing cells	

functional tumours can lead to a number of distinct clinical syndromes which are summarized in Table 6.1.1. A number of chapters in this section of the textbook will deal with the functional tumours in much more detail (see Chapters 6.3–6.10).

Diagnostic Investigations

Diagnosis of NENs requires biochemical, topographical imaging, and, importantly, histological diagnosis. Efforts should be made to identify the primary tumour site, which can be difficult since some primary lesions are small and not detected by conventional cross-sectional imaging.

Biochemical Tests

Patients with suspected NENs should undergo biochemical testing, including fasting gut hormones (glucagon, vasoactive intestinal peptide, somatostatin (SST), and gastrin), chromogranin A, and pancreatic polypeptide. Urinary or plasma 5-HIAA measurement should also be performed in all patients with suspected carcinoid syndrome [15, 16]. Table 6.1.2 shows the different biochemical tests that are used for diagnosis of NENs.

Histology

Histology remains the gold standard for diagnosing NENs (see Figure 6.1.1). Along the diagnostic work-up it is advised to provide histological rather than cytological samples in order to achieve an accurate diagnosis. Specimens should be immunostained with a panel of antibodies to general neuroendocrine markers to demonstrate the neuroendocrine nature of the neoplasm. These include chromogranin A and synaptophysin; other general markers such as PGP9.5, neuron-specific enolase and CD56 N-CAM may also be of help specially to elucidate the neuroendocrine nature of poorly differentiated NENs. In addition, the sample should be stained with an antibody to the Ki-67 protein, since the Ki-67 proliferation index is necessary for grading neoplasms and has important significance for prognosis and treatment (see Figure 6.1.1). If required and upon the clinician's request, the sample may be stained for specific hormones, in order to support the clinically observed hyperfunction. The histological characteristics of NENs vary according to the degree of differentiation. Low-grade, well-differentiated NENs originating from the gut were previously termed 'carcinoids' and are now defined as NETs. These tumours had classic histological architecture of solid islet, trabecular, or ribbon-like cell patterns, with little or no cellular pleomorphism, occasional mitoses and absent or only spotty necrosis [17]. Usually NETs show a delicate stroma rich in vessels. According to the current classification by WHO and AJCC [18–21]. NETs are graded in three tiers as grade 1, grade 2, and grade 3 based on mitotic count and Ki-67%. The morphology of NETs is rather similar between grades, while only NETs G3 may show a somehow more solid structure with focal/spotty necrosis, a stroma more evident and often thick, evident mitoses, usually below 20 per 2 mm^2, and Ki-67% above 20%. Due to their non-typical morphology this type of NETs were previously defined as 'atypical carcinoid', a term which is still retained for NETs of the thoracic region [22]. High-grade, poorly differentiated NENs are currently

Table 6.1.2 General biochemical plasma markers raised in neuroendocrine tumour-dependent on anatomical site

Type of tumour	Plasma marker	Urinary marker
NEN	Chromogranin A, chromogranin B, neuron-specific enolase	5-Hydroxyindoloacetic acid
Phaeochromocytoma	Chromogranin A, chromogranin B, Neuron-specific enolase, β-human chorionic gonadotropin, neuropeptide Y, plasma-free metanephrines, α-fetoprotein	Fractionated metanephrines
Pancreatic NETs	Chromogranin A, chromogranin B, neuron-specific enolase, gastrin, pancreatic polypeptide, somatostatin, VIP, PTHrP	

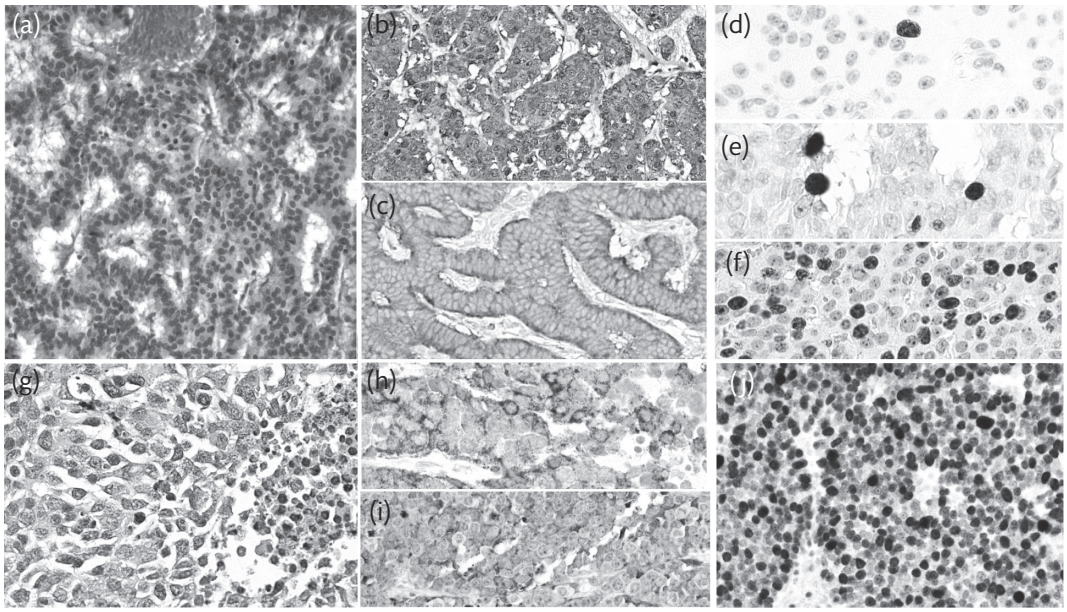

Figure 6.1.1 Histology of digestive neuroendocrine neoplasms (NENs): neuroendocrine tumours (NETs) are shown in pictures (a–f); neuroendocrine carcinomas (NECs) in pictures (g–j) (a) and (g) haematoxylin and eosin; (b–f) and (h–j) immunoperoxidase. (a) Colon non-functioning L-type cell NET showing a trabecular structure rich in delicate vessels and low cell atypia; (b) chromogranin A diffuse staining of a non-functioning pancreas NET with solid islet structure; (c) synaptophysin diffuse staining in a non-functioning colon trabecular L-type NET; d.-f. Ki67 nuclear labelling in NET G1 (pancreas insulinoma, **d**), G2 (pancreas non-functioning, **e**) and G3 (colon non-functioning, **f**); (g) NEC large cell type of the duodenum showing severe atypia and necrosis (right part of the micrograph); (h) chromogranin A faint but diffuse staining in a NEC of the gall-bladder, large cell type; (i) synaptophysin diffuse and intense staining in a colon NEC, large cell type; (j) diffuse nuclear labelling for Ki67 in a gastric NEC, small cell type.

defined as neuroendocrine carcinomas (NEC), by default G3. These tumours display solid or organoid structure with extensive necrosis, a usually thick/desmoplastic stroma, severe cellular atypia with evident mitoses, often atypical. The WHO classification gives clear parameters for categorizing NENs into the two categories of NET and NEC and the three NET classes described earlier. A minimal diagnosis of NEN should comprise the definition of the tumour category, whether NET or NEC, the definition of the grade for NETs and, for surgical specimens only, the stage definition. NETs are staged according to a site-specific NEN-dedicated staging system [23, 24]. NECs are staged following the site-corresponding adenocarcinoma/squamous cell carcinoma staging scheme.

Imaging

Cross-sectional imaging is usually with contrast computed tomography (CT), including arterial phase enhancement, of the abdomen, chest, and pelvis [25]. MRI is the most sensitive modality for liver metastases [26]. Studies of CT in carcinoid tumours show an overall sensitivity of 80% in detecting lesions [15, 25]. The sensitivity and specificity of CT and MRI alone are lower than the combination of ^{111}in-octreotide scan with CT or MRI.

Nuclear Medicine

Nuclear medicine imaging is important in staging of disease and determining suitability for therapy with somatostatin SST analogues and peptide receptor. The main nuclear imaging technology modalities are octreotide scintigraphy based and positron emission tomography (PET) scanning. Somatostatin receptor scintigraphy used to primarily be based on ^{111}In-Octreotide scintigraphy, however, more recently Tc-99m-tektrotyd scintigraphy has demonstrated similar if not superior sensitivity and specificity [27]. However, this is still inferior in terms of sensitivity and specificity to Ga-68 DOTATATE PET imaging [28].

There are five different SST receptors (SST_s) subtypes, all of which have strong affinity for SST [29]. Octreotide is an SST analogue which has a strong affinity for SST_2 and, to a lesser extent, SST_5 receptors [29]. NENs predominantly express SST_2 and this expression is mostly restricted to well-differentiated low-grade NETs. Synthetic radiolabelled SST analogues, such as ^{111}In-pentetreotide, enable SST_s scintigraphy to be performed [30]. The sensitivity of SST_s scintigraphy for the detection of GEP NETs has been well studied. The sensitivity has been reported to be between 67% and 100%, with no significant difference in carcinoid tumours from foregut, midgut, or hindgut origin. With pancreatic NETs, sensitivity of SST_s scintigraphy is dependent on the type of functional tumour. Gastrinomas detection has a sensitivity between 56 and 80%, VIPoma is 60–70%, and insulinoma lower at 50% due to a lower expression of SST_2. With pheochromocytomas, SST_s scintigraphy is often negative and other imaging modalities, such as MIBG, should be used. Medullary thyroid cancer express SST_1 therefore may be negative on SST_s scintigraphy. False-positive scans can be seen in patients with chronic inflammation and granulomatous disease. SST_s scintigraphy detection is also affected by the size of NETs and will often not detect lesions less than 1 cm.

MIBG has been used for two decades to visualize pheochromocytoma and paraganglioma. MIBG shares the same method of uptake as noradrenaline and is not dependent on SST receptor expression. In pheochromocytomas, MIBG has sensitivity of 87% and specificity of 99% [31].

FDG-PET scanning in other malignancies is well established; however, its role for NENs is still evolving. [^{18}F]2-fluoro-2-deoxyglucose (FDG)-PET is only suitable for intermediate (G2) and high-grade tumours (NET G3 and NEC) and is of minimal use in low-grade tumours due to their slow glucose turnover. Studies with Ga-68 DOTA-octreotide had a greater sensitivity than conventional SST_s scintigraphy [32]. Ga-68 DOTATATE PET has become standing functional imaging investigation in a number of centres [33–35].

Management of Neuroendocrine Neoplasms

Therapies for NENs incorporate those required for control of symptoms due to hormonal secretion from tumours, and also antiproliferative therapies. The management of NENs requires the use of a number of different therapies including surgery, biotherapy, chemotherapy, peptide receptor targeted therapy, and tumour embolization. The best way to provide the most appropriate management plan for patients is through a multidisciplinary approach for a patient-tailored therapy [15, 36]. Different therapies may be required for different grade NETs and for different clinical stages. In patients with indolent disease and mild symptoms merely symptomatic relief may be all that is required for some years.

Surgery remains the only method of cure and this should be offered to all patients when appropriate. If there is no evidence of metastatic disease, then resection of the primary should be considered to give the best outcomes and also for high-grade NENs [17, 36]. However, if there is metastatic disease the role of surgery is less clear, generally surgery can be considered if significant debulking can be achieved. There is also evidence suggesting the benefit of resection of small bowel primary tumours in the context of metastatic disease if there are causing symptoms [38, 39]. The ENETS guidelines recommend palliative resection of the primary tumour and mesenteric metastases in the setting of stage IV NET disease for symptomatic patients with intestinal obstruction, ischaemia, or tumour bleeding [16].

Non-Surgical Therapy

Liver Directed Loco-Regional Therapy

The most common site of metastatic disease from a NEN is the liver and current experience is almost restricted to NETs. There are a number of different liver-directed therapies that can be performed to reduce tumour volume and control disease progression [40, 41].

Hepatic Artery Embolization

NET liver metastases are highly vascular with an arterial supply thats if occluded will lead to ischaemia and necrosis. By performing hepatic artery embolization of the tumours, normal liver tissue is supplied from the portal vein and preserved during embolization of hepatic arteries. Hence the tumour blood supply can be embolized without significant damage to the surrounding liver. The process of embolization involves passing a catheter to the hepatic artery or branch and material (gelfoam powder, microembospheres, and polyvinyl alcohol particles) released to occlude the vessel in bland embolization. In chemoembolization, cytotoxics (like cisplatin, miriplatin, gemcitabine, doxorubicin, streptozocin, and 5-FU) are injected prior to arterial embolization in order to achieve higher concentrations and prolonged action in necrotic tissue. Contraindications to embolization include occlusion of the portal vein, severe liver dysfunction, and presence of biliary anastomosis. Relative contraindications include tumour burden, renal impairment, and heart disease (including carcinoid heart disease) [42, 43]. Median progression-free survival (PFS) rates of around 18 months after transarterial embolization (TAE) or chemoembolization (TACE) in patients with liver metastases [42, 44, 45]. Clinical response rates in terms of reducing in symptoms from carcinoid syndrome have been reported as high as 90%.

Selective internal radiation therapy (SIRT) otherwise known as radioembolization is performed using ^{90}Ytrrium resin microspheres that are injected through a percutaneously placed hepatic artery catheter via the femoral artery; this leads to cell death and tumour shrinkage [46, 47]. The contraindications to SIRT are similar to that of bland embolization. Long-term radiologic and biological responses can be achieved with radioembolization with partial or complete response seen in 63% [44, 45]. Median survival varies from 36 to 70 months [41, 48]. To date there is no randomized evidence that radiologic and symptom response rates following SIRT are different from those seen with TACE or TAE [43, 49].

Radiofrequency ablation of liver metastases is a well-established technique for management of liver metastases from a number of different tumours. The criteria are usually lesions less than 5 cm in maximum dimension and less than eight in number. The procedure involves electrical energy delivered to the tumour via a catheter that is inserted percutaneously or laparoscopically. This electrical energy leads to heating and cell death. High symptomatic response rates of 70–80% have been reported in patients with functional tumours such as those with carcinoid syndrome [50].

Systemic Medical Therapy for NENs

For patients with extensive metastatic disease a more systemic approach to treatment is usually considered. There are number of therapies available for treatment of NENs depending on grade, stage, and the site of the primary tumour [51]. A brief overview of these therapies is described next, with more detail regarding specific therapies in the forthcoming chapters.

Somatostatin Analogues

Over 70% of NENs express somatostatin receptors (SSRs) on their cell surface. SSRs expression is usually restricted to well-differentiated low-grade neoplasm (NETs) though up to 25% of NET G3 and NEC may also express SSTRs [52]. These can be targeted by synthetic somatostatin analogues. Initial, studies demonstrated a significant improvement in terms of controlling hormonal secretion and symptoms in patients with functional tumours, especially carcinoid syndrome. Over the past 10 years two randomized control trials (RCTs) have been published that have also demonstrated an antiproliferative effect of somatostatin analogues [53, 54]. The CLARINET trial was an RCT in which lanreotide was compared with placebo, was associated with significantly prolonged PFS (median not reached vs. median of 18.0 months, P <0.001). The estimated rates of PFS at 24 months were 65.1% (95% CI, 54.0–74.1)

in the lanreotide group and 33.0% (95% CI, 23.0–43.3) in the placebo group.

Chemotherapy

There have been a number of trials regarding chemotherapy in GEP NENs, most evidence is in treatment of pancreatic NENs with streptozocin-based chemotherapy for well-differentiated tumours and platinum-based chemotherapy for poorly differentiated neoplasms [55–57]. There is increasing data for the use of temozolomide monotherapy or in combination with capecitabine in pancreatic NENs [56]. The role of chemotherapy in PanNETs will be discussed in more detail in a later chapter. In the ENETS guidelines there is a recommendation for chemotherapy in PanNETs as a second-line therapy in patients with metastatic disease [51]. In small bowel NETs the evidence for chemotherapy is limited, and recent ENETS guidelines suggest chemotherapy for NECs only [16, 51]. There are no specific trials studying chemotherapy in bronchial NETs, however, patients with typical and atypical bronchial NETs are often treated with chemotherapy. Temozolomide is advocated as palliative treatment in bronchial NETs as it has been the most widely studied in the subgroup of lung NET and has an acceptable safety profile [58].

Molecular Targeted Therapy

There are two molecularly targeted therapies in management of metastatic NETs. Everolimus is an oral inhibitor of the mammalian target of rapamycin (mTOR) pathway and has activity against pancreatic NETs through a mechanism of cellular apoptosis and antiangiogenesis [59]. Median PFS is significantly longer in those treated with everolimus over placebo (11 vs. 4.6 months) [59]. Severe adverse events like hyperglycaemia and anaemia were rare, with stomatitis, diarrhoea, and fatigue are more commonly seen. Everolimus is also licenced for patients with pulmonary NETs and non-functional gastrointestinal NETs following the positive results obtained from the RADIANT-4 trial [60]. This trial demonstrated everolimus improved median PFS by 7.1 months in patients with advanced, progressive, well-differentiated (grade 1 or grade 2), non-functional lung or gastrointestinal NETs vs. placebo (hazard ratio, 0.48; 95% confidence interval [CI], 0.35–0.67; P <0.00001). In a subsequent subgroup analysis of the RADIANT-4 data. There were 90 of the 302 patients enrolled in the study had primary lung NET (everolimus, n = 63; placebo, n = 27). Median PFS (95% CI) by central review was 9.2 (6.8–10.9) months in the everolimus arm vs. 3.6 (1.9–5.1) months in the placebo arm (hazard ratio, 0.50; 95% CI, 0.28–0.88). More patients who received everolimus (58%) experienced tumour shrinkage compared with placebo (13%) [61].

Sunitinib, a multitargeted tyrosine kinase inhibitor, has activity against a range of molecular targets, including vascular endothelial growth factor (VEGF) receptors and platelet-derived growth factor receptors, and has been shown to have antitumour activity in pancreatic NETs. Median PFS is significantly longer in patients treated with sunitinib over placebo (11.4 vs. 5.5 months) [62]. Frequent adverse events encountered include diarrhoea, nausea, vomiting, asthenia, and fatigue. The long-term outcome is a 10 month longer survival in the treatment arm, but this did not reach statistical significance, likely because of the high cross over rate [63].

Peptide Receptor Radionuclide Therapy

Somatostatin receptor subtype 2 is expressed in the majority of NETs and confirmed through uptake in octreotide scintigraphy or somatostatin-based PET imaging. This offers a therapeutic option by attaching a β-emitting radioisotope to a molecule that will bind to somatostatin receptor-2 then particle binds to neuroendocrine tumour cells and leads to cell death. The two commonly used radioisotopes are Lu-177-DOTATATE which is a beta and gamma emitter and Y-90 DOTATATE which is primarily a beta emitter. Therapy is usually administered over four cycles spaced 8–12 weeks apart. Contraindications to therapy are significantly impaired renal function, severely suppressed bone marrow. There have a been a number of reports from single centres regarding peptide receptor radionuclide therapy (PRRT) demonstrating a partial response rate up to 30% with stabilization of disease in more than 60% of patients. The average time to progression of 40 months from commencing therapy [64]. One study demonstrated that from the point of diagnosis, there is a survival benefit of 40–72 months compared to historical controls [65]. Adverse events include bone marrow and liver toxicity as well as radiation-induced loss of renal function and gastrointestinal disturbance from the use of renoprotective agents (amino acid infusions). A recent phase 3 RCTs comparing Lutathera, a commercially developed Lu-177-DOTATATE, against high-dose Sandostatin LAR (60 mg every 28 days) in patients with progressive metastatic functional midgut NENS. This demonstrated a significant response rate of 18% in the 177Lu-Dotatate group versus 3% in the control group (P <0.001). In the planned interim analysis of overall survival, 14 deaths occurred in the 177Lu-Dotatate group and 26 in the control group (P = 0.004). The estimated rate of PFS at month 20 was 65.2% (95% confidence interval [CI], 50.0–76.8) in the 177Lu-Dotatate group and 10.8% (95% CI, 3.5–23.0) in the control group.

Prognosis of NENs

Survival in NENs has been improved over the last few years [13]. Recent data from the SEER database suggests there has been an improvement in survival over the last 30 years [9]. The overall median survival of all NENs in the SEER database was 9.3 years (112 months). Localized NETs had better median OS (>30 years) compared with regional NETs (10.2 years) and distant NETs (12 months) (P<0.001). The overall survival is dependent on stage, grade, and site of primary. In terms of factors that determine prognosis these are also dependent on primary site, grade, and tumour, and tumour burden.

6.2

Neuroendocrine Tumour Markers

Waljit Dhillo and Paul Bech

Neuroendocrine Cells

In 1938, Friedrich Feyrter identified the presence of pale cells (Helle Zellen) distributed throughout the body and with greater preponderance in the intestinal tract. As these cells could secrete chemical messages, Feyter proposed the diffuse endocrine system. With advances in histochemistry and electron microscopy, understanding of the cell type progressed. In 1969, Everson Pears proposed the amine precursor uptake and decarboxylation (APUD) to describe the production of biogenic amines and polypeptide hormones [1]. Neuroendocrine (NE) cells make up the diffuse NE system and occur either singly or in small groups in a variety of tissues and organs. Although morphologically and embryologically diverse, they are now defined by the production of neuropeptides and neurotransmitters, and the presence of dense core secretory vesicles in the cytoplasm from which neuropeptides are released into the circulation by exocytosis. However, unlike neurones, NE cell do not possess synapses or axons. NE cells can be identified by the use protein components of the secretory granules unique to this cell.

Neuroendocrine Tumours (NETs)

Classification

Siegfried Oberndorfer was the first to investigate tumours in the bowel that were rare and indolent. He used the term '*Karzinoid*' ('carcinoid') (carcinoma-like) to describe the small tumours he found in the submucosa of the gut. The classification of NETs has changed over the years. In 1960 the World Health Organization (WHO) published a classification for carcinoids of the diffuse endocrine system, and subdivided the carcinoid group into enterochromaffin cell carcinoids, gastrin cell carcinoids, and other carcinoids. A second WHO classification was published in 2000, it uses the term NET, and classification is based on size, proliferation, localization, and differentiation. Distinction is made between well-differentiated NET (benign behaviour or uncertain malignant potential), well-differentiated NE carcinomas (low-grade malignancy), and poorly differentiated (usually small cell) NE carcinomas of high-grade malignancy. The latest WHO classification in 2010 defined NETs as neuroendocrine neoplasia and gastrointestinal NETs are classed according to their proliferative index and mitotic count. The most recent WHO classification published in 2017 introduced a new category of well-differentiated neoplasms, neuroendocrine tumours G3, in addition to the previous categories of neuroendocrine tumours G1 and G2 [2]. Despite the reclassifications older terms such as carcinoid are still used (see Chapter 6.1).

Types of NETs

Cells of the diffuse endocrine system are particularly prominent in the gastrointestinal tract, pancreas, C cells of the thyroid, adrenal medulla, parathyroid tissue, respiratory tract, skin, and genitourinary system. NETs are known to occur in all these tissues and, therefore, constitute a very heterogenous group of tumours.

Despite the large number of peptides in the gut, only a few when secreted in excess by NETs, result in clinical syndromes. The majority of gut-hormone secreting tumours originate in the pancreatic islet cells and in the midgut. Gastroenteropancreatic neuroendocrine tumours can be divided into functioning and non-functioning tumours. Functioning tumours include insulinomas, gastrinomas, VIPomas, glucagonomas, and somatostatinomas. The symptoms are caused by the excess peptide hormone secretion. The hormone secreted may be eutopic or ectopic.

Diagnosis

Historically, the diagnosis of NET was determined by histological findings. The significantly worse prognosis in advanced disease and the availability of multiple therapeutic options have highlighted the need for robust tumour markers that can be used both for diagnosis and follow-up. Currently, a number of normal and abnormal forms of peptides, biogenic amines, and hormones, secreted by NETs are routinely measured as markers of disease.

An ideal tumour biomarker would be one that is secreted exclusively by the tumour cells. Biomarkers can be useful (i) for screening and differential diagnosis of NET, (ii) as a prognostic indicator, (iii)

as an estimate of tumour burden, and (iv) as a surveillance tool. Although none of the currently available markers completely fit the paradigm for an ideal tumour marker, when measured in conjunction with each other, they are useful not only for making a diagnosis but also for monitoring response to therapy and in surveillance post-remission. Consensus on biomarkers for NETs have advocated the use of three biomarkers groups originally identified for clinical drug discovery. Type 0 biomarkers should indicate the natural history of the disease, type 1 biomarkers should show the effect of intervention and type 2 biomarkers are surrogates for clinical endpoints [3].

General Neuroendocrine Markers

NETs often express and secrete peptides that are common to most neuroendocrine cells and to cells that have undergone neuroendocrine differentiation.

Chromogranins

Dense core secretory vesicles, present throughout the neuroendocrine system, store and release chromogranins. Chromogranins are a group of acidic, soluble secretory proteins which are thought to play a role in the formation of vesicles.

Chromogranins (A, B, and C) form a major constituent of these granules [4] and are widely distributed in the neuroendocrine system. As a result, they are excellent tissue and serum markers for neuroendocrine tumours.

Chromogranin A

Chromogranin A (CgA) was the first of the 'granins' to be identified and has the widest distribution [4, 5]. It is quantitatively the major constituent of the secretory granules in the NE cells and is expressed in the cells of the anterior pituitary, C cells of the thyroid, chief cells of the parathyroid, islet cells of the pancreas and the chromaffin cells of the adrenal medulla. It is also widely distributed in the neuroendocrine cells of the bronchial and gastropancreatic systems and the skin.

The human form of CgA is an acidic 439 amino acid protein that is preceded by an 18 amino acid signal peptide. Both the N and C terminals are well conserved between species. The CgA molecule contains a number of mono and dibasic amino acid sites, thus implying fairly extensive and varied post-translational processing. This suggests that it may be a precursor to a number of other peptides. Although the function of CgA has not yet been fully elucidated, it is often cosecreted with the neuroendocrine hormones and peptides and therefore thought to play a role in the processing, packaging, and secretion of neuropeptide precursors and hormones [6].

The sensitivity and specificity of circulating CgA measurement in the biochemical diagnosis of NET have been extensively studied and values calculated range from 56% to 100%. This variation in values can be attributed to the heterogeneous composition of NET subtypes used in the patient groups, the varying number of subjects used in the patient and control groups, the different reference intervals used, the different methods to obtain the reference intervals and the different CgA assays used.

To investigate the difference between CgA assays, a comparison of four kits demonstrated no significant difference in sensitivity between the assays, however, the sensitivity could be increased significantly when a combination of two non-cross reacting assays were used [7].

A meta-analysis of 13 studies meeting the inclusion criteria out of 78 potential studies revealed a sensitivity and specificity of 73% and 95%, respectively. Furthermore, the area under the curve was 0.896 indicating the usefulness of CgA [8]. Therefore, most NETs are associated with increased circulating levels of CgA. Even tumours that produce hormones with no identifiable clinical features or have lost the ability to synthesize peptides, continue to express CgA [4] As a result, CgA is routinely used as a marker for both diagnosis and monitoring of NETs. It is particularly useful (i) when existing cell-specific markers (explained later in the chapter) are either unstable, rapidly fluctuating or inconvenient for clinical use; (ii) to confirm the neuroendocrine origin of a tumour; and (iii) as a general marker of disease when the neoplastic disease involves multiple neuroendocrine tissues (e.g. multiple endocrine neoplasia) [4].

CgA has been shown to correlate with tumour burden and extent of metastases. Increasing concentrations of CgA can also indicate worse prognosis. However, high circulating CgA concentrations have been measured in gastrinoma patients despite the small primary tumour and absence of metastases.

CgA can be used to monitor recurrence of disease. A comparison of CgA, urinary 5HIAA and radiological measurements in patients with a midgut NET found that elevated plasma CgA was the first to indicate disease recurrence.

There are, however, some limitations to using CgA as a tumour biomarker. An increase in circulating CgA levels due to a tumour often goes undetected until it has reached a size capable of producing appreciably increased amounts of CgA. Further, CgA cannot differentiate between different subtypes of NET and it is not equally expressed in all NETs. Some only weakly express CgA (e.g. small cell carcinoma of the lung) [9] Concentrations are only minimally elevated in patients with insulinomas. Most patients with metastatic foregut and midgut carcinoids have increased (tumour burden dependent) levels of CgA. Gastrinomas may show increased levels of CgA even in patients with very limited disease. This is probably because chronic hypergastrinemia causes hyperplasia of the enterochromaffin cells [10].

The biological variation of circulating CgA levels has been studied extensively and levels can vary by 30% from day to day in healthy controls and patients alike. In addition, there are a number of non-neoplastic conditions are associated with high CgA levels. Patients on proton pump inhibitors (PPI) have raised CgA levels. Renal impairment, and to a lesser extent, liver failure can also result in increased levels [11].

CgA undergoes post-translational changes before release. Tumours may, therefore, release different molecular forms of CgA [12]. As a result, a number of different forms of CgA are released into circulation. Thus, levels measured are dependent on the antiserum used. Some assays measure only the whole CgA, while others measure the whole CgA plus fragments that contain the specific epitope to which the antisera was developed. Thus reference ranges are assay-specific. A lack of standardization between the various commercially available immunoassays makes comparison difficult. However, sequential measurement with the same assay can reliably be used to monitor disease progression in a patient.

Pancreastatin is a 49-amino acid (CgA 240–288) peptide produced by dibasic cleavage of CgA. Pancreastatin assays that use

antisera raised to the mid-molecule cross-react strongly to CgA and can be used to measure both pancreastatin and CgA. Assays using antisera raised to the N or C terminals of pancreastatin are, however, specific for pancreastatin. Pancreastatin concentrations are shown to correlate well with extent of liver involvement. Specific pancreastatin assays may therefore be used to assess and monitor the extent liver involvement in patients with NET [13]. The advantage of assays using antibodies specific for pancreastatin is that they are unaffected by PPIs [14].

Chromogranin B

Chromogranin B (657 amino acid peptide) (CgB) or GAWK (a partial sequence of CgB 420–493) coexists with CgA in the secretory granules and bears a strong homology to CgA in the terminal regions. Like CgA it is an acidic protein [15]. The relative abundance of CgA and CgB is cell specific. CgA is the dominant granin in the pancreatic endocrine tumours and in the serotonin secreting tumours in the ileum and appendix. However, in rectal carcinoids, where CgA is virtually absent, CgB is the most abundant granin [16]. Elevated CgB concentrations have been detected in some NET patients when CgA is not raised [17]. It is, therefore, measured complementary to CgA in some centres, and improves diagnostic sensitivity. CgB has also been shown to be a more sensitive marker of PNETs than CgA [18]. CgB assays are, however, associated with the same problems of standardization as the CgA assays [17, 19]. The combined measurement of CgA and CgB has a sensitivity of 89% for NETs [20]. A polyclonal antiserum with cross reactivity to both CgA and B has been developed by Eriksson *et al.* [21].

Circulating levels of CgB have only been shown in phaeochromocytoma to correlate with tumour bulk [22] and there is little evidence to suggest that CgB can be used to predict disease recurrence. Unlike CgA, CgB is not affected by PPI treatment. It is, however, like CgA effected by renal impairment [23].

Chromogranins are best measured in plasma. Fasting samples are not required. Samples must be centrifuged, plasma aliquoted, and stored at –20°C immediately after collection, to prevent degradation of the peptide. Patients on acid suppressive therapy should be advised to come off treatment before CgA is measured (see summary).

Neuron-Specific Enolase

α-γ and γ-γ isomers of the glycolytic enzyme phosphopyruvate hydratase, 2-phospho-D-glycerate hydrolase occur mainly in the neuronal and neuroectodermal tissue and are collectively known as neuron-specific enolase (NSE). NSE is expressed in a number of primary neuroendocrine tumours and in tumour with neuroendocrine differentiation [24, 25]. It is specifically used in the diagnosis and follow-up of patients with neuroblastoma and small cell carcinoma of lung. This is particularly helpful as CgA is poorly expressed in small cell lung carcinoma [26]. Although the specificity of serum NSE in the diagnosis of neuroendocrine tumours is lower than that of CgA, the combination of both markers has a higher sensitivity than both markers separately [27].

Other Markers

Pancreatic polypeptide (PP) is a 36 amino acid peptide secreted by the normal pancreas. Levels increase in response to food. Although its function has not been fully elucidated, PP is known to slow gastric motility and is thought to play a role in the initiation of satiety [28]. Its levels are increased in 74% of gastropancreatic tumours and roughly 50% of carcinoids. The term PPoma is used to describe tumours secreting particularly high levels of PP. Although no specific clinical symptoms have so far been attributed to elevated PP levels [12, 21] these tumours are sometimes associated with non-specific gastrointestinal symptoms. Due to a significant response to food, PP is best measured in plasma samples taken after an overnight fast. Samples must be centrifuged, plasma aliquoted, and stored at –20°C immediately after collection, to prevent degradation of the peptide.

Somatostatin secreting tumours (somatostatinoma), although rare, have been identified for some time and are associated with diabetes mellitus, jaundice, diarrhoea, steatorrhoea, weight loss, and gall bladder disease) [29]. Other very rare secreting tumours include ghrelin secreting tumours [30, 31] which are not associated with features of acromegaly and GLP-1 secreting tumours which have symptoms of reactive hypoglycaemia [32]. Most recently a cholecystokinin secreting tumour has been identified; the symptoms included severe weight loss, non-watery diarrhoea, gall bladder, and peptic ulcer disease despite consistently low plasma gastrin concentrations [33]. Due to significant changes in circulating concentrations after food, all of these hormones are best measured in samples taken after an overnight fast. Samples must be centrifuged and plasma aliquoted and stored at –20°C immediately after collection, to prevent degradation of the peptide.

Neurokinin A and substance P are members of the tachykinin family and are expressed in midgut carcinoid cells. They act on lymphocytes and mast cell degranulation and cause vasodilatation and flushing and effect gastrointestinal motility. Levels of neurokinin A and its fragment neurokinin K are increased in 46% of patients with midgut carcinoids and serve as good prognostic markers as levels correlate well with tumour burden and therapeutic response. Increases in neurokinin A can predict worse survival [34]. Tachykinins can be measured in either plasma or serum. As tachykinins do not show a significant rise post-prandially, fasting samples are not required [35].

Alpha subunit of the glycoprotein hormones and/or β-HCG are elevated in about 25% of patients with neuroendocrine tumours like carcinoids, islet cell tumours, medullary thyroid cancer, and small cell lung cancer. Locally invasive NETs are associated with higher prevalence of increased β-HCG and alpha subunit expression and circulating levels [36].

Carcinoembryonic antigen (CEA) is not specific to neuroendocrine tumours but is found to be elevated in some NETs, such as medullary thyroid carcinoma. When used in conjunction with calcitonin, the specific marker for medullary thyroid carcinoma, CEA is a good prognostic marker as increased levels are associated with greater tumour aggressiveness and poorer prognosis [37].

Ki-67 is a proliferation antigen, which is expressed in G1, S, G2, and M phases of the mitotic cycle. Cells in G0 phase (resting phase) of the mitotic cycle do not express Ki67. As a result, actively proliferating cells are seen to have a higher expression of Ki67 on immunocytochemistry (ICC). Ki67 proliferation index is a measure of its expression in the cell based on the intensity of staining on ICC. Non-functioning and metastatic NETs are seen to have a higher Ki67 staining index. Increased expression of Ki67 is associated with a poorer prognosis. Levels, however, cannot be measured in circulation, thus limiting the use of the marker to ICC [38].

A number of other peptides including adrenomedullin [39] and cocaine-and-amphetamine-regulated-transcript (CART) [40] have been proposed as candidate markers for NETs. The highest levels of adrenomedullin are found in neuroendocrine tumours of bronchial, midgut, and unknown origin. Levels seem to be predictive of progressive disease, thus suggesting a role for adrenomedullin as a prognostic marker. CART has been found to be a specific tumour marker in patients with a range of neuroendocrine tumours and a more useful marker than either CgA or CgB in patients with phaeochromocytoma or paraganglioma [18]. Used in combination with CgA, CART, measurement has the potential to improve sensitivity in diagnosis and follow-up of neuroendocrine tumours, in particular progressive pancreatic neuroendocrine tumours. CART expression in small bowel tumours taken from 97 patients has shown that it is associated with worse survival [41].

Cell-Specific Markers

In addition to the markers just mentioned, NE cells are often associated with the synthesis of specific hormones/peptides. Excessive production and/or release of hormones by tumours arising from these cells may result in clearly identifiable clinical syndromes (e.g. Zollinger–Ellison syndrome in patients with gastrinomas and recurrent hypoglycaemia's in patients with insulinomas). Other NETs may present with unusual clinical symptoms as a result of ectopic secretion of hormones such as growth hormone or adrenocorticotropic hormone (ACTH). In such tumours (also known as functioning tumours), the specific hormone can be used as a marker for diagnosis, monitoring, and surveillance of disease. Some of these tumours and their markers are listed in Table 6.2.1. Each of these tumours is discussed in detail (see specific chapters in section 6).

Measurement of serum hormone concentrations can also be useful in the diagnosis of NETs in which the hormonal products produce a few non-specific or no clinical symptoms. Hormones such as calcitonin, PP, somatostatin, and pro-hormones like pro-opio-melanocortin (POMC) and calcitonin-gene-related-peptide (CGRP) are examples of this.

Most peptides, hormones, and neuropeptides secreted by neuroendocrine cells are first synthesized as precursors or pro-hormones. In normal NE cells they are then processed into mature hormones by sequence-specific and tissue-specific, post-translational modifications including glycosylation, amidation, phosphorylation, and sulphation. However, these processes are often defective in NETs. As a result, tumour cells may secrete a number of heterogeneous unprocessed or incorrectly/incompletely processed forms of hormones/peptides. A classic example is POMC, which is cleaved to ACTH and β-endorphin in an ordered manner in the normal pituitary. But in the presence of a tumour, high-molecular-weight forms of ACTH, as well as POMC are secreted into the circulation. Other common examples of pro-hormones secreted by tumours include CGRP, pro-gastrin, and pro-insulin. Thus, the presence of incompletely or incorrectly processed pro-hormones is suggestive of the presence of a tumour.

This fact has particular implications when validating assays for measuring hormones/peptides as tumour markers. The antibody used, must cross-react with as many forms of the hormone/peptide as possible, in order to avoid false negative results.

Dynamic function tests may sometimes improve the diagnostic sensitivity of hormone measurements. Common examples include the pentagastrin stimulation test for medullary thyroid carcinoma and 72-hour fasting test for insulinomas.

Table 6.2.1 Cell-specific markers for some of the NETs

Tumour/syndrome	Marker (peptide(s)/hormone(s))
Gastrinoma	Gastrin *(elevated fasting plasma levels, off acid suppressive treatment)*
Insulinoma	Insulin, pro-insulin, and C-peptide
	(inappropriately non-suppressed in the presence of hypoglycaemia: plasma glucose <2.2 mmol/L)
Glucagonoma	Glucagon *(elevated fasting plasma levels)*
VIPoma	Vasointestinal peptide *(elevated fasting plasma levels)*
Carcinoids	5-Hydroxyindoleacetic acid (5-HIAA)
	(elevated 24-hour urinary)
	(elevated in midgut, occasionally in foregut, and rarely in hindgut carcinoids)
Pheochromocytoma, carcinoids *(occasionally)*	Metanephrines, *(elevated plasma and 24 hr urinary)*
	Catecholamines *(elevated plasma and 24 hr urinary)*
Hypercalcaemia	Parathyroid hormone (PTH) related peptide
	(elevated in association with raised serum calcium and suppressed PTH)
Medullary thyroid carcinoma	Calcitonin
	(elevated plasma calcitonin)
Acromegaly	Growth Hormone releasing Hormone
	(elevated plasma levels due to ectopic secretion)
	Growth Hormone
	(elevated plasma levels due to ectopic secretion)
	Insulin like Growth Factor
	(elevated plasma levels due to ectopic secretion)
Cushing's syndrome	Adrenocorticotropic Hormone
	(elevated plasma levels due to ectopic secretion)
	Cortisol
	(elevated plasma levels due to high ACTH)

Glycine Extended Peptides and Considerations for New Assays

Most peptide hormones secreted from NE cells are α-amidated and this constitutes the final hormonal processing step. Many of these hormones promote cellular growth and often secretion increases in NETs and therefore, may act as tumour growth factors. The preceding precursor to the α-amidated peptide is the glycine extended peptide, whereby the glycine residue donates the amide for the C-terminus of the mature peptide. As the glycine extended precursor is the penultimate step in the pathway it is often released with mature α-amidated peptide. Early studies showed that the glycine extended peptide, may also be a tumour growth factor and have its own receptor. This prompted further studies to corroborate the potential significance of an alternative receptor for glycine extended peptides. However, failure to confirm the initial findings in the subsequent years has left researchers to conclude that there are no such receptors

[42]. What it does demonstrate, however, is that care should be taken to develop NET biomarker assays which do not distinguish between the two forms so that maximum sensitivity can be achieved. This is further highlighted with gastrin measurement. Gastrin is processed into various different forms with 14, 17, 34, and 71 amino acids. The 17 and 34 amino acid forms predominate in the circulation and can be α-amidated or glycine extended, furthermore, gastrin can be sulphated at a tyrosine residue. Therefore, to increase detection of gastrin all these forms should be detectable by the assay [43].

Summary

CgA is currently the best general available NET marker. However, none of the currently available tumour markers are specific or sensitive enough to be used as a single definitive marker and for most NETs, diagnosis by means of plasma level estimations of one hormone is not always clear cut. Therefore, two or more hormones are used for the diagnosis of most NET tumours.

Apart from the cell-specific hormones associated with functioning tumours, it is useful to monitor CgA (+/– Cg B) as a marker of disease in almost all NETs. NSE is particularly useful in monitoring small cell carcinoma lung and neuroblastomas.

A panel of tumour markers is used to investigate both functioning and non-functioning gastropancreatic tumours. The markers most commonly measured include PP, somatostatin, CgA, CgB, VIP, gastrin, glucagon, and insulin.

Of note, a number of these hormones (PP, somatostatin, VIP, gastrin, glucagon, and insulin) show a significant change in levels in response to food. Samples to measure these hormones must therefore be collected after an overnight fast.

Before collecting samples, it is always advisable to confirm sample requirements from the assaying laboratory, as requirements and reference ranges may sometimes differ. Guidelines offered by the supraregional assay service for gut hormone measurement in the United Kingdom (Imperial College Healthcare NHS Trust, London) suggest that all of these hormones, including CgA and CgB, are best measured in plasma samples collected in bottles containing ethylenediaminetetraacetic acid (EDTA) or LiHeparin (+ aprotinin). Neurotensin can only be measured in plasma samples collected in Li Heparin (+ aprotinin) bottles.

The peptides are prone to degradation. Samples must therefore be centrifuged, aliquoted, and frozen at –20°C, immediately after collection. Both CgA and gastrin levels are significantly affected by acid suppressive therapy. Unless contraindicated in the patient with clinical Zollinger–Ellison syndrome, all patients must stop PPIs for two weeks, histamine-2 receptor blocker therapy for three days and any other antacid therapy for one day before the measurement of CgA or gastrin [44]. (Further details on sample requirements can be found at pathology.imperial.nhs.uk.)

It is important to remember that, as with all other tumour markers, NET markers are only valuable when measured in the context of corroborative clinical and radiological findings.

It is hoped that future advances in microarrays and proteomics will lead to the discovery of more specific markers that will not only be more accurate diagnostic and prognostic indicators, but will also enable the use of highly effective, targeted, and individualised treatments for patients with NETs.

6.3

Carcinoid Syndrome

Dominique Clement, Raj Srirajaskanthan, and Martyn E. Caplin

Introduction

Neuroendocrine tumours (NETs) are derived from cells of the diffuse neuroendocrine system, which are present in organs throughout the body. The term 'Karzinoide' (meaning carcinoma like) was initially introduced by Siegfried Oberndorfer in 1907 [1]. The term carcinoid tumour has historically been used; however, with advances in the understanding of the tumour biology, the term NET is considered more appropriate. The term carcinoid syndrome arose from the clinical syndrome associated with carcinoid tumours. NETs commonly arise from the gastroenteropancreatic tract. The majority of these tumours are non-functional tumours, meaning that they do not secrete proteins that can cause a clinical syndrome. Around 30–45% can cause a functional syndrome and the most common clinical syndrome is carcinoid syndrome [2]. This most commonly presents with symptoms of diarrhoea, abdominal pain, and flushing. It is thought to arise due to the production of serotonin and kinins from the tumour cells which lead to the symptoms of carcinoid syndrome. The small bowel is the most common primary site that leads to carcinoid syndrome. Treatment strategies are aimed at reducing tumour load and decreasing hormone secretion from the tumour. This can be achieved through a number of different therapies and modalities including medical therapy, surgery, liver-directed therapy, and radiotargetted therapy. Carcinoid crisis is a life treating condition which can appear spontaneously or precipitated by surgery or anaesthesia. A number of systemic complications can arise secondary to serotonin or kinin secretion and are commonly seen in carcinoid syndrome. These include carcinoid heart disease which can develop with tricuspid and pulmonary valve regurgitation or stenosis. Another complication of the carcinoid syndrome can be mesenteric fibrosis with ischaemia or small bowel obstruction. Nutritional deficiencies can also occur such as pellagra, which can develop as result of niacin deficiency due to serotonin overproduction. In this chapter, we will discuss the prevalence of carcinoid syndrome, its pathophysiology, and discuss treatment options and systemic complications seen in carcinoid syndrome.

Prevalence

Carcinoid syndrome was first described in the literature by Thorsson *et al.* in 1954, they described a series of 16 patients with a new syndrome [3]. Based on clinical findings diarrhoea, skin flushing, oedema, and ascites. Autopsies performed in these cases confirmed a small intestine carcinoid tumour with liver metastases, valvular disease of right side of the heart with septal defects.

Since 1954 the prevalence of carcinoid syndrome has been extensively studied. For metastatic NETs the prevalence was reported between 8% [4] and 72% [5]. More recent European data show a prevalence of carcinoid syndrome in around 20% of NET patients [6, 7]. A recent article by Halperin *et al.* analysed the Surveillance, Epidemiology, and End Results (SEER) database in the USA, demonstrated 19% of patients with NETs had carcinoid syndrome [8].

Signs and Symptoms

The first symptoms Thorsson described with the carcinoid syndrome are diarrhoea, skin flushing, oedema, and ascites [3]. The most common symptom is diarrhoea which is reported in around 80% of patients [2, 9, 10]. Diarrhoea is the secretory type and due to gastrointestinal motility factors. The frequency is defined as at least three times a day [11, 12]. Skin flushing appears in 50–85% of

patients and is described as red appearance of skin face, neck, and upper part of chest. A flush can last from seconds to several minutes and has characteristic appearances. Flushing episodes can be infrequent, however, in untreated patients can occur at least once a day but often more frequent [2, 11–14]. Flushing may appear spontaneously but can be provoked by emotional stress, alcohol, or tyramine containing foods such as cheese, coffee, chocolate, nuts, avocado, bananas, and red wine [11, 14–16]. Individuals may not be aware of the flushing episodes, however, often family members or friends note the flushing episodes.

Abdominal pain was described in around 40% of patients, peripheral oedema in 50–60%, heart lesions in 20%, and pellagra in around 1% [2, 9, 17].

Other studies describe wheezing or bronchospasm in 10–20% of patients [8, 11, 18–20] and telangiectasia around 25% of patients [11, 21–24]. Cardiac palpitations are a common symptom often reported as occurring spontaneously or following a stressful episode. The palpitations can be short in duration of persist for long periods of time around 20–30 minutes [11, 21]. In patients with carcinoid heart disease at presentation they may have clinical signs of heart failure, usually right sided heart failure. This can include peripheral oedema, ascites, elevated jugular venous pressure, and cardiac murmurs [23].

Patients with carcinoid syndrome experience worse quality of life and more anxiety, based on hospital anxiety and depression scores, compared to NET patients without carcinoid syndrome [24, 25].

Diagnosis

Diagnosis of carcinoid syndrome is based on clinical symptoms, biochemical, imaging, and histological diagnosis. Biochemical tests for diagnosis of carcinoid syndrome are primarily the 24-hour urine collection for 5-hydroxyindolacetic acid (5-HIAA) this is a breakdown product of serotonin and has a sensitivity and specificity around 90% for NETs [26]. Certain serotonin-rich foods (bananas, avocados, plums, eggplant, tomatoes, plantain, pineapples, kiwis, and nuts) and medications (analgesic acetaminophen, cough syrups, and warfarin) can increase urinary 5-HIAA levels and should be avoided 24 hours before and during specimen collection. More recently, there has been development of plasma 5-HIAA assays, however, these are not currently widely available [27]. Chromogranin A is another useful biomarker of NET, however it cannot be used in isolation to make the diagnosis [10, 14, 16, 23].

Cross-sectional imaging with a dual-phase staging computed tomography (CT) scan of the chest, abdomen, and pelvis may be appropriate if any hormonal tests are abnormal. Somatostatin receptor scintigraphy (Octreoscan), a nuclear medicine imaging modality, should be considered in any patients with histologically proven NETs or in patients with suspected NETs and lesions identified on CT. More recently ^{68}Ga-DOTATATE PET scan is becoming the new standard of functional imaging since it is more sensitive than Octreoscan [28].

Pathophysiology

NETs normally produce and secrete several different amines like serotonin, kinins, kallikrein, and prostaglandins. However, when the primary site is within the gut, the secreted amines are degraded by the liver and symptoms do not generally occur. In the presence of hepatic metastases, metastatic lesions secrete amines mainly serotonin that will exceed and bypass the degradation capacity of the liver and then reach the systemic circulation. In these cases, carcinoid syndrome will develop. Exceptions for this pathway are ovary, testicular, retroperitoneal, bronchial primary NETs, or metastases because they can directly access the systemic circulation [10, 22, 29–32].

In healthy people, serotonin is inactivated and metabolized to 5-HIAA by the hepatic monoamine oxidase and which is cleared by the kidneys. In these people, approximately 99% of tryptophan is used for the synthesis of nicotinic acid and less than 1% is converted to serotonin. However, in patients with carcinoid tumours there is a shift toward the production of serotonin [33].

Medical Management of Carcinoid Syndrome

Therapy for the carcinoid syndrome is aimed at lowering the secretion of serotonin and other amines/peptides by reducing hormone secretion or by reducing tumour load by surgical intervention or non-surgical therapies.

The mainstay of medical therapy is focused around use of somatostatin analogues to reduce hormone secretion in carcinoid syndrome. In 1986 Kvols *et al.* reported on 25 patients with carcinoid syndrome treated with the somatostatin analogue octreotide subcutaneous administered three times a day. Nearly 90% of patients reported significant improvement of symptoms, 72% of patients demonstrated a 50% reduction of 24 hr urine 5-HIAA level [34]. Since then octreotide and later developed lanreotide are considered cornerstones in the treatment of carcinoid syndrome with good evidence demonstrating significant reduction in carcinoid syndrome symptoms following commencement of somatostatin analogues [35].

Somatostatin analogues are also used for tumour control. The PROMID trial investigated the effect of long-acting octreotide (LAR) 30 mg intramuscular every 28 days, compared to placebo in patients with inoperable or metastatic NET. After 6 months 67% of patients treated with long-acting octreotide showed stable disease versus 37% of patients treated with placebo. The median time to progression for long-acting octreotide was 14.3 months versus 6 months in placebo patients [36]. The Clarinet trial investigated the effect of long-acting lanreotide 120 mg subcutaneous every 28 days compared to placebo in patients with inoperable or metastatic non-functional NETs. At 18 months treatment progression free survival for lanreotide median was not reached, for placebo was 18 months [37].

Tachyphylaxis can occur during treatment with long-acting octreotide or lanreotide after 6–18 months, dose escalation can result in regain of symptom control [19, 38].

There are five somatostatin receptors on the surface of NET cells and while octreotide and lanreotide have a good affinity for somatostatin receptor-2 and modest affinity for somatostatin receptor-5, they have a weaker affinity for other receptors. Pasireotide (SOM 230) was developed as new multireceptor somatostatin analogue, with high affinity for somatostatin receptor 1, 2, 3, and -5, for patients with inadequately symptom control on long-acting octreotide. A phase III trial randomized 110 patients between

pasireotide 60 mg or long-acting octreotide 40 mg every 28 days. During interim analysis pasireotide and long-acting octreotide showed similar rates of symptom control 20.9% and 26.7%, respectively. Progression free survival of 11.8 months with pasireotide and 6.8 months with octreotide was noticed. Within this interim analysis pasireotide was not expected to show superiority over long-acting octreotide in terms of symptom control and therefore the trail was halted [39, 40]. Currently, pasireotide does not have a licence for use in NETs.

Recently a new therapy has been licensed for use in carcinoid syndrome. Telotristat ethyl (Xermelo®) is an oral systemically available inhibitor of tryptophan hydroxylase. The amino acid tryptophan is converted into serotonin or niacin by tryptophan hydroxylase. Therefore, telotristat can reduce the production of serotonin. The TELESTAR trial was a phase III double-blind placebo-controlled trial in which in which a 135 participants were randomized to receive 250 mg telotristat ethyl tablet, 500 mg telotristat ethyl tablet or placebo three times daily for 12 weeks in the double-blind treatment period, followed by a 36 week open-label extension period. There was a statistically significant reduction in bowel movements in 42–44% of patients (250 mg or 500 mg) compared to 20% reduction in placebo patients, in addition to a significant reduction in urine-5 HIAA level and improvement of quality of life scores [41]. A companion trial (TELECAST) looking at patients with carcinoid syndrome and less than four bowel motions a day also demonstrated good safety and efficacy data [42].

Surgical Treatment for Tumour Control and Managing Carcinoid Syndrome

Surgical resection is the only curative treatment option for NETs. In patients with carcinoid syndrome surgical resection of the primary tumour and any metastatic disease should be considered if patients are fit enough to undergo surgery [43]. Liver debulking surgery should be considered when greater than 70% debulking threshold can be achieved, including the use of parenchyma sparing techniques with ablation or enucleation of the tumour [44, 45]. There is also a role for debulking tumour in selected cases to enable better control of carcinoid syndrome. In patients with florid carcinoid syndrome it is recommended they are established on somatostatin analogues and given intravenous octreotide cover prior to and during surgery [46].

Liver-Directed Therapy

Metastases from NETs are often isolated to the liver and depend on hepatic artery blood supply while the normal liver has portal vein blood supply. Therefore, embolization of the liver can result in necrosis of tumour tissue and consequent decrease in hormonal secretion. Embolization is commonly performed radiologically and can be performed with particles or chemoembolization. Contraindications to performing hepatic artery embolization include portal vein thrombosis, liver failure, and biliary reconstruction.

Symptomatic response is seen in 40–80% of cases and radiological response in 11–80% of cases [47, 48]. A biochemical response for hepatic embolization of 7–75%, and 12–75% for hepatic chemoembolization is seen [47, 49]. In the latter study Gupta *et al.* demonstrated no additional benefit of chemotherapy to transarterial hepatic embolization in metastatic midgut tumours [50]. Complications post procedure include ileus, portal vein thrombosis, hepatic abscess, hepatic fistula, encephalopathy, and renal insufficiency.

There is increasing evidence for the role of selective intrahepatic radioembolization. This technique involves injecting ^{90}Yttrium microspheres in to the liver. Yttrium is a high-energy, pure β-emitter with a half-life of 64 hours and maximum tissue penetration of 11 mm, which makes it very suitable for treatment of liver tumours. The microspheres are approximately 35 μm diameter, which means that they become permanently trapped at the arteriolar end of the capillary bed. The number of microspheres administered is such that the procedure has little or no devascularizing component. Systemic response is seen in about 70% of patients with carcinoid syndrome, radiological response in 22–66% of cases [51, 52]. There are no large studies comparing embolization to radioembolization, choice of treatment is based on patients' characteristics like number of liver lesions vascularization and proliferation index as well on local expertise [53].

New Treatments

Well-differentiated NETs express high levels of somatostatin receptors which is a target for radiolabelled somatostatin analogue therapy. Lutetium-177-DOTATATE (^{177}Lu) is a beta- and gamma-emitting radionuclide with a maximum particle range of 2 mm and a half-life of 160 hours and was studied in the NETTER 1 study. In this study 221 patients with metastasized or locally advanced midgut NET were randomized between ^{177}-Lu-DOTATATE- or octreotide LAR 60 mg. The interim analysis after 20 months showed progression free survival for 65.2% of patients treated with ^{177}-Lu-DOTATATE and 10.8% of patients treated with octreotide LAR. The partial response rate was 18% for ^{177}-Lu-DOTATATE and 3% for octreotide LAR patients [54].

One abstract shows improvement of symptoms in 62% patients with carcinoid syndrome treated with ^{177}-Lu-DOTATATE [55].

Retrospective analysis of long-term follow-up of patients treated with ^{177}-Lu-DOTATATE shows a progression free survival of 29 months and overall survival of 63 months [56].

Quality of life is studied with before and 6 weeks after treatment with ^{177}-Lu-DOTATATE showed significant improvement of functional and quality of life scores in 50 patients with metastatic NETs [57].

The Radiant 2 trial randomized 429 patients with low or intermediate grade metastatic or unresectable NET with carcinoid syndrome to octreotide LAR 30 mg with everolimus or placebo. Patients treated with octreotide LAR and everolimus showed progression free survival for 16.4 months versus progression free survival 11.3 months for patients treated with octreotide LAR and placebo. Octreotide LAR with everolimus demonstrated more reduction in 24h u-5 HIAA levels compared to octreotide LAR with placebo. Effect of everolimus on carcinoid related symptoms was no part of the study design [58]. The trial did not meet its primary endpoint and currently everolimus does not have a license for use in patients with carcinoid syndrome.

Prognosis

In general patients with metastatic well-differentiated GEP-NET have a good prognosis with an overall 5-year survival rate of 67%, depending tumour grading, staging, and site of origin [2]. Looking at details, patients with small bowel NETs have a prognosis of 168 months (in case of local disease only), 145 months (in case of regional lymph node metastases), and 70 months in case of distant metastases [19, 59, 60].

Patients with carcinoid syndrome have an overall survival of 4.7 years, compared to 7.1 years in patients without symptoms of carcinoid syndrome [8]. This data is from the SEER database and therefore, cause of death is not reported.

Potential Complications in Carcinoid Syndrome

Carcinoid Crisis

Carcinoid crisis is an acute and life-threatening complication of carcinoid syndrome. Symptoms are severe flushing, bronchospasm, profound hypotension, and arrhythmias or hypertension, central nervous system disfunction (stupor, confusion), diarrhoea. It is a result of rapid release of vasoactive hormones by in carcinoid tumour cells. Carcinoid crisis appears spontaneously but can be precipitated by surgery, anaesthesia, chemotherapy, lutetium therapy, radiological procedures, and stress, with a prevalence reported in retrospective studies of around 30%. Lack of appropriate treatment can result in death. Octreotide administered intravenously is advised to prevent and treat the symptoms. A commonly used preventive protocol is starting of octreotide infusion 50–100 μg/h at least 12 hours preoperatively. The octreotide infusion should be continued until 48 hours after the procedure [30, 46, 61]. If carcinoid crisis develops treatment is with extra intravenous boluses of octreotide and a higher infusion rate. If the syndrome is still refractory and/or bronchospasm is present then intravenous steroids may be required [46].

Carcinoid Heart Disease

Patients with carcinoid syndrome can develop carcinoid heart disease. The prevalence of carcinoid heart disease is estimated in modern series to be around 20% of patients with carcinoid syndrome, but this is higher in older series, with rates up to 60% [62, 63].

Carcinoid heart disease develops as a result of fibrous plaques depositing on cardiac valves and endocardial thickening usually in the right side of the heart. This plaque formation leads to retraction and fixation of the leaflets of the tricuspid and pulmonary valve. Main findings can be tricuspid regurgitation or stenosis and pulmonary stenosis, and both valves can be involved in 31% of patients. Left side heart disease can occur in less than 10% of patients mainly because of patent foramen ovale [10, 61, 64, 65]. Carcinoid heart disease may be asymptomatic but may present as fatigue and progressive exertional dyspnoea. Progressive development of heart failure can occur and eventually severe heart failure presenting with oedema, weight gain, ascites, and right upper abdominal pain as signs of right sided heart failure can be the next symptoms. Distension of the external jugular vein can be a clinical marker [10, 61, 64, 66].

Diagnosis is made by echocardiogram as golden standard to evaluate valve leaflets, valves, atrial, or ventricular dilatation and endocardial thickening [23, 61, 66]. The ENETS guideline advises annual echocardiographic screening in patients with carcinoid syndrome and signs of carcinoid heart disease [67]. The UKINETS guideline advises screening with serum N-terminal pro-brain natriuretic peptide (NT-proBNP), a surrogate marker of carcinoid heart disease [43]. Patients should be referred for echocardiography with a serum NTproBNP concentration >260 picogram/ml [17, 43, 66, 68]. Carcinoid heart disease is associated with limited 3-year survival of 31% compared to patients with metastatic NET without carcinoid heat disease of 68% [66, 69, 70]. Risk factors for development or progression of carcinoid heart disease are 5-HIAA levels ≥300 micromol/24 hours, ≥3 flushing episodes per day or treatment with cytotoxic chemotherapy [62, 71].

Valve replacement surgery or valvuloplasty is only definitive treatment and should be planned carefully and early in the course of the disease [66, 72]. The perioperative mortality since 2000 is around 5% [73, 74]. After surgery the 1-year survival is around 70% and after 5 year around 40% [73, 74]. It is hypothesized that reducing serotonin levels may prevent the development of carcinoid heart disease [61, 62, 67].

Mesenteric Fibrosis

Small bowel NETs frequently metastasize to lymph nodes in the mesentery. These lymph nodes can produce hormones and growth factors which can result in mesenteric fibrosis [29, 75]. The exact mechanism of fibrosis formation is not elucidated but growth factors such as transforming growth factor B, connective tissue growth factor, platelet derived growth factor, insulin like growth factors, epithelial growth factor, and fibroblast growth factor may play a role [75, 76]. The fibrosis causes shrinkage and fixation of the mesentery and mesenteric root to the retroperitoneum leading to small bowel obstruction. The mesenteric vessels may also become entrapped or occluded with resulting venous stasis and ischaemia and occasionally impairment of the arterial and venous circulation. The fibrosis can extend to the retroperitoneum and cause stenosis of the ureters and hydronephrosis. Because of the risk of ischaemia or small bowel obstruction when possible the removal of the primary tumour and mesenteric mass is advised [29, 61, 67, 77]. Two recent studies [76, 78] investigated the effect of mesenteric fibrosis diagnosed on CT scans and survival. Blažević *et al.* [78] showed mesenteric fibrosis was present in up to 41.4% of patients with biopsy-proven small bowel NET visible on CT scan. Mesenteric fibrosis was not a prognostic factor of overall survival with a median survival of 8.7 year and 5-year survival of 71%. They showed no survival benefit for palliative surgery, metastasectomy of mesenteric mass, or prophylactic surgery. Although Laskaratos *et al.* [76] showed primary resection was associated with a longer overall survival. In both studies older age, higher 24-hour urine 5-HIAA levels and chromogranin A levels were associated with developing of mesenteric fibrosis.

Pellagra

In carcinoid syndrome pellagra can develop with symptoms of dermatitis, diarrhoea, and dementia. It develops because of niacin deficiency. The amino acid tryptophan is the precursor of both niacin and serotonin. The uncontrolled production of serotonin by

carcinoid cells may lead to a depletion of tryptophan and impossibility to produce niacin leading to a niacin deficiency. The prevalence of pellagra in patients with carcinoid syndrome is estimated around 5% [16, 22, 61]. The recommended treatment is niacin supplementation 25–50 mg once daily [79].

Special Circumstances: Anaesthesia

Anaesthesia can provoke a carcinoid crisis therefore specific measures and advice are given to prevent a crisis. It starts with preoperative optimization with fluid and electrolyte resuscitation in patients with diarrhoea, adequate dose of somatostatin analogues and benzodiazepines to avoid stress. Followed by an octreotide protocol (as mentioned in the section carcinoid crisis).

Special advice regarding anaesthetic medication is to avoid possible histamine-releasing drugs such as thiopental, mivacurium, atracurium, cis-atracurium, succinylcholine, meperidine, and morphine. Induction of anaesthesia can be achieved with etomidate and propofol, while for muscle relaxation rocoronium or vecuronium can be used. Anaesthesia can be successfully maintained using a high-dose opioid infusion or inhalation anaesthetics such as isoflurane. First choices for analgesia are short acting opioids such as fentanyl, remifentanil, sufentanil, and alfafentanyl [30, 46, 64].

Summary

Carcinoid syndrome occurs in 20% of patients with NETs, primarily of the small bowel and bronchial primary sites. The overall outcomes are similar to those with non-functional tumours. However, management is focused on symptomatic management of the syndrome in addition to obtaining tumour control and growth. There are complications associated with carcinoid syndrome: carcinoid heart disease is an independent prognostic indicator for worse survival and should be routinely screened for in patients with carcinoid syndrome. In addition, development of mesenteric fibrosis can significantly impact on patients' quality of life. Further research is underway to manage these complications and control hormone secretion in carcinoid syndrome.

Lung Neuroendocrine Tumours

Kok Haw Jonathan Lim, Juan W. Valle, and Wasat Mansoor

Epidemiology

Lung neuroendocrine tumours (NETs) account for 25–30% of all NETs (**Figure 6.4.1**a) [1–3], constituting the largest subgroup of NETs outside the gastroenteropancreatic (GEP) tract. In general, they represent 1% of all cases discussed at lung multidisciplinary team (MDT) meetings, and altogether they form up to 2% of all lung cancers [2, 4–6]. Incidence has dramatically increased over the past three decades from 0.3 per 100 000 in 1973 [7] to most recently 1.49 per 100 000 reported in the United States (US) Surveillance, Epidemiology and End Results (SEER) 18 (2000–2012) (**Figure 6.4.1**b) [8], making it the most rapidly increasing subgroup of NETs by approximately 6% per year [1]. It is believed that the disease remains largely undiagnosed in the general population. Thus, it is predicted to continue rising with improved awareness among respiratory physicians who are often the first point of referral and also with better diagnostic tools now available for this disease entity [9].

The peak incidence for lung NETs is observed in the fourth to sixth decade of life [4]. There is a slight female preponderance and they tend to be more common among white Caucasians, and are relatively rare in other ethnicities including among Blacks, Asians, or Hispanics [10]. Importantly, lung NETs are the most common primary lung neoplasms diagnosed in children and late adolescents, particularly typical carcinoid (TC) [11–15]. Lung NETs are not usually associated with a history of smoking, except in large cell neuroendocrine carcinoma (LCNEC) and small cell lung carcinoma (SCLC) which develop in heavy smokers [16].

Histological Classification

Lung NETs originate from specialized epithelial cells called pulmonary neuroendocrine cells (PNECs) which can be found interspersed among other cells lining the entire respiratory tract, from the nasal epithelium to the terminal bronchioles [17–19]. PNECs exist as individual cells or as a cluster of cells, also known as neuroepithelioid bodies (NEBs) [20]. They are thought to be key in regulating fetal and neonatal airway development and play a particularly significant role as chemoreceptors for hypoxia [21–23]. Throughout development, it is hypothesized that PNECs and NEBs exert a paracrine function in regulating the growth of surrounding epithelial cells, and continue their function as oxygen-sensitive chemoreceptors until adulthood [24, 25].

There is still no clear understanding in the pathogenesis and stepwise malignant transformation of these PNECs and NEBs to lung NETs. One postulated theory is the concept of a putative precursor lesion called diffuse idiopathic neuroendocrine cell hyperplasia (DIPNECH) [26–28]. DIPNECH is a rare abnormal growth or hyperplasia in the PNECs and NEBs, resulting in the formation of multiple carcinoid 'tumourlets', which are usually <0.5 mm nodules, and are often associated with a surrounding fibrotic process in the lung parenchyma (**Figure 6.4.2**) [27, 29, 30]. It is predominantly a benign condition confined to the bronchial epithelium, but there is compelling evidence to suggest that it can be potentially premalignant with higher prevalence of DIPNECH often observed in the background when lung NET is diagnosed [30, 31]. This is currently being investigated further through longer term observational studies. Intriguingly, DIPNECH is about ten times more common in females compared to males [32].

According to the World Health Organization (WHO) criteria [33], there are four known main subtypes of lung NETs,

characterized based on their morphology and pathological characteristics, as summarized in Table 6.4.1 and Figure 6.4.3. Historically, well-differentiated tumours are termed lung carcinoids, and consist of typical and atypical lung carcinoids (TC and AC). There is a stronger link between DIPNECH to the formation of TC, and less is known of its association to AC [27]. Apart from morphological appearance, the key differentiating factor between TC and AC is predominantly based on the proportion of actively dividing cells, quantified by the mitotic rate, and presence or absence of necrosis [2, 6]. TC has a mitotic rate of less than 2 per x10 high power field (HPF) and necrosis is not usually observed. In the commonly used three-tier tumour grading classification system, TC would be considered a low grade (grade 1) tumour. AC tends to be intermediate grade (grade 2) and has 2–10 mitoses per ×10 HPF and is often associated with focal areas of necrotic cells. Meanwhile the more aggressive poorly differentiated lung NETs are formed of LCNEC and SCLC which are almost entirely different entities, and have no known association with DIPNECH. In contrast to lung carcinoids, both subtypes of lung neuroendocrine carcinomas (NECs) (LCNEC and SCLC) are poorly differentiated (grade 3) tumours frequently found with evidence of extensive necrosis and will have more than 10 mitoses

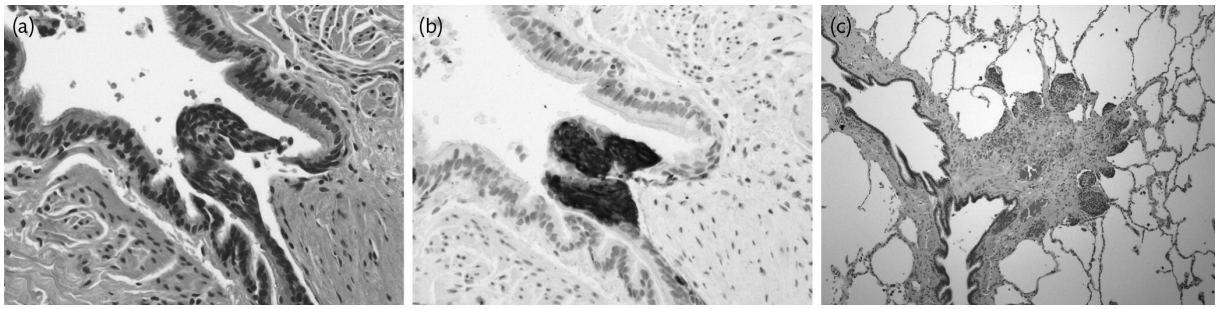

Figure 6.4.2 Morphological characteristics of neuroendocrine cell hyperplasia and carcinoid 'tumourlets'. (a) Early evidence of neuroendocrine cell hyperplasia illustrated with H&E staining with finger-like intraluminal projections from underlying stroma, ×200. (b) Similar cross-sectional view as (a), but with synaptophysin staining for neuroendocrine cell hyperplasia, ×200. (c) Low power (×100) overview of carcinoid 'tumourlets' with surrounding fibrotic changes in the stroma.

Table 6.4.1 World Health Organization (WHO) classification of lung neuroendocrine tumours (NETs)

	Premalignant	Lung Carcinoids (9%)		Lung NECs (91%)	
	DIPNECH	TC	AC	LCNEC	SCLC
Morphology	Well-differentiated	Well-differentiated	Well-differentiated	Poorly differentiated	Poorly differentiated
Grade	Low (Grade 1)	Low (Grade 1)	Intermediate (Grade 2)	High (Grade 3)	High (Grade 3)
Mitotic rate (×10 HPF)	None	<2	2–10	>10 (median 70)	>10 (median 80)
Necrosis	None	None	Punctate (Often)	Diffuse (Often)	Diffuse (Often)

per ×10 HPF (median mitotic rate of 70 per ×10 HPF for LCNEC and 80 per ×10 HPF for SCLC, respectively). In general, TC is 8 to 10 times more prevalent than AC, and together TC and AC constitutes 9% of all lung NETs, with the remaining 91% being high-grade NECs [1, 34].

Most lung NETs should demonstrate immunoreactivity to chromogranin A, and synaptophysin and/or CD56 on the immunohistochemistry panel [2, 16]. Cytokeratins, thyroid-transcription factor-1 (TTF-1) and the homeobox transcription factor CDX-2 may also be useful in the initial test to distinguish between primary lung NETs and other potential primary NETs with metastatic lung lesions [10]. Currently, the proliferation index Ki-67 which is widely used as a diagnostic tool in GEP-NETs is not yet assimilated as part of the classification criteria in lung NETs [10]. There have been several retrospective studies suggesting its utility as a prognostic tool [35–37], and there is a strong proposal for it to be incorporated into the next version update of the WHO classification to further guide clinical management.

Recently, there has also been interesting Next Generation Sequencing (NGS) data where targeted sequencing of 418 genes was performed on 53 TC, 35 AC, 27 LCNEC and 33 SCLC cases [38]. It appeared that NETs and carcinomas shared most of the mutated genes, but had different prevalence. There is a significant enrichment of mutations in TP53, RB1, cycle regulation genes and PI3K/Akt/mTOR in the carcinomas compared to NETs [38]. MEN1 alterations were exclusively a feature of well-differentiated NETs [38]. Intriguingly, novel mutations in chromatin-remodelling genes were also found in 45% of NETs and 50% of carcinomas, and were postulated by the authors to play a major part of the pathogenesis of NETs [38].

Clinical Features

The majority of lung NETs are found incidentally or diagnosed postoperatively. ACs are often peripherally located, and majority of patients are therefore asymptomatic [39]. On the other hand, TCs tend to be more centrally located and thus may report obstructive symptoms [39]. Despite this, lung carcinoids can occur anywhere in the lung parenchyma and in general, and remain difficult to diagnose. In most instances, patients report non-specific symptoms such as dyspnoea, wheeze, chest discomfort, haemoptysis, and recurrent chest infections [9, 10]. As a result, many patients tend to have advanced disease at diagnosis [40]. A recent study estimated

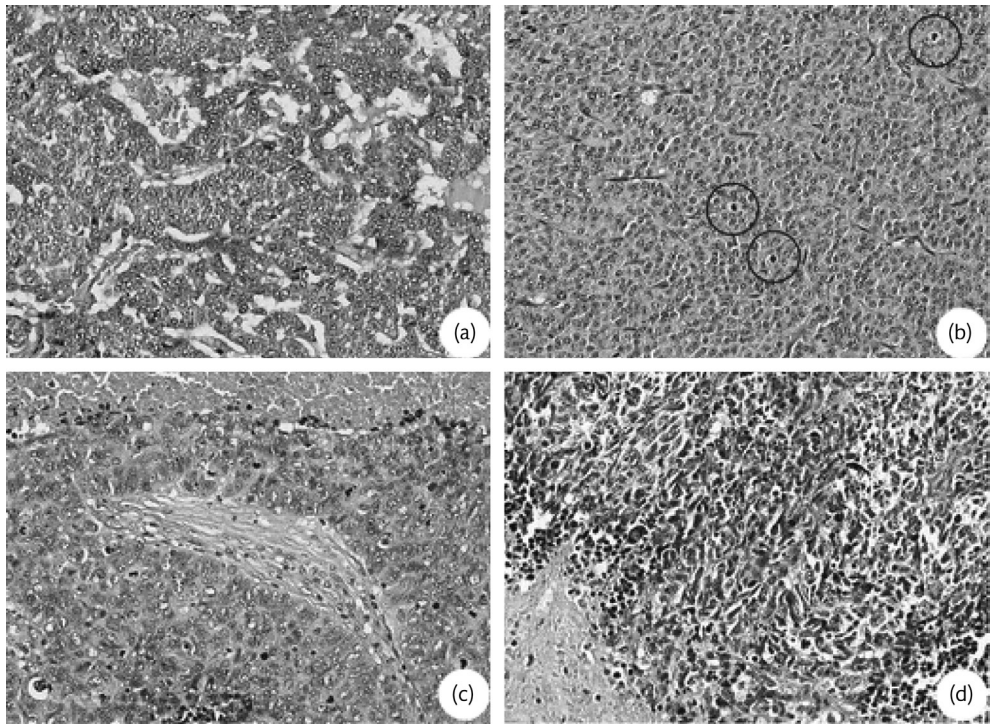

Figure 6.4.3 Morphological appearance and description of the four subgroups of lung neuroendocrine tumours (NETs). (a) Typical carcinoid (TC) is characterized by bland, polygonal, and uniform tumour cells with round nuclei with no areas of necrosis. (b) Atypical carcinoid is similar to TC but has higher mitotic activity and focal areas of necrosis (*circles*). (c) Large cell neuroendocrine carcinoma (LCNEC) consists of large tumour cells arranged in organoid, trabecular, or palisading patterns with prominent nuclei, granular chromatin, and diffuse necrosis. (d) Small cell lung carcinoma (SCLC) consists of small round/oval and angulated cells with dispersed 'salt and pepper' chromatin and extensive necrosis.

the median time to diagnosis of lung NET from being initially symptomatic was reported to be 2 years [41].

It is important to be aware that while uncommon, a small proportion (1–5%) of cases may present with carcinoid syndrome, and this can be independent of the presence of liver metastases [9, 10]. In even rarer circumstances, lung NETs may be discovered as part of other syndromes such as Cushing's syndrome (~40% of ectopic adrenocorticotropic hormone (ACTH) production are from lung carcinoids) (1–6%), multiple endocrine neoplasia type 1 (MEN-1) associated forms (less than 5%) especially among those with a strong family history, and acromegaly due to ectopic release of growth hormone-releasing hormone (GHRH) or insulin-like growth factor-1 (IGF-1) (very rare) [9, 10].

Diagnosis

Initial investigations will be guided by thorough history taking and vigilant clinical examination. In most patients who are relatively asymptomatic, baseline biochemical tests performed should include assessment of renal function, calcium, glucose, and serum chromogranin-A levels [10]. Chromogranin-A is raised in up to 75% of lung carcinoids and 60% of SCLC [42]. Neuron-specific enolase (NSE) may be raised in high-grade NETs [43]. Specific tests such as serum/urinary 5-hydroxyindoleacetic acid (5-HIAA), serum/urinary cortisol, serum ACTH, and serum GHRH or IGF-1 should only be requested if there is clinical suspicion of paraneoplastic syndromes [10]. Serum calcium and parathyroid hormone (PTH) levels can be simple screening tests for MEN-1, and further investigations should be undertaken by specialist services with appropriate genetic counselling. Currently, there is no validated molecular tests used and therefore is not routinely recommended outside clinical trials.

Plain imaging with chest X-ray may be useful as a screening tool (up 40% of incidental cases [44]) although smaller lesions are likely to be missed. All patients suspected to have NETs should have a contrast-enhanced full staging computed tomography (CT) scan of the thorax, abdomen, and pelvis as the standard of care [10]. Note that DIPNECH are best diagnosed using high resolution CT (HRCT) scan with an additional expiration study [10]. The current gold standard investigation in the diagnosis of lung carcinoids (both TC and AC) is ^{68}Gallium (^{68}Ga)-DOTA (DOTATOC or DOTATATE)-PET CT scan (not indicated in DIPNECH), and is recommended as a baseline imaging for all patients including those who had curative resection for their disease and also in advanced lung carcinoids [45].

The main indication for performing an ^{18}F-fluorodeoxyglucose (FDG)-PET CT scan is in high-grade (grade 3) tumours [46], although a proportion of patients might have already had this as part of their lung cancer preoperative work-up. This is generally only helpful in tumours with Ki-67 of more than 10% [47]. Other nuclear medicine imaging modalities such as somatostatin receptor scintigraphy (SRS) with ^{111}Indium pentetreotide and OctreoScan can be useful alternatives in instances when ^{68}Ga-DOTA-PET CT scan is not available or funded [10]. In other specific situations, MRI scan with contrast is often useful in characterizing indeterminate liver lesions when metastatic disease is suspected. Another simple alternative to MRI when contraindicated is a triple-phase contrast-enhanced ultrasound scan of the liver. In cases where bone metastases are suspected, a whole-body nuclear medicine bone scan is standard practice [10]. MRI scan can also be useful to guide surgical or radiotherapy interventions in circumstances when patients are symptomatic of their specific areas of bone metastases.

As tissue biopsy is the gold standard for definitive diagnosis, both rigid and flexible bronchoscopy can be helpful to obtain tissue sample in centrally located tumours. This must be performed with caution in view of risks of bleeding. Most patients with peripheral tumours commonly have a CT-guided biopsy instead. In addition, it is also good practice to perform a baseline echocardiogram to ensure no evidence of carcinoid heart disease, particularly in symptomatic patients. Where patients are frail or elderly, there may be safety concerns in pursuing a biopsy to obtain a tissue diagnosis. In this situation, it is reasonable to assume the diagnosis if the lung lesion is negative on FDG-PET but avid on a ^{68}Ga-DOTA-PET CT scan or OctreoScan.

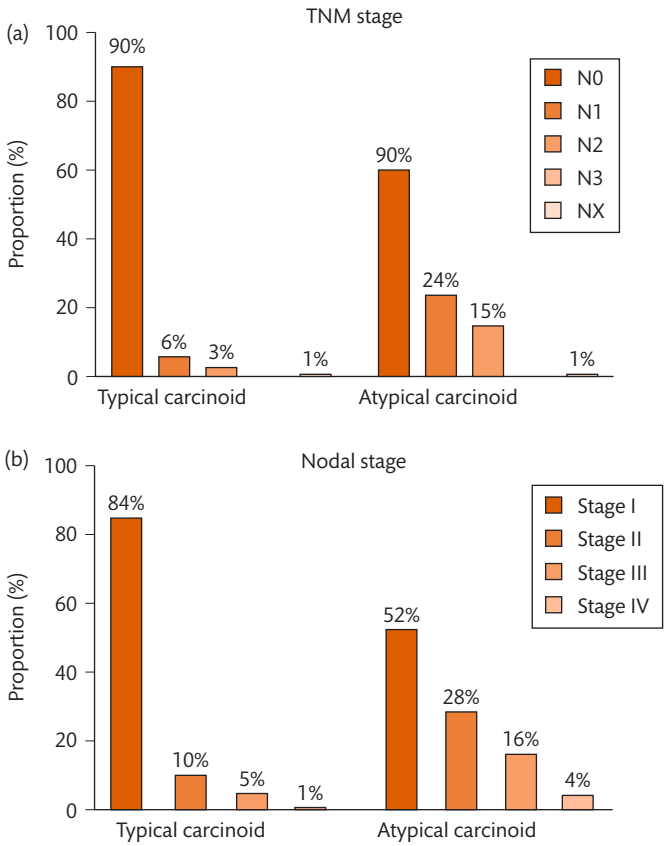

Figure 6.4.4 Bar graph comparing the nodal and AJCC TNM stage distribution between typical carcinoid (TC) and atypical carcinoid (AC) at presentation.

Data sourced from Filosso PL, Ferolla P, Guerrera F, Ruffini E, Travis WD, Rossi G, *et al.* Multidisciplinary management of advanced lung neuroendocrine tumors. *J Thorac Dis.* 2015;7(Suppl 2):S163–71.

Staging

The clinical staging of lung NETs follows the current American Joint Committee on Cancer (AJCC) TNM (**T**umour, lymph **N**odes affected, **M**etastases) staging system for lung cancer (8th edition) [48]. More than 90% of TC are node-negative, and therefore a majority (84%) of patients present with stage 1 disease, compared to about 60% of AC being node-negative (52% stage 1) (Figure 6.4.4) [49].

Management

The only curative treatment for lung NETs is by surgery. Complete anatomical resection either in the form of lobectomy or segmentectomy with adequate lymph node dissection (minimum of six nodes/stations, including three mediastinal and subcarinal stations) is recommended for R0 resection [10, 50]. In oligometastatic disease, metastasectomy should also be strongly considered particularly in syndromic patients with liver metastases (including complex cases as long as >90% of tumour burden can be removed) [10, 51].

For patients who are poor surgical candidates due to frailty or age, then more conservative approaches have been adopted. In these situation debulking surgery has been shown to be beneficial in delaying progression using endoluminal therapies such as diathermy, localized laser ablative therapy or radiofrequency ablation (RFA) [52].

Despite complete surgical resection of early disease, there is a risk of relapse and this is often with distant metastases particularly in the liver (55%), lung (25%), and bone (20%) [53, 54]. In a large prospective observational study of 337 patients with resected TC and AC, after a median follow-up time of 3.5 years, the recurrence rate is 6%, of which 95% were distant metastases [53]. Interestingly, most recurrences (76%) were symptomatic and not detected as part of scheduled imaging surveillance [53]. Recurrence rates vary widely across studies. There is a tendency for AC to relapse earlier, within the first 2 years of follow-up, with median time to recurrence of 1.8 years [53]. The median time to recurrence in TC is 4 years [53]. In both, late recurrences have also been reported, which therefore warrants the need for long-term surveillance [10].

To date, there is still no good quality prospective randomized control trials providing sufficient evidence base to advocate any

adjuvant treatment. Therefore, while this divides opinions, adjuvant chemotherapy or radiotherapy is not currently considered standard of care following curative surgery [10]. There are a number of small retrospective cohort studies which investigated the utility of adjuvant chemotherapy with or without radiotherapy following curative surgery. All of these studies investigated the role of combination chemotherapy with cisplatin and etoposide only in AC. In one of the largest cohort studied, a total of 39 node-positive AC patients received adjuvant chemotherapy out of 629 eligible patients identified, and did not demonstrate a statistical benefit in 5-year overall survival between having adjuvant chemotherapy versus surgery alone (69.7% vs. 80.9%, $P = 0.096$) [55]. Similarly, in another study with 89 node-positive AC out of 581 eligible patients, the 5-year overall survival is 47.6% in the adjuvant chemotherapy arm versus 67% in the observation arm ($P = 0.46$) [56]. In this study, there was no difference among those with node-positive disease or not. In fact, North American Neuroendocrine Tumor Society (NANETS) does not recommend any adjuvant treatment due to the lack of supportive evidence [57]. Meanwhile, in the National Comprehensive Cancer Network (NCCN) guidelines, stage II and III AC may be considered for adjuvant treatment [58]. Similarly, European Neuroendocrine Tumour Society (ENETS) suggests selective use of adjuvant chemotherapy in patients with AC who are node-positive and have a high proliferation index [10]. Adjuvant treatment is generally not recommended for TC [10].

There is also no robust imaging surveillance schedule currently recommended in guidelines, and this tends to vary between centres and treating physicians. The general consensus is that postoperative follow-up in high-volume centres is important and the intensity of active surveillance is determined predominantly by the nodal status at outset. The European Society for Medical Oncology (ESMO) published the ENETS expert consensus statement recommending: for resected TC—standard CT imaging at 3, 6, and 18 months followed by annual chest X-ray and 3-yearly CT scan thereafter; and a more intense schedule for resected AC—standard CT imaging at 3 months, followed by 6-monthly for up to 5 years [10].

There have been promising advances in recent years on the management of advanced or metastatic lung carcinoids. As this is a really heterogenous group of rare disease, treatment decisions can differ between individual treating physicians and in view of this, the key recommendation is to centralize treatment in high-volume centres with access to a specialist MDT input. Treatment options are guided by the aims of treatment. In about a third of patients who present with carcinoid syndrome, the first priority would be to control hormone-related symptoms with somatostatin analogues. Both ocreotide LAR 30 mg given intramuscularly (phase III PROMID trial [59]) and lanreotide autogel 120 mg subcutaneously (phase III CLARINET trial [60]) given 4-weekly, respectively, have been shown to be clinically beneficial and have now been licensed by Food and Drug Administration (FDA) and European Medicines Agency (EMA) for control of carcinoid syndrome. Both forms of somatostatin analogues have also been shown to have some antitumour or disease-modifying effect, and therefore are reasonable options in the first-line setting, particularly in patients with slowly growing TC or AC.

More recently, the phase III RADIANT-4 trial [61] led to the FDA and EMA approval of everolimus in non-functional lung NETs. Everolimus is an oral targeted therapy which inhibits the mammalian target of rapamycin (mTOR) pathway which is activated in some lung NETs [62]. In this randomized placebo-controlled prospective trial, there were 90 lung NETs patients included out of a total of 302 patients with non-functioning midgut NETs [61]. Treatment with everolimus 10 mg orally per day led to an superior median progression-free survival of 11.0 months (95% CI 9.2–13.3) compared to 3.9 months (95% CI 3.6–7.4) in the placebo arm, and was associated with a 52% risk reduction of progression or death, hazard ratio(HR) 0.48 (95% CI 0.35–0.67) (P <0.00001) [61]. The main grade 3 or 4 adverse events included stomatitis (9% vs. 0%), diarrhoea (7% vs. 2%), infections (7% vs. 0%), anaemia (4% vs. 1%), fatigue (3% vs. 1%) and hyperglycaemia (3% vs. 0%) [61]. Previously, the phase III RADIANT-2 trial [63, 64] did not demonstrate statistically significant overall survival benefit of everolimus in functional lung NETs following independent analysis of a small subgroup of patients, and therefore has not been recommended in functional lung NETs.

Treatment with palliative chemotherapy is mainly considered in AC which are 'actively progressive' [10]. There is no robust prospective clinical trial data to support specific regimes, but the most explored chemotherapy is the combination containing either 5-fluorouracil (5-FU) or oral capecitabine with streptozotocin or temozolomide [65–67]. This experience is built on small cohort of lung NETs analysed retrospectively. Other chemotherapy regimens potentially used include monotherapy with 5-fluorouracil (5-FU) or oral capecitabine, dacarbazine, or temozolomide [57]. Generally, it is estimated that response rates to chemotherapy range from 0 to 32%, with stabilization of disease in up to 70% of patients, and an estimated progression-free survival in the region of 5 to 10 months [68]. Prospective series are still lacking. Immunomodulating agent with interferon 2a can be considered in a selected group [57].

Peptide receptor radionuclide therapy (PPRT) is a promising alternative in patients with advanced disease following systemic treatment. In an Italian single-centre cohort study with 114 patients with advanced lung carcinoids, PRRT had been found to delay disease progression by a median of 28.0 months with objective response observed in 26.5% of patients [69]. This treatment tends to be well tolerated. The use of PRRT in lung NETs await outcomes from prospective studies and is not currently licensed for the treatment of advanced lung NETs in the United Kingdom. See **Box 6.4.1** and **Figure 6.4.5**.

There are several ongoing trials investigating further treatment options for lung NETs (**Table 6.4.2**). The Phase II LUNA trial [71] investigating treatment with pasireotide vs. everolimus vs. combination had enrolled 121 lung NET patients and recently met its primary endpoints of efficacy and safety in all three cohorts. The Phase III SPINET trial (lanreotide vs. placebo) also specifically for lung NETs will potentially provide the first robust evidence to support the use of somatostatin analogues in this subgroup of

Box 6.4.1 Factors to consider when deciding management plans

Factors when considering treatment

- Pathology
- Proliferation (mitotic index, Ki67)
- Somatostatin receptor expression
- Growth rate
- Stage
- Associated syndromes
- Performance status

NET. The phase II ATLANT trial will examine the combination of lanreotide and temozolomide. Other promising antiangiogenesis agents are also being investigated including sunitinib, axitinib, and cabozantinib. There are also many upcoming signal-finding studies with immunotherapy being explored, including treatment with monotherapy anti-PD1 agent pembrolizumab (within KEYNOTE-058 trial) or PDR001, or administered in combination anti-PD1 and anti-CTLA4: nivolumab and ipilimumab (DART trial) or durvalumab (MEDI4736) and tremelimumab (DUNE trial). Interestingly, there is also a pilot study investigating the combination of lanreotide and metformin (MetNET-2 trial).

Prognosis

Generally, patients with TC have better survival outcomes compared to those with AC. The 5-year median overall survival in TC is 92–100% compared to 61–88% in AC [4, 49, 72]. Table 6.4.3 shows the overall survival of lung NETs according to stage at diagnosis. In comparison, the 5-year median overall survival in LCNEC is 16–57% and SCLC had the worst outcome with only 2–5% of patients alive at 5 years [72]. The strongest predictor for recurrence remains the nodal status and potentially extent of surgery (R1 and R2 resections at higher risk compared to R0) [73].

Future Work

Lung NET is a heterogeneous group of rare tumours whereby further understanding of the biological basis of its pathogenesis and natural history will be pivotal in driving improvement in management options available. Prospective trials particularly in the adjuvant setting are much needed to improve success in curative treatments. There should be a systematic approach to personalize treatment for each patient following treatment line failure in the metastatic setting, including consideration of basket and umbrella trials with progress made in further understanding molecular pathways and genetics in lung NETs.

Table 6.4.2 Repertoire of clinical trials relevant to lung neuroendocrine tumours (NETs) currently recruiting or awaiting report

Study name	Phase	Study location	Experimental arm	Control arm	Study population	Estimated sample size	Primary end point	Primary completion date
NCT02683941 SPINET	III	Multicentre; Austria, Canada, Denmark, France, Germany, Italy, Netherlands, Poland, Spain, United Kingdom, United States	Lanreotide Autogel/ Depot	Placebo	Unresectable or metastatic grade 1 or 2 lung NET, previously treated ≤2 prior systemic antiproliferative agents	216	PFS	August 2019
NCT02698410 ATLANT	II	Single centre; Italy	Lanreotide Autogel + Temozolomide	–	Unresectable or metastatic, progressive, grade 1 or 2 lung/ thymic NET, ≤3 lines of previous treatment	40	DCR	May 2019
NCT02823691 MetNET-2	I	Single centre; Italy	Lanreotide Autogel + Metformin	–	Unresectable or metastatic, grade 1 or 2 lung NET, pretreated	20	Incidence of SAE/ AEs	April 2022
NCT01563354 LUNA	II	Multicentre; Denmark, France, Germany, Greece, Italy, Netherlands, Spain, Sweden, United Kingdom	Pasireotide LAR vs. Pasireotide LAR + everolimus	Everolimus	Advanced, progressive grade 1 or 2 lung/thymic NET, treatment-naïve, or pretreated	124	PFR at 9 mo	November 2017
NCT01253161	II	Single centre; United States	Pasireotide LAR	–	Unresectable or metastatic, progressive, grade 1 or 2 lung or pancreatic NET, no prior systemic antiproliferative agents	29 (total)	PFS	December 2018
NCT02588170 SANET-EP	III	Multicentre; China	Sulfatinib	Placebo	Advanced grade 1 or 2 unresectable or metastatic extrapancreatic NET, previously treated ≤2 prior systemic antiproliferative agents	273 (total)	PFS	December 2018
NCT01744249 AXINET	II/III	Multicentre; Germany, Italy, Spain, United Kingdom	Axitinib + Sandostatin LAR	Placebo	Unresectable or metastatic grade 1 or 2 extrapancreatic NET, previously treated ≤2 prior systemic antiproliferative agents	253 (total)	PFS	November 2019
NCT01466036	II	Single centre; United States	Cabozantinib	–	Cohort 2: Unresectable or metastatic, progressive, grade 1 or 2 lung NET, pretreated	35	ORR	October 2018
NCT03375320 CABINET	III	Multicentre; United States	Cabozantinib	Placebo	Unresectable or metastatic grade 1 or 2 NET, following previous everolimus	395 (total)	PFS	January 2021
NCT02259725	II	Single centre; United States	Regorafenib	–	Unresectable or metastatic, progressive, grade 1 or 2 lung or GEP- NET, no prior targeted or antiangiogenic therapy	48 (total)	PFS	August 2019
NCT02399215	II	Single centre; United States	Nintedanib	–	Unresectable or metastatic grade 1 or 2 non-pancreatic NET, on stable dose of Ocreotide LAR or Lanreotide for 3 mo	30 (total)	PFS	July 2018

NCT02318784	II	Multicentre; United States	Carfilzomib	–	Unresectable or metastatic grade 1 or 2 NET (excluding ACs)	62 (total)	ORR	February 2019
NCT02575300	II	Single centre; United States	Ibrutinib	–	Cohort 1: Unresectable or metastatic grade 1 or 2, progressive, GI, lung, or unknown primary carcinoid	30	ORR	December 2018
NCT02936323	I/2a	Multicentre; United Kingdom, United States	PEN-221	–	Unresectable or metastatic all grades of NET including LCNEC and SCLC, progressive, pretreated	90 (total)	AEs, ORR, DOR	December 2018
NCT02628067 KEYNOTE-158	II	Multicentre; Australia, Brazil, Canada, Colombia, Denmark, France, Germany, Israel, Italy, Japan, Korea, Mexico, Netherlands, Norway, Philippines, Russia, South Africa, Spain, Taiwan, United Kingdom, United States	Pembrolizumab	–	Cohort 3: Unresectable or metastatic grade 1 or 2 lung, appendix, small intestine, colon, rectum, and pancreas NET, pretreated	1350 (total)	ORR	August 2023
NCT02955069	II	Multicentre; Australia, Austria, Belgium, Canada, France, Germany, Israel, Italy, Japan, Netherlands, Spain, Sweden, Switzerland, United Kingdom, United States	PDR001	–	Unresectable or metastatic, progressive, grade 1 or 2 GI, pancreatic, lung or thymic NET (non-functional), and GEP-NEC, pretreated	110 (total)	ORR	December 2019
NCT02834013 DART	II	Multicentre; United States	Nivolumab + Ipilimumab	–	Cohort 23: Neuroendocrine carcinoma including lung NET	707 (total)	ORR	August 2020
NCT03095274 DUNE	II	Single centre; Spain	Durvalumab (MEDI4736) + Tremelimumab	–	Cohort 1: Unresectable or metastatic grade 1 or 2 lung NET, previously treated ≤2 prior systemic antiproliferative agents	126 (total)	CBR	March 2018

NET, neuroendocrine tumour; GI, gastrointestinal; GEP, gastroenteropancreatic; ACs, atypical carcinoids; LCNEC, large cell neuroendocrine carcinoma; SCLC, small cell lung carcinoma; LAR, long-acting repeatable; AE, adverse event; SAE, serious adverse event; PFS, progression-free survival; PFR, progression-free rate; ORR, objective response rate; DOR, duration of response; DCR, disease control rate; CBR, clinical benefit rate.

Table 6.4.3 Table summarizing Kaplan–Meier estimates of overall survival in lung neuroendocrine tumours (NETs) according to stage at diagnosis

Stage at diagnosis	Median overall survival	5-year overall survival
Stage I	*Not reached*	86%
Stage II	*Not reached*	69%
Stage III	3.4 years	45%
Stage IV	5.1 years	56%

Epidemiology

Pancreatic neuroendocrine tumours (panNET) are a heterogeneous group of NETs which account for 3–5% of all NETs (see Figure 6.4.1a in Chapter 6.4) and 18% of gastroenteropancreatic (GEP) NETs [1, 2]. They constitute approximately 3% of all neoplasms in the pancreas, making panNET the second commonest after exocrine pancreatic adenocarcinoma (~90%) [3]. Like all NETs, the incidence of panNET has continued to rise with improved awareness and diagnostic tools, gradually increasing from 0.18 to 0.36 per 100 000 from 1973 to 2003 [1], but has been exponentially increasing over the past decade with its incidence up to 0.86 per 100 000 in 2012 (see Figure 6.4.1b in Chapter 6.4) [2]. The peak incidence is in the sixth to seventh decades of life and there is a slight preponderance for males over females [4]. Pancreatic NETs appear to predominantly affect the white population (84%), with a much lower reported incidence among Blacks (8%), Asians (5%), and others [4].

In health, the endocrine cells of the pancreas produce hormones including insulin, gastrin, glucagon, vasoactive intestinal peptide (VIP), and somatostatin. Pancreatic NETs can, therefore, take on this phenotype and are broadly categorized into functioning (F-panNET) or non-functioning (NF-panNET), by virtue of the presence of syndromic features secondary to excess secretion of any of these hormones [5]. Non-functioning pancreatic NETs form 60–90% of all panNETs, and most patients (>80%) present with advanced or metastatic disease due to the asymptomatic nature of this subgroup of panNET [4, 6, 7]. Within the remit of this chapter, only NF-panNET will be discussed and the other specific subtypes of F-panNET (gastrinoma, insulinoma, glucagonoma, VIPoma, somatostatinoma) will be covered in detail in subsequent chapters.

Histological Classification and Staging

The endocrine pancreas forms only 1–2% of volume of the adult pancreas, and is made up of clusters of cells called islets of Langerhans [8]. These pancreatic islets are formed of specialized cells which secrete hormones into the bloodstream through tightly regulated feedback loops: alpha (α) cells (glucagon), beta (β) cells (insulin), pancreatic polypeptide (PP) cells (pancreatic polypeptide and somatostatin), and delta (δ) cells which regulate other pancreatic cells. The pathophysiology and abnormal proliferation of these cells which eventually lead to the formation panNET remains poorly understood [9].

While the majority of panNETs (60%) have unknown aetiology or are sporadic, about 10-30% are diagnosed as part of an inherited syndrome [7]. Of these, multiple endocrine neoplasia type 1 (MEN-1) is the most common whereby it has been reported that 20-80% of patients with MEN-1 (see Chapter 6.11.2) will have panNETs, a large majority of whom were NF-panNETs [10]. About 10–17% of patients with von Hippel–Lindau (VHL) disease may have panNETs, almost all of which will be NF-panNETs (>98%) [10]. Meanwhile, panNETs are generally very rare in patients with Recklinghausen's syndrome (neurofibromatosis type 1, NF1), or tuberous sclerosis [7, 10].

Recently, Scarpa *et al.* [11] performed whole-genome sequencing on 102 primary panNETs, and described four 'core pathways' that may be implicated in the pathogenesis of panNETs. These may be categorized into somatic mutations involving the following cellular processes: chromatin remodelling (inactivation of *MEN1, SETD2, ARID1A* and *MLL3*); DNA damage repair (*MUTYH,*

CHEK2, and *BRCA2*); activation of mTOR signalling (inactivation of *PTEN, TSC2, TSC1*, and *DEPDC5*); and telomerase maintenance (upregulation of *TERT*, and inactivation of *DAXX* or *ATRX*) (Figure 6.5.1). Intriguingly, it is also known that overall panNET has more than three times less mutational burden compared to pancreatic ductal adenocarcinoma (mean 0.82 vs. 2.64 per megabase) [11, 12]; thus highlighting the very different nature of these entities.

Irrespective of whether panNETs are functioning or non-functioning, most demonstrate immunoreactivity to synaptophysin and chromogranin-A on histopathological analysis [13, 14]. Other non-specific neuroendocrine markers, for example Neuron-specific enolase (NSE) and CD56, may also be positive [15]. Additional pancreas-specific staining for ISl1 and PAX8 may be useful in cases where the primary cannot be easily determined at outset [16, 17]. Unlike in lung NETs, the proliferation index Ki-67 has been validated for use and should be reported as standard of care as it is a vital component of the classification criteria and also serves as a significant prognostic factor of the natural history of the patient's disease [7, 18].

Over the years, there have been several systems used to classify panNETs, and this has been progressively refined with improved understanding of the disease biology and physicians' growing clinical experience. There are currently two widely used systems as per the most recent ENETS consensus statement [7]. The main one is the recently updated World Health Organization (WHO) classification of panNETs which, as previously, recognizes clear morphological distinction between well- and poorly differentiated malignancies and also makes an assessment of grade based on the Ki-67 (Table 6.5.1) [19]. Well-differentiated grade 1 and 2 panNETs are distinguished by a mitotic count of <2 per 10× HPF, and Ki-67 of <3% versus mitotic count of 2–20% and Ki-67 of 3–20%, respectively [19]. Most patients with grade 3 neoplasms have poorly differentiated neuroendocrine carcinomas. However, the observation that some neoplasms with a Ki-67 of >20% also have a well-differentiated morphology has led to the addition of a well-differentiated grade 3 subgroup to include these patients [19]. A relatively rarer subgroup composed of a combination of both exocrine and endocrine components has now been renamed mixed neuroendocrine non-neuroendocrine neoplasm (MiNEN), previously known as mixed adeno-neuroendocrine carcinoma (MANEC) [19, 20], in recognition that the non-neuroendocrine carcinomatous component can be other than adenocarcinoma (e.g. squamous cell carcinoma). The ENETS TNM classification is also widely used in parallel to the WHO classification (Table 6.5.2) [21].

Table 6.5.2 European Neuroendocrine Tumour Society (ENETS) TNM Staging for pancreatic neuroendocrine tumours (panNETs)

Tumour (T)	
Tx	Statement concerning the primary tumour not possible
T0	Primary tumour not verifiable
Tis	Carcinoma in situ
T1	Limited to the pancreas, ≤2 cm
T2	Limited to the pancreas, >2 cm – ≤4 cm
T3	>4 cm or with invasion of duodenum and common bile duct, limited to the pancreas
T4	Infiltration of proximal organs (stomach, spleen, colon, adrenal gland) or vascular invasion (coeliac trunk, superior mesenteric artery)

Node (N)	
Nx	Statement concerning the regional lymph node metastases not possible
N0	Regional lymph node metastases not verifiable
N1	Regional lymph node metastases

Metastases (M)	
Mx	Statement concerning the distant metastases not possible
M0	No distant metastases
M1	Distant metastases

Stage	
I	T1, N0, M0
IIa	T2, N0, M0
IIb	T3, N0, M0
IIIa	T4, N0, M0
IIIb	Any T, N1, M0
IV	Any T, any N, M1

Clinical Features

A majority of patients demonstrate no signs or symptoms of their disease and their panNET is found incidentally. This is partly attributed to the fact that about two-thirds of primary panNETs are located in the body and tail of the pancreas [22, 23], thereby unlikely to present with obstructive jaundice. As NF-panNET patients are also not syndromic, patients often present late with advanced disease with constitutional symptoms such as anorexia, weight loss, abdominal pain, and nausea. Fewer patients, particularly those with their primary lesions in the head of pancreas, may present with symptoms of mass-effect including jaundice (often painless) and an abdominal mass.

In patients with a strong family history and suspicion of an inherited syndrome, other symptoms and signs associated with MEN-1 and VHL disease as already described should be taken into consideration.

Diagnosis

Following thorough history taking and a physical examination, a standard panel of blood tests including full/complete blood count, biochemistry, liver function tests, clotting screen, and specifically urinary/serum chromogranin-A, 5-hydroxyindoleacetic acid (5HIAA), and pancreatic polypeptide (PP) are recommended [5, 7]. While these neuroendocrine biomarkers may not be necessarily elevated, if they indeed are, they can be utilized to monitor response to treatment or disease progression [7].

In order to identify and characterize the primary tumour better and also the disease distribution, cross-sectional imaging is necessary. The standard of care should be a contrast-enhanced full staging computed tomography (CT) scan of the thorax, abdomen and pelvis; in addition the gold-standard functional imaging modality with the best sensitivity and specificity for panNETs (especially in NF-panNETs), like in lung NETs, is a ^{68}Gallium (^{68}Ga)-DOTA (DOTATOC or DOTATATE)-PET CT scan [7]. This ^{68}Ga-DOTA-PET CT scan is recommended as a baseline imaging for all patients and is now preferred to conventional somatostatin-receptor scintigraphy (SRS) with single-photon emission computed tomography (SPECT) or

OctreoScan [7]. An MRI scan of the liver and/or pancreas may be useful if closer examination of the anatomical distribution of the disease is required, for instance for the purpose of surgical planning.

Once a primary lesion is uncovered, a definitive diagnosis can only be made with histological confirmation of panNET. In early-stage disease, endoscopic ultrasound (EUS) has been shown in many studies to improve diagnostic confidence and further characterize the extent of primary tumour in relation to its surrounding structures, and is also a useful diagnostic tool to obtain biopsy samples from the pancreas [24, 25]. In metastatic disease, biopsy samples may be more easily accessible from the liver, for example.

In view of the heterogeneity of panNETs and the various treatment options available, all patients and the results of investigations performed should be discussed in a specialized multidisciplinary team (MDT) meeting in a centre experienced in treatment of NETs [7].

Management

There are several important prognostic factors to be considered when deciding on the management plan for a patient with panNET including the location of the primary tumour, extent of disease, tumour stage, degree of proliferation/proliferation index, tumour grade, patient's age and performance status [1]. The only curative-intent management option for NF-panNETs is surgery [7]. This is strongly indicated particularly in early disease when complete staging reveals no evidence of distant metastasis (M0 disease), and the primary tumour is more than 2 cm and technically resectable [7].

The preferred oncologic resection choice is based on the anatomical location of the tumour, and is usually in the form of an enucleation (particularly in the setting of MEN-1-related panNET, as other lesions are likely to develop over time and sparing of the pancreatic parenchyma is preferred in these, often young, patients), distal pancreatic resection with or without splenectomy, or in some selected cases pancreaticoduodenal resection or Whipple's surgery [15]. In all cases, it is important to achieve sufficient lymph node clearance, particularly when enucleation is performed for NF-panNET [15, 26]. It is the consensus among all the ESMO, ENETS, and NANETS guidelines that laparoscopic procedures instead of laparotomy are not recommended due to the need for adequate lymphadenectomy and complete surgical exploration intra-abdominally [7, 15, 26].

The recommended management for small primary NF-panNET ≤2 cm remains an area of contention. In a large retrospective Italian study, outcomes were categorically compared by their tumour sizes in 177 patients with NF-panNET who underwent R0 resection: 90 patients (51%) ≤2 cm, 46 patients (26%) >2 and ≤4 cm, and 41 patients (23%) >4 cm [27]. In their multivariable analysis, a NF-panNET of >2 cm was an independent predictor of malignancy, and this study proposed that incidental NF-panNETs ≤2 cm can be conservatively managed as they had excellent long-term outcomes [27]. In contrast, in a more recently published retrospective study of 1854 patients with all NF-panNETs ≤2 cm from the US National Cancer Database (1998–2011), the 5-year overall survival was significantly inferior among those who did not have surgery (28% vs. 72–86%, P <0.01), and outcomes were better for those who had surgery irrespective of the type of surgery performed or adequacy of lymphadenectomy [28]. In the absence of a prospective study, a conservative approach is considered safe and has been recommended in the ENETS consensus guidelines [7]. A systematic review has now confirmed the safety of watchful waiting in those with small (≤2 cm), asymptomatic, sporadic NF-panNETs [29]. There is now also a large prospective study of Asymptomatic Small Pancreatic Endocrine Neoplasms (ASPEN) (NCT03084770) currently open for recruitment which will provide further concrete guidance on the management of this subgroup.

In patients with locally advanced NF-panNET (grades 1 and 2) and those with liver-only metastases, surgery with curative intent may still be pursued as long as this is technically possible [30, 31]. Interventional radiological options may be considered as bridging or downstaging approaches with a view of surgery later, and these include radiofrequency ablation (RFA), laser-induced thermotherapy (LiTT), transarterial chemoembolization (TACE), and selective internal radiation therapy (SIRT) (**Figure 6.5.2**) [31]. Most surgeons will now also consider cytoreductive surgery for metastatic disease when more than 70% of patient's total tumour bulk can be excised [15, 32, 33]. In carefully selected cases, liver transplantation may be considered but these are few and far in between as most patients will still relapse with metastatic disease [34, 35]. Therefore, liver transplantation for panNET is still not standard of care in most countries in Europe [31].

Generally, following radical surgery, there is currently no clear evidence for adjuvant systemic treatments for grades 1 and 2 NF-panNETs. However, in patients with G3 NF-panNET or panNEC with a known high risk of relapse despite surgery, adjuvant chemotherapy may be considered [36]. The most commonly recommended regimen is the combination of cisplatin or carboplatin with etoposide [36].

In most NF-panNET patients who present with metastatic disease at outset, it is important to consider the patients' condition carefully. It is not unreasonable to take the watchful waiting approach in patients with grades 1 or 2 NF-panNET who are relatively asymptomatic and has slow-growing disease if surgery is not considered feasible or is contraindicated for other reasons [30]. Alternatively, antiproliferative agents in the form of somatostatin analogues have been shown to be effective in prolonging progression-free survival in NETs. In the Phase III double-blind placebo-control PROMID trial, 42 patients (n = 42/85, 49%) with non-functioning midgut NETs who were randomized to receive octreotide LAR 30 mg given intramuscularly every 28 days had median time-to-progression of 28.8 months compared to 5.9 months in the placebo arm, HR 0.25 (95% CI 0.10-0.59), P = 0.0008 [37]. This trial allowed crossover, and 88% eventually went on to receive octreotide [37]. There was no statistically significant difference in the octreotide and placebo arm after long-term follow-up [37]. Note that PROMID did not include any patients with panNETs. Meanwhile in the Phase III double-blind placebo-control CLARINET trial, 101 patients (n = 101/204, 50%) who received lanreotide autogel 120 mg subcutaneously also had superior progression-free survival of 38.5 months versus 18 months, P <0.001 [38, 39]. It is important to note that both trials included slightly different cohorts of patients, which may account for the stark difference in outcomes. In PROMID, 98% had grade 1 intestinal NET, while CLARINET had a Ki-67 cut-off of <10% and included grades 1 and 2 midgut and hindgut NETs, with 96% of patients having no tumour progression 3–6 months prior to randomization [37, 38]. In CLARINET, there were 91 NF-panNET

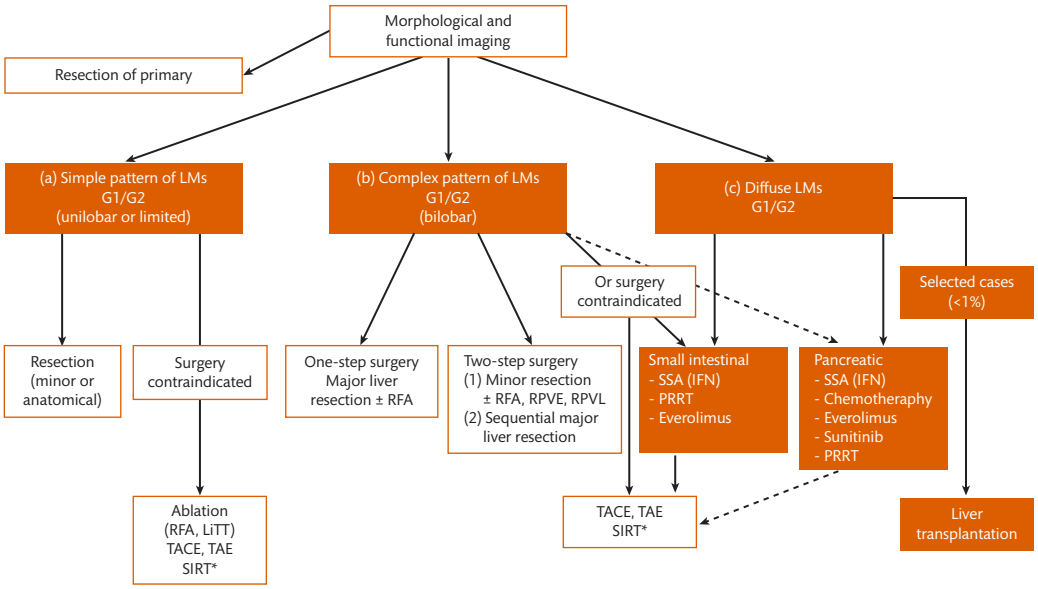

Figure 6.5.2 ENETS consensus guidelines/algorithm for the management of liver metastases in G1/G2 neuroendocrine tumours (NETs) in those without extrahepatic disease.

patients included (n = 91/204, 45%), with 42 and 49 patients receiving lanreotide LAR versus placebo, respectively [38, 39]. In the exploratory subgroup analysis, these patients derived a similar magnitude of benefit compared to other GI NETs, affirming the utility of somatostatin analogues, lanreotide in particular, in panNETs.

Chemotherapy remains the mainstay of systemic treatment for patients with high volume and/or symptomatic and/or rapidly growing (in ≤6–12 months) grade 2 NF-panNET and grade 3 NF-panNET or panNEC (15, 31). First-line standard cytotoxic option for metastatic grade 2 or 3 NF-panNETs is the combination of streptozotocin and 5-fluorouracil (5-FU) or doxorubicin with a 35–40% response rate [15, 31, 40–42]. Alternative chemotherapy options include temozolomide +/– capecitabine, and oxaliplatin-based chemotherapy + 5-FU or capecitabine with retrospective studies suggesting a response rate of 40–70% [15, 31, 43, 44]. Meanwhile in grade 3 NF-panNEC, carboplatin and etoposide combination regime is now standard first-line, with estimated response rate between 30 and 70%, conferring a median progression-free survival of 5 months and median overall survival of 15 months with treatment [31, 45]. FOLFOX (containing folinic acid/leucovorin, 5-FU and oxaliplatin; also known as oxaliplatin and modified de Gramont, OxMdG) and FOLFIRI (containing folinic acid/leucovorin, 5-FU, and irinotecan; also known as irinotecan and modified de Gramont, IrMdG) are reasonable second-line options following failure to carboplatin and etoposide in G3 NF-panNEC [31, 46, 47].

Targeted therapies have also shown to be efficacious in NF-panNETs. In the Phase III RADIANT-3 randomized placebo-control trial, 410 patients with radiologically proven progressive well- to moderately differentiated (grade 1 or 2) locally advanced or metastatic panNETs were randomized to continuous everolimus 10 mg orally once a day or placebo [48]. The 207 patients (n = 207/410; 50%) receiving everolimus had a median progression-free survival of 11.0 months compared to 4.6 months in the placebo arm, HR 0.35 (95% CI 0.27–0.45), P <0.001 [48]. Everolimus was well-tolerated with anaemia (6% vs. 0%) and hyperglycaemia (5% vs. 2%) being the main reported grade 3 or 4 adverse events (48). Similarly, there was a Phase III randomized placebo-control trial of sunitinib in 171 patients with radiologically proven progressive well-differentiated (grade 1 or 2) advanced panNET [49]. Sunitinib conferred a gain in median progression-free survival of 11.4 months compared to 5.5 months in the placebo arm, HR 0.42 (95% CI 0.26–0.66), P <0.001 [49]. The main reported grade 3 or 4 toxicities of sunitinib are neutropenia (12% vs. 0%), hypertension (10% vs. 1%), palmar-plantar erythrodysesthesia (6% vs. 0%) and stomatitis (4% vs. 0%) [49]. Currently, both everolimus and sunitinib are widely available and recommended after progression to either somatostatin analogue and/or chemotherapy (**Figure 6.5.3**) [31].

An important question often facing clinicians remains the most effective sequencing or combination of treatments. There is already evidence that targeted therapies remain beneficial for patients irrespective of whether they have received prior chemotherapy or somatostatin analogues [48]. The SEQTOR trial (NCT02246127) is an innovative Phase III study aimed at addressing how to best sequence chemotherapy and targeted therapy, and is currently recruiting grade 1 or 2 advanced progressive panNET patients to receive combination chemotherapy with streptozotocin/5-FU upfront followed by everolimus upon progression, or in the reverse order. There is also evidence from the Phase III RADIANT-2 trial to support the use of everolimus in combination with octreotide patients with high volume and/or symptomatic and/or rapidly growing grades 1 or 2 NF-panNET [50]. More work is now needed to personalize the optimal treatment pathway for each individual patient.

Evidence is emerging in the use of liver-directed therapies in the form of peptide receptor radionuclide therapy (PRRT) in grade 1 and 2 midgut NETs. Preliminary data from the recently published NETTER-1 trial reported that the use of ^{177}Lu-Dotatate PRRT after progression on first-line octreotide was beneficial in patients with

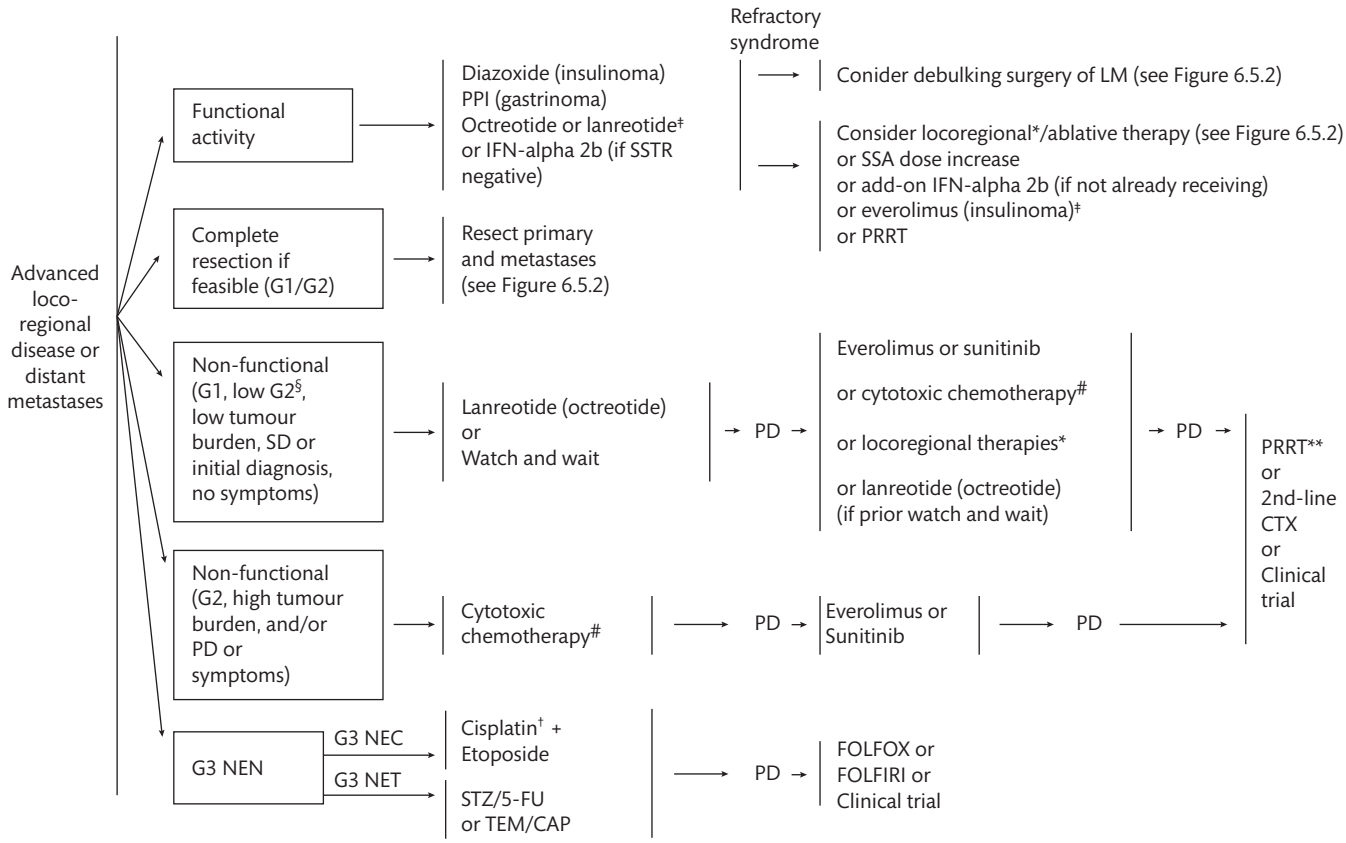

Figure 6.5.3 ENETS consensus guidelines/algorithm for the management of locally advanced or metastatic pancreatic neuroendocrine tumours (panNETs).

somatostatin-receptor positive midgut NETs (no patients with panNET were included) compared to those who received an escalated dose of octreotide [51]. The median progression-free survival in the PRRT arm was not reached after a follow-up of 20 months (65.2%) versus 10.8% in the control group [51]. There appears to be an overall survival advantage, and further mature data are awaited [51]. Non-randomized, retrospective data from a large Dutch cohort, which included a subgroup of 112 panNET patients (133 panNETs in total), demonstrated clinical benefit in 85% of patients (complete response/partial response/stable disease) with a median progression-free survival of 30 months and median overall survival of 69 months [52]. The magnitude of benefit was comparable between patients with panNETs and those with intestinal NETs.

Prognosis

Compared to F-panNET, NF-panNET has been found to have an inferior prognosis, with median overall survival of 26 months (95% CI 23–30) compared to 54 months (95% CI 37–75) [HR 0.71 (95%CI 0.57–0.84), $P = 0.004$] [4]. This is likely to be due to the lead-time bias of patients presenting with earlier disease due to hormone-related symptoms, but may also be potentially attributed to a difference in disease biology.

In general, the 5-year survival rate of panNET is favourable particularly when patients are diagnosed with early disease which may remain indolent for a number of years. In fact, the estimated 5-year survival in well-differentiated localized disease is between 60% and 100%, compared to around 40% for locally advanced or regional disease [6, 15]. Patients who undergo successful metastasectomies may achieve a 5-year overall survival of more than 60%, and if R0 resection is performed, this may even be up to 80% [53]. The outcomes are much worse in those with poorly differentiated tumours (NETs or NECs) with their 5-year survival estimated to be around 12% [6]. With modern treatment options available, it is predicted that more than 25% of those with metastatic panNETs on the whole will be alive at 5 years [15, 31].

Future Work

NF-panNET is a heterogenous group of GEP NETs and the challenge remain in the early disease whereby more prospective studies are needed to identify better predictors of the disease in order to de-escalate treatment in those who may not need it at all and at the same time guide timely treatments for those who require earlier intervention. There also remain questions on the most efficacious sequence and/or combinations of various treatment modalities which are now approved and available for use in treating NF-panNETs, some of which will be hopefully addressed by the several ongoing and upcoming clinical trials. Immunotherapy agents may be promising in well selected groups, although more preclinical data and better biomarkers are necessary to inform more rational use of these drugs. There will be a rapidly expanding use

of various radionuclide-based theranostics which will then need longer term clinical experience to understand if there are any potential late effects of treatment.

6.6

Gastrinoma

Christos Toumpanakis and Martyn E. Caplin

Introduction

Gastrin is a gastrointestinal hormone, produced predominantly by the G cells of the gastric antrum and duodenum, although small amounts of gastrin have been isolated in the pituitary and some vagal nerve fibres. The biologically active forms of gastrin include carboxy-amidated-gastrin-17, and also carboxy-amidated-gastrin-34, which bind mainly to cholecystokinin (CCK)-2 receptor. The main role of amidated gastrin is the stimulation of gastric acid secretion by regulating histamine release from the gastric enterochromafin-like (ECL) cells, while it may also have a trophic effect on gastric mucosa. There is evidence that the precursor forms of gastrin, such as progastrin and glycine-extended gastrin are also of biological importance, binding to a separate 'CCK-C' receptor. They may induce cellular and tumour growth and these precursors are implicated in several cancers, such as colon and pancreatic adenocarcinomas.

Gastrinomas represent a group of functional predominantly duodenal and pancreatic neuroendocrine tumours, characterized by autonomous release of gastrin by the tumour cells, which results in symptoms not only due to the tumour growth *per se*, but also due to gastric acid hypersecretion.

In 1955 at the annual meeting of American Surgical Association, Dr Robert M. Zollinger and Dr Edwin H. Ellison presented a study entitled 'Primary Peptic Ulcerations of the Jejunum Associated with Islet Cell Tumour of the Pancreas' [1]. They proposed a new clinical syndrome of: (a) ulceration in unusual locations in the upper gastrointestinal tract or recurrent ulcerations; (b) gastric acid hypersecretion; and (c) non-beta islet cell tumours of the pancreas. However, the potent gastric secretagogue for the 'Zollinger–Ellison syndrome' (ZES) was not identified until 1960, when Rodney Gregory and Hilda Tracy of the University of Liverpool discovered that, the extract from the pancreas of a patient with ZES was the hormone 'gastrin'. Thus, these pancreatic tumours have been called 'gastrinomas'.

Epidemiology

The incidence of gastrinomas is 0.5–21.5/million population/year. There is a slight male predominance with an average age of diagnosis in the mid-forties, although patients may well have had symptoms for 5–6 years [2].

Genetics

Gastrinomas can either be sporadic or can be associated with multiple endocrine neoplasia type 1 (MEN-1) syndrome in 25% of cases [3]. This syndrome should always be considered and excluded in every patient with gastrinoma, as it may have significant implications in patient management and also prognosis. MEN-1 is an autosomal-dominant disorder due to mutations in MENIN, with high penetrance (see Chapter 6.11.1). Approximately, 23–29% of patients with gastrinomas associated with MEN-1, may develop gastric neuroendocrine (carcinoid) tumours type II. Recently, it was found that somatic *MEN-1* mutations are found also in 37% of sporadic gastrinomas, which indicates that *MEN-1* may be involved in the pathogenesis of both familial and sporadic cases. Other genetic alterations associated with sporadic gastrinomas include those in $p16^{INK4a}$ gene on chromosome 9p21 and in the *HER2/neu* gene. Mutations of p53 gene are not common in gastrinomas [4].

Pathophysiology and Molecular Pathogenesis

Gastrinomas secrete mainly the carboxy-amidated-gastrin-17, which is associated with gastric acid hypersecretion and relevant

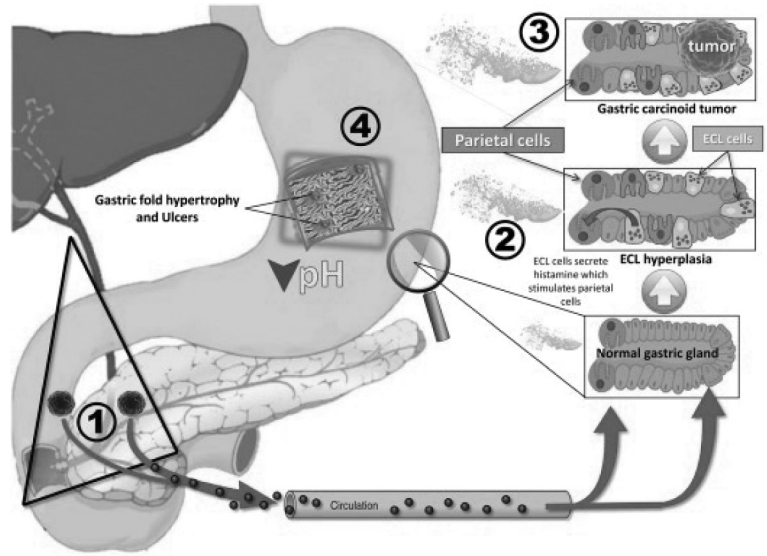

Figure 6.6.1 Pathophysiology of type II gastric carcinoids within the context of gastrinomas associated with MEN-1 syndrome. Gastrinomas usually located inside the gastrinoma triangle (duodenum or pancreas) secrete excess amount of gastrin (1). Gastrin stimulates parietal cells to secrete gastric acid (2). Gastrin also stimulates mucosal growth in the stomach causing ECL cell hyperplasia (3), which can then lead to the formation of a neuroendocrine tumour (gastric carcinoid type II).

clinical features. This autonomous hypergastrinaemia induces ECL cell hyperplasia, which may lead to the development of gastric neuroendocrine tumours (Figure 6.6.1) [5]. Apart from amidated gastrin, these tumours may also secrete precursor forms, progastrin, and glycine-extended gastrin [6]. Gastrinomas overexpress various growth factor receptors (epidermal growth factor receptor, insulin growth factor 1 receptor and hepatocyte growth factor receptor) but among these, only epidermal growth factor receptor (EGFR) is known to correlate with angioinvasion. The activation of CCK-2 receptor by carboxy-amidated-gastrin-17 initiates multiple signal transduction pathways, including activating EGFR.

Clinicopathological Features

Although gastrinomas were previously reported to be located predominantly in the pancreas, recent series have shown that the duodenum (especially the first and the second part) is the most common location for both sporadic and MEN-1 associated gastrinomas (50–88% and 70–100% of cases, respectively). In cases of pancreatic gastrinomas, the tumour is usually located (70%) in the pancreatic body/tail. At surgery, 70–85% of all gastrinomas are found in the so-called gastrinoma triangle, an anatomical area that is defined, superiorly by the confluence of the cystic and common bile duct; inferiorly by the junction of the second and third portions of the duodenum; and medially, by the junction of the neck and body of the pancreas. Rarely (10%), gastrinomas can be found in other abdominal (stomach, liver, bile duct, ovary) or extra-abdominal (heart, small lung cancer) sites.

At presentation, pancreatic gastrinomas are usually large lesions (mean size 3.8 cm), whereas the duodenal ones, especially those associated with MEN-1, are small (1–20 mm). The latter are usually multiple, while sporadic gastrinomas are predominantly (80%) solitary tumours.

Gastrinomas may metastasize to the liver, lymph nodes, and rarely to the bones. At presentation, the majority of patients have either localized (36%) or locally advanced disease with only lymph node metastases (29%). The development of metastases is independent of tumour size, as even small (<5 mm) duodenal gastrinomas may have a high malignant potential. However, liver metastases seem to be more common in pancreatic rather than duodenal gastrinomas (22–35% vs. 0–10%, respectively) [7].

Gastrinomas share the same histopathological features with the other gastroenteropancreatic neuroendocrine tumours (Figure 6.6.2). Additionally, they predominantly express gastrin (Figure 6.6.3), and can produce other gastrointestinal peptides as well, such as insulin. However, such additional peptides are either not released in the systemic circulation or they are released in small quantities and thus, they are not usually of any clinical significance. Other

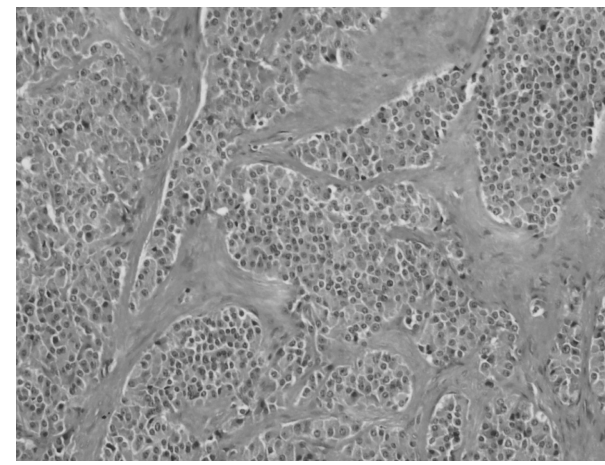

Figure 6.6.2 Well-differentiated, grade 1, pancreatic gastrinoma.

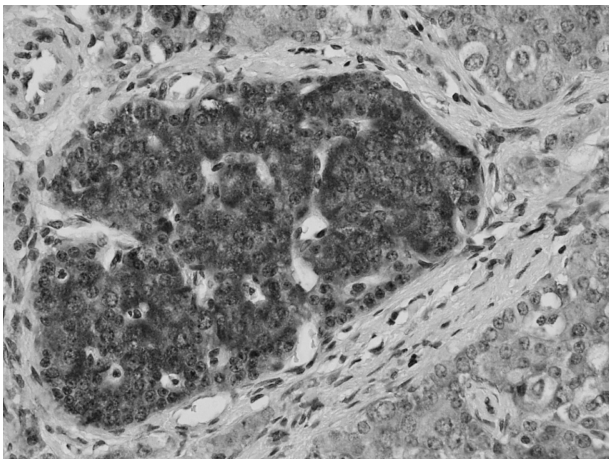

Figure 6.6.3 Gastrin immunostaining in the above patient with pancreatic gastrinoma.

neuroendocrine tumours may express gastrin, but they are not considered gastrinomas if clinical and biochemical features are lacking.

According to the recent (2017) World Health Organization (WHO) for pancreatic neuroendocrine neoplasms, gastrinomas are divided into: (1) well-differentiated neuroendocrine tumours of grade(G) 1, G2, or G3; and (2) poorly differentiated neuroendocrine carcinomas (either small-cell or large-cell type) with high-grade (G3) malignant behaviour. Criteria for categorization of these tumours include general morphologic description, mitotic rate (two or more mitoses/mm^2), proliferation index (as assessed by nuclear Ki67 expression), tumour size, and evidence of invasion of blood vessels/nerves/adjacent organs. The majority of gastrinomas are well-differentiated neuroendocrine neoplasms.

In 2010, the European Neuroendocrine Tumour Society suggested the TNM system for staging of pancreatic neuroendocrine tumours, including gastrinomas, which also included a grading system based on mitotic rate and proliferation index. That grading system was updated in 2017, as part of the new WHO classification [8]. The TNM system as well as, the 2017 grading system are summarized in Box 6.6.1 and Table 6.6.1.

Box 6.6.1 TNM classification for neuroendocrine tumours of the pancreas

T—primary tumour

Tx: primary tumour cannot be assessed

T0: no evidence of primary tumour

T1: tumour limited to the pancreas with size <2 cm

T2: tumour limited to the pancreas with size 2–4 cm

T3: tumour limited to the pancreas with size >4 cm or invading duodenum or bile duct

T4: tumour invading adjacent organs or the wall of large vessels

N—regional lymph nodes

Nx: regional lymph nodes cannot be assessed

No: no regional lymph node metastases

N1: regional lymph node metastases

M—distant metastases

Mx: distant metastases cannot be assessed

M0: no distant metastases

M1: distant metastases

Stage I: T1, N0, M0

Stage IIa: T2, N0, M0

Stage IIb: T3, N0, M0

Stage IIIa: T4, N0, M0

Stage IIIb: any T, N1, M0

Stage IV: any T, any M, M1

Diagnosis

Clinical Presentation

Most of the symptoms in patients with gastrinomas are associated with gastric acid hypersecretion. The latter can lead to the development of peptic ulcers, erosive oesophagitis, and chronic diarrhoea. Symptoms associated with peptic ulcers and their complications (bleeding, perforation, pyloric stenosis) are the most common presenting clinical features in patients with gastrinoma (80%). Peptic ulcers in these patients are often multiple, located in unusual anatomic sites and resistant to treatment. They are less associated to *H. pylori* infection compared to idiopathic peptic ulcers (24–48% vs. >90%, respectively) and are not associated with use of non-steroidal anti-inflammatory drugs (NSAIDS). Erosive oesophagitis causing heartburn and potentially dysphagia occur in 50–60% of these patients. Finally, chronic diarrhoea is a result of inactivation of pancreatic enzymes (especially lipases), and damage of the intestinal mucosa, due to acid hypersecretion. Gastrinoma-related diarrhoea is usually watery, may be associated with malabsorption, while it is the only diarrhoea that responds dramatically to proton pump inhibitors (PPIs). It occurs in 40–70% of patients with gastrinoma, and may be the only symptom in 20% of cases [9].

Clinical suspicion for a gastrinoma associated with MEN-1 syndrome is raised when one or more of the aforementioned clinical features coexist with hyperparathyroidism or any other MEN-1 related endocrinopathies, and when there is a family history of MEN-1 syndrome.

In patients with sporadic gastrinomas, the mean age at the onset of symptoms is 48–55 years, while patients with MEN-1 present usually at an earlier age (32–35 years). The frequency of most symptoms in similar between these two groups of patients, although it seems that diarrhoea is less common in MEN-1 patients.

Less than 10% of gastrinoma patients develop features of Cushing's syndrome due to ectopic production of adrenocorticotrophic hormone (ACTH), which represents a poor prognostic sign.

Table 6.6.1 WHO 2017 Grading for pancreatic neuroendocrine neoplasms

	Mitotic count (10 HPF)	Ki67 index (%)
Well-differentiated Neuroendocrine Neoplasms		
Neuroendocrine tumour (G1)	<2	<3
Neuroendocrine tumour (G2)	2–20	3–20
Neuroendocrine tumour (G3)	>20	>20
Poorly differentiated neuroendocrine neoplasms		
Neuroendocrine carcinoma (G3)	>20	>20

Table 6.6.2 Clinical features indicating gastrinoma

Clinical feature	% of patients
Peptic ulcers resistant to treatment, multiple, located in unusual anatomic sites, resistant to treatment, less associated to *H. pylori*, and not associated with use of NSAIDS	80
Erosive oesophagitis causing heartburn and potentially dysphagia, resistant to treatment	50
Diarrhoea responding to proton pump inhibitors	40–70
The above features in combination with other endocrinopathies	20
The above features in combination with family history of neuroendocrine tumours	25

NSAIDS, non-steroidal anti-inflammatory drugs.

Suspicious clinical features that may indicate gastrinoma are summarized in Table 6.6.2.

Laboratory Tests

The biochemical confirmation, following a clinical suspicion, of a gastrinoma requires a significant elevation of **fasting serum gastrin**, in combination with hyperchlorhydria. The presence of the latter is very important, as hypergastrinaemia alone can be result of chronic hypochlorhydria/achlorhydria, that is associated with chronic fundus atrophic gastritis, chronic use of PPIs, as well as vagotomy.

A fasting serum gastrin level of >10-fold the upper normal limit in the presence of gastric p H<2 or basal acid output (BAO)>15 mmol/h is considered as diagnostic of a gastrinoma. If possible, PPIs should be discontinued preferably at least ten days prior to serum gastrin estimation, while a discontinuation of histamine-2 receptor (H2R) antagonists for only 48–72 hours prior to the test seems to be adequate. However, discontinuation of PPIs should be performed with caution in patients who are at risk for complications (peptic ulcer bleeding or perforation, severe diarrhoea) and those patients should ideally be referred to specialist units with experience in diagnosis and management of gastrinomas. Moderately elevated serum gastrin levels (<10-fold the upper normal limit) and hyperchlorhydria may occur in 66% of gastrinoma patients, but in this situation other clinical disorders need to be excluded, such as: *H. pylori* infection, gastric outlet obstruction, antral G cell hyperplasia, short bowel syndrome, retained antrum, or renal failure. In this situation, a provocative test with intravenous (IV) administration of secretin is indicated [10]. After an overnight fast an IV bolus of secretin (2 U/kgr) is given to the patient. A rise of serum gastrin concentration of 120 pg/ml, noted within 10 minutes of secretin administration, can establish the diagnosis of gastrinoma (with sensitivity and specificity of 94% and 100%, respectively), whereas in the aforementioned non-tumour-related causes the serum gastrin level remains unchanged. A diagnostic algorithm for fasting serum gastrin levels is summarized in Figure 6.6.4.

Another biochemical test that contribute to the diagnosis is the estimation of *Chromogranin-A (CgA)* (see Chapter 6.2). However, recent studies in patients with gastrinomas suggest that there is not always precise correlation between CgA levels and tumour burden, as in these patients CgA may also be produced by the enterochromaffin-like cells of stomach in response to hypergastrinaemia.

As soon as the biochemical diagnosis of gastrinoma is established, it is important for all patients (even those without any suspicious clinical features) to be screened for MEN-1, with a baseline estimation of serum parathyroid hormone (PTH) levels, calcium levels (preferably ionized calcium or albumin-corrected calcium), as well as prolactin. In presence of suspicious clinical or biochemical data, a MEN-1 germline mutation DNA test should be performed, and if it is positive, genetic counselling is offered to all patients' kindreds after their first decade of life.

Rarely, patients with gastrinoma may have hypercalcaemia with normal PTH levels, which may be a result of parathyroid hormone-related peptide (PTH-r P) secreted by these tumours. Finally, in patients who develop clinical signs of Cushing's syndrome biochemical evaluation is needed (see Chapter 5.7).

Tumour Localization

Precise localization of the primary tumour lesion as well as metastatic deposits has a significant impact on the patient's management. Invasive and non-invasive localization studies are used in order to identify the primary lesion and determine the extent of resection

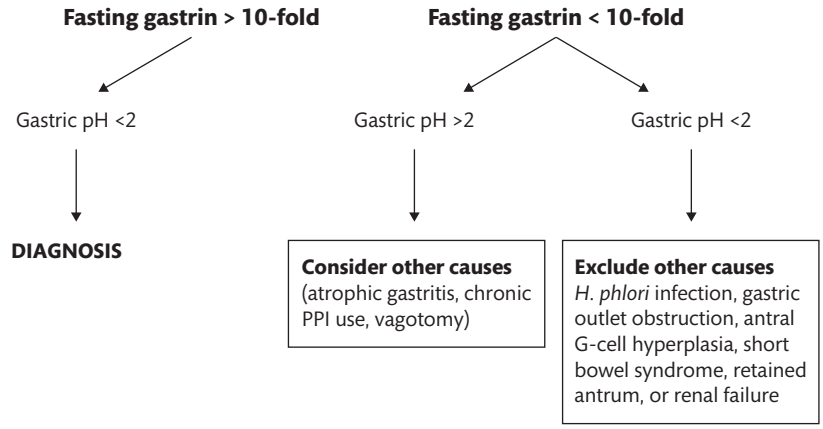

Figure 6.6.4 Differential diagnosis of hypergastrinemia (ULN: upper limit of normal).

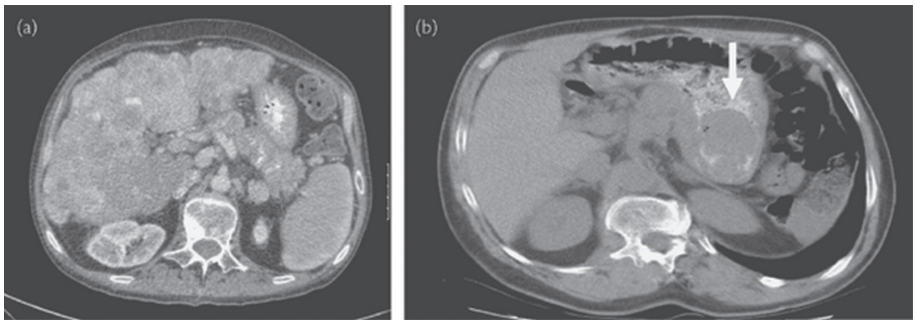

Figure 6.6.5 (a) CT in metastatic sporadic gastrinoma. (b) CT in a patient with MEN-1 gastrinoma and type II gastric neuroendocrine tumour (arrow).

when surgery is planned, and also to assess the tumour extent in patients with advanced disease.

Non-Invasive Techniques

Among the conventional radiological studies, transabdominal ultrasound has the lowest sensitivity for detection of the primary site and hepatic metastases (20% and 45% respectively), but its specificity may be greater than 90%. Spiral computed tomography (CT) and MRI have better sensitivities for the primary lesion (59–78% and 40–85%, respectively) and for distant metastases (45–70% and 70–80%, respectively), while their specificity is also above 90% (Figure 6.6.5).

Indium-111-diethylentriamine penta-acetic acid (DTPA)-octreotide (OctreoScan) was previously recognized as the most sensitive modality for gastroenteropancreatic neuroendocrine tumours' imaging (Figure 6.6.6). Recently the introduction of positron emission tomography (PET) molecular imaging with 68Ga-labelled somatostatin analogues provides clear advantages over conventional OctreoScan with better sensitivity and specificity and is logistically easier as it is a single scan compared to the requirement with OctreoScan to scan at 4 hours, 24 hours, and 48 hours post injection of isotope. ^{68}Ga-somatostatin analogue PET imaging is now considered the gold standard for nuclear medicine imaging of NETs. Multiple peptides have been used with in conjunction with ^{68}Ga. Somatostatin analogues such as DOTA-[Tyr3]-octreotide (TOC), DOTA-[Tyr3,Thr8]-octreotide (TATE), and DOTA-[Nal3]-octreotide (NOC) have recently been used with PET imaging. 68Ga-DOTA PET studies, that can be completed within 2–3 hours and visualize lesions as small as 7 mm, have a sensitivity of 97% and specificity of 92% (Figure 6.6.7). It provides not only an accurate localization of the primary and metastatic lesions, but also may detect unsuspected lesions, not shown by the previous conventional studies, which is crucial when surgery is planned. If, the aforementioned non-invasive techniques (including ^{68}Ga-DOTA PET) have failed to identify the primary tumour site, especially when surgery is planned, a variety of invasive localization studies can be performed.

Invasive Techniques

Oesophagogastroduodenoscopy (OGD) needs to be performed in every patient with gastrinoma. OGD not only corroborates the clinical suspicion by demonstrating severe oesophagitis, peptic ulcers in uncommon locations and prominent gastric folds, but also may reveal small duodenal gastrinomas, as well as gastric polyps that may represent gastric neuroendocrine tumours type II in patients with MEN-1 gastrinomas (Figure 6.6.8).

Endoscopic ultrasound (EUS) should be considered in all patients who are due to have an operation and especially in those with MEN-1 gastrinomas. In experienced hands, it has a sensitivity of 95% for pancreatic gastrinomas, while it also provides useful staging information. EUS can precisely estimate tumour size, distinguish a pancreatic tumour from a peripancreatic lymph node, and also enables histology samples via fine-needle aspiration. However, EUS has a lower sensitivity for duodenal gastrinomas (50%).

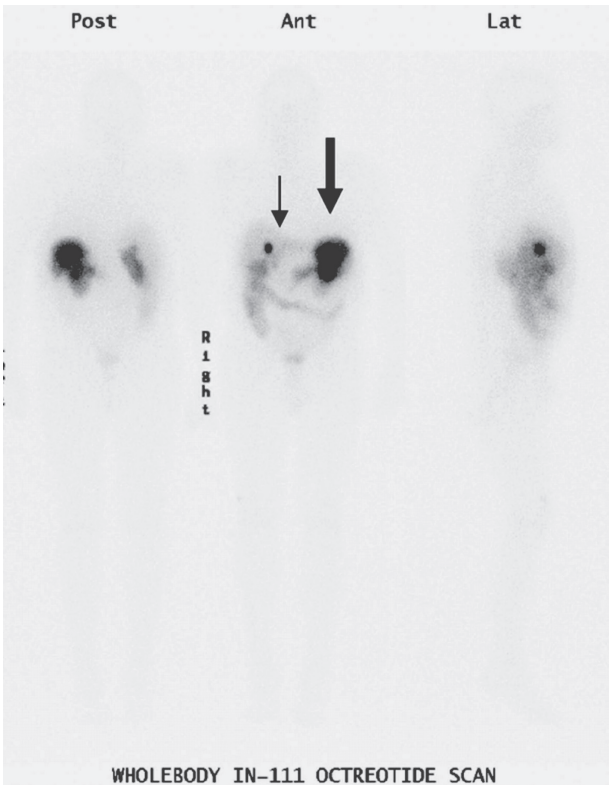

Figure 6.6.6 OctreoScan in patient with metastatic MEN-1 gastrinoma. Solitary hepatic metastatic deposit (thin arrow), gastric neuroendocrine tumour (thick arrow).

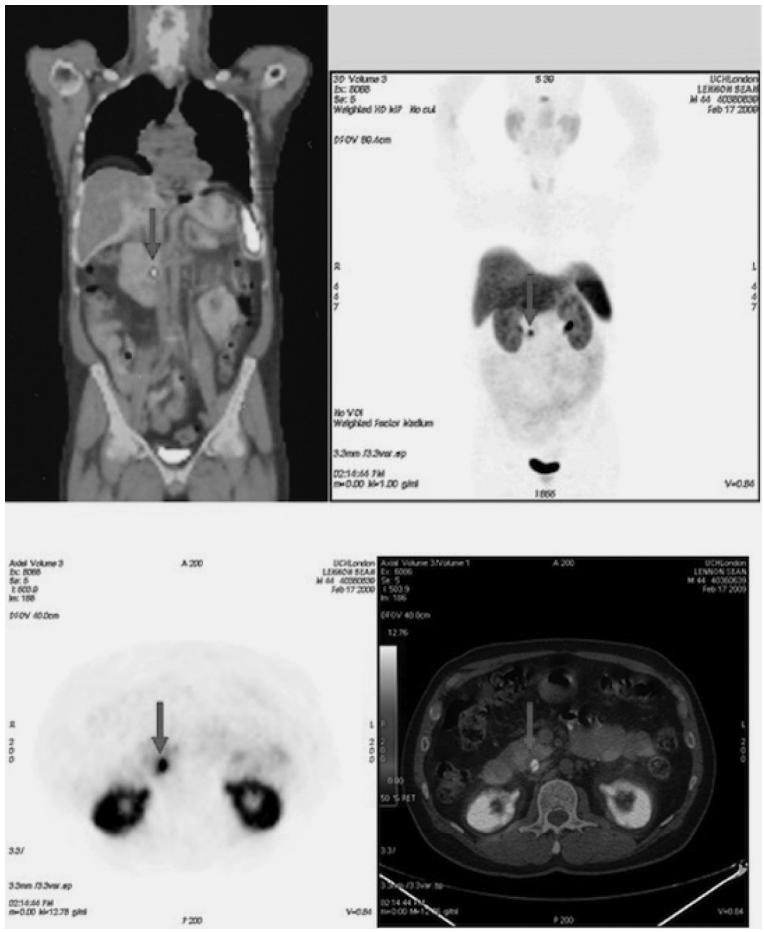

Figure 6.6.7 ^{68}Ga-DOTA PET in patient with sporadic gastrinoma and unknown primary, despite all previous imaging studies. A foci of uptake was demonstrated at the area of second part of duodenum thick red arrow).

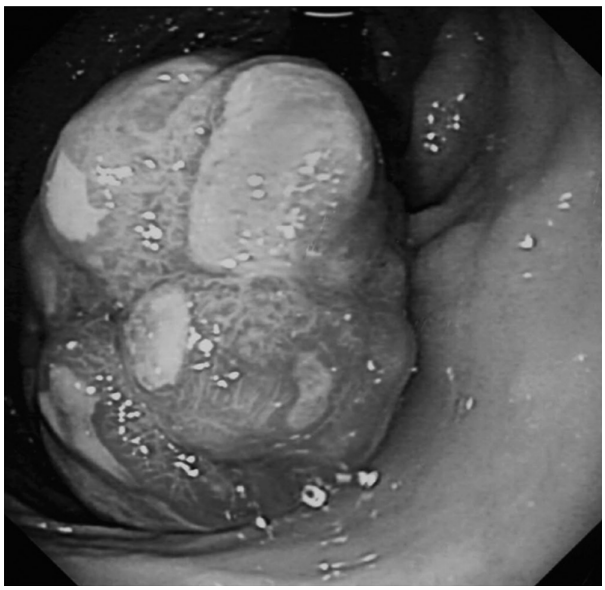

Figure 6.6.8 Gastric neuroendocrine tumour type II in a patient with MEN-1 gastrinoma (same patient as in Figure 6.5.3b).

Angiography is less commonly used nowadays, and usually includes angiography with secretin or calcium stimulation and hepatic venous sampling. During this test, small doses of secretin are injected into the splenic, hepatic, gastroduodenal, and then the superior mesenteric arteries, following a selective cannulation. Then, blood samples are taken from the right hepatic vein, at baseline, 20, 40, 60, and 120 seconds for gastrin estimation.

In patients, where all the aforementioned imaging techniques have failed to detect the primary lesion preoperatively, an intraoperative transillumination of the duodenum in combination with intraoperative ultrasound should always be performed. These tests should always be followed by duodenotomy, which is able to detect up to 50% of duodenal tumours.

Management

Once the diagnosis of Zollinger–Ellison syndrome is established, and even before the completion of localization studies, it is important to start medical treatment in order control gastric acid hypersecretion and prevent its complications.

Control of Symptoms

In the early years, the treatment of choice was total gastrectomy. However, as soon as the antisecretory medications, initially H_2-receptor antagonists and subsequently PPIs,) became widely available, effective control of gastric acid secretion was achieved, and thus, total gastrectomy is no longer necessary.

PPIs are superior to H_2-receptor antagonists, in terms of effectiveness in gastric acid control and long-term action, and therefore they are considered as first-choice medical treatment for these patients. The initial dose that is usually used is an equivalent dose to 60 mg of omeprazole/day in sporadic gastrinomas [11]. Patients with MEN-1 gastrinomas and hypercalcaemia, patients with severe gastro-oesophageal reflux symptoms as well as those with previous Bilroth-II resection may require higher initial doses (40–60 mg bd). The maintenance dose tends to be lower than the initial dose in 40–80% of the patients. PPIs are considered as safe long-term treatment with patients being treated for more than 15 years with no significant adverse effects and no evidence of tachyphylaxis. It has been, however, recommended that long-term treatment with PPIs may be associated with B_{12} malabsorption, and thus B_{12} levels need to be monitored once a year. There may also be an increased predisposition to osteoporosis.

Patients who cannot tolerate oral PPIs can be treated with high dose of H_2-receptor antagonists and the dose requirements tends to increase with time.

The use of somatostatin analogues (octreotide and lanreotide preparations) for antiacid control, although potentially effective, is not a first-line option and should be reserved only for patients with difficult to control hyperacidity and those who had developed gastric neuroendocrine tumours.

Gastric surgery (vagotomy, gastrectomy) for control of gastric acid hypersecretion is very rarely required in the era of antisecretory medications, and is only indicated in patients who cannot or will not take any antisecretory medications. Parathyroidectomy in patients with MEN-1 gastrinomas and parathyroid adenomas is usually indicated at an early stage, as results in a decrease in the basal acid output and fasting gastrin levels and therefore the required dosage of antisecretory medications as well.

Surgical Therapy

Sporadic Gastrinomas

The aim of surgery in sporadic gastrinomas patients is a long-term curative resection, in order to decrease the risk of distant metastases development, as well as to completely control of the hormonal symptoms.

Pancreatic head/body tumours may be enucleated, in combination with regional lymph node dissection (peripancreatic, periduodenal, and hepatoduodenal ligament), while duodenotomy is always required to detect small duodenal gastrinomas. Whipple's pancreaticoduodenectomy may be required for large gastrinomas. Tumours in pancreatic tail may be enucleated, or for larger lesions a distal pancreatectomy is performed [11, 12].

The overall 15-years survival following a curative resection in sporadic gastrinoma patients is between 80% and 100%.

MEN-1 Gastrinomas

The benefit of surgery in gastrinomas associated with MEN-1 syndrome is controversial. Tumours are usually small, multiple, and located in various sites in pancreas and duodenum. Surgical exploration, especially if the tumours have not been visualized in the preoperative imaging studies or their size is <2 cm, does not seem to be worthwhile, as the curative potential in these cases is low, metastases are usually regional, and the long-term prognosis is favourable. Surgical intervention should be considered in presence of tumour size >2 cm. The concept of this approach is to reduce the possibility of subsequent liver metastases, although its efficacy remains controversial [11–13].

Management of Advanced Disease

All patients with advanced disease, consisting mainly of hepatic metastases, should have antitumour treatment in order to prolong the survival rates. Treatment options include invasive procedures or systemic medical treatment.

Invasive Treatment

Cytoreductive surgery may be an option when hepatic metastases are confined to one lobe, and also in cases where more than 90% of disease can be removed surgically. Liver resection can also be combined with radiofrequency ablation (RFA) at the same time, for tumour lesions that cannot be resected.

In patients with disease predominantly in the liver, transarterial hepatic embolization (TAE) or chemoembolization (TACE) may be considered, especially when a clinical or radiological progression is noted. TAE or TACE cannot be performed in patients with occluded portal vein and poor performance status.

Finally, liver transplantation can be considered rarely in selective cases, mainly young patients with G1 tumours, no significant comorbidities, and no evidence of extrahepatic disease [14].

Non-Invasive Treatment

In patients unsuitable for surgery, systemic medical treatment should be considered in order to control tumour growth and improve survival.

Biological agents, such as somatostatin analogues and less commonly interferon, are considered as antitumour treatment in patients with G1/G2 tumour and slowly progressive disease [15]. A recent large randomized trial with Lanreotide Autogel (long acting preparation of lanreotide) demonstrated increased progression-free survival in a series of gastro-entero-pancreatic neuroendocrine tumours, including gastrinoma patients [16]. Overall, disease stabilization can be achieved in up to 50% of patients being treated with somatostatin analogues, whereas the objective response rate (decrease in tumour size >20%) with those medications is approximately 5–10%.

Novel molecular targeted treatments, such as oral everolimus (mTOR inhibitor) and oral sunitinib (tyrosine-kinase-inhibitor) have shown increased progression-free survival in large randomized studies of advanced pancreatic neuroendocrine tumours, which included patients with gastrinomas. Objective tumour responses with those agents are noted less than 10% of patients [17, 18]. Serum gastrin levels have been decreased, following commencement of everolimus, and that became more prominent when everolimus was combined with somatostatin analogues [19].

Cytotoxic chemotherapy, using combination regimens based on streptozotocin, and more recently temozolomide +/– capecitabine, may be an option in patients with well-differentiated G2/G3

tumours and disease progression despite treatment with biological or molecular targeted agents, and in patients with extensive tumour load and significant symptomatic deterioration. Objective responses and disease stabilization have been reported in 30–40% and 70% of patients, respectively. Cytotoxic chemotherapy, mainly platinum-based, remains the first treatment option in poorly differentiated, G3, neuroendocrine carcinomas [14, 20].

Peptide receptor radionuclide therapy, represent an alternative option to cytotoxic chemotherapy and can be considered in patients with avid tumour uptake in OctreoScan or in ^{68}Ga-DOTA somatostatin analogue PET. The concept of this treatment is to transfer cytotoxic radiation directly to the tumour cells, by using somatostatin analogues (octreotide or octreotate) radiolabelled with isotopes such as yttrium-90 or more commonly lutetium-177. Although data from large randomized trials are lacking for pancreaticoduodenal neuroendocrine tumours, peptide receptor radionuclide therapy, especially Lutetium-177 DOTATATE, has demonstrated high objective response rate, increased progression-free survival, as well as overall survival, based on several large retrospective series [21].

The optimal sequence of the aforementioned systemic treatments, in advanced gastroenteropancreatic neuroendocrine tumours, is currently being evaluated into clinical trials, which include patients with gastrinomas.

Prognostic Factors–Survival

The 15-year survival rate in patients either sporadic or MEN-1 gastrinomas and localized disease (including lymph nodes metastasis) is >90%, whereas in those with hepatic metastases the 5-year survival is between 50% and 70%. Other poor prognostic factors include: short disease history; female gender; pancreatic primary location; primary tumour size >3 cm; absence of MEN-1 syndrome; extremely high serum gastrin levels; ectopic Cushing syndrome; and presence of bone metastases [11]. Histological features such as: angioinvasion, perineural invasion, mitotic rate > 2/20HPF, Ki67>2% are associated with poor prognosis, as is the overexpression of EGFR and *HER2/neu* gene expression.

Insulinoma and Hypoglycaemia

Ingrid Y.F. Mak and Ashley B. Grossman

Key Points

1. Hypoglycaemia is not uncommon in both hospitalized and ambulatory patients, diabetic and non-diabetic individuals. This condition is potentially life-threatening if left untreated, hence it is crucial to identify and treat hypoglycaemia and its underlying cause as early as possible.
2. Insulinoma is the most common cause of endogenous hyperinsulinaemic hypoglycaemia in otherwise well patients. It is small, benign, solitary, and intrapancreatic in most cases, and may be associated with the MEN1 syndrome.
3. The diagnosis of insulinoma should be suspected in patients having symptomatic hypoglycaemia typical of Whipple's triad, spontaneously or during a 48–72 h fast, with elevated blood insulin and C-peptide levels in the absence of sulphonylureas in the blood or urine and autoantibodies to insulin or insulin receptors. These biochemical test results, together with careful history taking and imaging studies, are useful in differentiating between the various causes of endogenous hyperinsulinaemic hypoglycaemia.
4. Tumour localization for diagnostic confirmation and guidance of surgical treatment is usually possible by non-invasive techniques with good diagnostic performances such as CT, MRI, endoscopic ultrasound, and functional imaging. Selective arterial calcium stimulation with hepatic venous sampling, the more sensitive but invasive approach, is currently regarded as the gold standard for preoperative localization of insulinoma and should be considered in cases with diagnostic difficulty, although it may soon be superseded by radionuclide functional imaging.
5. Surgical excision, particularly laparoscopic enucleation, with the use of diazoxide for preoperative glycaemic control, is the treatment of choice for insulinomas. For inoperable or metastatic cases, other treatment options include everolimus, somatostatin analogues, peptide receptor radionuclide therapy, chemotherapy, and liver-debulking procedures.

Insulinomas

Introduction and Epidemiology

Hypoglycaemia is an important and life-threatening condition which may occur in many circumstances, and especially in patients with significant disease in intensive care units, and in patients with type 1 and type 2 diabetes mellitus. However, in the previously-well patient with bouts of confirmed hypoglycaemia, the major differential diagnoses will be either an insulinoma or factitious hypoglycaemia. Insulinomas, although rare, are the most common hormone-producing neuroendocrine tumour (NET) of the gastrointestinal tract, with an estimated annual incidence of 0.5–1 per million of the population per year (similar to that of phaeochromocytomas). Insulinomas are four times more common in females. They can occur at any age, but present most commonly in middle age, with a median age at diagnosis of 47 years for sporadic cases and 23 years in patients with multiple endocrine neoplasia type 1 (MEN1) syndrome [1]. Most insulinomas are solitary (90%), benign (90%), small (65% with diameter <1.5 cm), intrapancreatic (99%), and are distributed equally throughout the pancreas: 16% are associated with the MEN1 syndrome and these tumours are bigger, multiple, malignant in 25% of cases, and more resistant to treatment with a higher recurrence rate. Features such as young age of onset (<40 years), multifocal disease, and/or a suspicious family history should prompt screening for the MEN1 syndrome.

Clinical Presentation

Hypoglycaemia is the hallmark of an insulinoma. Patients usually present with non-specific, episodic hypoglycaemic symptoms, which fall into two categories: neuroglycopaenic or autonomic (adrenergic/neurogenic). Neuroglycopaenia occurs when plasma glucose levels fall below 2.2 mmol/L and is due to glucose deprivation in the central nervous system. These symptoms include dizziness, confusion, fatigue, difficulty in speaking or concentrating, headache, changes in vision, seizures, and loss of consciousness.

Autonomic symptoms caused by sympathoadrenal activation consist of sweating, hunger, paraesthesiae, tremor, anxiety, palpitations, and nausea. All these symptoms usually resolve with the ingestion of carbohydrate or injection of glucose. Most patients with insulinomas are exclusively symptomatic in the fasting state (73%), some in the post-prandial period (6%), or both (21%) [2]. They may accommodate by eating regular, high-sugar snacks, exacerbating weight gain (although the hyperinsulinaemia may also contribute to this). Diagnosis is often delayed due to the non-specific presentation.

Diagnosis

The symptoms of hypoglycaemia are often non-specific. Objective measurement of hypoglycaemia during a symptomatic period with relief following administration of glucose (Whipple's triad) is strongly suggestive of endogenous hyperinsulinaemia. During endogenous insulin synthesis by pancreatic β-cells, the precursor hormone proinsulin requires post-translational proteolytic cleavage of C-peptide to release the active hormone insulin. Insulin and C-peptide are thus secreted in equimolar amounts and C-peptide acts as a surrogate marker of endogenous insulin production. In the presence of excessive insulin actions, blood ketones and β-hydroxybutyrate would be suppressed indicating inappropriate inhibition of ketogenesis during fasting. Without any drug exposure, the combination of documented Whipple's triad with simultaneous biochemical hypoglycaemia (blood glucose <3 mmol/L), C-peptidaemia (>0.2 nmol/L), hyperinsulinaemia (>3 uU/ml), and suppressed serum β-hydroxybutyrate (<2.7 mmol/L) is usually pathognomonic of an insulinoma (Table 6.7.1), with a sensitivity and specificity of higher than 90% and 70%, respectively [2]. Some advocate a lower glucose value of less than 2.2 mmol/L as the cut-off, and it has to be admitted that there is a 'grey area' in the range 2.2–3.0 mmol/L. Provocation tests such as a prolonged fasting test and a mixed-meal test should be carried out if there is no hypoglycaemia spontaneously or after an overnight fast.

The 72-h Fast

The prolonged (72-h) supervised fast is considered the gold-standard test. According to previous reports, 65% of patients with insulinoma developed hypoglycaemia at 24 h, 84% at 36 h, 93% at 48 h, and 99% at 72h [3]. Food is withheld and intravenous access is established, although the patient may consume water or non-caloric beverages. Blood glucose is checked every 4–6 hours and when the patient develops symptoms suggestive of hypoglycaemia, and the frequency should be increased when the glucose level becomes relatively low (e.g. <3.5 mmol/L). When the laboratory-measured glucose concentration falls below 3.0 mmol/L, simultaneous serum samples for insulin, C-peptide and β-hydroxybutyrate, as well as blood and/or urine sulphonylurea screening, should be sent for analysis before carbohydrate replacement. If the patient is asymptomatic at the end of the test, a short period of exercise (10–15 min) may provoke hypoglycaemia. In those diseases with abundant insulin or insulin-like growth factor (IGF) levels, blood glucose concentration would increase by more than 1.4 mmol/L after intravenous glucagon reflecting adequate hepatic glycogen stores (Table 6.7.1). However, in our experience the glucagon test is rarely required. In some centres the fast is only continued for 48 hours. It should be emphasized that the patient should be under regular nursing supervision throughout, and if they become stuporous or even develop seizures, then intravenous 5% glucose should be immediately administered (a basal blood sample should always be taken if possible just before the glucose is given). The test is terminated whenever significant hypoglycaemia is confirmed on a venous sample, or if the patient develops their typical symptomatology and the glucose is shown to be normal.

Mixed-Meal Test

A small proportion of insulinoma patients (5%) who do not develop hypoglycaemia during prolonged fasting may have a positive mixed-meal test instead, especially those presenting with postprandial symptoms [4]. During the test, a mixed meal prepared from commercial nutritional supplement formulary or food reported by patient as the possible culprit for inducing hypoglycaemic symptoms is given after an overnight fast. Multiple blood samples are taken regularly (e.g. every 30 minutes until 5 h). The interpretation of test findings is similar to that under fasting conditions.

Tumour Localization

Most insulinomas (>80%) are benign and solitary, rendering surgical cure with complete resection possible. Once a biochemical diagnosis of insulinoma has been established, preoperative localization, and definition of the anatomy is necessary for an optimal surgical outcome. Virtually all insulinomas arise from within the pancreas and therefore localization techniques should be directed to this organ. Some advocate that intraoperative bimanual palpation and ultrasonography by an experienced surgeon may be more sensitive than preoperative localization, but this method requires an open surgical approach and may subject those with other causes of endogenous hyperinsulinism to unnecessary operation. Various modalities such as cross-sectional imaging, endoscopic ultrasonography, functional imaging techniques, and selective intra-arterial injection of calcium with hepatic venous sampling have been adopted for preoperative localization, with different degrees of invasiveness and diagnostic accuracy.

Computer Tomography (CT) and Magnetic Resonance Imaging (MRI)

Multidetector CT (MDCT) is the most popular preoperative imaging for insulinomas. It allows rapid acquisition of images in multiple contrast-enhancement phases with excellent spatial resolution. As insulinomas are usually well-circumscribed oval hypervascular tumours, they in general exhibit more avid contrast enhancement than the background normal pancreatic tissue on CT images in the arterial or pancreatic phase, producing good visual contrast for lesion detection [5]. During the venous phase, there is in general a reduction in the difference in attenuation of the hypervascular tumour and background pancreatic parenchyma, resulting in lower visual conspicuity of the tumour.

MRI at 1.5 T or 3.0 T has become more widely performed nowadays for further lesion characterization due to its high soft tissue contrast. On MRI, insulinomas are typically hypointense on T_1-weighted images and hyperintense on T_2-weighted images compared with the background pancreatic parenchyma, and are more conspicuous on fat-suppressed T_1-weighted images [5]. As in CT, there is often marked enhancement after the intravenous administration of gadolinium with the maximal visual conspicuity in

Table 6.7.1 Interpretation of various biochemical parameters in symptomatic patients with confirmed hypoglycaemia (blood glucose <3.0 mmol/L)

Diagnosis	Insulin	C-peptide	β-HBA	Glucose increase after glucagon	Other suggestive features
Normal response	↓	↓	↑	↓	Malnutrition and/or acute illnesses
Insulinoma	↑	↑	↓	↑	Fasting hypoglycaemia (more common), pancreatic tumour on imaging, MEN1 syndrome
Primary nesidioblastosis	↑	↑	↓	↑	Postprandial hypoglycaemia
PGBH (post gastric bypass)	↑	↑	↓	↑	Postprandial hypoglycaemia, history of bypass surgery
Insulin autoimmune syndrome	↑↑	↑↑	↓	↑	Postprandial hypoglycaemia (more common), presence of other autoimmune diseases or culprit drugs, autoantibodies to insulin
Exogenous insulin	↑↑	↓	↓	↑	History or evidence of prior insulin injection or ready access to insulin
Oral hypoglycaemic agents	↑	↑	↓	↑	Ready access to insulin secretagogues, positive sulphonylurea screen
IGF-mediated	↓	↓	↓	↑	Presence of mesenchymal tumour, ↑pro-IGF-2 and free IGF-2, ↓IGF-1, IGF-2/IGF-1 >3:1 (typically >10:1)

the arterial phase. As diffusion-weighted imaging (DWI) detects changes in molecular diffusion of water in tissues, it may be a promising tool for detecting small insulinomas, especially those without a hypervascular pattern, and liver metastases. Our own study showed the clear advantage of MRI over CT [6], while a recent prospective study demonstrated that contrast-enhanced CT, MRI without DWI, and MRI with DWI yielded sensitivities of around 70%, 80%, and 90% respectively upon analysis of 47 confirmed cases of insulinoma with 51 lesions in total [7]. CT and MRI also allow better delineation of the anatomical location of the tumour and its relationship with vascular structures and the ductal system for surgical planning, in addition to the extent of regional involvement, especially liver metastases.

Endoscopic Ultrasonography (EUS)

Transabdominal ultrasound has a limited role in detecting pancreatic tumours and sonographic visualization of the pancreas due to partial obscuration by stomach and bowel gas, with a sensitivity of only 9–64% [8]. Although EUS is relatively more invasive, it demonstrates high diagnostic accuracy and possesses the benefit of obtaining simultaneous cytology using fine needle aspiration. A recent meta-analysis showed that the pooled sensitivity and specificity of EUS in detecting pancreatic NETs were 87% and 98%, respectively [9]. In another analysis, the mean detection rates of preoperative EUS and intraoperative ultrasound for insulinoma were both found to be 92% [10]. EUS should be considered when cytological diagnosis is desired or when other non-invasive imaging studies are negative or inconclusive. However, this procedure is highly operator-dependent and may miss lesions that are very small, isoechoic, or located at the pancreatic tail. Contrast-enhanced EUS using gas-filled microbubbles as contrast agents is one of the latest advances that may potentially improve lesion conspicuity.

Somatostatin Receptor (SSTR) and Glucagon-Like Peptide-1 Receptor (GLP-1R) Scans

Nuclear medicine makes use of the functional aspects of the tumour rather than simple dimensions alone, thereby providing valuable information when other anatomical studies have failed to localize an occult insulinoma before proceeding to the more invasive approach. In addition, whole body functional scintigraphy allows screening for ectopic lesions and distant metastases.

The importance of somatostatin receptor scintigraphy in the management of both non-functioning and other functioning NETs such as gastrinomas is well-acknowledged in recent literature. Although earlier studies have questioned its utility in localizing insulinoma as its sensitivity could be as low as 24% [11], malignant insulinomas often express SSTR particularly type 2 (SSTR2) [12], so paradoxically this functional technique may be more useful for the more malignant tumours. However, with the advent of newer techniques using high-affinity radioligands targeting SSTR2 coupled with PET/CT e.g. ^{68}Gallium-DOTATATE-PET/CT, there may be more of a role for SSTR-based imaging in the localization of insulinoma. A recent retrospective study demonstrated that ^{68}Gallium-DOTATATE-PET/CT correctly identified the culprit lesion in 9 out of 10 patients with insulinomas (median tumour size of 1.5 cm), in one of which it was the only positive imaging [13]. Apart from localization of insulinoma and preoperative staging of disease, having a positive SSTR scan can also suggest the feasibility of using peptide receptor radionuclide therapy (PRRT) as a therapeutic option in those with metastatic disease (see next).

The vast majority (>90%) of benign insulinomas, as opposed to the malignant and metastatic ones, strongly express GLP-1R with a high-density distribution even when lacking SSTR [14]. These tumours are often smaller and more indolent in nature, and therefore more challenging to identify precisely before surgery. In the recent decade, some researchers have recognized the emerging role of GLP-1R-based imaging in detecting occult insulinomas, using ^{111}Indium- or ^{99m}Tc-labelled scintigraphy and ^{68}Gallium-labelled positron emission tomography (PET)/CT. ^{111}Indium-DTPA-exendin-4 single photon emission computer tomography (SPECT)/CT was found to have a much higher sensitivity (95%) when compared to CT/MRI (47%) in an early study including 23 patients with histologically-confirmed insulinoma [15]. The most recent prospective study of 38 patients having histology-proven benign insulinoma with a median size of 1.3 cm showed that ^{68}Gallium-DOTA-exendin-4 PET/CT had a significantly higher accuracy and

sensitivity (94% and 95%, respectively) than ^{111}Indium-DOTA exendin-4 SPECT/CT (68% and 58%) and contrast-enhanced MRI (68% and 69%), influencing the surgical plan in 40% of patients [16]. The diagnostic superiority of GLP-1R PET/CT over SPECT/CT can be attributed to its greater spatial resolution, scanner sensitivity, and tumour-to-background ratio, as well as lower radiation dose and shorter acquisition time. However, these scans are often costly and not widely available, and the physiological high renal uptake may compromise the detection of lesions over the tail of pancreas which is in close proximity to the left kidney.

A prospective study compared the aforementioned imaging techniques and demonstrated that ^{68}Ga-NOTA-exendin-4 PET/CT correctly detected lesions in 42 of 43 patients with mostly benign insulinomas, resulting in a sensitivity of 98%, whereas ^{99m}Tc-labelled somatostatin receptor scintigraphy only yielded a sensitivity of less than 20%; the sensitivities of CT, MRI and EUS in this study were 74%, 56%, and 84% respectively [17]. ^{68}Ga-exendin-4 PET/CT scanning was also shown to be specifically beneficial in detecting MEN1-associated insulinomas [18]. However, GLP-1R and SSTR scans may be complementary to each other in tumour localization as all insulinomas are likely to express either one or both of these receptors, and the combination of these two peptide receptor imaging techniques could yield a sensitivity of 100% [12], facilitating a minimally invasive surgical approach.

Selective Intra-Arterial Calcium Stimulation with Hepatic Venous Sampling

Selective arteriography alone was formerly considered the gold-standard method, but has been superseded by selective arterial calcium stimulation with hepatic venous sampling. This has been proposed as the most sensitive preoperative localization technique. An angiogram is carried out by selective cannulation of the splenic (supplying the pancreatic body and tail), superior mesenteric (supplying the uncinate process) and gastroduodenal artery (supplying the head of the pancreas). Calcium gluconate, a potent β-cell secretagogue, is injected locally into each respective artery. Blood samples are taken from the right hepatic vein at 0, 30, 60, and 120-s post-injection to measure insulin. A twofold increase in insulin in the 30- and/or 60-s sample confirms the diagnosis [19]. This technique has a reported sensitivity of over 90% (range 87.5–100%) in the **regionalization** of pancreatic insulinomas, but is invasive and not routinely available. It is therefore only considered when there is strong clinical suspicion of an insulinoma, but diagnosis with other tests has proved elusive [20]. This technique also has the advantage that it confirms functionality of any lesion seen on cross-sectional imaging. However, it is likely that in due course functional radionuclide imaging will replace its use.

Management

Surgical Management

As most insulinomas are benign and solitary tumours, surgical resection remains the mainstay of treatment which offers a definitive cure together with the elimination of hormonal effects. The surgical decision depends upon patient's fitness, stage at presentation, tumour location, and limits of resection. After successful surgical removal, prognosis is good, with a 10-year survival of 88% [19]. Surgery may be laparoscopic or open and may involve enucleation, pancreatic resection, and metastasectomy. Enucleation is the preferred method of removal, ideally laparoscopically. Almost all insulinomas possess a pseudocapsule with a clear plane of dissection between the tumour and the surrounding soft pancreatic parenchyma. Enucleation is sufficient if the lesion is small, clearly localized before surgery, at or near the pancreatic surface, and easily defined intraoperatively [21]. Resection is indicated when the lesion is sizeable with considerable ductal or vascular invasion, or where malignancy is suspected with a hard, infiltrating tumour and puckering of the surrounding soft tissue, distal dilatation of the pancreatic duct, or lymph node involvement. Regional lymphadenectomy should be routinely carried out during pancreatectomy for pancreatic NETs of >2 cm due to the higher risk of lymph node metastases. Splenic preservation is ideal to minimize postoperative complications, but may not always be possible. Histological analysis is important to confirm the diagnosis of insulinoma, tumour grade and proliferation rate (Ki-67 index and/or mitotic count), and adequacy of resection.

Hepatic metastases indicate a poor prognosis. Malignant insulinomas with minimal extrahepatic disease and satisfactory performance status are managed with pancreatectomy, metastasectomy, and/or adjunctive treatment such as hepatic artery embolization, and/or chemotherapy.

With advances in laparoscopic techniques, both laparoscopic enucleation and resection have been performed successfully. Although the conversion rate to open surgery is 14%, this most probably represents the learning curve for this procedure [22]. Surgical treatment of insulinomas is effective and safe; reported success rates lie between 77% and 100% and mortality and morbidity rates are 2% and 26%, respectively, including postoperative infection (particularly post-splenectomy) and pancreatic abscess, pseudocysts, and fistula formation. After resection, the risk of recurrence is greater in patients with MEN 1 (21% at 20 years) than those without MEN 1 (5% at 10 years and 7% at 20 years).

For insulinomas as well as other functioning pancreatic NETs that are unsuitable for surgery, there is an increasing literature on the use of EUS-guided ablation techniques (such as ethanol or radiofrequency ablation) to reduce the symptoms due to hormone excess [23]. More data are certainly required to confirm their role in these unresectable cases.

Medical Management

Patients may be medically managed while awaiting surgery or medical therapies may be used alone for patients deemed unsuitable for surgery due to a high anaesthetic risk or inoperable disease related to local invasion or distant metastases, or for those with unsuccessful surgical outcomes such as persistent symptoms post-resection and failure to localize tumour in the theatre. The goal of medical management is to correct hypoglycaemia, prevent disease progression where possible, preserve quality of life, and avoid comorbidities from detrimental side effects.

Dietary and Lifestyle Advice

Patients are encouraged to eat frequent, small meals to avoid hypoglycaemia. Regular consumption of complex carbohydrates and foods with a low glycaemic index is recommended for the maintenance of blood glucose level while high glycaemic index foods are reserved for relieving acute, symptomatic hypoglycaemic attacks.

Guar gum has been shown to reduce insulin secretion in patients with insulinoma. Guar gum is an indigestible saccharide that delays gastric emptying and thus reduces the peak glucose load presented to the small intestine, which acts as a stimulus for insulin secretion, thereby slowing the rate of glucose absorption. Those with great fluctuations in glucose levels should refrain from driving, excessive alcohol intake, operation of dangerous machinery, and strenuous exercise.

Diazoxide

Diazoxide is an effective first-line medical treatment for alleviating hypoglycaemic episodes. It works directly on β-cells to suppress insulin secretion via activation of ATP-dependent potassium channels that leads to cell membrane hyperpolarization and a decrease in calcium influx. Significant side effects occur in 10–50% of patients, including oedema, weight gain, hirsutism, and hypokalaemia. Serious side effects, such as cardiomyopathy, cardiac arrhythmia, and myelosuppression, warrant close monitoring and cessation of therapy, but are rare. The usual initiating dose is 50 mg tds but dosing up to 100 mg tds may be used.

Somatostatin Analogues

In light of the impressive results from clinical trials such as *PROMID* and *CLARINET*, octreotide and lanreotide have become established systemic treatments for enteropancreatic NETs. These synthetic somatostatin analogues bind strongly to SSTR2, and to a lesser extent SSTR5, and are useful in controlling symptoms related to hormonal excess as well as tumour cell proliferation. Their therapeutic value is controversial in benign insulinoma since hypoglycaemia is usually manageable with diazoxide prior to surgical resection and there is a variable expression of SSTR2 on benign tumour cells. However, somatostatin analogues may be considered as first-line option in unresectable low-grade malignant insulinoma for tumour stabilization [24]. Although somatostatin may improve hypoglycaemia through inhibition of autonomous insulin secretion from tumour tissues, they may also paradoxically **worsen** hypoglycaemia by suppressing counter-regulatory hormones such as glucagon or growth hormone. Therefore, blood glucose levels should always be monitored closely upon treatment initiation preferably with administration of subcutaneous short-acting octreotide, and this should be initiated as an in-patient. Pasireotide, a novel somatostatin analogue which binds to SSTR 1, 2, 3, 5 with high affinity, can be potentially more effective in insulinoma due to its greater hyperglycaemic effects and the strong expression of SSTR5 in malignant insulinoma. Well-designed therapeutic trials are warranted to explore the antihormonal and antiproliferative effects of somatostatin analogues on insulinoma. Patients who are selected for these medications require positive somatostatin receptor scintigraphy. Side effects are generally tolerable, such as nausea, flatulence, diarrhoea, or steatorrhoea related to pancreatic enzyme insufficiency, fat-soluble vitamin deficiencies, and the development of gallstones.

Other older therapies include calcium antagonists such as verapamil and membrane stabilizers such as phenytoin, but these are rarely used nowadays.

Everolimus

Everolimus is registered in many countries for treating advanced, progressive, low, or intermediate grade non-functional NETs of gastrointestinal or lung origin. It is an oral mammalian/mechanistic target of rapamycin (mTOR) inhibitor which can potentially produce direct antitumour effects and impact on glucose homeostasis via growth factor signalling (cell growth, proliferation, and angiogenesis) and insulin-mediated pathways, thereby controlling both hypoglycaemic symptoms and tumour proliferation in malignant insulinoma. It probably works principally on modulating insulin release rather than blocking the action of insulin as it is ineffective in insulin-like growth factor 2 (IGF-2)-mediated hypoglycaemia [25]. A recent report described rapid changes in serum insulin and glucose levels following initiation, discontinuation, and re-administration of everolimus, with further *in-vitro* experiments confirming its direct inhibitory effect on insulin secretion independent of tumour regression [26]. The landmark study RADIANT-3 involving 410 patients with advanced progressive pancreatic NETs, including 24% with functioning lesions, showed that everolimus modestly prolonged progression-free survival (11.0 months with everolimus vs. 4.6 months with placebo) while stabilizing the disease in 73% of patients. Among patients with aggressive insulinoma and refractory hypoglycaemia despite multiple lines of treatment evaluated after receiving everolimus, immediate and substantial normalization of glucose levels and disease stabilization were achieved in most of them [27–28], and the median symptom-free survival with everolimus and placebo were 6.5 months and less than 1 month, respectively [27]. Stomatitis, skin rash, and diarrhoea are common side effects, whereas important adverse reactions include myelosuppression and pneumonitis.

Peptide Receptor Radionuclide Therapy (PRRT)

PRRT is a relatively new technique, which allows radiolabelled peptide hormone agonists, with ^{111}indium, ^{90}yttrium, and ^{177}lutetium being the most popular radionuclides, to specifically bind to somatostatin receptors on the NET cell surface, thereby delivering focused radioactivity. There is a growing body of evidence, including the first phase-III randomized controlled *NETTER-1* trial, that clearly demonstrate the efficacy and durability of PRRT in terms of improvement in symptom control and quality of life as well as tumour response and disease stabilization in well-differentiated midgut NETs, with median progression-free survival reaching 3–4 years and an objective response rate of around 30% [29]. Several case reports also illustrated its potential therapeutic value in malignant insulinoma with uncontrolled hypoglycaemia despite the use of multiple treatment modalities. In a case series of five patients with metastatic insulinoma requiring continuous glucose infusion, all of them achieved stable disease for a mean period of 27 months without any recurrence of hypoglycaemic episodes after PRRT despite tumour progression in three patients, suggesting additional mechanisms for glycaemic control (e.g. induction of tumour de-differentiation) [30]. PRRT should be considered in well-differentiated but inoperable cases with multiorgan involvement who have failed first-line therapy. Sufficient tumour uptake greater than the liver on somatostatin receptor imaging is mandatory. Such therapy is usually well tolerated, with ^{177}Lutetium-DOTATATE, the first PRRT agent that has been recently approved for the treatment of somatostatin receptor-positive enteropancreatic NETs, yielding a more favourable toxicity profile. Theoretically, it could cause transient hypoglycaemia due to the release of peptide hormones during rapid tumour necrosis, hence careful monitoring of glucose

level together with adjustment of concomitant therapies is necessary. Other acute side effects include nausea and vomiting, while myelotoxicity and renal impairment are rare but important complications in the longer term.

Chemotherapy

Specific data on the chemotherapy in the treatment of insulinoma are lacking, while regimens containing streptozotocin and 5-fluorouracil (5-FU) have been extensively studied in pancreatic NETs with promising results. Although these potent chemotherapeutic agents carry a considerable risk of drug toxicity, they may be useful in the palliative setting for rapidly progressive or highly proliferative malignant insulinoma. Capecitabine generally replaces 5-FU nowadays, while temozolomide can be tried in place of streptozotocin.

Liver-Directed Therapies

Liver-debulking surgery should always be considered in patients without extrahepatic disease if the majority of the liver metastases can be resected. For patients with high tumour burden in the liver who are not suitable candidates for surgical treatment, locoregional therapies such as transarterial bland embolization, chemoembolization, or radioembolization, and radiofrequency ablation may be reasonable alternatives based on individual tumour characteristics. For instance, hepatic artery embolization to deprive tumour tissues of their blood supply may be an option in a patient with multiple vascularized liver metastases and refractory hypoglycaemia but acceptable residual liver function and a patent portal vein.

Other Causes of Hypoglycaemia

Glucose is a critical fuel for all body organs and especially the brain, and therefore it is imperative to recognize the possibility of significant hypoglycaemia and reverse it promptly, and treat the underlying disease. Hypoglycaemia is usually a consequence of inadequate glucose intake or production relative to glucose utilization from the circulation (Table 6.7.2). Iatrogenic or factitious hypoglycaemia from exogenous administration of antidiabetic agents (insulin or insulin secretagogues) is the most common cause of hypoglycaemia among both diabetic and non-diabetic individuals. In a hospital setting, hypoglycaemia due to critical illnesses such as major organ failure, sepsis and malignancy are frequently encountered, particularly when there is reduced food intake or concomitant use of glucose-lowering medications.

Besides insulinoma, endogenous hyperinsulinaemic hypoglycaemia may also be due to β-cell stimulation by autoantibodies or β-cell hyperplasia associated with nesidioblastosis. These diseases typically demonstrate inappropriately raised insulin and C-peptide levels in response to hypoglycaemia [31]. Hypoglycaemia can also be caused by hypersecretion of abnormal IGF-2 from non-islet cell tumours.

Iatrogenic or Factitious Hypoglycaemia

Hypoglycaemia is a well-recognized side effect of insulin treatment and may account for 4% of deaths in patients with type 1 diabetes as they are vulnerable due to hypoglycaemic unawareness and impaired catecholamine responses. With the advent of insulin pump therapy, the frequency of severe hypoglycaemia in type 1 diabetes was shown to be markedly reduced (for continuous subcutaneous insulin infusion versus multidose insulin injections, a mean 2.9-fold reduction for randomized controlled trials, 4.3-fold for before/after studies, and 4.2-fold for all studies) despite superior glycaemic control [32]. Examples of insulin secretagogues include sulphonylureas and meglitinides, but these have become less popular in the treatment of type 2 diabetes considering the availability of other newer agents that are less likely to cause hypoglycaemia. Elderly patients with cognitive or renal impairment and those using multiple or more potent agents are more prone to hypoglycaemia.

Factitious hypoglycaemia in diabetic patients can be secondary to accidental overdose or inappropriate self-manipulation of these medications. As for non-diabetic individuals, unexpected administration of hypoglycaemic agents as in dispensing errors, and in situations where these drugs are easily accessible, surreptitious, or even malicious, hypoglycaemia may not be evident upon initial evaluation. Meticulous history taking together with thorough review of drug records is thus essential. Patients receiving insulin injections typically have very high blood insulin but low C-peptide levels. However, the biochemical pictures in the use of oral hypoglycaemic agents and insulinoma are similar: elevated blood insulin

Table 6.7.2 Causes of hypoglycaemia in adults

Endogenous hyperinsulinism	Hormonal deficiencies	Acute illnesses	Non-islet cell tumour hypoglycaemia	Drugs	
				Classification	Examples
Insulinoma Functional β-cell disorders (CHH, NIPHS, PGBH) Autoimmune hypoglycaemia	Cortisol Glucagon and epinephrine (in type 1 & advanced type 2 diabetes) Growth hormone	Liver, renal, or heart failure Sepsis Starvation or malnutrition	Mesenchymal tumours Malignant epithelial tumours (e.g. hepatocellular carcinoma, renal cell carcinoma & gastrointestinal tumours)	Antidiabetic (Iatrogenic or factitious hypoglycaemia)	Insulin Insulin secretagogues
				Alcohol	Salicylates
				Anti-inflammatory	Indomethacin Quinolones
				Antimicrobial	Quinine Chloroquine Pentamidine Trimethoprim-sulfamethoxazole
				Antihypertensive	ACE inhibitors β-adrenoceptor blockers
				Others	Disopyramide Haloperidol

and C-peptide levels. Demonstration of detectable sulphonylurea level in the serum and/or urine is therefore a crucial clue in such a scenario, assuming the relevant agent can be assayed.

Alcohol and Other Drugs

Alcohol ingestion influences glucose metabolism in several ways. Ethanol inhibits gluconeogenesis (but has no effect on hepatic glycogenolysis) and the counter-regulatory hormones of insulin—glucagon, adrenaline, growth hormone, and cortisol. Furthermore, patients may not be aware of and compensate for hypoglycaemic symptoms during mild alcohol intoxication. Classically, they present with hypoglycaemia with a normal ethanol level a few days after binge drinking with reduced food intake, when the hepatic glycogen store is depleted, and gluconeogenesis becomes the main source of fuel.

Some other medications are reported to cause hypoglycaemia (Table 6.7.2) [31, 33].

Post-Prandial Syndrome

Postprandial syndrome (formerly called 'reactive hypoglycaemia') refers to a functional and idiopathic condition, observed mostly in young and female patients, with mild symptoms of sympathetic overactivity (2–4 hr after a meal) caused by hyperinsulinaemia in response to a high carbohydrate intake. Although some have proposed the use of an oral glucose tolerance test (OGTT) for diagnosis, the diagnostic glucose value is difficult to define due to a considerable overlap between normal subjects and patients, and there is lack of correlation between symptoms and low glucose levels during the OGTT. Indeed, some have questioned the existence of the syndrome. Nonetheless, the symptoms are usually self-limiting and should resolve after dietary modification with frequent, small meals.

Primary Functional β-Cell Disorders (Nesidioblastosis)

Congenital hyperinsulinaemic hypoglycaemia (CHH) is characterized by inappropriate insulin secretion and nesidioblastosis with islet cell hypertrophy ± hyperplasia in infants and children due to genetic defects involved in the regulation of insulin release from β-cells (channelopathies or metabolopathies) [34]. While some forms tend to abate later in life, the more severe ones, usually caused by mutations in *ABCC8* and *KCNJ11* genes that encode the sulfonylurea receptor (SUR1) and inwardly rectifying potassium channel (Kir6.2) proteins respectively, are invariably resistant to medication and often require operative intervention. Non-insulinoma pancreatogenous hypoglycaemic syndrome (NIPHS) has a similar histopathology causing β-cell hyperfunction and endogenous hyperinsulinaemic hypoglycaemia in adults with a male predominance, but its genetic mechanisms are poorly understood [34–35].

These rare functional β-cell disorders are biochemically indistinguishable from insulinomas, but in contrast to insulinomas they typically give rise to post-prandial hypoglycaemia and negative radiological localization studies [31]. Although both NIPHS and insulinoma may produce positive responses to the selective intra-arterial calcium stimulation test, it was observed that the maximum insulin concentration as well as the extent of insulin increase from baseline during hepatic venous sampling were significantly higher in insulinoma [36]. Medical treatment with diazoxide and/or octreotide is preferred for both CHH and NIPHS. Surgery is only considered when medical options fail and should be restricted to removal of mostly 80% of the pancreas, which can be guided by the selective intra-arterial calcium stimulation test, and usually results in symptomatic improvement.

Post-Gastric Bypass Hypoglycaemia (PGBH)

Some patients develop postprandial hypoglycaemia after Roux-en-Y gastric bypass surgery due to nesidioblastosis, which is possibly a result of dysregulation of gut hormones and insulin after gastroduodenal surgery and significant weight loss, but the exact mechanisms are uncertain [37, 38]. It may also occur following the simpler sleeve gastrectomy. Unlike NIPHS, PGBH has a female predominance and can coexist with insulinoma. Most patients improve with frequent, small meals containing slowly absorbed, complex carbohydrates. Medical therapies such as diazoxide, α-glucosidase inhibitors and octreotide can also be effective. We have reported one patient with the 'dumping syndrome' due to over-rapid transport of glucose to the small intestine and consequent hyperinsulinaemia following oesophagectomy for oesophageal carcinoma: the assumed excessive responses to GLP-1 and GIP could be inhibited by pasireotide, and the patient remains well on this therapy [39]. Partial pancreatectomy is no longer recommended after bypass surgery or sleeve gastrectomy as many patients experienced recurrent hypoglycaemia after the procedure [38].

Non-Islet Cell Tumour Hypoglycaemia (NICTH)

NICTH is a rare paraneoplastic phenomenon characterized by the excessive secretion of aberrant pro-IGF-2 related molecules (or 'big IGF-2'), which are incompletely processed precursors of IGF-2 with potent insulin-like effects. These precursors cannot readily bind with the usual IGF-binding proteins such as BP3 and ALS, and thus the fragment is able to cross blood vessels and gain access to the insulin receptor of target tissues causing hypoglycaemia. Large mesenchymal tumours (e.g. solitary fibrous tumour, haemangiopericytoma and mesothelioma) located in retroperitoneal, intra-abdominal, or intra-thoracic regions are the most common tumours causing this condition. It is occasionally caused by epithelial tumours such as hepatocellular carcinoma, renal cell carcinoma and tumours arising from the gastrointestinal tract [40].

These big IGF-2 molecules inhibit the secretion of both insulin and growth hormone via negative feedback mechanisms which in turn reduces the serum concentrations of IGF-1 and IGF-binding protein. Therefore, this further decreases binding of IGF-2 and contributes to a high proportion of free IGF-2 [40]. Circulating total IGF-2 level may be raised or normal depending on the assay, as these IGF-2 variants can only be detected by special chromatography-based methods [41]. Hence, an IGF-2:IGF-1 ratio of greater than 3:1 (often >10:1) may be helpful in diagnosing NICTH. Apart from IGF-2 mediated hypoglycaemia, other possible mechanisms for tumour-related hypoglycaemia include extensive tumour load in the liver or adrenal glands, emaciation with depleted glycogen reserve, and insulin secretion from the tumour.

Debulking surgery is the treatment of choice in reversing the metabolic derangements associated with NICTH. However, surgery may not be always immediately feasible due to various patient and disease factors. Glucagon infusion is useful in short-term alleviation of hypoglycaemia. Glucocorticoids are known to be an effective

maintenance therapy as they stimulate hepatic gluconeogenesis, suppress the production, and increase the clearance of IGF-2, but their chronic use may be limited by systemic adverse effects. Recombinant human growth hormone can be used alone at high doses, or preferably in combination with glucocorticoids [40]. Diazoxide and octreotide are not useful.

Autoimmune Hypoglycaemia

Insulin autoimmune syndrome (IAS) is a rare disease which was first reported and is most prevalent in Japan, and is defined as endogenous hyperinsulinaemic hypoglycaemia associated with the presence of insulin autoantibodies (IAA) in patients without a prior history of insulin treatment. Sometimes it is associated with autoimmune diseases such as Graves' disease or rheumatoid arthritis, or drugs containing a sulfhydryl group such as methimazole, carbimazole, penicillamine, tiopronin, and glutathione [42]. The suggested mechanisms for hypoglycaemia in IAS are the release of free insulin from the large buffering reservoir of insulin-IAA complexes, which can dissociate unpredictably, and potentiation of insulin bioactivity [43]. Symptoms usually occur in the late postprandial rather than the fasting period because the initial binding of insulin to IAA after food ingestion further stimulates the secretion of free insulin, the insulin-IAA complexes then dissociate spontaneously several hours after eating to release more free insulin leading to hypoglycaemia. In patients with autoimmune disease, hypoglycaemia caused by autoantibodies against insulin receptors which activate insulin receptors regardless of circulating insulin concentrations have also been described. An increase in blood insulin with low C-peptide levels in these rare cases is probably related to the decrease in insulin clearance.

Insulin-IAA complexes often interfere with insulin assays to produce spuriously high insulin levels. Total insulin levels in IAS can be up to 100-fold higher than free insulin. Laboratory confirmation can be obtained by directly measuring IAA in the blood or using polyethylene glycol immunoprecipitation and gel filtration chromatography to confirm the presence of autoantibodies [44]. In contrast to hyperinsulinaemia due to exogenous insulin or insulin receptor autoantibodies, the C-peptide level is not suppressed.

Treatment of IAS consists of small frequent meals with low contents of simple sugars, discontinuation of culprit drugs, diazoxide, plasmapheresis, and corticosteroid therapy. Plasmapheresis removes IAA mechanically, whereas steroids decrease IAA production and alters their properties (binding and dissociation capacities). Most cases resolve spontaneously within one year but may recur if a culprit drug is re-administered.

Critical Illnesses

Besides those with diabetes mellitus receiving hypoglycaemic agents, some hospitalized patients are susceptible to hypoglycaemia as a result of multiple factors such as failure of major organs involved in gluconeogenesis, sepsis, and chronic malnutrition. Regular blood glucose monitoring is essential in these patients who may be too weak to report their symptoms.

Major Organ Failure

The liver is largely responsible for gluconeogenesis and glycogenolysis. However, due to a large hepatic glycogen reserve, hypoglycaemia only ensues after hepatectomy or liver failure caused by extensive and rapid hepatic damage (such as fulminant viral or drug-induced hepatitis) in addition to defective peripheral glucose production. Key mechanisms leading to hypoglycaemia in renal failure include impaired renal gluconeogenesis, reduced insulin clearance, and coexisting heart failure, while hepatic congestion and hypoxia together with diminished gluconeogenesis may be responsible for hypoglycaemia associated with severe cardiac failure. Polypharmacy, sepsis, and poor nutrition may also contribute to hypoglycaemia in these conditions.

Sepsis

Patients with severe infection are prone to hypoglycaemia, which is known to increase mortality because of decreased hepatic glucose output, increased glucose utilization, and associated organ failure. Therefore, tight glycaemic control with the use of intensive insulin therapy in severe sepsis is not currently advocated [45].

Hormone Deficiencies

The insulin-antagonizing hormones play an extremely important role in maintaining glucose homeostasis. Subjects may be more vulnerable to hypoglycaemia when glucagon and catecholamines are insufficient in the context of insulin-deficient diabetes [31], but it is generally not a feature of isolated catecholamine deficiency resulting from bilateral adrenalectomy with glucocorticoid replacement or pharmacological catecholamine blockade, although postoperative hypoglycaemia due to a dramatic fall in catecholamine levels with rebound hyperinsulinism has been observed after resection of phaeochromocytoma. In the presence of intact catecholamine responses, glucagon deficiency would not be expected to cause hypoglycaemia.

Glucocorticoids have profound effects on glucose metabolism. Inadequate endogenous glucose production, escalated glucose disposal and oxidation, increased insulin sensitivity in the liver and peripheral tissues, and anorexia are the likely explanations for hypoglycaemia in adrenal insufficiency.

Hypoglycaemia is not a feature of growth hormone deficiency in adults. In contrast, young children are more susceptible to hypoglycaemia especially in cases of hypopituitarism and prolonged fasting, with diminished hepatic glucose output, depleted glycogen stores, increased glucose oxidation and consumption, and reduced fat mobilization, and lipolysis as contributing mechanisms.

Inborn Errors of Metabolism (IEM)

In rare occasions, fasting hypoglycaemia in adults can be a presenting feature of an IEM, such as glycogen storage disease (particularly Type I and III), defect of fatty acid oxidation and ketogenesis, or gluconeogenesis disorders [46]. These conditions should therefore be considered in patients having other cardinal features (e.g. lactic acidosis, hepatomegaly and myopathy, early onset of symptoms, a positive family history, and otherwise unexplained hypoglycaemia).

ACKNOWLEDGEMENTS

We would like to express our gratitude and appreciation to Puja Mehta and Jeannie Todd, authors of the chapter in the second edition, for their valuable and inspirational contributions.

Glucagonoma

Karim Meeran

Introduction

Glucagon is a peptide formed by alternative splicing of the pre-pro glucagon gene. Alpha cells of the islets of Langerhans secrete glucagon in response to hypoglycaemia.

Glucagonomas are neuroendocrine tumours arising from the alpha cells of the islets of Langerhans, which result in excessive secretion of glucagon and peptides derived from preproglucagon. Post-translational modification of proglucagon is tissue specific and results in various glucagon peptides [1]. It is the ratio of insulin to glucagon that controls the balance of gluconeogenesis and glycogenolysis in the liver. Glucagon stimulates hepatic gluconeogenesis and inhibits both glycolysis and glycogen synthesis. It increases production of free fatty acids from triglyceride breakdown by activating hormone-sensitive lipase; these undergo fatty oxidation in the liver via acetyl CoA, forming ketone bodies. The increase in free fatty acids from lipolysis inhibits hepatic lipogenesis. Glucagon also increases muscle proteolysis, resulting in an increase in amino acid supply to the liver.

Epidemiology

The annual incidence of glucagonomas is estimated to be only 1 per 20 million [2, 3] so that we would expect three new cases in the United Kingdom each year. The majority of glucagonomas are sporadic, with only 3% associated with multiple endocrine neoplasia type 1 (MEN 1) [4]. The current data in the United Kingdom is either based upon single case reports or a few small series of cases. Table 6.8.1 illustrates the clinical features of 192 patients between 1998 and 2016 [2] in China. The median age of presentation is 52 years.

Clinical Features

A series of cases of glucagon-secreting pancreatic tumours associated with necrolytic migratory erythema, weight loss, diabetes mellitus, and stomatitis was described in 1974 when the term glucagonoma syndrome was first coined [5]. Not all glucagonomas are symptomatic and they may be identified solely through screening of patients with MEN 1. The nutrient deficiencies arising due to hyperglucagonaemia and the secretion from the tumour of glucagon-like peptides 1 and 2, as well as cosecretion of other hormones such as pancreatic polypeptide, give rise to a spectrum of clinical features [6].

Necrolytic Migratory Erythema (NME)

NME is characterized by erythematous, well-demarcated plaques that are pruritic and painful, and often involve the intertriginous areas, perineum, and buttocks (Figure 6.8.1). This painful pruritic rash is a typical feature of the glucagonoma syndrome and one of the most common presenting signs, occurring in 82% of patients [3, 7]. Suspicion of the diagnosis by dermatologists, who may be the first people to see these patients has been the most common route of referral. An added clue is recent onset diabetes. Although characteristic for the glucagonoma syndrome, NME is not pathognomonic. The initial lesions of NME are erythematous plaques, which may be associated with bullae. These lesions form erosions and crusts, which eventually heal to leave central areas of hyperpigmentation and induration. The lesions demonstrate the Koebner phenomenon, i.e. occurring at sites of trauma [5]. Skin biopsy histology reveals necrolysis of the upper dermis and vacuolization of keratinocytes [8]. The occurrence of NME does not correlate with metastases and has been noted in 60% of patients with benign glucagonoma.

The exact pathogenesis of NME remains unclear. There have been several postulated theories; the condition appears to be a multifactorial disease caused by a combination of zinc, amino acid, and fatty acid deficiencies [9]. The glucagonoma syndrome shares a number of clinical features with vitamin B_2, B_3, B_6, and B_{12} deficiency. Indeed, vitamin B deficiency may arise as a result of hyperglucagonaemia

Table 6.8.1 Presenting clinical features in 192 patients with glucagonoma (1998–2016)

Clinical feature	Males (%) N = 85	Females (%) N = 107	Total (%) N = 192
Necrolytic migratory erythema	64 (75.3)	88 (82)	152 (79)
Diabetes mellitus or IFG	51 (60)	69 (64)	120 (62.5)
Weight loss	50 (58.8)	54 (50.5)	104 (54.2)
Anaemia	34 (40)	50 (46.7)	84 (43.8)
Angular chelitis	8 (9.4)	17 (15.9)	25 (13)
Glossitis	16 (18.8)	28 (26.2)	44 (23)
Diarrhoea	11 (12.9)	8 (7.5)	19 (10)
Psychiatric symptoms	9 (10.6)	8 (7.5)	17 (9)
Thrombosis	4 (4.7)	5 (4.7)	9 (4.6)

[6]. NME has been reported following intravenous glucagon treatment, suggesting that NME may be a direct consequence of glucagon action on the skin [10, 11]. NME has also been associated with conditions other than glucagonoma (e.g. coeliac disease and cirrhosis); both of these conditions may have raised glucagon or glucagon-like peptides levels [7].

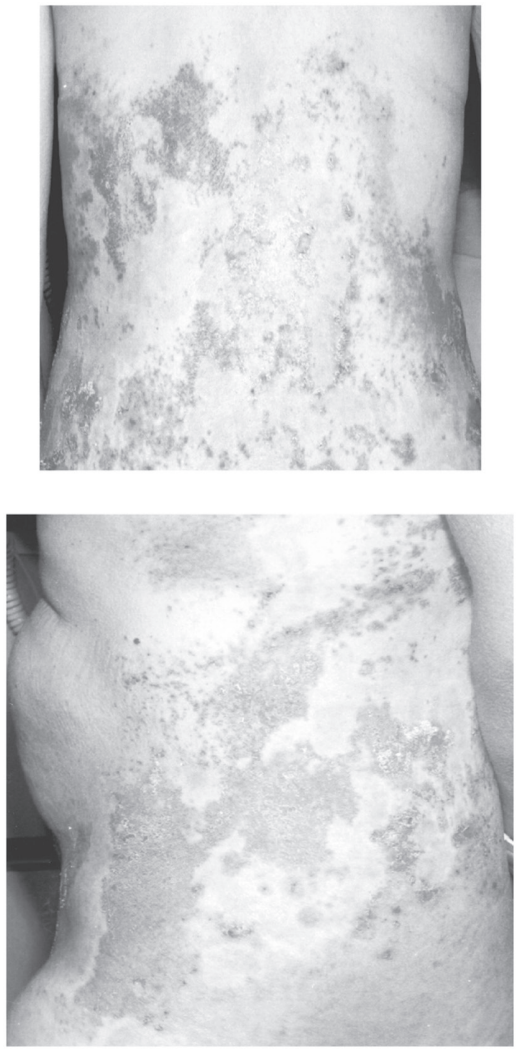

Figure 6.8.1 Necrolytic migratory erythema on the back and trunk of patient with malignant glucagonoma. (See also Plate 36.)

Diabetes Mellitus

Diabetes mellitus is common in sporadic glucagonomas, occurring in 55% of patients at presentation and eventually developing in 75% of cases. Of these three-quarters require insulin therapy [12]. Although rare, diabetic ketoacidosis has been reported [13].

Other Clinical Features

A review from the Mayo clinic of 21 patients with glucagonoma [12] suggested that weight loss or cachexia is a common presenting complaint, occurring in 71% of patients with metastatic glucagonoma. Similar rates of weight loss have been noted in the Hammersmith series [7] with 72% in patients with metastases and 40% with local disease. Normocytic normochromic anaemia was noted in approximately a third of patients and is probably the result of direct bone marrow suppression by glucagon [7]. Diarrhoea occurs in approximately one-fifth of patients with glucagonoma [12]. Of these, half also have elevated gastrin and pancreatic polypeptide levels [7]. Involvement of the mucous membranes may lead to the development of stomatitis, glossitis, and chelitis in a third of cases. Psychiatric symptoms occur in 20% of patients and may vary from depression to paranoid delusions. Thromboembolism is a major source of morbidity and mortality in the glucagonoma syndrome and occurs in up to 11% of cases [7] and may account for up to 50% of deaths [14].

Metastases and Site of Primary Tumour

Over 80% of patients with sporadic tumours have metastases at presentation [7, 12]. Hepatic metastases usually involve both lobes of the liver and are multiple in two-thirds of cases; of the single hepatic metastases 75% occur in the right lobe. Of primary tumours, 41% are confined to the tail of the pancreas, 14% involve the head and body, 14% occur in the head alone, and 9% in the body alone. The primary site of glucagonomas is the pancreas in 100% of cases. Sensitive imaging modalities and hepatic angiography may allow an increased detection of the primary tumour site [7].

Investigations

Biochemistry

Because of the rarity of glucagonomas, it is very important to minimize false positives by not screening patients who have a low prior probability of having a glucagonoma. For example patients with diabetes alone are very unlikely to have a glucagonoma, so this is a group who should not be screened, unless one is measuring glucagon for other reasons. Raised fasting plasma glucagon immunoreactivity is the basis for diagnosis. The reference range at the Hammersmith Clinical Chemistry Gut Hormone Laboratory is fasting plasma glucagon level below 50 pmol/L. False-positive results may occur due to other causes of a raised fasting plasma glucagon such as renal or hepatic failure, drugs, and prolonged fasting [15]. Plasma glucagon levels may be elevated to various degrees ranging from only 1.5 to 150 times the upper limit of normal [7]. Thus, if clinically supported, a marginally elevated plasma glucagon level may still be suspicious [16].

A raised fasting plasma gastrin level is noted in one-fifth of patients at presentation and may be associated with the Zollinger–Ellison syndrome [17]. Plasma gastrin levels should be monitored regularly since they may rise up to 6 years after initial diagnosis. Other hormones may also be elevated, for example insulin, 5-hydroxyindoleacetic acid, human pancreatic polypeptide, chromogranin, and vasoactive intestinal peptide. It is therefore important an annual assessment of fasting gut hormone profile should be undertaken [7].

Biochemical investigations may reveal hypoproteinaemia, hypoalbuminaemia, and hypocholesterolaemia [14]. Specific nutritional deficiencies (e.g. zinc deficiency), should be screened for, although plasma levels of trace elements may not reflect tissue levels [7]. Patients with MEN-1 should be screened with fasting gut hormones, including glucagon levels on an annual bases [18].

Imaging

Gallium (68)-labelled octreotide scanning [19], contrast-enhanced computed tomography (CT), and visceral angiography are the imaging modalities of choice and are more sensitive than abdominal ultrasound in tumour detection [20] (Figure 6.8.2) (see also Chapter 6.11). Gallium scanning can be coregistered with a low dose CT scan, so that areas of increased uptake can be correlated with anatomical landmarks. Using colour for increased uptake superimposed on a black and white CT scan is most useful. MRI also has a high sensitivity [21] both in detecting the primary tumour and in detecting metastases. Repeated MRI scanning is preferable to repeated CT scans when screening individuals with MEN1 as repeated CT scans can cause a significant cumulative radiation exposure over time [7]. Nuclear medicine scanning with indium 111 or gallium 68 labelled octreotide reveals the presence of somatostatin receptors on these tumours [22].

Treatment

To ensure that all aspects of treatment are considered at the outset, a multidisciplinary approach to treatment is required. Review by a team that includes an endocrinologist, a pancreatic and upper gastrointestinal (GI) surgeon, an interventional radiologist, a histopathologist, a nuclear medicine physician, and an oncologist is required. Nutritional assessment, correction of any deficiencies, and implementation of weight maintenance strategies is imperative. Where required, diabetic control should be optimized. Anticoagulation therapy should be instigated although there are currently no guidelines regarding which anticoagulant to use or the extent of anticoagulation required.

Surgical resection, either of the tumour itself or distal pancreatectomy and splenectomy in local disease, is the treatment of choice and offers 5-year survival rates of over 66% [7]. However, 90% of patients have metastases at presentation and these commonly extend beyond lymph node metastases. Nevertheless, surgical resection or debulking of the tumour or distal pancreatectomy and splenectomy may offer good symptom relief. Unfortunately, symptoms return in a quarter of patients by 1 year, and 1-year survival rates in those in this subgroup are only 50% [7].

Because the liver has a dual blood supply, and because liver metastases secrete angiogenetic factors that derive a blood supply exclusively from the hepatic artery, occlusion of the hepatic artery in a patient with hepatic metastases results in preferential death of metastatic cells, while hepatocytes survive on the portal vein supply. The metastases recur, and derive blood supply from other anastomotic blood vessels of the coeliac axis, so that hepatic artery occlusion cannot be repeated. However hepatic artery embolization with microspheres allows selective devascularization of hepatic metastases with minimal effect on the liver parenchyma. Careful angiography is required, and insertion of the catheter as far into a metastasis as possible minimizes hepatic damage. Such hepatic artery embolization allows symptomatic relief in 80% of patients; this may not correlate with a fall in plasma glucagon [23]. Prior to the procedure, the patency of the portal vein must be established to ascertain whether there is adequate supply to the normal liver parenchyma. Complications of the procedure include massive peptide release, the effects of this may be minimized with the use of octreotide. Vasodilating peptides and contrast load may lead to severe hypotension, thus optimal fluid balance must be maintained both pre-and postembolization. Additionally, there are risks of infection in the necrotic tissue and of hepatic abscess formation [7].

Somatostatin analogues such as octreotide are the mainstay of medical therapy and provide rapid symptomatic relief, especially of NME [24], although they are less effective in control of weight loss and diabetes [25]. Somatostatin inhibits growth hormone and other pituitary and pancreatic hormones. It has been demonstrated to both reduce plasma glucagon levels and shrink tumour size, but its use was restricted by its 2-minute plasma half-life. Octreotide is a somatostatin analogue with a longer plasma half-life of 2 hours after intravenous administration. Lanreotide is a longer-acting somatostatin analogue, which can be administered every 2 weeks, and has been shown to be effective in controlling the rash [26]. Octreotide LAR and Lanreotide Autogel are slow-release preparations that are administered monthly, and control glucagon levels [27] and control the NME rash in patients with glucagonomas. It is not known whether these drugs prolong life in patients with glucagonomas, but these drugs are required to control the NME rash. Patients may require increasing doses of octreotide or lanreotide after 6 months to control symptoms [7]. Patients should be monitored for symptoms of gall stone formation as cholestasis is noted in 50% of patients [7].

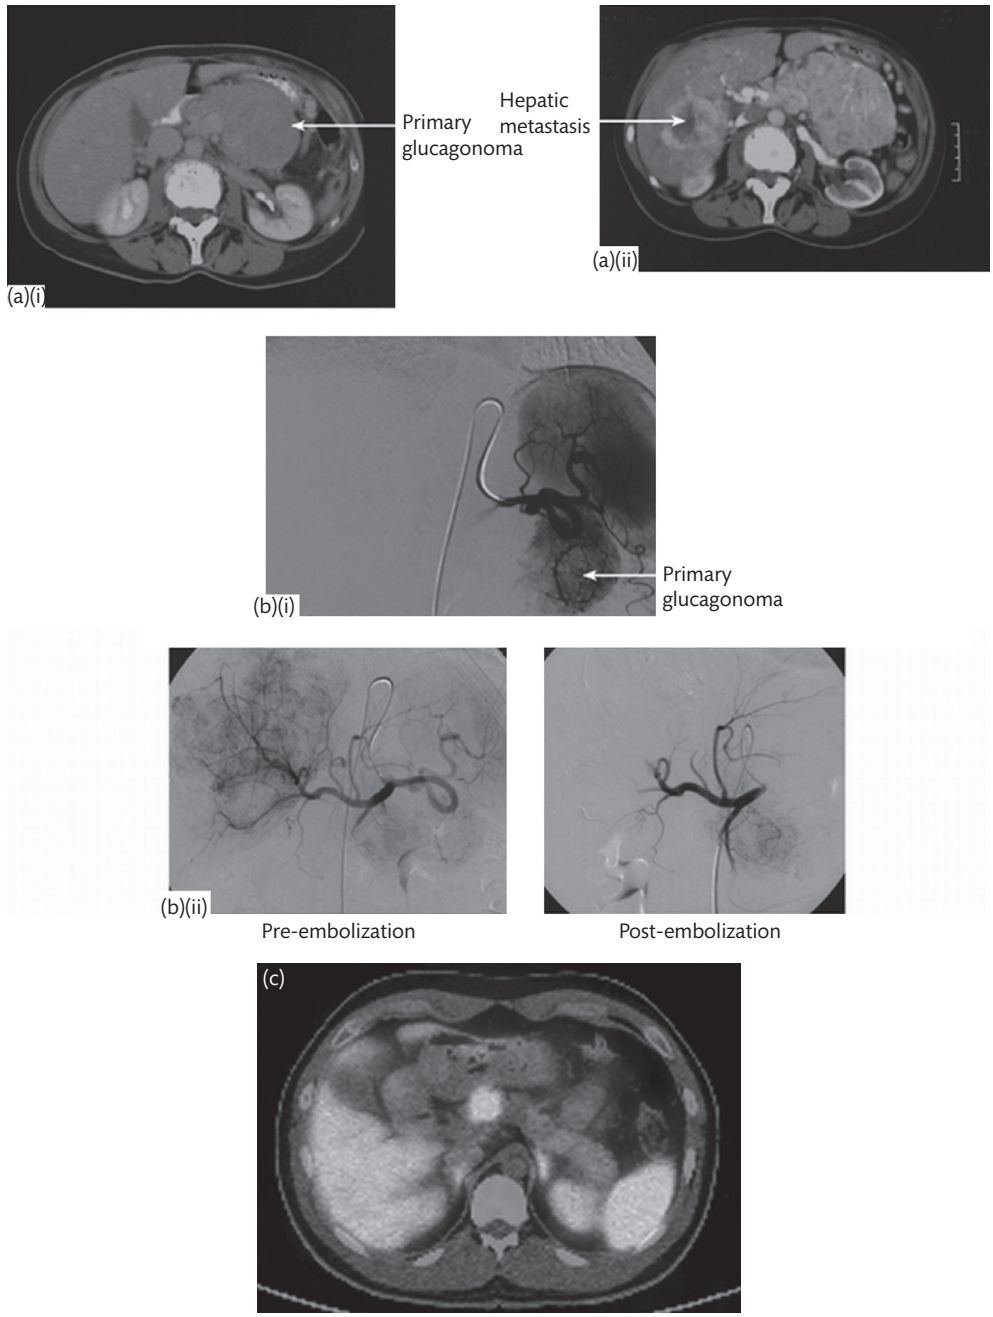

Figure 6. 8. 2 (a) Abdominal CT scans showing (i) primary glucagonoma, (ii) progression of primary glucagonoma, and hepatic metastases after 4 years. (b) (i) visceral angiogram showing cannulation of the splenic artery and vascular blush of primary glucagonoma, (ii) visceral angiogram showing cannulation of the hepatic artery and vascular blush of hepatic metastases, pre- and post-hepatic artery embolization. (c) Gallium (68) octreotate (colour) scan coregistered with a black and white CT scan showing a primary glucagonoma in the pancreas. Somatostatin receptors are bright yellow or white. The spleen has many somatostatin receptors and is thus bright white in all normal patients. The adrenal glands and liver have some receptors and are yellow in this scan. The glucagonoma expresses somatostatin receptors and is bright white on this scan. These receptors explain why the secretion of the hormone that causes the rash can be reduced by therapy with somatostatin analogues.

The PROMID study (Placebo controlled, Double-Blind, Prospective, Randomized study of the Effect of Octreotide LAR in the Control of Tumor Growth in Patients with Metastatic Neuroendocrine MIDgut Tumors) did not investigate glucagonomas, but its results probably apply to them. It was the first randomized trial to investigate the antitumor effect of octreotide LAR Depot [28, 29]. Eighty-five treatment-naïve patients with locally inoperable or metastatic NET were randomized to receive 30 mg octreotide LAR Depot or placebo. The median time to progression was 14.3 months in the treatment group versus 6 months in the placebo group (P = 0.000072) [28]. The European Society for Medical Oncology recommends octreotide LAR or lanreotide LA for managing patients with recurrent, inoperable, or metastatic GI NETs.

Chemotherapeutic agents such as streptozocin and 5-fluorouracil have been used in the treatment of glucagonoma. Streptozocin is a nitrosourea antibiotic with selective toxicity to pancreatic B cells,

demonstrated in animals, and 5-fluorouracil inhibits DNA synthesis. Chemotherapy has a very limited role in management in those with symptoms persisting at 6 months and patients tend to survive for less than a year [7].

Treatment with systemic radiolabelled lutetium (177) has been shown to help with remission for up to two years in a patient with a glucagonoma [22].

Combining the technology of hepatic embolization with yttrium-90 radiolabelled beads is also effective for hepatic metastases and is known as selective intrahepatic radiolabelled therapy (SIRT).

Prognosis

Patients with benign disease have an 85% survival rate at a mean follow-up of 4.7 years. Those with malignant disease treated with combination therapy have a 60% survival rate with a mean follow-up of 4.8 years.

Vasointestinal Polypeptide Secreting Tumours

Alia Munir

Introduction

Vasointestinal polypeptide (VIP) secreting tumours (VIPomas) are rare functioning neuroendocrine tumours. The first case was reported in 1957. This patient presented with diarrhoea, islet cell tumour, peptic ulceration, and hypokalaemia [1, 2]. This was thought initially to be a variant of the Zollinger–Ellison syndrome. However, not until Verner and Morrison in 1958, described their eponymous syndrome, was this recognized as having an alternative hormonal aetiology [3]. They described a syndrome comprising of profuse, refractory watery diarrhoea, with severe hypokalaemia and dehydration, in association with non-insulin-secreting tumours of the pancreatic islets. VIP as the cause of the diarrhoea was confirmed by Kane in 1983 [4]. Bloom *et al.* suggested the term VIPoma syndrome in 1973 [5]. The absence of gastric hypersecretion and even achlorhydria was noted. Later termed 'pancreatic cholera' due to the resemblance to the severe diarrhoea caused by *Vibrio cholera* [6]. The acronym WDHA (watery diarrhoea hypokalaemia achlorhydria) has also been used to describe the VIP syndrome [6]. Notably, bicarbonate wasting is the cause of the associated systemic acidosis. Other tumour sites have been reported to secrete VIP including: in adults: lung cancer, colorectal cancer, phaeochromocytoma, hepatoma, hypernephroma, cutaneous mastocytoma and adrenal tumours [7–11]; in children: VIPomas may occur in sympathetic ganglia (ganglioneuroblastoma) and the adrenal glands [12].

Epidemiology

VIPomas are rare, with the reported annual incidence of 1 per 10 million in the general population (0.05–0.2 new cases per million per year) [13, 14]. In adults, 90% arise from the pancreas, but 10% are reported to arise from neural tissue, sympathetic ganglia, colon, bronchi, and adrenals. Some 40–70% are malignant and 5% occur as part of MEN 1 [13–15]. They are usually solitary and occur in the tail of the pancreas in up to 75% of patients, with up to 60–70% having already metastasized at the time of diagnosis. In children, VIPomas can occur along the autonomic chain and in the adrenal medulla, as ganglioneuromas and ganglioblastomas [16]. In adults, the typical age of presentation is 30–50 years and in children between 2 and 4 years [13, 14].

Pathogenesis

Recent whole-genome sequencing of 102 primary pancreatic neuroendocrine tumours (pNETs) has demonstrated that sporadic pNETs contain a larger than expected proportion of germline mutations [17]. Mutations in DNA repair genes *MUTYH, CHEK 2*, and *BRCA 2* (previously unreported), together with mutations in *MENIN* and *VHL*, have been shown to occur in 17% of patients. Point mutations and gene fusions were found in genes involved in the four main pathways including chromatin remodelling, DNA damage repair, activation of the mammalian target of rapamycin (mTOR) signalling (including previously undescribed EWSR1 fusions) and telomere maintenance [18]. A hypoxia and HIF subgroup was also identified in the gene analysis [19].

Pathophysiology

Pre-proVIP is a 170 amino acid precursor which is post-translationally modified to the 28 amino acid polypeptide, VIP, which binds to high affinity receptors on intestinal epithelial cells [20]. Other peptide fragments including peptide histidine methionine are also produced [21–23]. VIP is structurally similar to secretin and normally functions as a neurotransmitter within neurones. The cloned receptors are G-protein coupled receptors of the secretin family. It is a potent vasodilator and stimulates gastrointestinal and pancreatic secretion. It can inhibit gastric acid secretion. VIP binds to receptors on epithelial cells in all segments of the intestine and activation of cellular adenylate cyclase and the production of cAMP results in net fluid and electrolyte secretion (Na, K, Cl, HCO3 and water) into the lumen causing diarrhoea and hypokalaemia [24]. Hypercalcaemia and hyperglycaemia may also occur. Other agents that maybe implicated in the diarrhoea syndrome include gastrin, glucagon, pancreatic polypeptide, thyrocalcitonin, prostaglandins, or other peptides from pre-proVIP.

Diagnosis and Clinical Features

Diagnosis can sometimes be challenging due to overlap with other causes of diarrhoea. A raised fasting VIP, with profuse secretory diarrhoea (of no other aetiology) that occurs despite fasting and characteristic symptoms are usually diagnostic. This occurs in nearly all patients (90–100%), with hypokalaemia (often less than 2.5 mmol/L) present in 80–100% and dehydration in 83%. In a review of 55 patients with diarrhoea and hypokalaemia, the most dominant feature was high volume profuse cholera-like diarrhoea, often present for 3–4 years prior to diagnosis [15, 18, 25, 26]. The common features of the VIP syndrome are shown in Table 6.9.1 and the causes of secretory diarrhoea are shown in Box 6.9.1.

In VIPoma, the diarrhoea will not disappear with 48–72 hours of fasting, and has the appearance of dilute tea. Stool volumes frequently exceed 6–8 litres of stool per 24 hours [15, 18, 25]. The average potassium loss from stool is of the order of 300 mmol/24 hours. The presence of a secretory diarrhoea may be confirmed by finding an osmotic gap of <50 mOsmol/kg between serum and stool osmolality: serum osmolality (or 290) minus the product of twice the stool potassium plus sodium concentrations (290–2(Na+K) mOsm/Kg) [27].

Early in the disease the diarrhoea may be intermittent and episodic, but as the tumour enlarges it becomes continuous and life-threatening electrolyte abnormalities ensue. Other notable clinical and biochemical features include: hypercalcaemia, stimulation of glycogenolysis causing hyperglycaemia, and gallbladder distension. The cause of hypercalcaemia is unknown, but maybe attributed to diarrhoea, parathyroid hormone-related peptide secretion (PTH-rp) or coincidental, and coexistent primary hyperparathyroidism in the context of MEN 1. Only 8% of VIPomas are associated with facial flushing, which when it occurs, tends to be patchy and urticarial. Hypomagnesaemia has also been associated and maybe responsible for tetany in some patients. Abdominal pain is mild or absent and symptoms relate to dehydration, hypokalaemia, and include lethargy, nausea, vomiting, muscle weakness, and muscle cramps.

Box 6.9.1 Causes of secretory diarrhoea

- Infection
  - Cholera
  - *E. coli*
- Villous adenoma of the rectum
- Laxative abuse
- IgA deficiency
- Congenital
  - Dysautonomia
  - Chloridorrhoea
  - Structural enteric abnormalities
- Neuroendocrine tumours
  - VIPoma
  - Carcinoid
  - Gastrinoma (Zollinger–Ellison syndrome)
  - Medullary carcinoma of the thyroid
- Miscellaneous
  - Systemic mastocytosis
  - Basophilic leukaemia
- Idiopathic

Localization

Numerous localization studies are recommended in an effort to accurately localize, stage, and plan treatment in VIPoma, especially to determine whether the tumour is amenable to surgical resection with curative intent. Conventional imaging studies, such as contrast computerized tomography (CT) scan are standard first-line imaging tools. Magnetic resonance imaging (MRI) and endoscopic ultrasound scan (EUS) [28] (useful for fine-needle aspiration) may be used to ascertain liver involvement and to confirm a tissue diagnosis, respectively. Functional imaging with somatostatin receptor scintigraphy (SRS) has been superseded, where available,

by ^{68}Gallium-DOTATATE/TOC due to the higher sensitivity and specificity for diagnosis and staging of neuroendocrine tumours. Fluorodeoxyglucose (FDG) positron emission tomography (PET) CT may be positive in tumours with higher grade. Nuclear imaging modalities may also be accurate predictors of octreotide responsiveness and guide future therapies. Other isotopes also used include ^{11}C-5HTP and ^{18}F DOPA, but availability of these may be limited.

Treatment

The treatment of VIPoma, as with other functional pancreatic neuroendocrine tumours, has two main goals: (1), control of clinical symptoms resulting from the hormonal excess; (2), control of tumour growth. Given the high incidence of metastatic disease at diagnosis, combinations of therapies are frequently employed. It is recognized that cytoreductive surgery can facilitate the management of hormonal excess and should be considered where 70–90% of the visible disease is potentially resectable [19]. There is, however, a paucity of control studies, but the ENETS guidelines recommend surgery with curative intent wherever possible [18]. Liver-directed therapies such as transarterial chemoembolization (TACE) or radioembolization, selective internal radiotherapy (SIRT) as well as radiofrequency ablation (RFA) can be employed where appropriate [29] but data specifically in VIPoma is limited.

Management

Initial management is focussed on correction of electrolyte abnormalities and restoration of renal function and maintenance of cardiac stability, and high dependency or intensive care monitoring is usually needed. Parenteral crystalloid fluids (3–6 litres per day) of with potassium replacement (up to 350 mmol/day) may be required at initial presentation. The next aim is to slow the diarrhoea. This frequently requires somatostatin analogue therapy to block the secretion of VIP [30]. In addition, somatostatin analogues have been shown to have a tumour antiproliferative effect with significantly increased progression free survival [31, 32] (see Chapters 6.4 and 6.5). Glucocorticoids (such as prednisolone 10–30 mg/day) may be effective at reducing the volume of diarrhoea. Glycaemic control frequently requires insulin. In selected cases ongoing parenteral nutrition/fluid maybe needed to facilitate discharge from hospital and promote medical fitness for ongoing treatments.

Surgery

In non-metastatic disease, surgery can offer cure in up to 50%, and a large adult series of 241 case reports of VIPoma showed a 5-year survival of 89% with pancreatic VIPoma and 68.5% in neurogenic VIP producing tumours [15, 33]. Debulking surgery may also be of benefit. Perioperative proton-pump inhibition is recommended to prevent rebound gastric acid secretion. Careful monitoring of fluid balance is imperative, both peri and postoperatively, as fluid overload may occur as VIP levels fall after surgery.

Pharmacotherapy

Somatostatin analogues provide a symptomatic response in 80–90% of neuroendocrine tumours within days of initiation and are therefore drug of choice to control diarrhoea in VIPomas [34, 35]. Dosing can vary, depending on clinical need, but initiating at 100 mcg subcutaneously every 8 hours is a reasonable starting dose, with increments of 50 mcg to 200 mcg as needed [36]. Intravenous octreotide may need to be considered if control poor. Response should be measured by stool output and not plasma VIP levels, initially. Loperamide and codeine phosphate may useful to help control diarrhoea. Somatostatin analogue-induced steatorrhoea is responsive to oral pancreatic enzyme supplementation. Mild glucose intolerance and asymptomatic gallstones may occur in up to a quarter of patients on somatostatin analogues [37]. Once over the initial acute presentation patients can be switched to long-acting somatostatin analogues [38]. Escape of control may occur quite frequently in VIPomas and more definitive treatments are usually required in the longer term. Frequently the addition of glucocorticoids gives symptomatic relief and when used in combination with somatostatin analogues can prove effective. This may necessitate more intense glycaemic control, usually with insulin therapy. Consideration may be given to other drugs which enhance sodium absorption from the jejunum or inhibit intestinal secretion such as clonidine and opiates, respectively, but these may have limited long-term impact.

Metastatic Disease

There is a wide range of available treatments in patients with metastatic disease, and patients should be discussed in a neuroendocrine multidisciplinary meeting (NET MDT) by multiple specialists within the field in order to optimize outcomes [13].

Limited hepatic metastases may be considered for resection. Debulking the disease may have a positive effect on hormonal control and tumour load. Liver transplantation may be indicated in a limited small number of patients in whom life-threatening hormonal symptoms persist despite maximal medical therapy and standard therapy is not feasible. This is only undertaken in the context of discussion in a specialist NET MDT [13].

Hepatic artery embolization may be used in symptomatic liver metastases not amenable to surgery [39]. Infection, hormonal secretory crisis, and post-procedure hyperuricaemia must be proactively avoided in such cases [40]. Hepatic radiofrequency ablation, cryotherapy, and laser therapy are regarded as less invasive therapies but are limited in general to smaller sized metastases (4–5 cm).

The recommended sequencing of therapies has not been evaluated in VIPomas, but there is a suggestion that PRRT should be considered prior to embolization of the hepatic artery to maximize delivery of the therapy to liver metastases.

Chemotherapy, Targeted Therapies, and Peptide Receptor Radionuclide Therapy (PRRT)

The efficacy of chemotherapy in VIPomas is difficult to determine as very small numbers of patients have been treated with

chemotherapy and in most studies all types of pancreatic neuroendocrine have been included. Chemotherapy agents have been well established in the treatment of pancreatic neuroendocrine tumours in general (see Chapters 6.4 and 6.5). The use of streptozocin, temozolomide, capecitabine, fluorouracil, and cisplatin has been published, usually in combination with somatostatin analogues for symptom control [41–43]. In a randomized multicentre study of 80 patients with metastatic NET, there was no significant difference between those given lanreotide autogel, interferon alfa or both [44]. Interferon alfa has been used in VIPomas with refractory symptoms showing some benefit in terms of symptom control [45].

There have also been reports of positive use of multitargetted tyrosine kinase inhibitors (TKI) (Sunitinib) [46, 47] and mTOR inhibitors (Everolimus) in VIPomas, with an increase in progression free survival by up to 18 months.

The effect of the tyrosine kinase inhibitor, Sunitinib was studied recently in a randomized control trial of 171 patients with advanced well differentiated pancreatic neuroendocrine tumours, including VIPomas. The progression free survival rate was 11.4 months in the sunitinib group compared to 5.5 months in the placebo group. Less toxicity was reported when compared to systemic chemotherapy [48]. Other TKI such as pazopanib and cabozantinib have also shown some activity in NET demonstrating antiproliferative and antihormonal effects (see also Chapters 6.4 and 6.5).

Everolimus is now licenced for use worldwide for use in pNETS, GI and lung neuroendocrine tumours (NETS) with advanced progressive disease supported by data from recent placebo-controlled randomized controlled trials [49, 50]. In RADIANT 1, a phase II study, everolimus alone stabilized disease in 67.8% of patients and in combination with octreotide LAR, stabilized disease in 80% [51]. In RADIANT III, 410 patients, with radiological progression, were randomized to everolimus or usual therapy. Progression free survival was 11 months compared to 4.6 months with usual therapy [49].

Peptide receptor radiotherapy (PRRT) using radiolabelled somatostatin analogues have been approved for the treatment of metastatic neuroendocrine tumours [52, 53], and can be highly effective in metastatic disease and in controlling the functional aspects in pNETS [54, 55]. High-dose β radiation is delivered to tumours following receptor binding and internalization of a somatostatin analogue labelled with a radionuclide (^{177}lutetium- or ^{90}yttrium). There have been case reports of success with reduced tumour burden and improved symptoms following PRRT in patient with VIPomas [56].

Somatostatin analogues, interferon alfa, and PRRT have been shown to improve quality of life but formal data on overall tumour response are limited [44].

Prognosis

Given the rarity of VIPomas accurate survival data are limited. It is known, however, that smaller tumours without metastases have a more favourable prognosis. In metastatic disease electrolyte stabilization and use of more modern therapies may be of benefit. A small study of pancreatic VIPoma has reported a 5-year survival of up to 68% [33].

Although there has been great progress in the management of NETs, VIPoma remains a rare and challenging neuroendocrine tumour to diagnose and manage. In particular, VIPoma demands meticulous management of electrolytes, acid-base status, and glycaemia. With respect to the antitumour and hormonal control, somatostatin analogues remain the mainstay of treatment, with newer targeted agents showing great promise. Ideally a worldwide study for this rare functioning neuroendocrine tumour would be required to evaluate and assess treatment sequencing, quantify tumour and hormonal response, and measure long-term survival.

Somatostatinoma

John A.H. Wass

Introduction

Somatostatin was isolated in 1973 by Paul Brazeau in Roger Guillemin's laboratory. It was found to have a widespread distribution, not only in the hypothalamus and brain but also in the gastrointestinal tract. Sixty-five per cent (65%) of the body's somatostatin is in the gut, mostly in the D cells of the gastric and intestinal epithelium. It is also present in the myometric and submucosal plexuses. The highest concentration is in the antrum of the stomach and there is a gradual decrease of concentrations down the gastrointestinal tract. Five per cent (5%) of the body's somatostatin is in the pancreas.

Infused somatostatin, which has a short half-life of 3 minutes, has a large number of actions on the pituitary gland, the endocrine and exocrine pancreas, gastrointestinal tract, other hormones, and on the nervous system (Box 6.10.1). Among its various actions of importance in the gastrointestinal tract is the inhibition of gastrin and cholecystokinin (CCK). In the pancreas, insulin and glucagon are inhibited. Non-endocrine actions include inhibition of gastric acid secretion, pancreatic exocrine function, gall bladder contraction, and intestinal motility. Intestinal absorption of nutrients, including glucose, triglycerides, and amino acids, is also inhibited [1].

Somatostatin and its long-acting analogues, lanreotide, and octreotide are also potent inhibitors of tumour growth including that of neuroendocrine tumours.

Somatostatin exists in two main forms, as a 14-amino acid peptide (somatostatin 14) present mainly in the pancreas and the stomach, and as a 28-amino acid peptide present mainly in the intestine. Somatostatin 14 is the peptide present in enteric neurons.

Somatostatin receptors are present on many cell types, including the parietal cells of the stomach, G cells, D cells themselves, and cells of the exocrine and endocrine pancreas. A large number of tumours also have somatostatin receptors and these include pituitary adenomas, endocrine pancreatic tumours, carcinoid tumours, paragangliomas, phaeochromocytomas, small cell lung carcinomas, lymphomas, and meningiomas. This fact aids detection of these tumours by PET-CT scanning (^{68}Ga-DOTATATE). Five different somatostatin receptors (SSTRs) have been cloned (SSTR1–SSTR5) and all are on different chromosomes. These have a varying affinity for somatostatin 14 and somatostatin 28 and a varying

Box 6.10.1 Actions of exogenously administered somatostatin on endocrine and exocrine secretion

Endocrine secretion—inhibits the secretion of:

Pituitary
- Growth hormone
- Thyroid-stimulating hormone

Gastrointestinal tract
- Gastrin
- Cholecystokinin
- Secretin
- Vasoactive intestinal polypeptide
- Gastrin-inhibiting peptide
- Motilin
- Enteroglucagon
- Pancreatic polypeptide
- Insulin
- Glucagon
- Somatostatin

Other peptides
- Renin

Exocrine secretion—inhibition of:
- Gastric acid secretion
- Gastric emptying rate
- Pancreatic exocrine function: volume, electrolytes, and enzyme content
- Gall bladder contraction
- Intestinal motility
- Intestinal absorption of nutrients
- Splanchnic blood flow
- Renal water reabsorption
- Activity of some central nervous system neurons

tissue distribution with SSTR2 and 5 being predominant in the pituitary [2].

Somatostatin can act either as an endocrine hormone or in a paracrine or autocrine way. It probably also has luminal effects in the gastrointestinal tract. Lastly, it can act as a neurotransmitter [3].

Somatostatinoma

Somatostatinomas are neuroendocrine tumours [4, 5]. They are rare, with an estimated incidence of about 1 in 40 million. In total, over 200 have been described. They may be sporadic (90%) or familial (10%). Two main types exist: pancreatic somatostatinomas (56%), which are large tumours often associated with features of somatostatin excess; and duodenal tumours (44%), which are usually small and more amenable to surgical resection [6]. They have also been described in the jejunum and cystic duct. The two types are compared in Table 6.10.1. They are infrequently associated with multiple endocrine neoplasia type 1 syndrome (7%), neurofibromatosis type 1, or Von Hippel–Lindau syndrome. The somatostatinoma syndrome is a triad of diabetes mellitus, diarrhoea, and gallstones [7].

Pancreatic Somatostatinoma

Somatostatinoma syndrome was first described in 1977 [8]. Over 100 such cases have now been reported with features as in Box 6.10.2. The syndrome consists of cholelithiasis, the cause of which is multifactorial, including suppression of CCK production which results in impaired gallbladder contractility. High levels of somatostatin also inhibit bowel transit, which alters bowel flora, thus increasing bile acid reabsorption and this is associated with super saturated bile [9]. Mild diabetes occurs and has often been present for many years before diagnosis. It is probably due to suppression of insulin secretion. Diarrhoea and steatorrhoea also occur and relate to the inhibition of pancreatic exocrine function. Hypochlorhydria relates to the inhibition of gastric acid secretion and gastrin. Anaemia, abdominal pain, and weight loss are also present and are non-specific. They are probably related to the size of the tumour, which is usually large, and also to the fact that it is malignant. Those tumours are often diagnosed late and distant metastases may be present in lymph nodes, liver, or bone (55% are in the head of the pancreas).

Plasma and tissue levels of somatostatin are elevated and levels are higher in pancreatic as opposed to duodenal somatostatinomas. These somatostatin-secreting cells often also secrete adrenocorticotrophic hormone (ACTH), calcitonin, insulin, or some other peptides. This means that Cushing's syndrome, flushing, or hypoglycaemia (if there is cosecretion of insulin) may be present [10].

Table 6.10.1 Comparison of pancreatic and extrapancreatic somatostatinomas

Feature	Pancreatic	Extrapancreatic (duodenal)
Number of patients	81	81
Inhibitory syndrome (%)	18.5	2.5
von Recklinghausen's disease (%)	1.2	43.2
Large tumour (>20 mm) (%) (NFI)	85.5	41.4
Multisecretorary activity (%)	33.3	16.3 No differences
Metastatic rate and malignancy		
5-year survival	75.2% overall 59.9% with metastases 100% without metastases	

Box 6.10.2 Features of pancreatic somatostatinoma

- Hyperglycaemia 95%
- Cholelithiasis 68%, if inhibitory syndrome present
- Steatorrhoea 47%
- Hypochlorhydria
- Diarrhoea 60% with pancreatic; 11% with duodenal
- Abdominal pain 40%
- Weight loss 25%
- Anaemia 14%
- Elevated plasma and tissue somatostatin
- Histologically malignant, may be associated with ACTH, calcitonin, and insulin secretion

Duodenal Somatostatinoma

Duodenal somatostatinomas tend to be smaller and present earlier. The vast majority occur near the ampulla of Vater where they tend to cause obstructive biliary disease (NFI) (39%). Some are associated with neurofibromatosis type 1 and some are occasionally associated with phaeochromocytoma. Radiologically they can be difficult to diagnose. This may need endoscopic techniques. At presentation paraduodenal lymph nodes are involved because there is a high malignancy rate, although this is usually low grade. None of the duodenal somatostatinoma patients have developed the full-blown somatostatinoma syndrome but diabetes and gall stones have been noted in some cases.

Recently gain of function hypoxia-inducible factor 2 (HIF 2A) post-zygotic somatic mutations (mosaicism) were detected in ampullary somatostatinoma associated with multiple paraganglioma and polycythaemia [11, 12]. Although originally described only in females it has also been described in males [13].

Histologically these are psammomatous tumours. Treatment is with surgery if this is feasible, chemotherapy, and, if necessary, hepatic embolization. Somatostatin analogues may lower somatostatin levels and improve symptoms (such as diarrhoea) of both types of somatostatinoma if metastases are present.

Localization

The radiopharmaceutical ^{68}Ga-DOTATATE combined with CT or MRI is superior to previous imaging methods and is now the gold standard in localization of NETs.

Treatment

Surgical treatment provides the best chance of cure. If this is not possible, surgical debulking will provide significant relief and

prolongs survival rate. Liver resection can be considered with solitary metastasis.

Somatostatic analogues relieve symptoms and inhibit growth. Lanreotide may prolong progression free survival [13].

Radiotherapy with 177 lutetium (177-lu-octreotate) causes tumour response in those with a high uptake on the OctreoScan; capecitabine can also be used in combination. In ENETS grade 1 and 2 tumours, everolimus or sunitinib may be useful for progressive disease.

Treatment Outcomes

There is a high prevalence of metastatic disease in somatostatinomas, likely a consequence of late diagnosis. Patients with somatostatinoma tend to have a long survival rate and complete removal of sporadic or hereditary somatostatinoma is usually effective and ensures prolonged survival. Most duodenal somatostatinomas survive and for pancreatic somatostatinoma 10-year survival is around 70% [12].

Imaging Neuroendocrine Tumours of the Gastrointestinal Tract/ Gastroenteropancreatic Neuroendocrine Tumours (GEP-NET)

Prakash Manoharan

Introduction

The incidence of neuroendocrine neoplasms (NENs) has increased over the last decades [1]. NENs constitute a heterogeneous group of malignancies originating from cells of the endocrine (hormonal) and nervous systems. Due to the heterogeneity, these tumours have a varied clinical presentation and proliferation. The heterogeneous nature of these tumours creates a challenge with regards to diagnosis, staging, and management. Within the gastrointestinal system, NENs can be broadly defined as tumours arising from the hollow viscus such as the stomach, small bowel, appendix, colorectal regions (extrapancreatic), and from the solid organs, essentially and exclusively the pancreas (pancreatic). NENS arising from other solid organs of the gastrointestinal region are exceedingly rare [2]. They are further subdivided into non-functioning tumours, which have a higher incidence and functioning NENs producing peptides that can cause distinct clinical symptoms such as flushing and diarrhoea (carcinoid syndrome), hypoglycaemia (insulinoma), gastric ulcers (gastrinoma) or skin rash (glucagonoma). Collectively these NENs are termed gastroenteropancreatic neuroendocrine tumours [3, 4] (GEP-NETs). The key factor differentiating NENs from other types of malignancies is based on pathological findings (see Chapter 6.1). Therefore, investigating and imaging GEP-NETs is dependent on a variety of factors, including symptom profile, site of tumour, functioning versus non-functioning (hormonal profile) and tumour pathology. Tumour pathology especially the grade of the tumour (grades 1 to 3) plays a crucial role with regards to the direction and choice of imaging modality.

Imaging Modalities

Imaging continues to undergo rapid and sustained technological advances. Imaging modalities can be divided into non-invasive and invasive techniques. Non-invasive imaging modalities consist of morphological modalities such as multidetector computed tomography (MDCT), which is a cross-sectional modality and molecular imaging modalities that image biological activities such as positron emission tomography (PET) techniques. Invasive techniques include endoscopic modalities (e.g. endoscopic ultrasound) and interventional radiology (e.g. vascular angiography). More recently a process of hybridization of imaging modalities has created several new hybrid modalities that have combined traditional morphological and molecular imaging techniques to create a host of emerging and evolving modalities such as PET-MDCT. Imaging plays a key role in investigating GEP-NET patients. Due to the complexity and heterogeneity of this disease process, a multimodality approach is now routinely utilized.

Non-Invasive Morphological Imaging Modalities

With regards to conventional radiological imaging modalities, ultrasound (US), MDCT and magnetic resonance imaging (MRI), are the most routinely employed modalities in abdominal imaging and this also applies to GEP-NETs.

Ultrasound (US)

Transabdominal ultrasonography (US) is a non-ionizing, readily available non-invasive technique. The role of US in GEP-NET

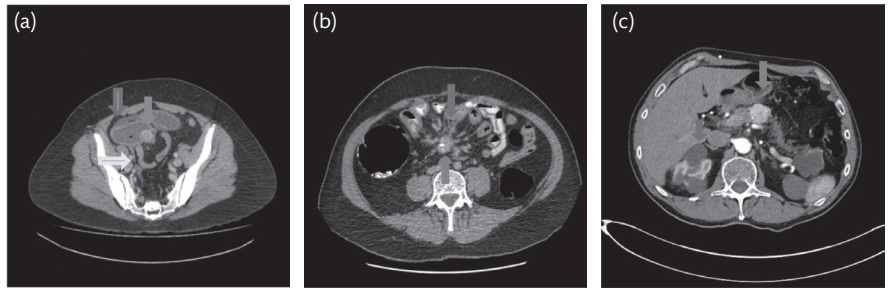

Figure 6.11.1 (a) Arterially enhancing tumour (red arrow) involving the ileal small bowel causing bowel obstruction- dilated proximal bowel loops (blue arrow) and collapsed distal small bowel loops (yellow arrow). (b) Classic example of a mesenteric nodal mass with internal calcification (red arrow) and fibrotic bands (blue arrow). (c) Arterially enhancing pancreatic body mass (red arrow) and multiple benign renal cysts (blue arrow) in a patient with Von Hippel–Lindau.

patients is limited, although it is sometimes the modality through which abnormalities in symptomatic GEP-NET are incidentally detected in patients at initial presentation. In certain circumstances, US has a role in the management of younger patients (under 16 years) and patients who are pregnant due to its ease of access and non-ionizing properties. It is not utilized as a staging tool due to difficulties in imaging the entire body and limitations in assessing abdominal organs due to overlying bowel gas. Classically, primary and metastatic GEP-NETs appear as a hypoechoic space occupying lesions surrounded by a hyperechoic halo. US, however, has a significant role in image-guided biopsies to obtain pathology specimen including sampling of more superficial sites such as lymph nodes.

MDCT

MDCT is a cross-sectional imaging modality and is considered the 'work horse' of oncology imaging modalities with high spatial and temporal resolution. MDCT is not only important in identifying a primary site of GEP-NETs but also enables whole-body assessment of tumour burden in a number of seconds. On the whole, patients find investigation with MDCT acceptable, particularly due to the speed, ease, and availability of this technique. MDCT also allows multiphasic contrast assessment and multiplanar reconstruction of images increasing the likelihood of detecting the extent of disease and aiding interventional/surgical planning. Typically, primary and metastatic GEP-NETs appear as hypervascular lesions (**Figure 6.11.1**—vascular primary lesions) [5, 6]. These lesions also demonstrate a varying degree of calcification and fibrotic changes that are usually detectable on MDCT (**Figure 6.11.1b**—calcified and fibrotic mesenteric mass). Bone metastases appear sclerotic and can demonstrate increased uptake of somatostatin cell surface receptors (SSTR) on hybrid imaging (**Figures 6.11.2**). Despite these advantages, MDCT holds some limitations depending on the grade and

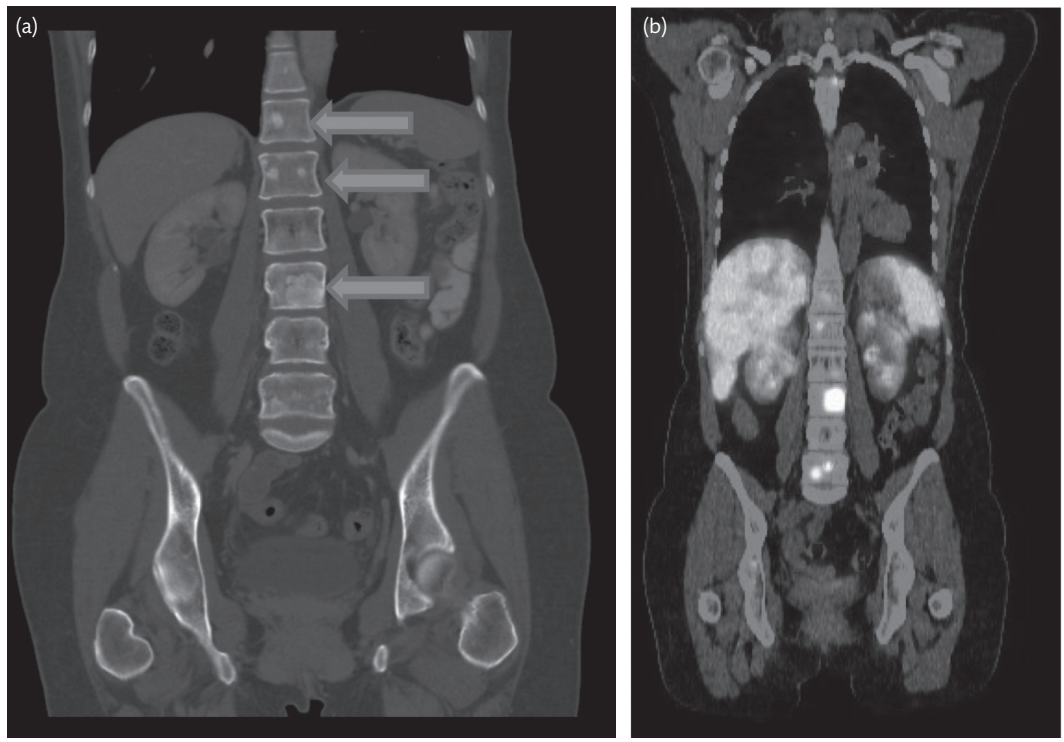

Figure 6.11.2 (a) Multiple metastatic sclerotic bone lesions (blue arrows). (b) Multiple metastatic sclerotic bone lesions demonstrating increased uptake of tracer on somatostatin cell surface receptors (SSTR) on hybrid PET-MDCT imaging.

Table 6.11.1 Cross-sectional morphological MDCT and MRI imaging protocols for GEP-NETs.

(a) MDCT, multiphasic iodinated contrast-enhanced protocol for GEP-NETS

Iodinated contrast-enhanced MDCT with pump bolus injection trigger utilizing 4 ml/s flow rate (sec) triggered by bolus tracking of the descending aorta		
Arterial	Portal venous	Pancreatic
12 sec	60–90 sec	30–45 sec

(b) MRI multiphasic contrast-enhanced/multiparametric protocol for GEP-NETS

Morphological		Diffusion-weighted imaging (DWI) clinical	Gadolinium contrast-enhanced utilizing either extracellular (hepatic and extra hepatic) or Hepatobiliary (hepatic)
T_1-weighted (T1W) imaging with multiplanar acquisition (axial, coronal, and sagittal)	T_2-weighted (T2W) imaging with multiplanar acquisition (axial, coronal, and sagittal)	A minimum of 2 b values (s/mm^2) is recommended to calculate the Apparent diffusion coefficient (ADC) ideally b values (50, 200, 400, 800)	Dynamic contrast-enhanced volumetric, fat-saturated (FS), gradient-echo T1W sequences with multiplanar reconstruction

site of tumour; mainly lack of specificity and sensitivity especially at sites involving the nodes, liver, and bones. Table 6.11.1 details a detailed multiphasic iodinated contrast-enhanced MDCT imaging protocol of GEP-NETs.

MRI

As an imaging modality MRI has superior intrinsic soft tissue contrast when compared to other technologies. This, coupled with the multiplanar and multiphasic contrast-enhanced acquisition capabilities, makes it a very important tool to assess GEP-NETs [7, 8]. Most protocols utilize a combination of T_1- and T_2-weighted sequences combined with or without fat saturation. Newer sequences such as diffusion-weighted imaging (DWI) have been incorporated into the majority of protocols. DWI sequences are particularly useful in detecting small liver and pancreatic lesions non-invasively that are occult in other cross-sectional imaging modalities (Figures 6.11.3).

MRI is a non-ionizing radiation modality. It is generally utilized as a problem-solving tool and is usually used as a more focused examination of a site of abnormality/clinical concern. Part of the limitation of MRI is that even with recent software and hardware improvements, MRI image acquisition still takes longer than MDCT. Depending on the site of examination it usually takes between 30 and 60 minutes to complete an examination. Although a non-ionizing modality, there are restrictions to MRI due to magnetic radiation safety issues [9]. In addition, access to MRI technology is more limited due to scarcity of equipment and it is also a more expensive modality. Patients tend to tolerate MRI less well when compared to MDCT due to a longer scan time and longer bore of the equipment. Patient cooperation with the scanning protocol is also quite crucial to achieve better quality images.

GEP-NETs have a varied appearance on MRI. The MRI appearance is dictated by the grading and tumour biology. Majority are of low signal intensity on T_1-weighted MR images and have a varying hyperintensity on T_2-weighted images [7, 8]. Cystic tumour changes which are a feature of a spectrum of GEP-NETs are better detected on MRI due to enhanced inherent tissue contrast. As per MDCT, on contrast-enhanced MR images, these tumours are often hypervascular in the arterial phase and show varying degrees of contrast enhancement (Figure 6.11.4).

For a detailed multiphasic gadolinium contrast-enhanced and multiparametric MRI imaging protocol please refer to Table 6.11.1.

Non-Invasive Molecular Imaging Modalities (Hybrid Molecular Imaging Modalities)

Hybrid molecular imaging is a specialized field of imaging where biological activity is imaged utilizing labelled radioactive tracers. This requires a nuclear medicine department with access to a radiopharmacy, physicist, and specialized imaging experts to interpret the scans. There are also usually stringent national and international legislative requirements in place due to the handling and administration of radioactive particles. These factors coupled with fewer scanners make this modality fairly specialized and expensive.

Single Photon Emission Tomography/Multidetector Computed Tomography (SPECT-MDCT)

SPECT-MDCT is a hybrid molecular imaging modality combining detection of biological activity after administration of an intravenous labelled gamma emitting nuclear medicine tracer with a scintillation camera and cross-sectional MDCT. Most modern nuclear medicine departments utilize these hybrid imaging systems replacing traditional stand-alone SPECT camera. With SPECT-MDCT, the sensitivity, specificity, and accuracy of detecting the biological activity including in GEP-NET is improved when compared to SPECT [10]. Therefore, in the current era, this is the nuclear medicine modality of choice and most large healthcare centres will have access to this modality. GEP-NETs have cell surface receptors and biological activities that can be detected with SPECT-MDCT. This modality is utilized for further characterization and assessment of GEP-NETs; especially grade I and II tumours. Detection of tumour or metastatic site is dependent on the size, location, biological activity, and concentration of the biological activity (e.g. receptor density) and if positive, it is seen as a focal 'hot spot' when compared to the background. There is usually a long period for the background activity to reduce to improve detection of pathology. Typically in GEP-NETs, the imaging protocol requires imaging at 4 hours post injection of a

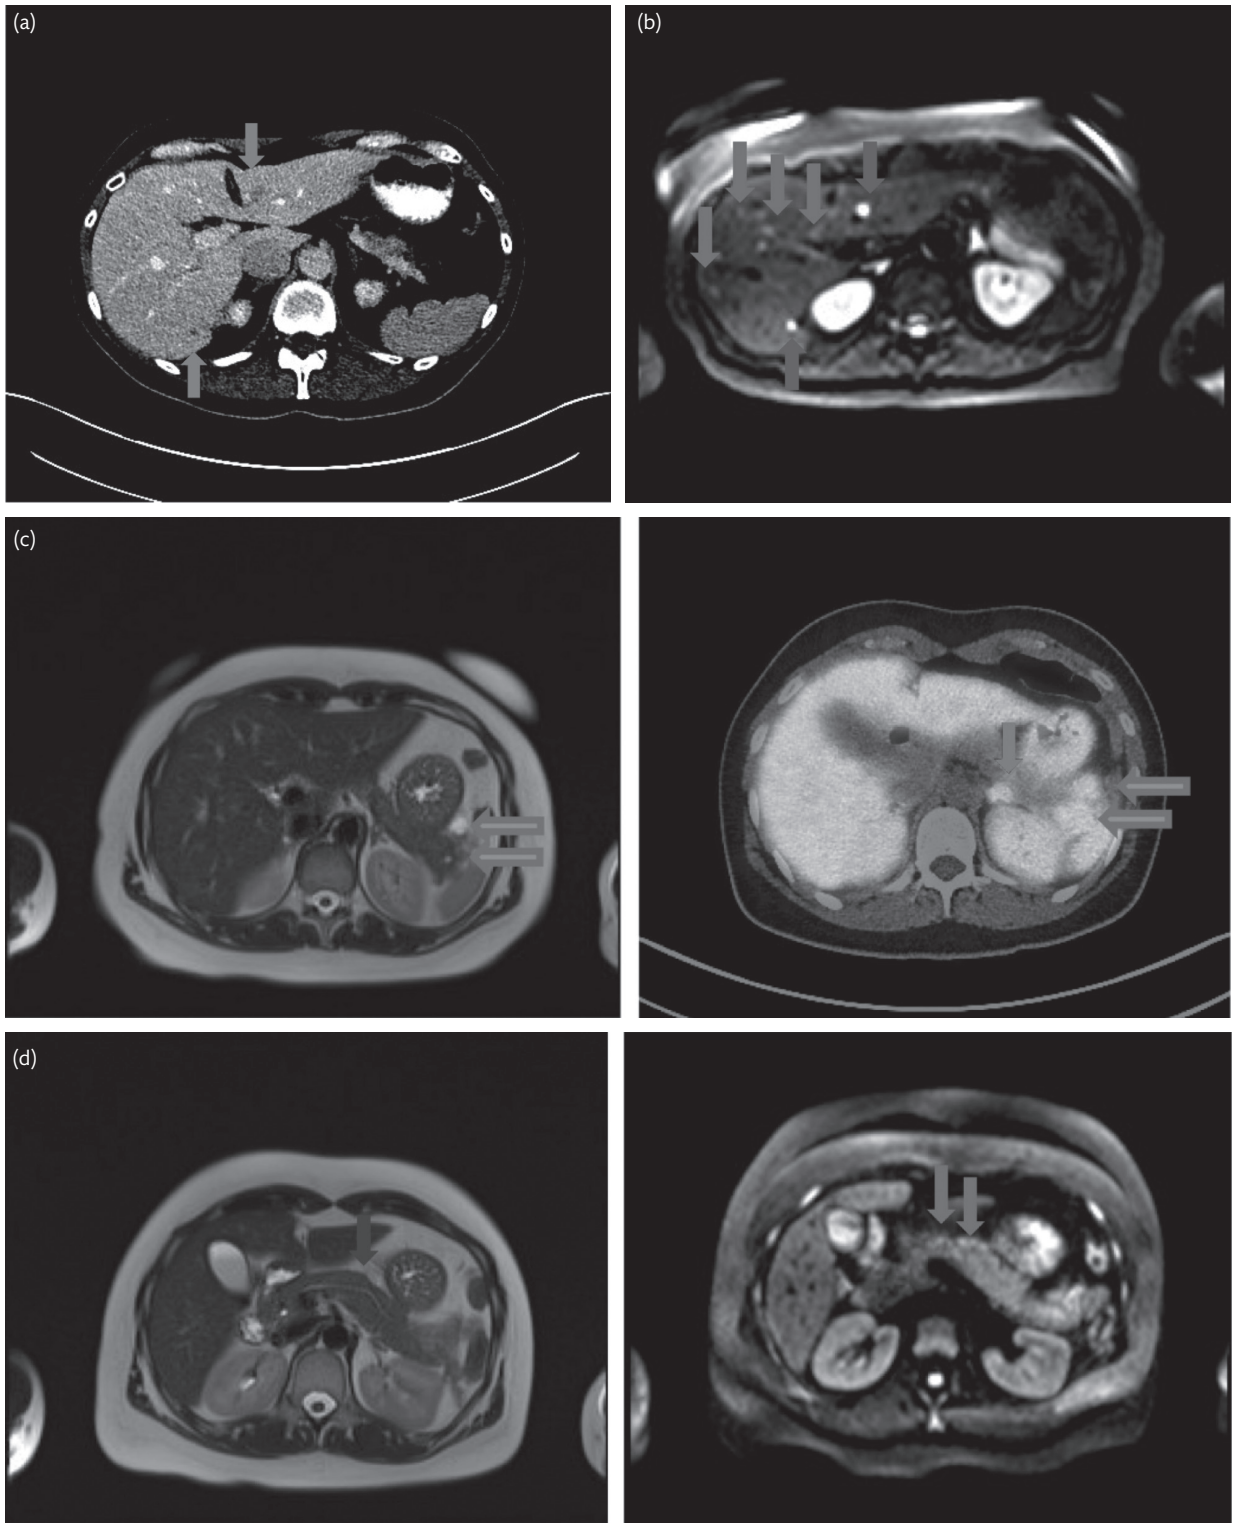

Figure 6.11.3 The IV contrast CT scan (a) detects two liver metastases (red arrows). The corresponding MRI DWI image (b) demonstrates the two liver metastases detected on the CT scan (red arrows) and multiple other liver metastases (blue arrows). (c) Patient with MEN 1. On the left, the T2W MRI of the pancreas has two partly cystic pancreatic tail pancreatic NET (blue arrows). On the right, these tumours in the tail demonstrate intense uptake of tracer on the Ga68 DOTATOC SSTR PET-CT, demonstrated here on the fused image (blue arrows). No further areas of abnormal uptake detected (intense uptake labelled with red arrow is physiological left adrenal gland uptake). (d) Patient with MEN 1 as per case 3c. On the left, T2W MRI of the pancreatic body demonstrate normal pancreatic signal (red arrow). On the right, the MRI DWI image of the body demonstrates multiple tumours non-invasively (blue arrows) which was confirmed on EUS.

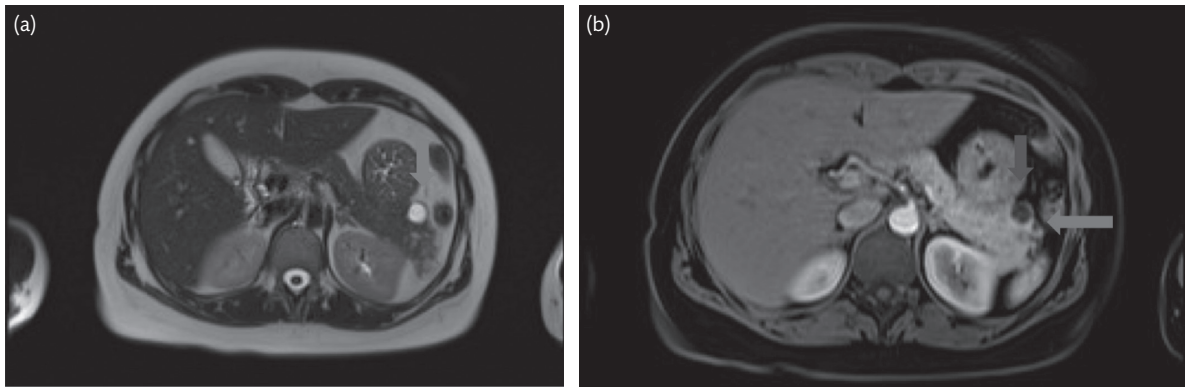

Figure 6.11.4 (a) Cystic component of the tail of pancreas NET 'bright' on T2W MRI (red arrow). (b) Post-gadolinium-enhanced T1W fat supressed MRI demonstrating non-enhancing cystic component (red arrow) and rim of arterial hypervascular enhancement (blue arrow).

radioactive tracer and then a further imaging event at 24 hours post injection of tracer.

PET-MDCT

PET-MDCT is a hybrid molecular imaging modality combining detection of biological activity after administration of an intravenous labelled positron emitting radiotracer with a PET camera and cross-sectional MDCT. Again, increase in sensitivity, specificity, and accuracy is achieved with a hybrid PET-MDCT when compared to a PET alone system [11, 12]. GEP-NETs have cell surface receptors and biological activities that can be detected with PET-MDCT. This modality is utilized for further characterization and assessment of GEP-NETs; especially grade 1 and 2 tumours (and to a lesser extent grade 3 tumours). Detection of tumour or metastatic site is dependent on the size, location, biological activity, and concentration of the biological activity (e.g. receptor density) and if positive is seen as a focal 'hot spot' when compared to the background. However, when compared to SPECT-MDCT, in the imaging of GEP-NET patients, all PET-MDCT tracer-based imaging is completed on the same day usually within 180 minutes. In general, PET-MDCT has a much higher sensitivity and specificity for like for like tracers when compared to SPECT-MDCT (Figures 6.11.5). It is considered the 'gold standard' molecular imaging modality but is reasonably expensive and thus has restricted availability.

GEP-NETs Radioactive Tracers (SPECT-MDCT and PET-MDCT)

The radiotracers utilized in imaging GEP-NETs broadly target SSTR, amine precursor uptake and decarboxylation (APUD) and glucose metabolism [13, 14]. Specific tracers and mechanism of actions including experimental novel tracers are detailed in Table 6.11.2.

Invasive Imaging Modalities: Endoscopy and Endoscopic Ultrasound (EUS)

Endoscopic Techniques

Endoscopic techniques allow the direct visualization and biopsy of tumours in hollow viscus (stomach, small bowel, and colon/rectum). It is the predominant modality to assess the stomach, proximal small bowel, and the colorectal regions. Small bowel enteroscopy, either with an endoscope or a capsule allows visualization of portions of the small bowel but it is limited by the length of small bowel and by lesions that obstruct the lumen. These modalities are operator depended but crucial in the assessment of the hollow viscus in GEP-NETs.

EUS can depict small lesions not visible on other imaging methods. This modality utilizes ultrasound probes with high frequency (7.5–12-MHz), which are positioned in proximity to the organ of interest (stomach, pancreas, duodenum, and rectum). This allows an opportunity to directly visualize, characterize, and help obtain pathological specimen via guided endoscopic biopsy [15, 16]. This modality plays an important role in assessing GEP-NETs especially in the pancreatic region.

Interventional Radiology (IR)

One of the key roles of IR is obtaining tissue for pathological assessment utilizing image guidance. There is also a growing role in therapeutic IR in GEP-NET patients. The role of IR in the diagnostic pathway of GEP-NETs however has reduced significantly especially with the advent and progress in molecular imaging. Occasionally, angiographic techniques are required to make a diagnosis of GEP-NETs (please refer to pancreas section).

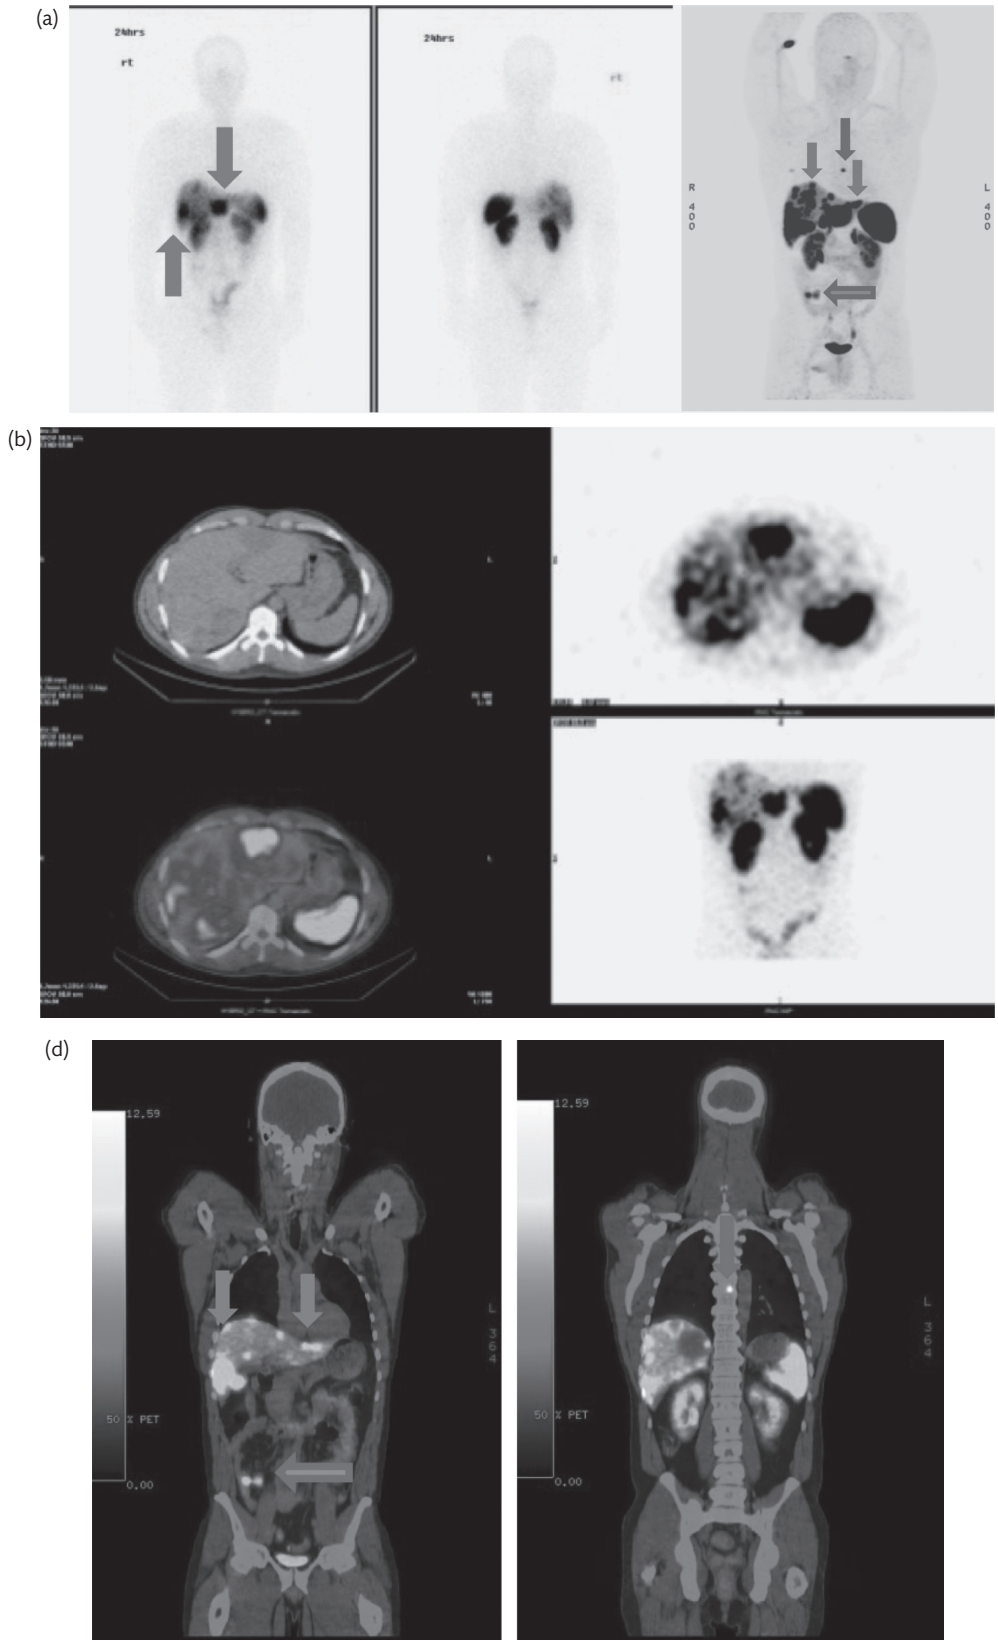
Role of Imaging Modalities in the Diagnosis, Staging, and Management of GEP-NETs

Extrapancreatic GEP-NETs

There are functioning and non-functioning extrapancreatic GEP-NETs. Functioning tumours classically present in the metastatic state with 'carcinoid syndrome'. The choice of the appropriate imaging strategy for detection and localization of GEP-NETs will largely depend on the clinical presentation however there are general strategies in setting out an imaging assessment.

Imaging/Detection of Primary Extrapancreatic GEP-NETs

Assessing and detecting suspected primary extrapancreatic GEP-NET will depend on the site of disease. Lesions in the stomach, duodenum, colon, and rectum are usually detected incidentally during endoscopic assessment in symptomatic/asymptomatic



Figures 6.11.5 Patient with grade II small bowel GEP-NET. 24-hour SPECT-MDCT (a, planar) and (b, with fused) demonstrating multiple liver metastases with increased uptake of tracer (Octreoscan®) with no further sites of abnormal uptake (red arrows). Same patient re-staged with Ga68 DOTATOC. 90 minutes PET-MDCT (c) and (d, fused) with areas of increased uptake of tracer ^{68}Ga-DOTATOC identifying primary small bowel tumour with mesenteric node (horizontal blue arrow), higher number of liver metastases (red arrows) and bone metastases (vertical blue arrow).

Table 6.11.2 Molecular imaging tracers for GEP-NETs (including novel tracers)

Tracer (trade name)	Mechanism	Clinical utility GEP-NET
(a) SPECT-MDCT		
111In-DTPA-octreotide (Octreoscan®)	SSTR agonist imaging	Grade I, II, and to a lesser extent III
99mTc-HYNIC-TOC	SSTR agonist imaging	Grade I, II, and to a lesser extent III
123I-Metaiodobenzylguanidine: 123 I-MIBG	APUD uptake	Has lower sensitivity and specificity. Not recommended for routine utility
Novel ^{111}In-DOTA-exendin-4	GLP-1R imaging	Benign insulinoma
(b) PET-MDCT		
^{68}Ga-DOTA-SSTR Peptides ^{68}Ga-DOTATOC (SomaKit TOC™) ^{68}Ga-DOTATATE (NETSPOT®)	SSTR agonist imaging	Grade I, II, and to a lesser extent III
^{18}F-Fluorodeoxyglucose (^{18}F-FDG)	Glucose metabolism	Grade III. Less of a role in grade I and II
^{18}F-Dihydroxyphenylalanine (^{18}F-DOPA)	APUD uptake	Insulinoma, grade I, and II NET
Novel ^{68}Ga-DOTA-exendin-4	GLP-1R imaging	Benign insulinoma
^{68}Ga-NODAGA-JR11	SSTR antagonist imaging	Grade I, II, and to a lesser extent III

patients. US has a very limited if any role in the wider context of imaging of primary extrapancreatic GEP-NETs. The sites of primary GEP-NETs as discussed are predominantly in gas filled viscus and therefore are difficult to assess with US. In contrast, endoscopic/EUS is essential to localize the primary lesion, assess mucosal invasion, and make a histopathologic diagnosis. Even though the appendix is one of the most common sites of extrapancreatic GEP-NETs, the vast majority of lesions in the appendix are detected incidentally in post-appendicectomy specimens in patients suspected of having appendicitis. These appendix GEP-NET lesions are also usually quite small measuring less than 1 cm. Cross-sectional and molecular imaging therefore play a very small or no role at all in the detection of primary lesions at these sites (stomach, duodenum, colon, rectum and appendix [15, 17–21]).

On the other hand, cross-sectional (MDCT/MRI) and molecular imaging (SPECT/PET-MDCT) play a crucial role in detecting extrapancreatic GEP-NET primary of ileal and jejunal small bowel origin. As discussed earlier, in general, these lesions share a number of similar features including arterial enhancement on cross-sectional imaging (MDCT/MRI). The primary disease without metastatic site can appear as mucosal, submucosal, and multifocal lesions. Not infrequently the primary tumour may also manifest on MDCT scans as asymmetric or concentric regions of mural thickening. The mural thickening occurs usually due to a combination of desmoplastic submucosal fibrosis and infiltrating tumour. This leads to thickening and stiffening of the intestinal wall, thus producing mural and irregular fold thickening (Figure 6.11.6a). There is usually associated mesenteric fibrosis and calcified nodal mass (Figure 6.11.1b). Patients present with a spectrum of clinical scenario, extending from non-specific

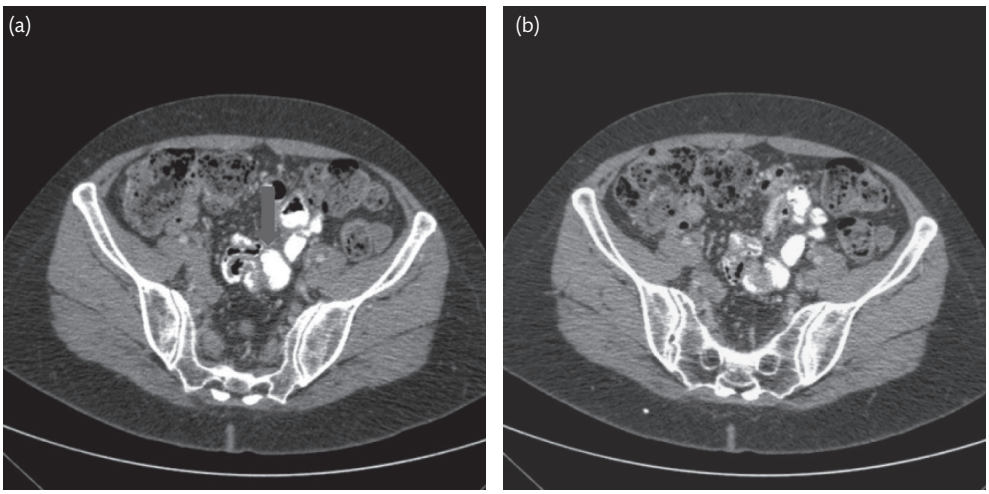


Figure 6.11.6 Patient with grade I small bowel GEP-NET. Mural thickening of primary tumour (a; red arrow) with early small bowel obstruction (b, blue arrow). 68Ga-DOTATOC MIP (c) with increased uptake of tracer in the primary small bowel site, mesenteric nodal, and liver metastases.

abdominal discomfort to intussusception and small bowel obstruction (Figure 6.11.6b). Even in cases of bowel symptomology and mechanical bowel obstruction, detection of the primary site in extrapancreatic GEP-NET with MDCT/MRI can be challenging due to the variable size of the primary disease; which can range between 43% and 50% [22]. However, utilizing MDCT and MRI cross-sectional modality but incorporating an enteroclysis protocol with intravenous contrast enhancement leads to a higher detection rate of tumours of the small bowel with reported sensitivity of detecting a primary lesion in the range of 85–94%. However, with respect to GEP-NETS, as the tumours in many cases are small nodular lesions, it may be very difficult to detect the primary lesion even with enteroclysis [23–25]. Molecular imaging fills this gap in the diagnostic pathway in the detection of occult/unknown primary extrapancreatic GEP-NETs. Molecular imaging has a higher sensitivity, specificity, and accuracy compared to cross-sectional imaging [26, 27]. As already discussed, molecular imaging detects cell surface receptors and cellular biological activity. With regards to grade I and II extrapancreatic GEP-NETs, the most sensitive molecular imaging modality to detect the primary site is somatostatin receptor imaging [26]. Most GEP-NETs have a varying amount of expression of cell surface SSTR. The expression of SSTR is dependent on the grade of the GEP-NET. Grades 1 and 2 have SSTR expression between 80% and 100%. There are currently up to five different SSTR subtypes that have been cloned and characterized (subtypes 1–5). Subtype 2 is the most expressed subtype. Therefore, in grade 1 and 2, GEP-NETs SSTR receptor detection is an integral part of the management especially with regards to detection of the primary lesion/diagnosis. It also plays an important role in staging and planning management including assessment for labelled molecular targeted radiotherapy. In the last decade, several clinical studies have compared the diagnostic accuracy of different ^{68}Ga-DOTA-SSTR Peptides (using PET-MDCT image acquisition) to ^{111}In-pentetreotide (Octreoscan®) (using SPECT-MDCT image acquisition) in patients diagnosed with NETs/GEP-NETs. Universally the results favour the use of these ^{68}Ga-DOTA-SSTR peptides in: (1) detecting small tumours or tumours bearing only a low density of SSTR; (2) offering excellent imaging properties and very high tumour/background ratios; (3) better intrinsic spatial resolution; and (4) detecting additional lesions and altering clinical management [28–30]. Therefore in the imaging and detection of extrapancreatic GEP-NETs grade I and II primary, ^{68}Ga-DOTA- SSTR Peptides PET-MDCT is currently the gold standard modality (Figure 6.11.5) (see also section on imaging metastatic extrapancreatic GEP-NETs, next). Recent advances in the synthesis and manufacturing of these tracers has led to two licensed ^{68}Ga-DOTA- SSTR Peptides; SomaKit TOC™ (Europe) and NETSPOT® (USA) [31].

Imaging Metastatic Extrapancreatic GEP-NETs

MDCT is the modality of choice in the initial imaging assessment of suspected metastatic extrapancreatic GEP-NET. This widely available modality can potentially detect and stage the entire extent of disease utilizing a multiphasic contrast-enhanced protocol (Table 6.11.1). MRI is reserved for focused assessment of anatomical sites with suspected abnormality on MDCT or as part of imaging due to risk stratification and high-risk sites of metastatic disease (bone and liver). However, these morphological cross-sectional modalities have reduced sensitivity, specificity and accuracy when compared to SSTR molecular imaging modalities with regards to detecting metastatic disease in lymph nodes, bones and liver [32] (please also see the later section on special imaging considerations). Cross-sectional modalities (MDCT and to a lesser extent MRI) are also limited with regards to assessing the biology of metastatic extrapancreatic GEP-NETs.

In the vast majority of clinical sites, the molecular imaging modality of choice would be SPECT-MDCT with Octreoscan® (partly due to the limited availability and cost of ^{68}Ga-DOTA- SSTR Peptides PET-MDCT). As well as being a superior staging modality, SSTR molecular imaging modality is the modality of choice to assess the biology of extrapancreatic GEP-NETs. The role of ^{18}F-FDG PET-MDCT is more limited but it can be instructive in the more histologically aggressive grade 3 extrapancreatic GEP-NETs. It has a growing role in the prognostic assessment of extrapancreatic GEP-NETs [33]. Also, there is growing evidence of a histological spectrum of metastatic disease that is influenced by the primary site and different metastatic sites of extrapancreatic GEP-NETs [34, 35]. This heterogeneity in biology may warrant the need to stage patients with different molecular imaging tracers. Imaging with two molecular tracers (^{18}F-FDG and ^{68}Ga-DOTA- SSTR Peptides) utilizing PET-MDCT is gaining traction. This strategy has an associated cost and is relatively scarce; thus, is best utilized for patients with atypical clinical presentation and where there is variable clinical metastatic behaviour (Figure 6.11.7).

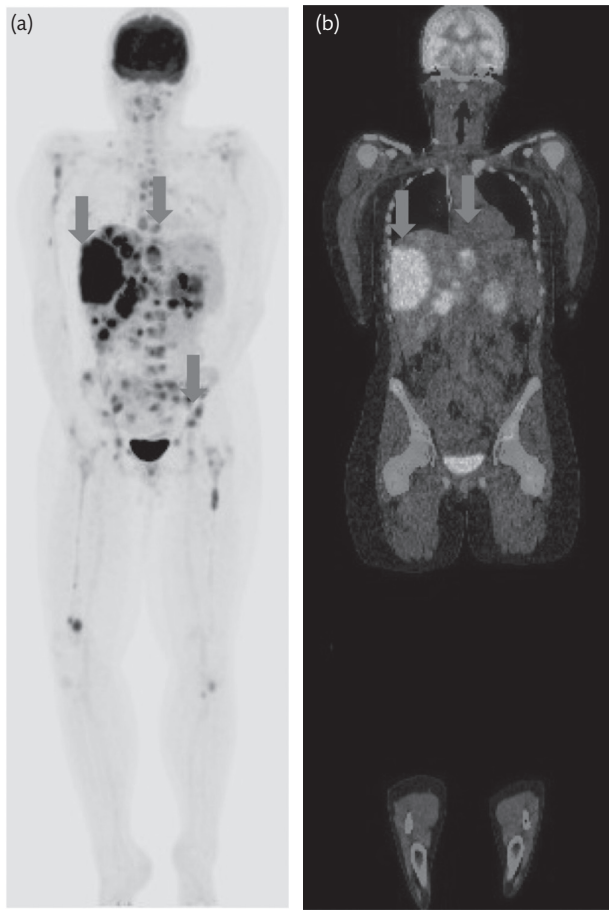

Figure 6.11.7 Patient with Grade III unknown primary GEP-NET. ^{18}F-FDG PET-MDCT (a, MIP) and (b, fused) with areas of increased uptake of tracer involving the liver, nodes, and bones (red arrows). ^{68}Ga-DOTATOC (c, MIP) and (d, fused) do not demonstrate increased uptake of tracer at metastatic sites identified on ^{18}F-FDG.

With the advent of hybrid imaging, more imaging departments are offering a 'one-stop shop' solution by combining contrast-enhanced MDCT and SPECT-MDCT/PET-MDCT in one visit. This allows the combination of high-resolution anatomical assessment along with molecular imaging, which improves sensitivity, specificity, and accuracy of staging metastatic extrapancreatic GEP-NETs [36]. With regards to this, intravenous multiphasic iodinated contrast-enhanced PET-MDCT with ^{68}Ga-DOTA- SSTR Peptides PET is currently the gold standard modality for assessing grade 1 and 2 GEP-NETs.

Pancreatic GEP-NETs

Pancreatic GEP-NETs are a heterogeneous group and typically demonstrate varied clinical presentation. Broadly, they can be divided into functioning and non-functioning tumours (each constituting approximately 50%). Functioning tumours such as insulinomas, gastrinomas, VIPomas, glucagonomas, and somatostatinomas classically present with different clinical syndromes dictated by secretion of vasoactive hormones. These are also related to hereditary and familial syndromes. Non-functioning tumours present with non-specific symptoms and are usually detected as 'incidental' findings during the course of investigating abdominal symptoms, which could be unrelated. Imaging pancreatic GEP-NETs is dictated by the clinical presentation and as per extrapancreatic GEP-NETs tumour grading, plays a crucial role in the selection of the imaging modality to further investigate this disease.

Imaging Primary Pancreatic GEP-NETs

Morphologically primary pancreatic GEP-NETs (functioning and non-functioning) share some common features on cross-sectional imaging modalities. These are usually arterially enhancing hypervascular lesions (Figure 6.11.8a is an example of an insulinoma with hypervascular blush) on MDCT/MRI, occasionally demonstrating cystic changes, can be multifocal, cause pancreatic ductal obstruction and atrophy (but to a lesser extent than pancreatic adenocarcinoma). On MRI scans these tumours demonstrate higher T2W signal than adenocarcinoma. Functioning primary pancreatic GEP-NETs tend to present earlier and are at times difficult to visualize. Two of the commonest tumours are insulinomas and gastrinomas. Insulinomas are the commonest, usually benign tumours, and are typically small at presentation, measuring less than 2 cm at time of diagnosis, and can be distributed throughout the pancreas (Figure 6.11.8a). There is a site predilection to some of the functioning tumours, as, for example, 80% of gastrinomas are found in the 'gastrinoma triangle' defined by the neck and body of the pancreas medially, confluence of the cystic and common bile duct superiorly and the second/third portions of the duodenum inferiorly. Again, gastrinomas are also typically small at presentation measuring between 1 cm and 3 cm.

Non-functioning tumours usually present as larger bulky tumours but do not exhibit as much adjacent vascular and structure invasion when compared to pancreatic adenocarcinoma. The first line modality of choice to investigate suspected tumours of the pancreas including pancreatic GEP-NETs is MDCT (Table 6.11.1). If this fails to detect a lesion, MRI is the next cross-sectional modality of choice. An EUS of the pancreas is usually, nearly always also performed for further characterization of the tumour, also providing tissue for pathological diagnosis. Furthermore, this can permit 'screening' of the pancreas as there may be multiple lesions especially in a syndromic patient. Molecular imaging has a function in detecting pancreatic GEP-NETs primary but plays an equally important role in the comprehensive staging of this disease, discussed next.

Imaging Metastatic Pancreatic GEP-NETs

There is variability with regards to the metastatic status of pancreatic GEP-NETs. Functioning tumours have differing metastatic potential. As an example, most insulinomas are 'benign' with solitary lesions but most gastrinomas are metastatic at presentation (Figure 6.11.9 demonstrates multifocal gastrinoma recurrence SSTR PET-CT imaging). As non-functioning tumours present late, there is a higher likelihood of nodal and liver metastases at diagnosis. MDCT is the modality of choice to investigate metastatic pancreatic GEP-NETs. However, MDCT underestimates metastatic disease especially metastases to nodal and liver sites. MRI has a higher detection rate of metastatic sites particularly in the liver (please refer to special imaging consideration section) but it does not provide a comprehensive whole-body staging and is utilized for focused assessment of anatomical sites.

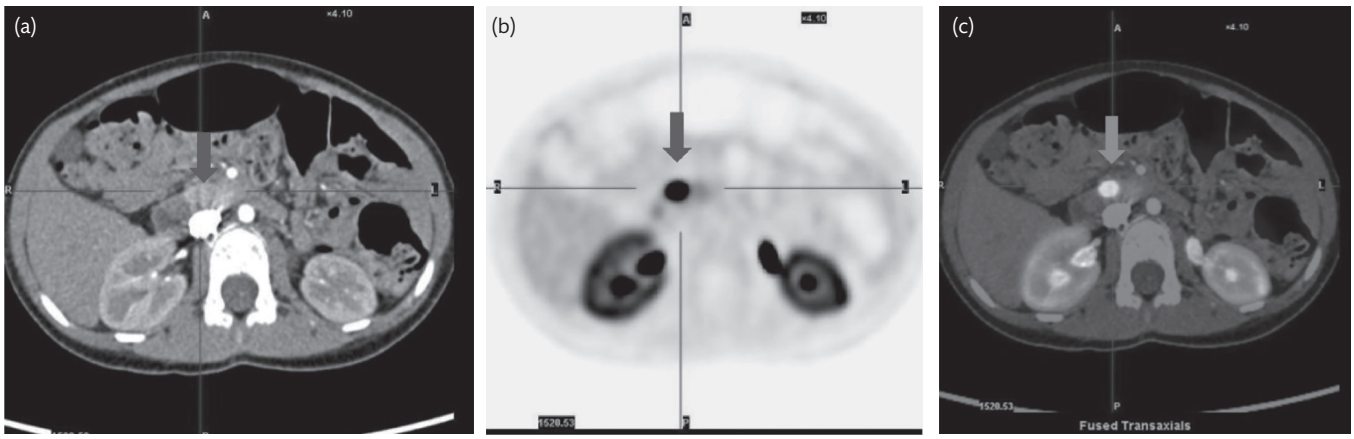

Figure 6.11.8 Patient with severe hypoglycaemia. MDCT (a) with a focus of increased enhancement in the head of the pancreas (red arrow). ^{18}F-DOPA PET-MDCT (b, PET) and (c, fused) with an area of intense focus of increased uptake of tracer at the site of increased enhancement (red arrow). Surgically proven insulinoma.

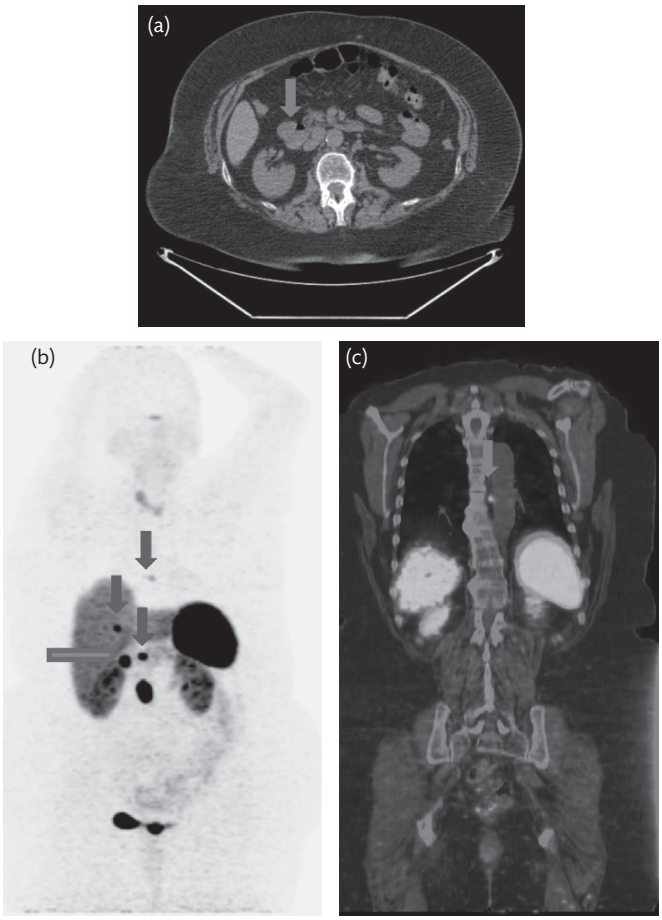

Figure 6.11.9 Patient with resected gastrinoma grade II. Rising gastrin level, presurgery MDCT detected enlarged periduodenal node (a, red arrow). ^{68}Ga-DOTATOC PET-MDCT (b) MIP confirms enlarged periduodenal node (horizontal blue arrow) and identified three further areas of metastases (red arrows): solitary liver metastasis and two metastatic nodes (b, MIP; c, fused).

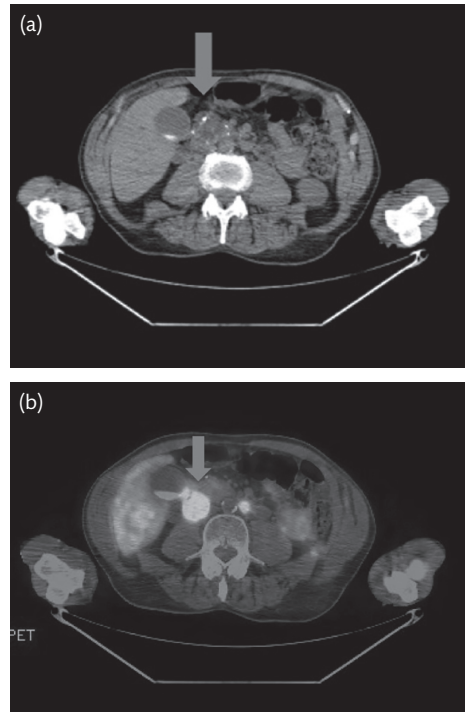

Figure 6.11.10 Patient with grade II non-functioning pancreatic GEP-NET. Planning MDCT accurately identified pancreatic head mass and no further sites of disease. Unenhanced MDCT (a) confirmed pancreatic head mass (red arrow). Fused ^{68}Ga-DOTATOC PET –MDCT (b) has concurrent finding with regards to pancreatic head mass (red arrow) but also identifies a further focus of abnormal uptake consistent with a metastatic peripancreatic node (blue arrow).

Molecular imaging has a significant and unique input into the management of primary and metastatic pancreatic GEP-NETs. The performance of the molecular tracers to detect and stage disease differs according to the type of tumour and grade. Somatostatin tracer imaging utilizing Octreoscan® and ^{68}Ga-DOTA-SSTR Peptides utilizing SPECT-MDCT and PET-MDCT, respectively, have good diagnostic sensitivity (80–100%) for nearly all grade I and II pancreatic GEP-NETs apart from insulinoma, which has poorer expression of somatostatin receptors. Pancreatic GEP-NETs apart from insulinomas imaged with ^{68}Ga-DOTA- SSTR Peptides PET-MDCT have been shown to have much better diagnostic accuracy for the detection of small primary tumours and metastatic disease (Figure 6.11.10) [37, 38]. There are also reports indicating that ^{68}Ga-DOTA- SSTR Peptides PET-MDCT is as accurate as EUS [39]; however, this finding requires further studies to confirm.

With regards to insulinomas, ^{18}F-DOPA PET-MDCT can be useful to detect benign insulinomas owing to the variable expression of SSTR in these tumours, however it has a variable sensitivity and specificity. This tracer is not available in most countries hence the scarcity of its availability (Figure 6.11.8b and c).

Despite recent advances in morphological and molecular imaging, due to the challenges in the detection of insulinomas, patients may still require an IR study. This angiographic assisted study is performed in highly specialized centres and involves selective pancreatic intra-arterial calcium stimulation of insulin release with hepatic venous sampling. This procedure has a reported localization rate of between 65% and 100% [14].

Special Imaging Consideration in GEP-NETs

Imaging Patients with Inherited/Genetic Preponderance for GEP-NETs

A subgroup of inherited genetic diseases such as MEN-1, NF1, Von Hippel-Lindau syndrome (VHL), and tuberous sclerosis complex (TSC) have a preponderance of GEP-NETs. These patients also develop GEP-NETs at an earlier age. Therefore, assessing and following up these patients requires a more nuanced utility of imaging modalities. The patients require multiorgan assessment and multitime point follow-up. As these patients present earlier and younger, repeated imaging with ionizing radiation presents a long-term risk of stochastic effects, potentially leading to a second tumour related to the radiation exposure. As per all GEP-NETs, a multimodal imaging approach is required. As with other non-familial GEP-NETs patients, ^{68}Ga-DOTA- SSTR Peptides PET-MDCT with iodinated contrast-enhanced MDCT obtained at the same time is a key imaging tool for grade I and II patients. However, after the initial diagnosis and intervention, follow-up should ideally be performed

with as little as or no exposure to ionizing radiation. Whole-body imaging MRI (WBMRI) is gradually gaining popularity for longitudinal imaging of these patients. Due to the rarity of these inherited familial diseases, comprehensive long-term strategy thus far has been lacking. A small number of recent studies have tried to address this lack of evidence-based practice, summarized in the paper by Ito *et al.* [40]. A recent multicentre, prospective study [41] found similar sensitivity between MRI and EUS in detecting pNETs. Both techniques had issues, and with regards to MRI, missed small lesions. Follow-up of this patient group remains difficult and as it currently stands, majority of the follow-up proposals are based on opinion based clinical practice [42]. A pragmatic way forward could be to utilize WBMRI for follow-up and EUS/^{68}Ga-DOTA- SSTR peptides PET-MDCT when the patient experiences biochemical or symptomatic changes.

Detecting and Staging Metastatic Liver Disease

The different modalities discussed here have differing detection capabilities depending on the region of interest. The liver is one of the commonest sites for metastatic disease in GEP-NETs, and GEP-NETs patients with liver metastases have a poorer prognosis. The problem is that due to the differing capability of the modalities to detect metastatic liver disease, the extent of disease can be easily underestimated. The gold standard for assessing metastatic liver disease is gadolinium contrast-enhanced MRI. It outperforms MDCT and the hybrid molecular imaging modalities, especially with the addition of DWI sequences [43, 44]. Therefore, a multimodal approach to imaging high-risk GEP-NETs patients is recommended. These patients should ideally be staged with ^{68}Ga-DOTA- SSTR Peptides PET-MDCT with iodinated contrast-enhanced MDCT and contrast-enhanced liver MRI with DWI (**Figure 6.11.11** illustrates the different sensitivities of the modalities in the same patient). This would serve as a reference baseline. With alterations in serum tumour biomarkers, a repeat MRI of the liver can be obtained to accurately and comprehensively identify interval changes to this organ, and thus inform management plan accordingly.

Assessing Cardiac Complications of GEP-NET

Patients with metastatic GEP-NETs (liver and nodes) often have cardiac complications secondary to systemic release of unmetabolized vasoactive 5-HIIAA. This leads to progressive valvular sclerosis (tricuspid) leading to right heart failure. Therefore, the heart is a target organ in the assessment of metastatic GEP-NETs. NT-pro-BNP and a baseline imaging with echocardiogram in a valvular heart specialist centre is recommended. Cardiac MRI might be required depending on the findings of the echocardiogram. Serial NT-pro-BNP serum levels can enable monitoring of cardiac status [45].

Follow-Up and Response Assessment

GEP-NET patients show a spectrum of disease phenotypes and trajectories, from the potentially curative disease, to those with a high burden of metastatic disease but slow progression, to a patient with

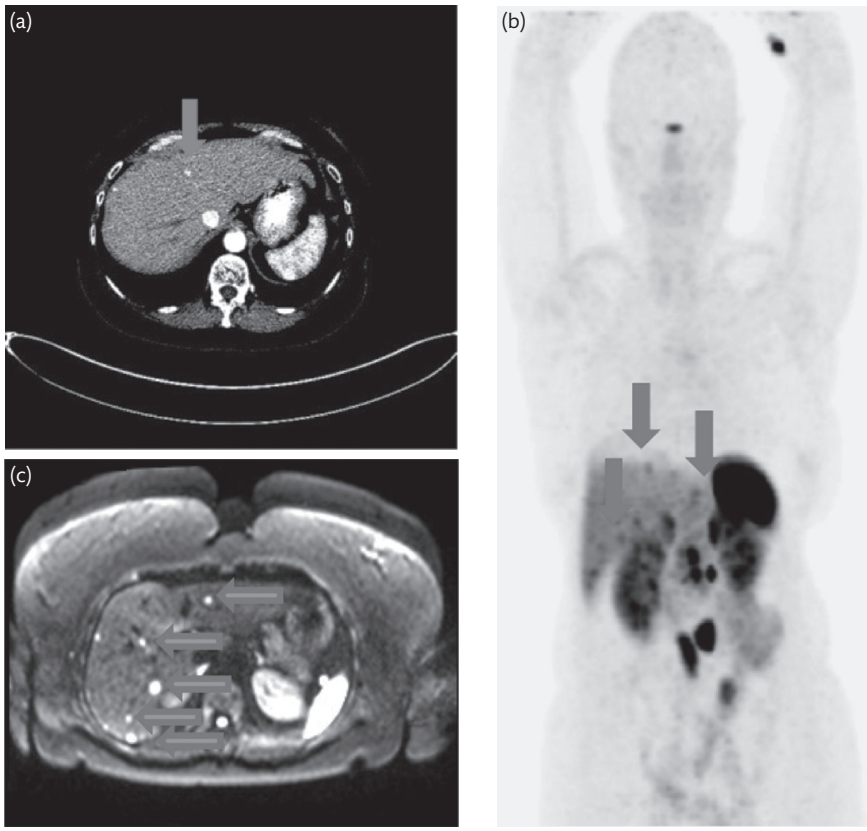

Figure 6.11.11 Patient with small bowel grade II GEP-NET. Arterial phase MDCT (a) demonstrating at least one arterially enhancing metastatic liver lesion (red arrow). Maximum intensity projection image (MIP) (b) of ^{68}Ga-DOTA-SSTR Peptides (^{68}Ga-DOTATOC) with a number of small areas of metastatic increased uptake within the liver (red arrows). DWI b (400) image (c) of the liver demonstrates vastly more restricted diffusion lesions (areas of focal high signal) consistent with multiple metastatic bilobar disease (blue horizontal arrows).

rapid progression based on tumour biology. Tailoring of imaging follow-up and response assessment is thus complex and challenging. Tumour biology drives the follow-up imaging matrix. In the vast majority of patients that have had a baseline multimodal approach including molecular imaging modalities, follow-up with MDCT is recommended. Molecular imaging, MRI, and EUS can be utilized more judiciously depending on the patient's clinical symptoms and biochemical status. This strategy is acceptable due to the exceedingly high cost and limited resource of some of these imaging modalities [46].

Future Directions: Novel Molecular Imaging Tracers and Hybrid Imaging

Glucagon-Like Peptide-1 Receptor (GLP-1R)

Almost all benign insulinomas overexpress GLP-1R. This overexpression therefore can be imaged with molecular imaging utilizing labelled GLP-1R. As already discussed labelled SSTR imaging to detect benign insulinoma has low sensitivity due to lower expression of SSTR receptors (50–60%) [13, 47, 48]. In contrast, malignant insulinoma, has lower expression of GLP-1R and express higher SSTR [49]. Radiolabelled GLP-1R analogues for SPECT/CT imaging have been developed and evaluated in patients with benign insulinomas (Table 6.11.2a) [50]. These tracers demonstrate a high benign insulinoma detection rate. Recently, it has been shown that PET-MDCT GLP-1R tracers might be more effective than GLP-1R labelled SPECT/MDCT and morphological imaging [51]. These tracers are still undergoing clinical trial assessments (Table 6.11.2b).

Somatostatin Receptor Imaging Using Antagonists

Currently all somatostatin-based radiotracers used in the clinic for diagnostic purposes are SSTR agonists. *In-vitro* and *in-vivo* data suggest SSTR antagonists have higher tumour uptake and retention [52]. The antagonist SSTR radiotracers (Table 6.11.2b) also exhibit higher number of potential binding sites on the receptor which might be responsible for higher tumour uptake [52, 53]. These tracers are currently undergoing clinical trials and appear promising [54].

Hybrid Imaging Technological Development

PET-MRI is the latest of the iterations of molecular imaging hybrid equipment. The theoretical and potential advantage of this imaging modality combining molecular imaging and exquisite MRI tissue contrast imaging is very appealing but is still under investigation. With regards to grade I/II GEP-NETs patients, recent publications of small series of patients demonstrate variation in findings compared to PET-CT [55]. As it currently stands this modality remains in the research realm.

Summary

Effective imaging of GEP-NETs relies on effective input from clinicians due to the varied clinical presentation. Optimal selection of imaging modality is driven by histopathological findings especially the grading of the tumour. While conventional cross-sectional modalities (MDCT/MRI) provide an important first step in tumour characterization, molecular imaging techniques can refine this further and thus inform management strategies. Hybrid molecular imaging (PET-MDCT) in the form of a 'one-stop' PET with iodinated intravenous contrast-enhanced MDCT together with ^{68}Ga-DOTA- SSTR Peptides represents the gold standard in GEP-NET imaging.

6.11.1 Multiple Endocrine Neoplasia Type 1

Rajesh V. Thakker

Introduction

Multiple endocrine neoplasia [1, 2] is characterized by the occurrence of tumours involving two or more endocrine glands within a single patient. The disorder has previously been referred to as multiple endocrine adenopathy (MEA) or the pluriglandular syndrome. However, glandular hyperplasia and malignancy may also occur in some patients and the term multiple endocrine neoplasia (MEN) is now preferred. Four major forms of MEN are recognized and referred to as types 1–4 (MEN 1–4). All these forms of MEN may either be inherited as autosomal dominant syndromes or they may occur sporadically (i.e. without a family history). However, this distinction between sporadic and familial cases may sometimes be difficult as in some sporadic cases the family history may be absent because the parent with the disease may have died before developing symptoms. Each form of MEN is characterized by the development of tumours within specific endocrine glands (Table 6.11.1.1). Thus, MEN 1 which is also referred to as Wermer's syndrome, is characterized by the combined occurrence of tumours of the parathyroid glands, the pancreatic islet cells, and the anterior pituitary, and is due to mutations of the tumour suppressor gene, *MEN 1* that encodes the protein menin [1]. MEN 2a (or MEN 2) and is also called Sipple's syndrome, is characterized by the occurrence of medullary thyroid carcinoma (MTC) in association with phaeochromocytomas, and parathyroid tumours. However, some patients and families may develop only MTC, and this variant is referred to as MTC-only (Table 6.11.1.1). MEN 2b (or MEN 3) is characterized by the occurrence of MTC and phaeochromocytomas, in association with: a Marfanoid habitus; mucosal neuromas of the lips, tongue, and eyelids; medullated corneal nerve fibres; and intestinal autonomic ganglion dysfunction leading to multiple diverticulae and megacolon. MEN 2a (MEN 2), MTC-only and MEN 2b (MEN 3) are due to mutations of the rearranged during transfection (*RET*) proto-oncogene, which encodes a receptor tyrosine kinase (RTK) (Table 6.11.1.1). Some patients with MEN1-associated tumours, such as parathyroid adenomas, pituitary adenomas, and pancreatic neuroendocrine tumours (NETs) who do not have mutations of the MEN 1 gene, but instead have mutations of the gene encoding the cyclin-dependent kinase inhibitor (CK1) p27kip (*CDNK1B*), are designated to have MEN 4 (Table 6.11.1.1). MEN 4 patients may also develop gonadal, adrenal, renal, and thyroid tumours. In this chapter, the main clinical features and molecular genetics of the MEN 1 syndrome will be discussed.

Clinical Features of MEN 1

Parathyroid, pancreatic, and pituitary tumours constitute the major components of MEN 1. In addition to these tumours adrenal cortical, carcinoid, facial angiofibromas, collagenomas, and lipomatous tumours may also occur in some patients [1–3]. Patients with MEN 1 have a decreased life expectancy, predominantly due to the pancreatic islet cell tumours, and the prognosis for MEN 1 patients may be improved by presymptomatic tumour detection with earlier and specific treatment for MEN 1 tumours [1].

Parathyroid Tumours

Primary hyperparathyroidism is the most common feature of MEN 1 and occurs in more than 95% of all MEN 1 patients [1]. Patients may present with asymptomatic hypercalcaemia, or nephrolithiasis, or osteitis fibrosa cystica, or vague symptoms associated with hypercalcaemia, for example polyuria, polydipsia, constipation, malaise, or occasionally with peptic ulcers. Biochemical investigations reveal hypercalcaemia, usually in association with raised circulating parathyroid hormone (PTH) concentrations. The hypercalcaemia is usually mild, and severe hypercalcaemia resulting in crisis or parathyroid carcinoma are rare occurrences [4]. Additional differences in the primary hyperparathyroidism of MEN 1 patients from that in non-MEN 1 patients include an earlier age of onset (20–25 years vs. 55 years), and an equal male:female ratio (1:1 versus 1:3) [1, 5]. Primary hyperparathyroidism in MEN 1 patients is unusual before the age of 15 years, and the age of conversion from being unaffected to affected has been observed to be between 20 and 21 years in some individuals

Table 6.11.1.1 Multiple endocrine neoplasia syndromes and their characteristic tumours and associated genetic abnormalities

Type (chromosome location)	Tumours (estimated penetrance)	Gene; Most frequently mutated codons
MEN1 (11q13)	Parathyroid adenoma (95%) Entero-pancreatic tumour (30–80%) • Gastrinoma (40%) • Insulinoma (10%) • Non-functioning & PPoma (20–55%) • Glucagonoma (<1%) • VIPoma (<1%) Pituitary adenoma (30–40%) • Prolactinoma (20%) • Somatotropinoma (10%) • Corticotropinoma (<5%) • Non-functioning (<5%) Associated tumours: • Adrenal cortical tumour (40%) • Phaeochromocytoma (<1%) • Bronchopulmonary NET (2%) • Thymic NET (2%) • Gastric NET (10%) • Lipomas (30%) • Angiofibromas (85%) • Collagenomas (70%) • Meningiomas (<10%)	*MEN1* 83/84, 4-bp del (≈4%) 119, 3-bp del (≈3%) 209–211, 4-bp del (≈8%) 418, 3-bp del (≈4%) 514–516, del or ins (≈7%) Intron 4 ss (≈10%)
MEN2 (10 cen-10q11.2)		
MEN2 (also known as MEN2A)	MTC (90%) Phaeochromocytoma (50%) Parathyroid adenoma (20–30%)	*RET* 634, missense e.g. Cys→Arg (~85%)
MTC-only	MTC (100%)	*RET* 618, missense (>50%)
MEN3 (also known as MEN2B)	MTC (>90%) Phaeochromocytoma (40–50%) Associated abnormalities (40–50%) Mucosal neuromas Marfanoid habitus Medullated corneal nerve fibres Megacolon	*RET* 918, Met→Thr (>95%)
MEN4 (12p13)	Parathyroid adenoma[a] Pituitary adenoma[a] Reproduction organ tumours[a] (e.g. testicular cancer, neuroendocrine cervical carcinoma) ?Adrenal + renal tumours[a]	*CDKN1B* No common mutations identified to date

Autosomal dominant inheritance of the MEN1 syndrome has been established. del, deletion; ins, insertion; PPoma, pancreatic polypeptide-secreting tumour; VIPoma, vasoactive intestinal polypeptide-secreting tumour; NET, neuroendocrine tumour; MTC, medullary thyroid cancer, [a] insufficient numbers reported to provide prevalence information.

[1]. Surgical removal of the abnormally overactive parathyroids is the definitive treatment [1, 6]. However, in MEN 1 patients, all four parathyroid glands are usually affected with multiple adenomas or hyperplasia, although this histological distinction may be difficult. Thus, there is a controversy regarding the type and extent of parathyroid surgery. One opinion is to undertake total parathyroidectomy with the resultant lifelong hypocalcaemia being treated with oral calcitriol (1,25 dihydroxyvitamin D_3) while the other option is to perform a subtotal parathyroidectomy (e.g. removal of 3.5 glands) [1, 6]. Minimally invasive parathyroidectomy is not recommended because all four parathyroid glands are likely to have neoplastic changes [1]. For the timing of surgery, it is recommended that parathyroid surgery should be reserved for the symptomatic hypercalcaemic patient with MEN 1, and that the asymptomatic MEN1 patient with mild hypercalcaemia (total serum calcium <3.00 mmol/L) should not have parathyroid surgery but have regular assessments for the onset of symptoms and complications, when appropriate parathyroidectomy should be undertaken [1]. Calcimimetics (e.g. cinacalcet), which act via the calcium-sensing receptor, have been used to treat primary hyperparathyroidism in some patients when surgery is unsuccessful or contraindicated [7].

Pancreatic Tumours

The incidence of pancreatic islet cell tumours, which are NETs, in MEN 1 patients varies from 30% to 80% in different series [1–3, 8].

Many of these tumours produce excessive amounts of hormone, for example gastrin, insulin, glucagon, or vasoactive intestinal polypeptide (VIP), and are associated with distinct clinical syndromes [1, 3, 8, 9], although ~40% of these pancreatic NETs are non-secreting (i.e. non-functional). Current treatments for pancreatic NETs in MEN 1 patients are based on extrapolations from outcomes in non-MEN 1 patients, as clinical trials have not been formally undertaken in MEN 1 patients [1, 3, 8].

Gastrinoma

These gastrin-secreting tumours represent over ~40% of all pancreatic islet cell tumours in MEN 1 and approximately 20% of patients with gastrinomas will have MEN 1. Gastrinomas are the major cause of morbidity and mortality in MEN 1 patients. This is due to the recurrent, severe multiple peptic ulcers which may perforate. This association of recurrent peptic ulceration, marked gastric acid production, and non-β-islet cell tumours of the pancreas is referred to as the Zollinger–Ellison syndrome. Additional prominent clinical features of this syndrome include diarrhoea and steatorrhoea. The diagnosis is established by demonstration of a raised fasting serum gastrin concentration in association with an increased basal gastric acid secretion [1]. Medical treatment of MEN 1 patients with the Zollinger–Ellison syndrome is directed to reducing basal acid output to less than 10 mmol/L, and this may be achieved by parietal cell H^+-K^+-ATPase inhibitors (e.g. omeprazole). The ideal treatment for a non-metastatic gastrinoma is surgical excision of the gastrinoma (1). However, in patients with MEN 1 the gastrinomas are frequently multiple or extrapancreatic and the role of surgery has been controversial [8, 10, 11]. For example, in one study [10], only 16% of MEN 1 patients were free of disease immediately after surgery, and at 5 years this had declined to 6%; the respective outcomes in non-MEN 1 patients were better at 45 and 40%; however, a more recent study has reported that following surgery >75% of hypergastrinaemic MEN 1 patients were engastrinaemic, with a negative secretion provocation test at 6-month follow-up [12], and further studies are required to identify whether surgery achieves long-term remission and an improvement in survival. The treatment of disseminated gastrinomas is difficult and hormonal therapy with human somatostatin analogues (e.g. octreotide), chemotherapy with streptozotocin and 5-fluoroaracil, hepatic artery embolization, and removal of all resectable tumour have all occasionally been successful [1].

Insulinoma

These β-islet cell tumours secreting insulin represent ~10% of pancreatic tumours in MEN 1 patients [1, 3]. Insulinomas also occur in association with gastrinomas in 10% of MEN 1 patients, and the two tumours may arise at different times. Insulinomas occur more often in MEN 1 patients who are below the age of 40 years, and many of these arise in individuals before the age of 20 years [1], whereas in non-MEN1 patients insulinomas generally occur in those above the age of 40 years. Insulinomas may be the first manifestation of MEN 1 in 10% of patients and <5% of patients presenting with insulinoma will have MEN 1. Patients with an insulinoma present with hypoglycaemic symptoms, which develop after a fast or exertion and improve after glucose intake. Biochemical investigations reveal raised plasma insulin concentrations in association with hypoglycaemia. Circulating concentrations of C-peptide and proinsulin, which are also raised, may be useful in establishing the diagnosis. It is important to demonstrate the absence of sulphonylureas in plasma and urine samples obtained during investigation of hypoglycaemia. Medical treatment, which consists of frequent carbohydrate feeds and diazoxide, may be useful in the short-term, with surgery being the definitive treatment. Preoperative localization with computed tomography scanning, coeliac axis angiography, and preoperative percutaneous transhepatic portal venous sampling is difficult and success rates have varied. Surgical treatment, which ranges from enucleation of a single tumour to a distal pancreatectomy or partial pancreatectomy, has been curative in some patients [1]. For metastatic disease, chemotherapy, which consists of streptozotocin, 5-fluorouracil and doxorubicin, and hepatic artery embolization, has been used with success in some patients [1, 3, 8].

Glucagonoma

These α-islet cell, glucagon-secreting pancreatic tumours occur in less than 1% of MEN 1 patients [1, 3]. The characteristic clinical manifestations of a skin rash (necrolytic migratory erythema), weight loss, anaemia, and stomatitis may be absent and the presence of the tumour may be indicated only by glucose intolerance and hyperglucagonaemia [1]. The tail of the pancreas is the most frequent site for glucagonomas and surgical removal of these is the treatment of choice. However, treatment may be difficult as 50% of patients have metastases at the time of diagnosis. Medical treatment of these with somatostatin analogues, or with streptozotocin and 5-fluorouracil, and hepatic artery embolization has been successful in some patients [1, 3, 8] (see Chapter 6.8, 'Glucagonoma').

Vasoactive Intestinal Peptide (VIP) Tumours (VIPomas)

VIPomas have been reported in only a few patients with MEN 1, who develop watery diarrhoea, hypokalaemia, and achlorhydria, referred to as the watery diarrhoea, hypokalaemia, and achlorhydria (WDHA) syndrome. This clinical syndrome has also been referred to as the Verner–Morrison syndrome or the VIPoma syndrome. The diagnosis is established by excluding laxative and diuretic abuse, confirming a stool volume in excess of 0.5–1.0 L/day during a fast, and documenting a markedly raised plasma VIP concentration [1]. Surgical management of VIPomas, which are mostly located in the tail of the pancreas, has been curative. However, in patients with unresectable tumour, treatment with somatostatin analogues, streptozotocin, corticosteroids, indomethicin, metoclopramide, and lithium carbonate has proved beneficial, along with hepatic artery embolization for treatment of metastases [1, 3, 8] (see Chapter 6.9, 'VIPomas').

Pancreatic Polypeptide-Secreting Tumours (PPomas) and Non-Functioning Pancreatic NETs

PPomas are found in ~40% of patients with MEN 1 [1, 9]. No pathological sequelae of excessive pancreatic polypeptide secretion are apparent and the clinical significance of PP is unknown. Many PPomas have been unrecognized or classified as non-functioning

pancreatic NETs, which likely represents the most common enteropancreatic NET in MEN 1 [1, 3, 8, 9]. The absence of both a clinical syndrome and specific biochemical abnormalities may result in a delayed diagnosis of non-functioning pancreatic NETs, which are associated with a worse prognosis than other functioning tumours, including insulinoma and gastrinoma [1, 8, 9].

The management of non-functioning pancreatic NETs is controversial, as the patients are usually asymptomatic [9, 13, 14]. One recommendation is to undertake surgery irrespective of tumour size, after biochemical assessment is complete. However, most centres recommend surgery based on tumour size, using either tumour diameters of >1 cm or >2 cm as the criteria for surgery [1]. Pancreatic duodenal surgery is successful in removing tumours in 80% of patients, but >40% of patients develop complications including diabetes mellitus, frequent steatorrhoea, dumping syndromes, and other gastrointestinal symptoms, although 50–60% of non-MEN 1 patients treated surgically survive >5 years [1, 8, 15]. However, occult metastatic disease is likely to be present in these and MEN 1 patients at the time of presentation [16], and inhibitors of RTKs (e.g. sunitinib) and of the mammalian target of rapamycin (mTOR) signalling pathway (e.g. everolimus) have been reported to be effective in treating such pancreatic NETs in non-MEN 1 patients and in doubling the progression-free survival time [17, 18].

Treatment of Advanced and Metastatic Pancreatic NETs

The choice of optimal antitumour therapies for advanced metastatic pancreatic NETs in MEN 1 patients remain a challenge, as such therapies have not been formally evaluated in MEN 1 patients [3, 8]. The treatments comprise locoregional and systemic therapies and are indicated for hormonal hypersecretion, symptoms directly related to metastases, and tumour progression [3, 8]. Locoregional therapies consist of cytoreductive surgery, radiofrequency ablation, and transarterial embolization/chemoembolization [3, 8]. Systemic therapies include: somatostatin analogues (e.g. octreotide and lanreotide); chemotherapy (usually combination therapy) using cytotoxic drugs (e.g. streptozotocin, 5-fluorouracil, doxorubicin, cisplatin, etoposide) that target different components of the cell cycle); RTK inhibitors (e.g. sunitinib); mTOR pathway inhibitors (e.g. everolimus); and peptide receptor radionuclide therapy, in which a somatostatin analogue (e.g. octreotide, octreotate, DOTATATE and DOTATOC) is labelled with a β-emitting nuclide such as lutetium-177 (^{177}Lu) or yttrium-90 (^{90}Y) [3, 8].

Pituitary Tumours

The incidence of pituitary tumours in MEN 1 patients varies from 15 to 90% in different series [1, 3]. Approximately 60% of MEN 1 associated pituitary tumours secrete prolactin, less than 25% secrete growth hormone, 5% secrete adrenocorticotrophic hormone (ACTH), and the remainder appear to be non-functioning. Prolactinomas may be the first manifestation of MEN 1 in less than 10% of patients and somatotropinomas occur more often in patients over the age of 40 years [1]. Less than 3% of patients with anterior pituitary tumours will have MEN 1. The clinical manifestations depend upon the size of the pituitary tumour and its product of secretion. Enlarging pituitary tumours may compress adjacent structures such as the optic chiasm or normal pituitary tissue and cause bitemporal hemianopia or hypopituitarism, respectively. The tumour size and extension are assessed radiologically by MRI, and if this is contraindicated by computed tomography (CT) scanning. Treatment of pituitary tumours in MEN 1 patients is similar to that in non-MEN 1 patients and consists of medical therapy (e.g. bromocriptine or cabergoline for prolactinoma; or octreotide or lanreotide for somatotropinoma) or selective hypophysectomy by the transphenoidal approach if feasible, with radiotherapy being reserved for residual unresectable tumour [1].

Associated Tumours

Patients with MEN 1 may have tumours involving glands other than the parathyroids, pancreas, and pituitary. Thus NETs, adrenal cortical, facial angiofibromas, collagenomas, thyroid, and lipomatous tumours have been described in association with MEN 1 (1).

Other NETs Associated with MEN 1

Other NETs occur in more than 3% of patients with MEN 1, and may be located in the bronchi, gastrointestinal tract, pancreas, or thymus [1]. Bronchial NETs (carcinoids) in MEN 1 patients predominantly occur in women (M:F = 1:4) whereas thymic carcinoids predominantly occur in men, with cigarette smokers having a higher risk of developing tumours. Most patients are asymptomatic and do not suffer from the flushing attacks and dyspnoea associated with the carcinoid syndrome, which usually develops after the tumour has metastasized to the liver. Somatostatin analogues have been successfully used to treat symptoms and may in some patients result in regression of gastric carcinoids [1, 19].

Adrenal Cortical Tumours

The incidence of asymptomatic adrenal cortical tumours in MEN 1 patients has been reported to be as high as 40% [1]. The majority of these tumours are non-functioning. However, functioning adrenal cortical tumours in MEN 1 patients have been documented to cause hypercortisolaemia and Cushing's syndrome, and primary hyperaldosteronism, as in Conn's syndrome [1].

Lipomas

Lipomas may occur in more than 30% of patients [1], and frequently they are multiple. In addition, pleural or retroperitoneal lipomas may also occur in patients with MEN 1.

Thyroid Tumours

Thyroid tumours consisting of adenomas, colloid goitres, and carcinomas have been reported to occur in over 25% of MEN 1 patients [1]. However, the prevalence of thyroid disorders in the general population is high and it has been suggested that the association of thyroid abnormalities in MEN 1 patients may be incidental and not significant.

Facial Angiofibromas and Collagenomas

Multiple facial angiofibromas, which are similar to those observed in patients with tuberous sclerosis, have been observed in >85% of

MEN 1 patients [1] and collagenomas have been reported in >70% of MEN 1 patients [1].

Molecular Pathology and Function of the *MEN 1* Gene

The gene causing MEN 1 is located on chromosome 11q13 and encodes a 610 amino acid protein called menin [1, 2]. The *MEN 1* gene, which is a tumour suppressor gene, consists of 10 exons with a 1830-bp coding region, and to date over 1300 germline and 200 somatic mutations of the *MEN 1* gene have been identified [2, 20]. The majority (>70%) of these *MEN 1* mutations are inactivating, and are consistent with its role as a tumour suppressor gene [2, 20]. These mutations are diverse in their types and approximately 25% are nonsense mutations, approximately 40% are frameshift deletions or insertions, approximately 5% are in-frame deletions or insertions, approximately 10% are splice site mutations, approximately 20% are missense mutations, and less than 1% are whole or partial gene deletions. More than 10% of the *MEN 1* mutations arise *de novo* and may be transmitted to subsequent generations [1, 2]. It is also important to note that between 5% and 10% of MEN 1 patients may not harbour mutations in the coding region of the *MEN 1* gene [1, 2], and that these individuals may have mutations in the promoter or untranslated regions, which remain to be investigated. The mutations are not only diverse in their types but are also scattered throughout the 1830-bp coding region of the *MEN 1* gene with no evidence for clustering as observed in MEN 2a (MEN 2) (Table 6.11.1.1 and Chapter 6.11.2, 'Multiple Endocrine Neoplasia Type 2a and 2b'). Correlations between the *MEN 1* mutations and the clinical manifestations of the disorder appear to be absent [1, 2]. Tumours from MEN 1 patients and non-MEN 1 patients have been observed to harbour the germ line mutation together with a somatic loss of heterozygosity (LOH) involving chromosome 11q13, as expected from Knudson's model and the proposed role of the *MEN 1* gene as a tumour suppressor [1, 2]. Menin, which has been shown to have three nuclear localization sites (NLSs) and to be located predominantly in the nucleus, is a ubiquitously expressed protein that functions as a nuclear scaffold protein with roles in transcriptional regulation, genome stability, cell division, cell cycle control and epigenetic regulation [1–3].

MEN 1 Mutational Analysis in Clinical Practice

MEN 1 mutational analysis is helpful in clinical practice in several ways that include: (1) confirmation of the clinical diagnosis; (2) identification of family members who harbour the *MEN 1* mutation and require screening for tumour detection and early/appropriate treatment; and (3) identification of the 50% of family members who do not harbour the familial germline *MEN 1* mutation and can therefore be reassured and alleviated of the anxiety burden of developing future tumours [1]. This latter aspect cannot be overemphasized as it helps to reduce the cost to the individuals and their children, and also to the health services in not having to undertake unnecessary biochemical and radiological investigations (Table 6.11.1.2) [1].

Indications for *MEN 1* Mutational Analysis

The guidelines [1] recommend that *MEN 1* mutational analysis should be undertaken in: (1) an index case with two or more MEN 1-associated endocrine tumours (i.e. parathyroid, pancreatic or pituitary tumours); (2) asymptomatic first-degree relatives of a known *MEN1* mutation carrier; (3) a first-degree relative of an *MEN 1* mutation carrier expressing familial MEN 1 (i.e. having symptoms, signs, biochemical, or radiological evidence for one or more MEN 1-associated tumours); or (4) in patients with suspicious or atypical MEN 1, which includes individuals with parathyroid adenomas occurring before the age of 30 years or multigland parathyroid disease, gastrinoma, or multiple pancreatic NETs at any age, or individuals who have two or more MEN 1-associated tumours that are not part of the classical triad of parathyroid, pancreatic islet, and anterior pituitary tumours (e.g. parathyroid tumour plus adrenal tumour). Such mutational analysis may be undertaken in children within the first decade because children with MEN 1-tumours have been reported by the age of 10 years, and appropriate intervention in the form of biochemical testing or treatment or both has been considered [1, 9, 21].

A DNA test identifying an individual, who may be an asymptomatic relative of a patient with MEN 1, as a mutant gene carrier

Table 6.11.1.2 Suggested biochemical and radiological screening in individuals at high risk of developing MEN 1

Tumour	Age to begin (yr)	Biochemical test (plasma or serum) annually	Imaging test (time interval)
Parathyroid	8	Calcium, PTH	None
Pancreatic NETs			
Gastrinoma	20	Gastrin (± gastric pH)	None
Insulinoma	5	Fasting glucose, insulin	None
Other Pancreatic NET	<10	Chromogranin A; pancreatic polypeptide, glucagon, vasoactive intestinal peptide	MRI, CT, or EUS (annually)
Anterior pituitary	5	Prolactin, IGF-1	MRI (every 3 years)
Adrenal	<10	None unless symptoms or signs of functioning tumour and/or tumour >1 cm identified on imaging	MRI or CT (annually with pancreatic imaging)
Thymic and Bronchial carcinoid	15	None	CT or MRI (every 1–2 years)

PTH, parathyroid hormone; NETs, neuroendocrine tumours; IGF-1, insulin-like growth factor 1; CT, Computed tomography; MRI, magnetic resonance imaging; EUS, endoscopic ultrasound.

Adapted from Thakker RV *et al.*: Clinical Practice Guidelines for Multiple Endocrine Neoplasia Type 1 (MEN1). *J Clin Endocrinol Metab*, 2012, 97:2990–3011.

is likely to lead to earlier and more frequent biochemical and radiologic screening rather than to immediate medical or surgical treatment. In contrast, those relatives who do not harbour the *MEN 1* mutation have their risk of developing MEN 1-associated endocrine tumours markedly decreased from 1 in 2 for an autosomal dominant disorder, to that of the general population, thereby freeing these relatives without the *MEN 1* mutation from the requirement for further repeated clinical investigations (Figure 6.11.1.1). Thus, identification of *MEN 1* mutations may be of help in the clinical management of patients and their families with this disorder. Finally, *MEN 1* mutational analysis in a symptomatic family member (i.e. an individual already showing a clinical manifestation of MEN 1), from a family with a known *MEN 1* mutation, has been challenged as being unnecessary to establish the diagnosis of MEN 1. However, studies have reported that 5–10% of MEN1 kindreds have the occurrence of phenocopies, which may confound the diagnosis, and therefore the guidelines suggest that MEN 1 family members with one MEN 1-associated tumour should be offered *MEN 1* mutation analysis [1, 22, 23].

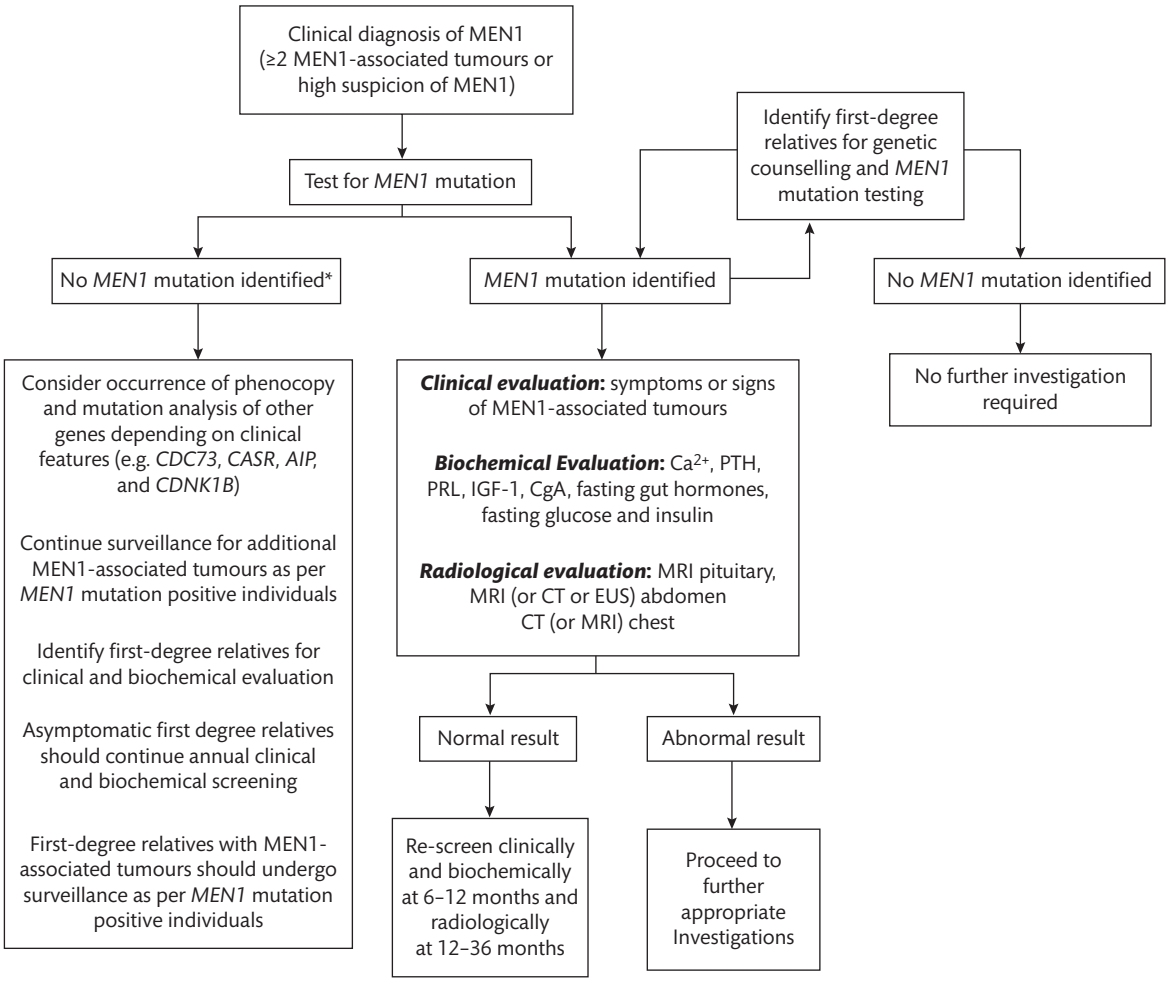

Figure 6.11.1.1 An approach to screening in MEN 1. Index cases, or individuals in whom there is a high suspicion of clinical MEN 1 (e.g. multigland parathyroid disease, parathyroid + adrenal tumour), should be offered genetic counselling and *MEN 1* mutation testing. Mutation testing should also be offered to those with familial MEN 1 (i.e. individual with one MEN 1-associated tumour and a first-degree relative with a known *MEN 1* mutation). The identification of a germline MEN 1 mutation should prompt entry into a periodic clinical, biochemical, and radiological screening programme. At the same time, first-degree relatives should be identified and offered genetic counselling and *MEN 1* mutation testing. Individuals who have inherited the *MEN 1* mutation should enter periodic screening, even if asymptomatic. First-degree relatives who have not inherited the MEN 1 mutation require no further follow-up and may be alleviated of the anxiety associated with the development of MEN 1-associated tumours. For index cases, in whom a *MEN 1* mutation, which includes testing for partial or whole gene deletions (asterisked), is not identified, additional genetic testing may be required depending on the specific clinical features. This may include examination for mutations in genes associated with familial endocrine tumour syndromes including: *CDC73* associated with the hyperparathyroidism-jaw tumour syndrome (HPT-JT); the calcium-sensing receptor (*CASR*) associated with familial benign hypercalciuric hypercalcaemia (FBHH); cyclin-dependent kinase 1B (*CDKN1B*) associated with MEN 4; and aryl hydrocarbon receptor interacting protein (*AIP*) associated with familial isolated pituitary adenomas (FIPA). Up to 10% of kindreds with clinical MEN 1 may harbour phenocopies emphasizing the importance of accurate genetic evaluation. For MEN 1 kindreds in whom no *MEN 1* mutation is identified a pragmatic approach is to offer clinical, biochemical and radiological screening to those with clinical manifestations of disease and to offer annual clinical and biochemical screening to asymptomatic first-degree relatives. Ca^{2+}, calcium; PTH, parathyroid hormone; PRL, prolactin; IGF-1, insulin-growth-factor-1; CgA, chromogranin A; MRI, magnetic resonance imaging; CT, computer tomography; EUS, endoscopic ultrasound.

Screening for MEN 1 Tumours

Biochemical screening for the development of MEN 1 tumours in asymptomatic members of families with MEN 1 is likely to be of benefit in as much as earlier diagnosis and treatment of these tumours may help reduce morbidity and mortality (Figure 6.11.1.1) [1]. Age-related penetrance (i.e. the proportion of gene carriers manifesting symptoms or signs of the disease by a given age) has been ascertained, and the mutation appears to be non-penetrant in those younger than 5 years [21]. Thereafter, the mutant *MEN 1* gene has a high penetrance, >50% penetrant by 20 years of age and >95% by 40 years [21]. Screening for MEN 1 tumours may be difficult because clinical and biochemical manifestations in members of any one family are not uniformly similar [1, 2]. Attempts to screen for development of MEN 1 tumours in the asymptomatic relatives of an affected individual have depended largely on measuring serum concentrations of calcium, gastrointestinal hormones (e.g. gastrin), prolactin and insulin-like growth factor (IGF-1), as well as on abdominal and pituitary imaging (Table 6.11.1.2). Parathyroid overactivity causing hypercalcaemia is almost invariably the first manifestation of the disorder and has become a useful and easy biochemical screening investigation [1]. In addition, hyperprolactinemia, which may be asymptomatic, may represent the first manifestation in ~15% of patients and may thus also be a helpful and an easy biochemical screening investigation [1]. Pancreatic involvement in asymptomatic individuals has been detected by measuring fasting plasma concentrations of gastrin, PP, glucagon, and chromogranin A and by abdominal imaging [1]. The guidelines suggest that individuals at high risk for MEN 1 (i.e. mutant gene carriers) undergo biochemical screening (Figure 6.11.1.1) at least once per annum and also have baseline pituitary and abdominal imaging (e.g. MRI or CT), which should then be repeated at 1- to 3-year intervals (Table 6.11.1.2) [1]. Screening should possibly commence in early childhood because the disease has developed in some individuals by the age of 5 years, and it should be repeated throughout life because the disease may not manifest in some individuals until the eighth decade [1].

Conclusions

Multiple endocrine neoplasia type 1 (MEN 1) is characterized by the occurrence of parathyroid, pancreatic islet, and anterior pituitary tumours. Some patients may also develop carcinoid tumours, adrenal cortical tumours, meningiomas, facial angiofibromas, collagenomas, and lipomas. MEN 1 is inherited as an autosomal dominant disorder that is due to mutations in the tumour suppressor gene *MEN 1*, which encodes a 610-amino acid protein, menin. Patients with MEN 1 have a decreased life expectancy. Moreover, the finding of MEN 1 in a patient also has important implications for family members, because first-degree relatives have a 50% risk of developing the disease, and these at-risk relatives can be identified by *MEN 1* mutational analysis. The prognosis of MEN 1 patients and that of the at-risk relatives may be improved by presymptomatic detection of the tumours and with implementation of earlier and specific treatments for the MEN 1 tumours.

6.11.2 Multiple Endocrine Neoplasia Type 2a and 2b

Electron Kebebew, Douglas Wiseman, and Mustapha El Lakis

Introduction

Multiple endocrine neoplasia (MEN) type 2a (also referred to as type 2) and 2b (also referred to as type 3) are autosomal dominant inherited multiglandular cancer syndrome, resulting from mutations in the *RET* (REarranged during Transfection) proto-oncogene. It is the only inherited cancer syndrome that results from a germline-activating mutation in one allele of a proto-oncogene. All of the other inherited cancer syndromes with known susceptibility genes result from germline mutations in tumour suppressor genes in one allele and a second hit in the other allele in the target organ. Together, MEN 2a and 2b have an estimated worldwide prevalence of 1 in 35 000 individuals [1].

MEN 2a (or MEN 2) is characterized by the development of medullary thyroid carcinoma (MTC), phaeochromocytoma (PHEO), and primary hyperparathyroidism (PHPT). MEN 2a (MEN 2) was first described by Sipple in 1961 when he reported a patient with PHEO and thyroid cancer [2]. Seven years later, Steiner and colleagues described a family with MTC, PHEO, PHPT, and Cushing's syndrome and suggested the entity characterized by MEN 2a (MEN 2) [3]. MEN 2b (or MEN 3) is characterized by MTC, PHEO, and distinct physical phenotypes such as mucosal neuromas and Marfanoid habitus. It was first described in 1966 by Williams and Pollak [4]. In 1986, familial medullary thyroid carcinoma (FMTC) was described as a syndrome distinguished by the presence of hereditary MTC but none of the extrathyroidal manifestations of MEN 2a or 2b. FMTC was then classified as a variant of MEN 2a along with three other MEN 2a variants: (1) Classical MEN 2a; (2) MEN 2a and cutaneous lichen amyloidosis (CLA); and (3) MEN 2a and Hirschsprung's disease (HD) (Table 6.11.2.1) [5, 6]. In this chapter, the genetics, diagnosis, and management of the various MEN 2a and 2b syndromes are discussed.

Multiple Endocrine Neoplasia Type 2a

MEN 2a (or MEN 2) accounts for more than 90% of combined MEN 2a and 2b cases [1]. Classical MEN 2a is the most common variant, and 95% of individuals test positive for *RET* germline mutations [7]. In this chapter, we will refer to classical MEN 2a (or MEN 2) as 'MEN 2a'. Virtually all individuals affected with MEN 2a who did not undergo prophylactic thyroidectomy will have biochemical signs of MTC by age 35, while up to 50% will develop PHEOs, and approximately 30% will develop PHPT [1].

MTC, a neuroendocrine tumour that originates from the calcitonin-secreting parafollicular (C-cells) of the thyroid gland, is the defining component of all patients with MEN 2a (MEN 2). It is usually the first to manifest with almost complete penetrance. The incidence of MTC peaks in the third decade of life and usually presents with a neck mass or neck pain in probands or in patients

MEN 2, multiple endocrine neoplasia type 2a; MTC, medullary thyroid carcinoma; PHPT, primary hyperparathyroidism; PHEO, phaeochromocytoma; CLA, cutaneous lichen amyloidosis; HD, Hirschsprung's disease.

unaware of their genetic predisposition. At the time of diagnosis, up to 70% of patients have cervical lymph node metastases if they present with clinically evident MTC.

PHEO, a neuroendocrine tumour originating from the adrenal medulla chromaffin cells, generally presents in MEN 2a (MEN 2) after or concurrently with MTC, but it can be the first presenting tumour in 15% of patients with MEN 2a [8]. PHEO is the second-most-common tumour in MEN 2. The penetrance and age at diagnosis of PHEO in MEN 2a (MEN 2) is dependent on the specific underlying *RET* mutation (often referred to as *RET* genotype-phenotype associations). For instance, in patients with *RET* codon 634 mutations, PHEO penetrance is 25% by age 30, 52% by age 50, and 88% by age 77 [9]. Compared to individuals without MEN 2a-associated PHEOs, patients with MEN 2a are diagnosed at a younger age and present with less-obvious symptoms. MEN 2a–associated PHEOs have a high tendency to develop synchronous or metachronous bilateral adrenal tumours in up to approximately 50% of patients by the age of 50. MEN 2a–associated PHEOs are rarely malignant, with only two reported cases out of 563 patients in a large multinational observational study [8]. In addition, the impact of MEN 2a–associated PHEO on mortality is lower than expected, but this may be due to active surveillance for PHEO in patients with MEN 2a.

PHPT usually presents years after the diagnosis of MTC, with an average age at presentation of 34 years [10]. PHPT penetrance in MEN 2a is dependent on the specific *RET* mutation [10]. The highest predisposition for PHPT is in kindred with cysteine–arginine mutations at codon 634, exon 11 (up to 30%). On the other hand, *RET* mutations in codons 609, 611, 618, and 620 are associated with a penetrance between 2% and 12% [11, 12]. The clinical course of MEN 2a-related PHPT is usually mild and associated with few if any symptoms. MEN 2a-related PHPT can be due to a single enlarged parathyroid gland but is also reportedly due to multiple enlarged glands in up to 82% of patients [13]. Parathyroid carcinoma is rare, and only a single case has been reported in the literature [14].

MEN 2a with CLA is a rare variant of the MEN 2a syndrome and was first described by Gagel and associates [15]. CLA is a rare skin condition usually located in the interscapular region (dermatomes T2–6) or on the extensor surfaces of the extremities and is a pruritic, scaly, papular, and pigmented lesion. The pruritus usually starts during childhood and predates the development of MTC by years. Pruritus improves with sun exposure and worsens during periods of stress. Repeated scratching of the pruritic zone causes epidermal hyperplasia and pigmentation [16].

MEN 2a (or MEN 2) with HD is also a rare variant of MEN 2a. One of the first reports highlighting the co-occurrence of HD in a large kindred with MEN 2a was published in 1982 [17]. HD clinically presents as either failure to pass meconium within 48 hours of birth, intractable constipation, or small bowel obstruction. HD, also known as aganglionic megacolon, occurs due to the congenital absence of parasympathetic neuronal ganglia in a segment of the hindgut. HD can precede C-cell hyperplasia or MTC, which is why children with HD should be tested for germline *RET* mutations.

Multiple Endocrine Neoplasia Type 2b

MEN 2b (or MEN 3) is very rare, with an estimated incidence of two per million live births annually. This is because most cases of MEN 2b (or MEN 3) are *de novo*, as patients typically die of their MTC before being able to have offspring. MEN 2b (MEN 3) is associated with the early onset of MTC and PHEO in approximately 50% of patients as well as phenotypical features such as ophthalmologic abnormalities (thickened and everted eyelids, inability to tear while crying, and prominent corneal nerves), skeletal malformations (Marfanoid body habitus, pes cavus, pectus excavatum, poor dentition, high-arched palate or nodules in the palate, scoliosis, and slipped capital femoral epiphyses), and a generalized ganglioneuromatosis (**Figure 6.11.2.1**). Neuromas can also occur anywhere along the gastrointestinal tract, resulting in loss of normal bowel tone, distension, segmental dilatation, and megacolon. Intestinal involvement usually presents early in childhood with abdominal pain and constipation before other extrathyroidal manifestations are perceived. In MEN 2b (MEN 3), MTC can occur in the first year of life, with the youngest patient reported at 9 weeks old [18].

Genetics of MEN 2a and 2b

MEN 2a and 2b result from germline gain-of-function mutations in the *RET* proto-oncogene located on chromosome 10q11.2, which contains 20 exons spanning a region of more than 55KB [19, 20]. *RET* was first discovered in 1985 by Takahashi and colleagues via transfection of murine NIH 3T3 cells with human lymphoma deoxyribonucleic acid (DNA) [21]. In 1993, mutations in *RET* were linked to MEN 2 and FMTC [22]. The following year, germline sequencing of DNA from a MEN 2b (or MEN 3) cohort revealed a point mutation in *RET* [23]. Later, in 1994, the International RET Mutation Consortium met for the first time in Stockholm, Sweden, where genetic data submitted from 361 MEN 2a and 2b families from Asia, Australia, Europe, and North America showed that 93–100% of MEN 2a families, 94% of MEN 2b families, and 87% of FMTC kindred had *RET* germline mutations, solidifying the relationship between MEN 2a syndromes and *RET* mutations [24]. The *RET* gene codes for a single-pass transmembrane receptor tyrosine kinase in cells of neural crest origin (**Figure 6.11.2.1**). The extracellular portion of the RET protein, which includes the N-terminus, has four cadherin-like domains as well as a cysteine-dense region that forms intermolecular disulphide bonds during homodimerization [25–27]. The transmembrane domain of the RET protein contains 22 amino acids. The C-terminus and the receptor tyrosine kinase

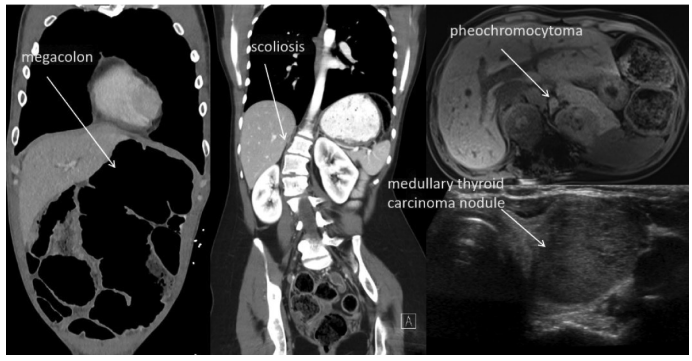

Figure 6.11.2.1 Imaging showing the manifestations of MEN 2b including megacolon, scoliosis, phaeochromocytoma, and medullary thyroid carcinoma.

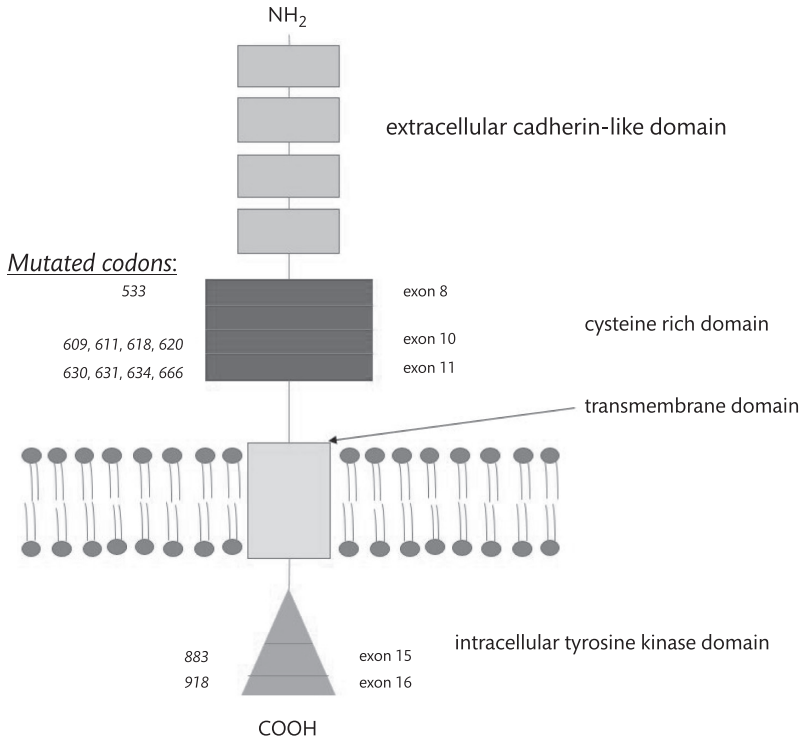

Figure 6.11.2.2 Schematic of the RET protein illustrating protein domains and codon mutations within the corresponding exons.

domain are positioned within the cytoplasm. RET protein plays a role in cell development and migration, and the mechanism of RET activation is via glial cell-derived neurotrophic factor (GDNF) ligands [28]. Pathogenic mutations in RET cause constitutive activation of the RET protein.

Ninety-five percent of MEN 2b (or MEN 3) patients have a missense mutation at codon 918 (M918T), located in the intracellular kinase region of the RET protein, while the other 5% of MEN 2b (MEN 3) mutations occur at codon 883 (A883F) [29]. Codon 918 (C918) mutations are characterized by aggressive MTC with onset in infancy, often with metastases to cervical lymph nodes and distant sites such as the mediastinum, lung, and/or bone. Fifty percent of MEN 3 patients will develop PHEOs. Other physical attributes characteristic of MEN 2b (MEN 3) described earlier are present in patients with either C918 or C883 mutations, and the patients have been described as indistinguishable on physical examination [30]. However, the C883 mutation may be associated with the less-aggressive MTC [31]. The current American Thyroid Association (ATA) guidelines place the MEN 2b C918 mutation in the highest-risk category and the MEN 2b C883 mutation in the high-risk category in regard to the aggressiveness of MTC.

Genotype-Phenotype Association

Eighty-five percent of patients with classical MEN 2a (MEN 2) have a missense mutation of *RET* in codon 634 (C634R), which is in the extracellular domain of the RET protein. Other mutations in the classical variant of MEN 2 involve codons 609, 611, 618, or 620 [9]. An uncommon missense mutation (V292M) in MEN 2a involving the extracellular domain of the RET protein has been documented [32]. All classical MEN 2a patients develop MTC. The 2015 ATA guidelines stratify MTC risk into three categories—moderate, high, and highest—for the aggressiveness and age of onset of MTC based on the specific *RET* mutation (Table 6.11.2.1). The penetrance of PHEO and PHPT in classical MEN 2a is dependent upon the specific *RET* mutation. A higher penetrance of PHEO and PHPT is associated with the C634R mutation, with decreasing penetrance for *RET* mutations in codons 609, 611, 618, and 620 (Table 6.11.2.2) [11, 12].

Genetic Testing

Germline *RET* mutations in MEN 2a (MEN 2) syndromes are driver mutations, and genetic testing and counselling is an important part of disease management. Genetic testing and counselling should be offered to all patients with MEN 2a and 2b. The ATA guidelines for the management of MTC recommend a single or tiered approach to genetic mutational testing in patients with MEN 2a. Single or

Table 6.11.2.2 *RET* mutations and MTC aggressiveness with PHEO and PHPT penetrance

RET mutation type	MTC aggressiveness [6]	PHEO penetrance	PHPT penetrance
M918T	highest	~50%	0%
C634F/G/R/S/W/Y, A883F	high	~50%	0–30%
All others	moderate	0–30%	0–10%

MTC, medullary thyroid carcinoma; PHEO, phaeochromocytoma; PHPT, primary hyperparathyroidism.

multitiered testing should be offered to search for *RET* mutations in exons 10 and 11 as well as exons 8, 13, 14, 15, and 16. Additional *RET* genetic testing should proceed if no mutations are found in the aforementioned coding regions of *RET*. However, with advances in sequencing technology and the decreasing cost of genetic testing, such tiered testing is probably unnecessary.

MEN 2b (MEN 3) patients should be offered genetic testing focusing on C918 and C883. If these two codons are free of mutation, all 20 exons should be analysed for possible mutations. Because MEN 2a and 2b (or MEN 2 and 3) syndromes are inherited in an autosomal dominant fashion, first-degree relatives of patients with known *RET* mutations should undergo *RET* mutational screening. Patients with exon 10 mutations and HD as well as patients with CLA should proceed with *RET* mutation testing. In patients with MEN 2a and exon 10 mutations, a search for HD mutations would be recommended. Finally, all patients with MTC should have genetic testing for germline *RET* mutations, as up to 8% of patients with apparently sporadic MTC (no family history) will be found to have a germline *RET* mutation.

Diagnosis and Management

The diagnosis of MEN 2a and 2b (MEN 2 and 3) syndromes begins with a complete history and physical and is confirmed with high accuracy via genetic testing for *RET* germline mutations. All patients presenting with MTC, PHEO, and C-cell hyperplasia (CCH) should be tested for *RET* germline mutations. In patients with a positive family history of MEN 2a or 2b, genetic testing should be pursued. A negative family history does not guarantee the absence of MEN 2. Up to 40% of patients with *RET* mutations will not develop clinically detectable disease, hence genetic testing should proceed if the patient has features suggestive of MEN 2a or 2b. At institutions or countries where genetic testing is not available, MEN 2a can be diagnosed clinically by the presence of at least two of the classical features (MTC, PHEO, and PHPT).

Medullary Thyroid Carcinoma

MTC is the most prevalent neoplastic feature of all MEN 2a and 2b syndromes and is usually the first manifestation, if not the only manifesting feature. It is also the most frequent disease-specific cause of mortality in MEN 2a and 2b patients. Surgery is the mainstay of disease management and offers the only viable option for remission. The goal of curative surgical therapy for patients with hereditary MTC is complete surgical resection prior to malignant transformation or spread beyond the thyroid gland.

MEN 2a patients with known *RET* mutations are stratified into moderate or high-risk ATA categories for the aggressiveness of MTC based on specific codon mutations (Table 6.11.2.2). Children with MEN 2a in the moderate-risk category often develop MTC at a later age compared to the high-risk category [33]. For moderate-risk category patients, screening, and surveillance for MTC should begin at age 5. Surveillance includes annual physical exam, ultrasound (US) of the thyroid, and measurement of serum basal and/or stimulated calcitonin (CTN) and carcinoembryonic antigen (CEA). Surveillance may last for several years before surgery is indicated, and parents may choose to forego a prolonged period of surveillance and proceed with prophylactic total thyroidectomy before elevation of biomarkers (CTN, CEA) are noted. It is recommended that prophylactic total thyroidectomy be pursued when serum basal CTN is 40 pg/ml or higher (Figure 6.11.2.3). Follow-up after prophylactic total thyroidectomy includes US of the neck and basal or stimulated serum CTN and CEA every 6 months for 1 year. If imaging is negative and biomarkers remain undetectable or normal, basal, or stimulated serum CTN and CEA should be performed annually. Any suspicious findings on surveillance US warrant a fine needle aspiration (FNA) biopsy.

For children with MEN 2a in the MTC ATA high-risk category, surveillance begins at age 3. Thyroidectomy is recommended at or before age 5, and the extent of surgery is guided by CTN levels [34]. Postoperative follow-up for high-risk MTC is similar to the moderate-risk category [6].

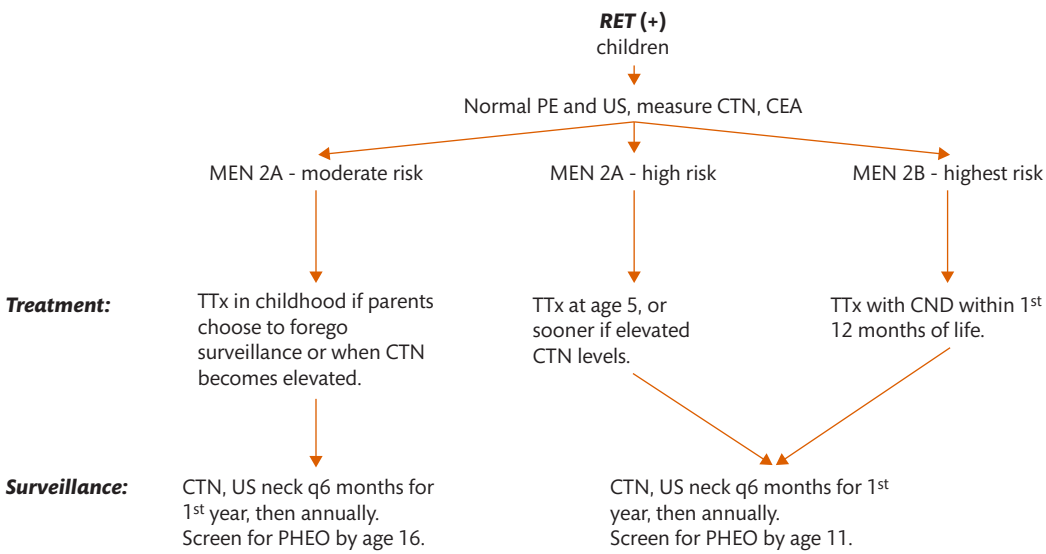

Figure 6.11.2.3 Flowchart for medullary thyroid carcinoma (MTC) management in *RET*-positive children. PE, physical exam; US, ultrasound, CTN, calcitonin; CEA, carcinoembryonic antigen; TTx, total thyroidectomy; CND, central neck dissection; q6, every six; PHEO, phaeochromocytoma.

The ATA highest-risk category for MTC is comprised of only MEN 3 patients with a *RET* codon 918 mutation. These patients can develop an aggressive variant of MTC within the first year of life. Patients can either inherit the 918 *RET* mutation or develop the mutation *de novo* [35]. Patients of a known MEN 2b (MEN 3) kindred should have prophylactic total thyroidectomy early, which may be in the first months of life and at least by 1 year of age [6]. Both high basal CTN levels in paediatric patients persisting to three years of age and higher values in males as compared to females have been noted [36]; therefore, in these young MEN 2b patients, CTN levels may not be useful. The decision to proceed with a central lymph node dissection (level VI) in the highest-risk patients should be determined by nodal status. Alternatively, central neck dissection may be performed prophylactically if the parathyroid glands can be identified and preserved *in situ* or reimplanted to avoid a complication of hypoparathyroidism. Patients with *de novo RET* codon 918 mutations typically present with a thyroid nodule [35, 37]. Age at identification in one cohort of *de novo* 918 mutations was from 1 to 31 years of age [38]. Because these patients typically present with advanced disease, extent of surgery is guided by imaging findings and biomarker levels (CTN, CEA). Foregoing a level VI lymph node dissection is not recommended [6].

Patients with clinically evident disease that is proven to be MTC by FNA cytology or histology should have serum CEA and CTN levels measured. MTC histology demonstrates amyloid staining of the stroma and parafollicular or C-cells. All patients with MTC should have genetic testing for *RET* mutations. The work-up for *RET*-positive patients with MTC includes a thyroid and cervical soft tissue US. Patients presenting with extensive cervical disease and/or serum basal CTN levels greater than 500 pg/ml should have a complete metastatic work-up including computed tomography (CT) of the neck and chest with intravenous contrast, contrast-enhanced magnetic resonance imaging (MRI) of the liver, MRI of the bony spine, and a bone scan to evaluate for distant metastases. Serum CTN levels have been correlated with locoregional and distant metastatic disease. Serum CTN levels above 500 pg/ml also indicate the need for additional imaging beyond US searching for metastases [6]. Functional imaging is not currently recommended [6] to evaluate a patient for MTC metastases due to lower sensitivity when compared to anatomic imaging [39]. However, literature exists to support tandem use of 18-F-DOPA PET/CT and 18-F-FDG PET/CT with improved sensitivities when CTN is above 150 pg/ml [40]. 18-F-FDG PET/CT use in some MTC cohorts has increased sensitivity of metastatic lesion detection for CTN >1000 pg/ml [41].

The extent of surgery for MTC is guided by imaging findings and biomarker levels. Prior to surgical management of MTC in a patient with MEN2/3, PHEO and PHPT should be excluded biochemically. A MEN2/3 patient presenting with MTC limited to the thyroid and CTN <20 pg/ml should undergo a total thyroidectomy (TTx) and level VI lymph node dissection. In the absence of gross locoregional disease, CTN levels may correlate with occult lymph node metastasis and subsequently will have implication for the initial surgical treatment. For instance, in patients with CTN levels of 50–200 pg/ml, the surgery should include TTx with level VI and ipsilateral levels II–V nodal dissection, while CTN above 200 pg/ml would include a TTx and bilateral levels II–V and level VI lymph node dissection for a patient with preoperative disease limited to the thyroid. However, the contralateral lateral neck dissection (levels II–V) may be performed in a staged fashion or not at all if postoperative CTN levels are undetectable.

All patients should have levothyroxine replacement after thyroidectomy with a goal of maintaining thyroid-stimulating hormone (TSH) in the normal range. TSH should be checked 6 to 8 weeks after thyroidectomy and the initiation of replacement levothyroxine therapy.

CTN and CEA are biomarkers used preoperatively and postoperatively to follow disease. Postoperatively, undetectable levels of serum biomarkers should be observed to indicate remission [42]. CTN and CEA should be checked three months after operation [43, 44] and should be checked every 6 months for 1 year and then annually thereafter if they remain undetectable or within the normal range [6]. Three-month postoperative CTN less than 150 pg/ml warrants a US of the neck and physical examination; if negative, the surveillance should be repeated at 6-month intervals [6]. Persistent or recurrent disease is indicated by elevated or rising serum levels, while the normalization of CEA and CTN has a favourable prognosis. It has also been shown that the doubling time of CTN and CEA over a period of less than two years is associated with a worse prognosis [7].

American Joint Committee on Cancer (AJCC) stage at diagnosis, nodal metastases, and age remain the main predictive factors for survival on multivariate analysis [45]. Torresan and colleagues reported on their single institution experience with MTC from 1980 to 2015, including 255 patients with sporadic and hereditary (34.9%) MTC. In their cohort, the cure rate was 56.8% in all patients after operation. Deaths occurred only in patients with stages III–IV, with 6% of MEN 2a and 66.7% of MEN 2b patients succumbing to disease and 17.7% of all patients having persistent or recurrent disease [45]. A French group presented a study of 899 patients with MTC published in 1998, in which 96% of patients were undergoing surgery and 43% of the cohort had familial forms of MTC [46]. Forty-three per cent (43%) of operated patients were biochemically cured. Overall survival (OS) was 85% at 5 years and 78% at 10 years. Multivariate analysis demonstrated that age and stage were independent predictive factors of survival while gender, type of surgery, and type of familial form were only predictive in univariate analysis. Biochemical cure predicted an OS rate of 98% at 10 years. Recurrence, defined as subsequent elevation of CTN after postoperative normalization, was found in 5% of their cohort. In patients with biochemical evidence of disease (57%), OS was 80% and 70% at 5 and 10 years, respectively. Biochemical cure was associated with stage in the French study.

MTC can spread to multiple organs including the liver, brain, bone, skin, lung, and mediastinum. Patients with isolated brain metastases are candidates for surgical resection or external beam radiation. External beam radiation is an option among others such as thermoablation and surgery for bone fractures secondary to metastasis. When lung and liver metastasis are solitary, surgical resection is a viable option. For disseminated liver metastasis, chemoembolization could be considered if there is significant disease progression. Palliation of patients with advanced MTC should be considered when metastatic lesions are causing pain, mechanical compression, or signs and symptoms of hormonal excess. Patients with bone metastasis to the spinal cord with compression symptoms require urgent treatment with glucocorticoid therapy and surgical decompression. Space-occupying metastases that cause bronchial

and oesophageal obstruction can be palliated by surgical resection, external beam radiation, or the administration of systemic therapy.

For patients with metastatic MTC, the rate of tumour progression and quality of life should be taken into consideration against the limited efficacy and potential toxicities of local and systemic therapies. For instance, systemic therapy is not recommended for patients with stable low-volume metastatic disease or patients in whom imaging finds no metastatic disease despite elevation in CTN. In recent years, targeted therapy with tyrosine kinase inhibitors (TKIs) has been evaluated in phase I, II, and III clinical trials in patients with advanced MTC. Currently, there are two Food and Drug Administration (FDA)–approved TKIs for the management of metastatic MTC: vandetanib and cabozantinib. In the two phase III trials, vandetanib [47] and cabozantinib [48] have shown the potential to provide high rates of disease control with durable responses and a highly significant improvement of progression-free survival. Thus, vandetanib and cabozantinib should be considered as single-agent first-line systemic therapies in patients with advanced progressive disease. Patients treated with TKIs for advanced MTC require careful monitoring because they are at increased risk for developing hypothyroidism and other toxicities.

Single-agent or combination cytotoxic chemotherapeutic regimens have shown low response rates (15–20%) of short duration. The most effective regimens are combination therapies with either doxorubicin and epirubicin or 5-fluorouracil and dacarbazine [49].

Phaeochromocytoma

Up to 50% of MEN2/3 patients will develop PHEO. All patients with MEN 2a/2b diagnosed with MTC should have biochemical testing for concurrent PHEO with plasma-free metanephrines or fractionated urine metanephrines before undergoing thyroidectomy and also during surveillance. Patients in the ATA highest- and high-risk *RET* mutations categories should be tested for PHEO beginning at age 11. Those in the moderate-risk group should be tested beginning at age 16 [6]. Once PHEO is diagnosed biochemically, anatomical imaging such as contrast CT or MRI of the adrenals should be obtained for localization. The patient should then be started on alpha blockade for 7 to 14 days prior to adrenalectomy. Adrenalectomy should precede any neck surgery for MTC to avoid intraoperative hemodynamic instability and to minimize associated complications such as cerebral vascular accident (CVA) or myocardial infarction (MI). Laparoscopic or retroperitoneoscopic adrenalectomy is the surgical procedure of choice for PHEO. If possible, patients with unilateral PHEO may be offered a partial or cortical-sparing adrenalectomy (**Figure 6.11.2.4**) [8]. We prefer this approach, as the malignancy risk is minimal, and it aims to retain needed adrenal cortical tissue. This may circumvent the need for exogenous steroids replacement, as the patient is likely to develop a contralateral PHEO within 10 years of the first PHEO and require additional adrenal surgery [6]. Bilateral PHEOs may also be amenable to minimally invasive resection techniques and should be evaluated for possible bilateral partial adrenalectomy. Generally, it is recommended that an adrenal remnant of at least one-third of the normal adrenal volume with the adrenal vein left *in situ* is needed to maintain adequate adrenal function. Postoperatively, an adrenocorticotrophic hormone (ACTH) stimulation test is usually carried out to test for the residual adrenal cortex function, and it may help guide the need for steroid replacement therapy. Patients undergoing partial adrenalectomy should be screened annually for PHEO recurrence with biochemical testing.

Hyperparathyroidism

PHPT is diagnosed biochemically with elevated serum calcium and inappropriately elevated intact parathormone (PTH). In patients with known MEN 2a, the initiation of surveillance for PHPT mirrors the initiation for surveillance of PHEOs. The penetration of PHPT is related to the specific *RET* mutations, with codon 634 mutation demonstrating the highest penetration (30%) [6]. PHPT is usually addressed surgically at the time of thyroidectomy for MTC, if present. Most MEN 2a/2b patients present with multiple enlarged parathyroid glands. The goal is to achieve a euparathyroid state with surgical intervention. Surgical management in a patient with MEN 2 syndrome and PHPT with no prior neck surgery should have a bilateral neck exploration with excision of only enlarged glands. If

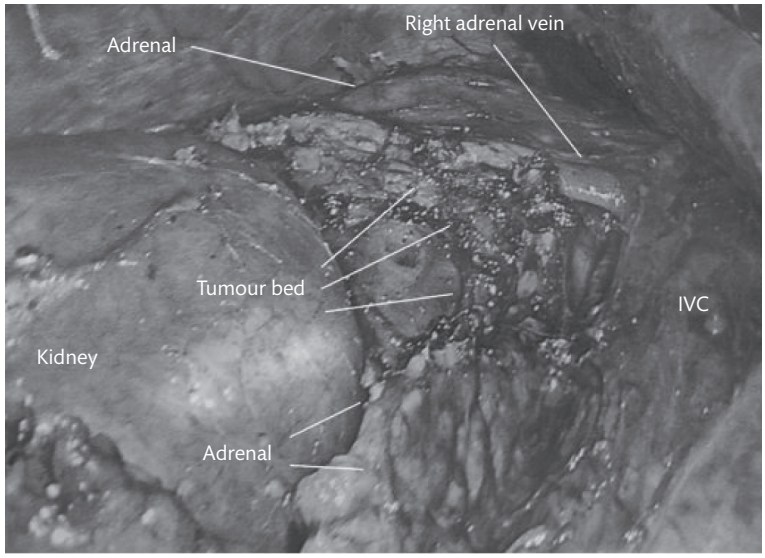

Figure 6.11.2.4 Partial adrenalectomy for a 2 cm phaeochromocytoma in a MEN 2a patient.

PHPT presents after MTC and thyroidectomy, localization studies (US, sestamibi, or CT) and laryngoscopy (to assess vocal cord function) should be performed prior to neck exploration, and all enlarged glands should be excised.

Conclusions

MEN 2a and 2b patients have distinct phenotypes that a clinician should be able to recognize. Genetic testing is an important part of disease management as it will allow for risk stratification of the patient's MTC and guide subsequent therapy. CTN and CEA are accurate biomarkers used to follow MTC for life in MEN2/3 patients. Early diagnosis and intervention are paramount to improving survival in this cohort of patients. All patients with MEN 2a/2b should have biochemical screening and surveillance for PHEO and PHPT. The body of knowledge regarding MEN 2a/2b syndromes continues to grow. As our understanding of the disease at the molecular level increases, we have changed practice in regard to diagnosis, management, and surveillance.

Familial Syndromes and Genetic Causes of Paraganglioma and Phaeochromocytoma

Eamonn R. Maher and Ruth T. Casey

Introduction

A phaeochromocytoma is a tumour arising from the adrenal medulla and a paraganglioma refers to its extra-adrenal counterpart, which can develop from sympathetic or parasympathetic tissue anywhere from the skull base to the pelvis. Phaeochromocytomas and paragangliomas (PPGL) are considered to be the most heritable tumours as up to 40% of patients who develop these tumours have a hereditary predisposition. This chapter provides an update on the clinical and molecular genetics of PPGL and related syndromes and offers a guideline for genetic testing and surveillance of those individuals identified as carriers for a known PPGL predisposition gene.

The Discovery Timeline of Phaeochromocytoma and Paraganglioma (PPGL) Predisposition Genes

Prior to the turn of this century, it was widely accepted that a phaeochromocytoma followed a rule of 'tens': (i) 10% were bilateral; (ii) 10% were malignant; (iii) 10% were extra-adrenal (now termed paraganglioma (PGL) arising from sympathetic ganglia anywhere from the thorax to pelvis); and finally and (iv) 10% were hereditary.

Familial occurrence of phaeochromocytoma (PC) was first recognized by Chase *et al.* in 1937 [1] and almost 50 years later the co-occurrence of PC and its extra-adrenal counterpart PGL in the same kindred was reported [2]. Those tumours that were familial were associated with hereditary syndromes such as neurofibromatosis type 1, caused by germline mutations in the neurofibromin 1 gene (*NF1*), multiple endocrine neoplasia type 2 (MEN2) caused by germline mutations in the *RET* proto-oncogene and Von Hippel–Lindau syndrome (VHL), caused by germline mutations in the *VHL* tumour suppressor gene. Each of these syndromes predispose to the development of bilateral phaeochromocytoma but extra-adrenal tumours are rarely encountered and typically each of these syndromes are associated with other characteristic phenotypic features.

Between the years 2000 and 2010, nine further phaeochromocytoma predisposition genes were identified and this era of discovery completely dispelled the contention that only 10% were hereditary. This era of discovery was triggered by the seminal finding that some families affected by a head and neck paragangliomas (HNPGL) such as a chemodectoma or glomus jugulare tumour, carried a mutation in the succinate dehydrogenase subunit D gene (*SDHD*) [3]. Between 2000 and 2011, all four of the succinate dehydrogenase subunit genes (*SDHA, SDHB, SDHC* and *SDHD*) were implicated in the development of familial PPGL[4, 5], as well as the *SDHAF2* gene which encodes its namesake protein responsible for the flavination of the SDHA protein [6].

In 2010, an integrated genomics approach led to the finding that a gene encoding a transmembrane protein (TMEM127) localized to chromosome 2, was implicated in familial PPGL [7]. This transmembrane protein normally functions as a modulator of the mTOR pathway and notably patients with mutations in the *TMEM127* gene were found to present at an older age compared to patients with other syndromic causes of PPGL [7]. Subsequently, whole-exome sequencing identified recurrent mutations in the *MAX* (MYC associated factor X) gene in three unrelated patients with hereditary PPGL [8]. Though all of these genes are inherited in an autosomal

dominant manner, *SDHD, SDHAF2*, and *MAX* are associated with predisposition to PPGL, almost always only after paternal transmission of a mutation [8].

Finally, mutations in another citric acid cycle enzyme encoding gene fumarate hydratase (*FH*) were implicated in hereditary phaeochromocytoma [9], in addition to its previously accepted role in hereditary leiomyomatosis and renal cell cancer.

Importantly, PPGLs are now considered to be the most heritable of all tumours with 40% of patients having a genetic predisposition in one of 11 major susceptibility genes routinely screened for in clinical practice (*SDHA, SDHB, SDHC, SDHD, SDHAF2, NF1, RET, TMEM127, MAX, FH, VHL*) [10]. Although several additional predisposition genes have been reported in the past five years (e.g. malate dehydrogenase 2 (*MDH2*) gene [11], *SLC25A11* gene, which encodes the mitochondrial 2-oxoglutarate/malate carrier and *EPAS1* [12], which encodes the hypoxia inducible factor-2 alpha (HIF-2alpha)), these are a rare cause of PPGL and not commonly analysed in first-line genetic testing.

Neurofibromatosis Type 1 (OMIM 162200)

Neurofibromatosis type 1 was first described by Von Recklinghausen in 1882 and is an autosomal dominant syndrome characterized by neuro-ectodermal abnormality and variable systemic manifestations affecting bone, nervous system, eyes, and other sites. The *NF1* gene maps to chromosome 17 and is 57 exons in length [13]. Generally, a diagnosis of neurofibromatosis type 1 is made on clinical criteria (including café-au-lait macules, neurofibromas, axillary or inguinal freckling, optic gliomas, Lish nodules in the iris, or a first-degree relative with a diagnosis of NF1[14]) and genetic testing is not routinely performed owing to the large size of the gene. Many mutations occur *de novo* with no preceding family history [13, 15]. However, recent reductions in the cost of next generation sequencing, have facilitated genetic testing in patients with suspected NF1 [15]. PC is a rare feature, affecting 0.1–6% of all patients with NF1 [16]. The median age of onset is approximately 41 years and most patients with NF1 will not have PC as the presenting feature. Extra-adrenal and malignant tumours are rarely associated with NF1 but up to a third of patients in one large study developed bilateral disease [16].

Multiple Endocrine Neoplasia 2 (MEN2) Syndrome (OMIM 171400)

In the early 1970s, Sizemore and his colleagues first described the syndrome of MEN2 and subclassified the syndrome into MEN2A and MEN2B. The MEN2A syndrome is an autosomal dominantly inherited disorder, characterized by a predisposition to medullary thyroid carcinoma, phaeochromocytoma, and hyperparathyroidism. MEN2B predisposes to the same tumour types but is also associated with mucosal neuromas and mesodermal abnormalities [17]. In 1993, activating mutations in the *RET* proto-oncogene on chromosome 11 were identified as the molecular drivers of MEN2 syndrome [18].

Increasing clinical data has led to the realization that very specific genotype–phenotype correlations exist in MEN2 syndrome. Overall, inherited mutations in the *RET* gene predict a 30–50% lifetime risk of developing a PC [19] and mutations in codon 634 and 918 of the *RET* gene are most commonly associated with the development of PC. The median age of onset is ~35 years and patients with a codon 634 mutation in *RET* have a 30% lifetime risk of developing bilateral tumours [20, 21]. Typically, patients with *RET* gene mutations will present with medullary thyroid carcinoma as the presenting disease but PC can be the presenting feature in ~5% of patients [21]. Similar to NF1, extra-adrenal and malignant tumours are very rarely associated with MEN2 [21] and the secretory pattern of *RET* mutated PC is predominately adrenergic [22].

Von Hippel–Lindau Disease (OMIM 193300)

VHL is a dominantly inherited familial cancer syndrome with multisystem involvement caused by germline inactivating mutations in the *VHL* tumour suppressor gene [23]. The most frequent features are retinal and central nervous system haemangioblastomas, renal cell carcinoma (RCC), and renal, pancreatic, and epididymal cysts [23]. The most important endocrine complications are phaeochromocytoma and non-functioning pancreatic islet cell neuroendocrine tumours. There are marked interfamilial differences in PC frequency in VHL disease. Thus in some families PC is the most common manifestation, but in others it is rare. These differences reflect genotype–phenotype correlations and the high risk of phaeochromocytoma associated with certain *VHL* missense mutations [24]. Large deletions, protein truncating mutations, and missense mutations that disrupt protein stability are associated with a high risk of retinal angioma, cerebral hemangioblastoma, and RCC, but a low risk of PC (type 1 VHL phenotype). On the other hand, missense mutations affecting amino acids on the VHL protein (pVHL) surface, predominate in VHL patients with PC (type 2 VHL) [24].

The clinical presentation of PC in VHL disease is similar to that in sporadic cases except that there is a higher frequency of bilateral or multiple tumours and, on average, an earlier onset (mean approximately 30 years) in VHL disease. As with sporadic tumours, PPGL in VHL disease may be sometimes be extra-adrenal and, in about 5% of cases, malignant. Interestingly, a particular secretory PC phenotype is associated with *VHL* gene mutations, namely a predominant noradrenergic secretory pattern related to down regulation of the phenylethanolamine N-methyltransferase (PNMT) enzyme in *VHL* mutated PC [22]. The PNMT enzyme normally acts to convert noradrenaline to adrenaline and therefore a predominant noradrenergic secretory phenotype in a PC can point towards an underlying *VHL* mutation [22].

Early detection of tumours in VHL disease can improve management and prognosis and affected individuals and at-risk relatives enter into an annual surveillance programme (see **Box 6.12.1**). All VHL patients and at-risk individuals are offered screening for a PC irrespective of whether there is a family history of PC but those with a positive family history of PC or a PC-associated missense mutation are given special attention. Patients with apparently non-syndromic familial or bilateral PC, or PC at a young age may have a germline *VHL* gene mutation [21] and should be offered *VHL* mutation analysis. In such cases the nature of the *VHL* mutation identified will indicate the risk of other types of VHL-related tumours. See **Figure 6.12.1**.

Box 6.12.1 Example of surveillance protocol for Von Hippel–Lindau disease in asymptomatic affected patients and at-risk relatives

1 Affected adult patient:
- Annual physical examination, and direct and indirect ophthalmoscopy
- MRI brain scan every 3 years to age 50 years and every 5 years thereafter
- Annual abdominal MRI (or ultrasonography if MRI is unavailable) for renal, adrenal, and pancreatic masses
- Annual 24-h urine collection for urinary fractionated metanephrines by mass spectrometric methods or plasma free metanephrines by mass spectrometric methods [45]

2 At-risk relative:
- Annual physical examination, and direct and indirect ophthalmoscopy from age 5 years until age 60 years
- MRI brain scan every 3 years to from age 15 to 40 years and then every 5 years until age 60 years
- Annual renal MRI or ultrasonography from age 16 years to age 65 years
- Annual 24-h urine collection for urinary fractionated metanephrines by mass spectrometric methods or plasma free metanephrines by mass spectrometric methods [45]

Succinate Dehydrogenase Subunit (*SDHA*, *SDHB* *SDHC*, and *SDHD*) Genes

The heterotetrameric succinate dehydrogenase enzyme complex (SDH) functions as a key enzyme coupling the oxidation of succinate to fumarate in the citric acid cycle and the reduction of ubiquinone to ubiquinol in the electron transport chain. Therefore, SDH facilitates the cellular metabolism of lipids, glucose, and amino acids, and feeds into the mitochondrial respiratory chain to generate cellular energy. The SDH complex comprises two hydrophilic subunits (SDHA and SDHB), and two hydrophobic subunits (SDHC and SDHD). The SDHA subunit is a flavoprotein, which covalently binds a flavine adenine dinucleotide (FAD) cofactor and contains the binding site for the succinate metabolite, coupling the oxidation of succinate to fumarate and reduction of FAD to FADH2. The SDHB subunit contains three iron clusters which are employed in the transfer of electrons from FADH2 to ubiquinone. Two LYR motifs are essential binding sites to enable the incorporation of the three Fe-S clusters within the final structure of complex II. The SDHC and SDHD subunits anchor the complex to the inner mitochondrial membrane and facilitate the binding of ubiquinone. Each subunit of the SDH complex is encoded by its namesake gene, the *SDHA* gene (OMIM 600857) maps to the short arm of chromosome 5 (5p15), *SDHB* (OMIM 185470) to 1p36.13, *SDHC* (OMIM 602413) to 1q23.3 and *SDHD* to 11q23.

Inactivation of the SDH complex results in accumulation of the metabolite succinate as oxidative dehydrogenation of succinate to fumarate in the citric acid cycle is no longer feasible [25]. Succinate accumulation is postulated to be a key driver in tumourigenesis and succinate is now referred to as an 'oncometabolite'[25]. Succinate accumulation inhibits 2-oxoglutarate-dependent dioxygenases, including DNA and histone demethylase enzymes and hypoxic gene response regulators. As a consequence, SDH-deficient tumours demonstrate epigenetic abnormalities, namely hypermethylation and an activated hypoxic gene response [26, 27]. See Figure 6.12.2.

To date >445 germline mutations have been described in SDH subunit genes and the majority of these have been described in association with PPGL [28]. *SDH* mutations are heterozygous mutations inherited in an autosomal dominant fashion and tumourigenesis is initiated by bi-allelic loss as per the Knudson 'two hit' hypothesis. The most common type of mutation affecting the *SDH* genes are missense mutations [28].

Mutations in one of the four *SDHx* genes account for 30–40% of hereditary PPGL cases and the majority of germline *SDHx* mutations reported to date have been identified in the *SDHB* gene (52%), followed by mutations in *SDHD* (35%) [28]. Mutations in the *SDHx* genes predispose to multiple, synchronous PGL, and bilateral PC. Similar to the secretory phenotype associated with *VHL* mutated PC, *SDHx* gene mutations also down regulate the intratumoural PNMT enzyme, resulting in a predominant noradrenergic secretory phenotype [22].

The strongest existing genotype–phenotype correlation for *SDHx*-mutated PPGL, is the risk of malignancy associated with *SDHB* mutated PPGL. Germline *SDHB* gene mutations have been detected in up to 50% of patients with a malignant PPGL and associated 5-year survival is less than 50% [29]. Extra-adrenal PGLs in the abdomen and pelvis as well as adrenal PC are more commonly associated with *SDHB* mutations than other *SDHx* gene subunits but tumours can arise in the neck and thorax [29–31].

Mutations in the *SDHC* and *SDHD* genes are most commonly associated with head and neck paraganglioma (HNPGL, derived from parasympathetic ganglia) than PC or PGL. *SDHD* is the most common of the *SDHx* subunit genes to be implicated in HNPGL and tumours are frequently multifocal with a lower malignant potential compared to *SDHB* [32]. Until 2010, *SDHA* gene mutations were only associated with autosomal recessive metabolic encephalopathy

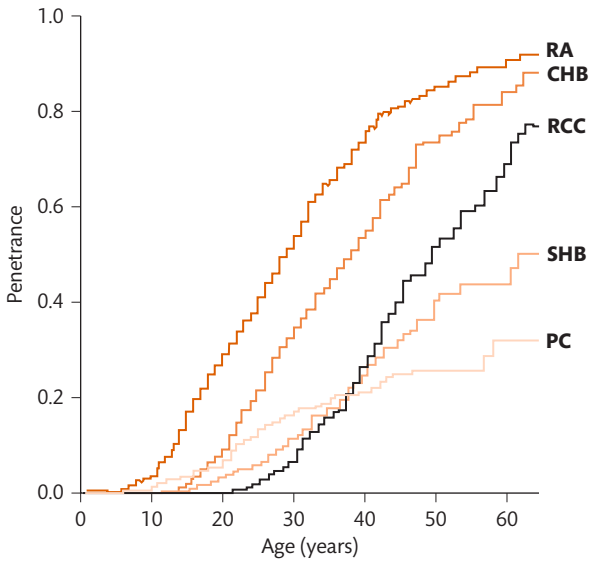

Figure 6.12.1 Age-related risks for the five major manifestations of von Hippel–Lindau disease. RA, retinal angioma; CHB, cerebellar haemangioblastoma; SHB, spinal haemangioblastoma; RCC, renal cell carcinoma; PC, phaeochromocytoma.

syndrome (Leigh syndrome) but *SDHA* mutations are now also recognized as rare cause of hereditary PPGL [33, 34].

Mutations in the *SDHx* complex genes are also associated with the development of other tumour types including gastrointestinal stromal tumours (GIST), RCC, and pituitary tumours. GIST is the second most common tumour phenotype after PPGL [28]. Most GIST tumours in adults harbour somatic mutations in the *KIT* or *PDGFRA* genes and respond to the tyrosine kinase inhibitor Imatinib. Wild-type GIST (wtGIST), refer to tumours that are negative for *KIT* and *PDGFRA* gene mutations and account for 15% of adult and 85% of paediatric GIST tumours [35]. Almost 90% of wtGIST are associated a germline mutation in the *SDHx* complex genes (75%) or a somatic epigenetic inactivation of the *SDHC* gene [35]. Interestingly *SDHA* mutations are more frequent than other SDH subunit genes [28, 34]. Non-SDH associated wtGIST are associated with germline mutations in *NF1* or less commonly somatic *BRAF* mutations. Differences in clinical phenotype, tumour location and histology can help guide genetic testing further in wtGIST (Figure 6.12.3).

Germline *SDHx* gene mutations have been described in the context of renal and PPGL tumour syndrome (RAPTAS) [36, 37]. SDH-deficient RCC account for approximately 0.2% of all cases of RCC and to date 83% of the germline mutations identified in SDH-deficient RCCs occurred in *SDHB* [28, 37]. SDHB-deficient renal carcinoma was accepted as a provisional entity in the 2013 International Society of Urological Pathology (ISUP) Vancouver Classification and a unique morphology consisting of solid architecture, intracytoplasmic inclusions and intratumour mast cells is characteristic of SDHB-deficient RCC [38]. Pituitary tumours have also occasionally been associated with *SDHx* gene mutations and the estimated incidence is 0.3% [28].

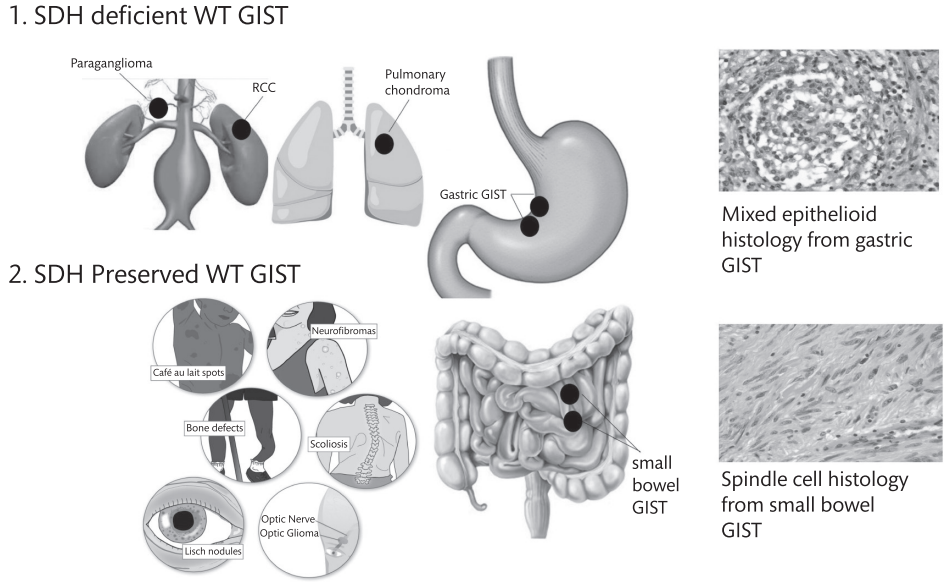

Figure 6.12.3 Differences in clinical presentation and histology between SDH-deficient and SDH preserved (e.g. *NF1*-related) wild-type GIST.

The *SDHAF2* gene (OMIM 613019) responsible for the flavination of the SDHA protein has very rarely been implicated in hereditary PPGL since its discovery in 2009 and a recent study of over 900 patients, has reported the prevalence of *SDHAF2* mutations in patients presenting with PPGL as 0.1% [39].

TMEM127, *MAX*, and *FH* Gene Mutations

The *TMEM127* gene (OMIM 613403) is localized to chromosome 2 and functions as a tumour suppressor gene. Although the precise molecular function of *TMEM127* remains poorly understood, this gene product participates in the mTor signalling pathway [7]. The largest studies to date investigating the role of *TMEM127* in hereditary PPGL, have estimated the incidence of mutations in this gene at approximately 2% [39, 40]. Mutations in *TMEM127* predispose to the development of PC, with a later age of onset (41.2 years) compared to other gene mutations such as *VHL* or *SDHB*. Extra-adrenal, malignant and bilateral tumours are rare with *TMEM127* [7, 39, 40], as are cases of RCC or co-occurring cases of RCC and PPGL [36, 41].

Biallelic loss of the *MAX* tumour suppressor gene was first implicated in hereditary PPGL in 2011 [8]. The *MAX* gene (OMIM 154950) localizes to chromosome 14 and the MAX protein contains a basic helix loop helix zipper that is commonly involved in a complex formation and sequences in the promoter region of hundreds of genes encoding for proteins essential in cellular metabolism and angiogenesis [42]. The estimated incidence of *MAX* mutations in PPGL is less than 2% and typically associated with adrenal PC and rarely with extra-adrenal or malignant PPGL [8, 39] or RCC [36, 42].

The most recent PPGL predisposition gene to be discovered and routinely screened for in clinical practice, is *FH* (OMIM 136850), which is localized to chromosome 1 and encodes its namesake enzyme in the citric acid cycle. Mutations in *FH* cause accumulation of the 'oncometabolite' fumarate which, similar to succinate accumulation in SDH-deficient tumours, drives tumourigenesis through inhibition of 2-oxoglutarate-dependent dioxygenases and promoting a pseudohypoxic and hypermethylation phenotype [27, 43]. *FH* mutations are most commonly associated with renal cell carcinoma (type 2 papillary RCC) and cutaneous and uterine leiomyomas (hereditary leiomyomatosis and renal cell cancer syndrome, HLRCC) and are rarely associated with PPGL [9, 44].

The Role of Next Generation Sequencing in PPGL

The Endocrine Society guidelines on the management of PPGL recommended that genetic screening should be considered in all patients with PPGL and that *SDHx* mutations in particular should be screened for in patients with extra-adrenal PGL [45]. Next generation sequencing (NGS) has facilitated a cost effective and time efficient transition from previous methods of targeted, sequential, analysis of individual susceptibility genes in hereditary PPGL. It has been estimated that a second-generation sequencing test for a 'panel' of nine susceptibility genes predisposing to PPGL (*MAX, RET, SDHA, SDHB, SDHC, SDHD, SDHAF2, TMEM127*, and *VHL*), can achieve a 70% cost reduction compared to standard targeted sequencing methods of individual candidate genes [10]. More recent NGS panels also include *FH*. It is advised that genetic testing is offered within the framework of best clinical practice and that patients are offered genetic counselling before and after genetic testing [45]. Furthermore, it is very important that each identified variant is correctly interpreted before presymptomatic genetic counselling of relatives is performed or a personalized management approach for the patient is adopted [45].

SDHB Immunohistochemistry in Clinical Practice

Biallelic inactivation of any of the *SDH* subunit genes, will usually result in destabilization of the SDH enzyme complex, which can be detected by loss of staining for the SDHB protein on immunohistochemistry (IH) [46]. Negative immunostaining for SDHB is now a validated marker for germline mutations in *SDHA*/*SDHB*/*SDHC*/*SDHD* and provides a reasonable assessment of pathogenicity of an identified novel *SDHx* variant [46]. SDHB IH has been adapted into clinical practice and serves a number of important clinical applications including: (i) the early diagnosis of SDH deficiency in specific phenotypes such as PPGL, wild-type GIST and specific histological subtypes of RCC; (ii) additional prognostic information regarding malignant risk associated with PPGL [47]; (iii) a cost effective functional tool for the assessment of *SDHx* variant pathogenicity; and (iv) SDHB IH can also identify those tumours that are SDH-deficient due to a somatic mutation or epigenetic inactivation.

Surveillance Protocol for PPGL Predisposition Syndromes

The cumulative evidence to date would suggest that surveillance of asymptomatic gene carriers can lead to early tumour detection and therefore surveillance protocols should be designed to maximize the benefit of early tumour detection and minimize risks associated with ionizing radiation exposure and anxiety generated by false positive test results. At present, given the low incidence of PPGL associated with *NF1* and the diverse clinical phenotype, the current recommendation is for annual clinical review in dedicated specialist clinics and testing only if patients are clinically symptomatic [16].

The most robust evidence and experience for surveillance protocols exist for VHL and MEN2A. See **Box 6.12.1**.

Surveillance for *RET* mutation carriers differs depending on the exact genotype due to the well-defined genotype–phenotype correlations [19]. It is recommended that those patients identified with a highest risk mutation (such as mutations in codon 918), undergo a prophylactic thyroidectomy in the first year of life and that screening for PC is commenced at the age of 11 years [48] using the same biochemical tests as described for *VHL* mutation carriers in **Box 6.12.1**. For those carriers with a high risk *RET* mutation (e.g. codon 634) a review and prophylactic thyroidectomy is recommended before the age of five years and that screening for PC is commenced at the age of 11 years. For moderate or low-risk *RET* mutations, a review and surgery are advised from the age of 5 years and screening for PC is advised to commence from the age of 16 years [48]. Annual clinical review and biochemical measurements of serum calcitonin

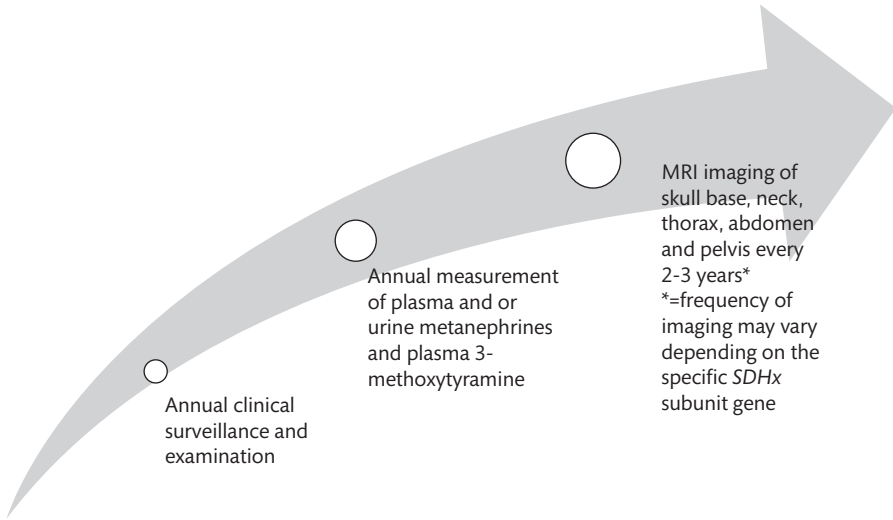

Figure 6.12.4 Demonstrates an acceptable clinical, biochemical, and radiological surveillance strategy for *SDH* gene carriers.

following thyroidectomy and calcium testing from the onset of PC screening, is also recommended [48].

Unlike VHL and MEN2 disease, there is relatively less experience of the utility of surveillance in *SDHx* gene carriers or carriers of the rare predisposition genes (*TMEM127, MAX, FH, SDHAF2*).

At present surveillance for *SDHx* gene carriers is advised to begin at the age of 5 years for *SDHB* carriers and 10 years for carriers of a pathogenic variant in *SDHA*/*SDHC*/*SDHD* [49, 50] and to continue lifelong, if acceptable to the patient [51]. Although regular surveillance for *SDHx* mutation carriers is a widely accepted clinical practice, there is no consensus on the frequency of surveillance or on the optimal radiological modality. The current recommendation is that annual clinical review is performed in addition to measurement of plasma metanephrines or urine metanephrines (Figure 6.13.4) [44]. However the frequency of cross-sectional imaging and the choice of radiological modality differs between practices and although the Endocrine Society guidelines recommend cross-sectional imaging for *SDHx* carriers, to diagnosis non-secretory tumours, they do not specify appropriate time intervals between imaging studies or a preferred imaging modality [45]. In recent years, as updated information regarding disease penetrance of the *SDHx* mutations has become available, concern regarding unnecessary radiation exposure in this group has mounted and more centres are recommending MRI alone as the imaging modality of choice [50]. This approach is supported by a recent study which identified that MRI was as sensitive as 18F-fluorodeoxyglucose (FDG) PET CT in the diagnosis of occult tumours in *SDHx* carriers [51]. Finally the interval frequency at which radiological screening is carried out remains contentious but it is widely accepted that the first radiological screen is the most important and yields the highest diagnoses of tumours in this cohort [50, 51]. At present, studies would support baseline MRI imaging of skull base, neck, thorax, abdomen, and pelvis at first clinic visit for all asymptomatic *SDHx* carriers, followed by two to three yearly interval MRI scanning. An individual approach to radiological surveillance based on the individual subunit gene is now recommended (e.g. *SDHB* carriers require more frequent imaging compared to *SDHA*/*SDHC*/*SDHD* carriers [52]; see Figure 6.12.4). There is a need for additional long-term surveillance data to better inform this challenging area of practice.

Finally, data is lacking to guide surveillance protocols for the less common predisposition genes (*TMEM127, MAX, FH, SDHAF2*) and at present annual clinical review, annual biochemical testing with urinary or plasma metanephrines and judicious, individual case-based use of cross-sectional imaging is advised.

Carney's Complex

Constantine A. Stratakis and Fabio R. Faucz

Introduction

Carney's complex (CNC) is an autosomal dominant disorder, which was described in 1985 as 'the complex of myxomas, spotty pigmentation, and endocrine overactivity' in 40 patients [1]. Since then, several hundred index cases have been reported, including the first molecularly confirmed CNC patient seen by Dr Harvey Cushing in 1914, resulting in better definition of the disease and the establishment of diagnostic criteria [2–4]. As implied from the initial description, CNC is not only a multiple neoplasia syndrome, but it is also associated with pigmented lesions of the skin and mucosae, as well as other non-endocrine tumours [5]. Before the characterization of CNC as a syndrome, several patients described under the acronyms NAME (nevi, atrial myxomas, and ephelides) and LAMB (lentigines, atrial myxomas, and blue nevi) can now be probably considered CNC patients [6, 7]. Thus, lentigines, blue nevi, café-au-lait spots, and cutaneous tumours, such as myxomas, fibromas, and others, are major features of the disease [5, 8–11]. However, we cannot say that CNC is completely understood. Interestingly, in 2017, two cases of corticotropinoma in CNC patients have been published, adding a new uncommon feature [12, 13].

The clinical characteristics of CNC have been reviewed and are presented in **Box 6.13.1** [3, 10]. A definite diagnosis of CNC is given if two or more major manifestations are present [5, 10, 14, 15]. Other related manifestations may accompany or suggest the presence of CNC but are not considered diagnostic of the disease (**Box 6.13.1**). Cutaneous manifestations constitute three of the major disease manifestations: (1) spotty skin pigmentation with a typical distribution (lips, conjunctiva, and inner or outer canthi, genital mucosa); (2) cutaneous or mucosal myxoma; and (3) blue nevi (multiple) or epithelioid blue nevus. Suggestive or associated with CNC findings but not diagnostic are: (1) intense freckling (without darkly pigmented spots or typical distribution); (2) multiple blue nevi of common type; (3) café-au-lait spots or other 'birthmarks'; and (4) multiple skin tags or other skin lesions, including lipomas and angiofibromas.

The relationship between the cutaneous and non-cutaneous manifestations of CNC appears to be an essential clue to the molecular aetiology of the disease. According to the latest reports, more than half of CNC patients present with both characteristic dermatological and endocrine signs; however, a significant number of patients present with skin lesions that are only 'suggestive' and not characteristic of CNC [10]. A recent classification based on both dermatological and endocrine markers has subgrouped CNC patients as: multisymptomatic (with extensive endocrine and skin signs); intermediate (with few dermatological and endocrine manifestations); and, paucisymptomatic (with isolated primary pigmented nodular adrenocortical disease (PPNAD) alone and no cutaneous signs) [10]. A recommended clinical surveillance of patients with CNC is presented in **Box 6.13.2.**

Skin Manifestations in CNC

Skin lesions are consistently reported in the majority of the CNC patients (above 80%), the most common being lentigines (in 70–75% of cases). Other pigmented lesions, most frequently blue nevi and café-au-lait spots, with or without lentigines, are seen in approximately 50% of CNC patients. The effort to systemize the knowledge on the cutaneous lesions in CNC patients is driven by their high diagnostic value—presented early in life and easily recognizable, the skin manifestations are an early sign that directs dermatologists' attention towards underlying endocrine or other pathology. In an attempt to outline the most specific and sensitive skin abnormalities in CNC, several research groups have published exhaustive analyses that add to an improved diagnostic and preventive approach [10, 11, 16]. The major challenge appears to be in distinguishing the disease-associated prominent lesions from the more common non-CNC-specific, age- or sun-related skin alterations.

Lentigo is a hamartomatous melanocytic lesion, clinically similar but histologically different from freckles [17]. Morphologically, lentigines are flat, poorly circumscribed, brown-to-black macules,

Box 6.13.1 Diagnostic criteria for Carney's complex

Major diagnostic criteria for Carney's complex

1. Spotty skin pigmentation with typical distribution (lips, conjunctiva, and inner or outer canthi, vaginal and penile mucosal)
2. Myxoma[a] (cutaneous and mucosal)
3. Cardiac myxoma[a]
4. Breast myxomatosis[a] or fat-suppressed magnetic resonance imaging findings suggestive of this diagnosis
5. Primary pigmented nodular adrenocortical disease[a] or paradoxical positive response of urinary glucocorticosteroid excretion to dexamethasone administration during Liddle's test[b]
6. Acromegaly due to growth hormone-producing adenoma[a]
7. Large-cell calcifying Sertoli cell tumour[a] or characteristic calcification on testicular ultrasound
8. Thyroid carcinoma[a] or multiple, hypoechoic nodules on thyroid ultrasound in a young patient
9. Psammomatous melanotic schwannomas[a]
10. Blue naevus, epithelioid blue naevus[a]
11. Breast ductal adenoma[a]
12. Osteochondromyxoma[a]

Supplementary criteria

1. Affected first-degree relative
2. Inactivating mutation of the *PRKAR1A* gene

Findings suggestive of or possibly associated with Carney's complex, but not diagnostic for the disease

1. Intense freckling (without darkly pigmented spots or typical distribution)
2. Blue naevus, common type (if multiple)
3. Café-au-lait spots or other birthmarks
4. Elevated insulin-like growth factor-1 levels, abnormal glucose tolerance test, or paradoxical growth hormone response to thyrotropin-releasing hormone testing in the absence of clinical acromegaly
5. Cardiomyopathy
6. Corticotropinoma
7. Pilonidal sinus
8. History of Cushing's syndrome, acromegaly, or sudden death in extended family
9. Multiple skin tags or other skin lesions; lipomas
10. Colonic polyps (usually in association with acromegaly)
11. Hyperprolactinaemia (usually mild and almost always combined with clinical or subclinical acromegaly)
12. Single, benign thyroid nodule in a young patient; multiple thyroid nodules in an older patient (detected on ultrasonography)
13. Family history of carcinoma, in particular of the thyroid, colon, pancreas, and ovary; other multiple benign or malignant tumours

[a] After histological confirmation.
[b] It has been shown that patients with primary pigmented nodular adrenocortical disease exhibit a paradoxical increase in cortisol secretion in response to Liddle's test (administration of dexamethasone at doses of 2 mg/d for 2 days followed by 8 mg/d for 2 days); this abnormal cortisol response is now used as a criterion for the diagnosis of the disease.

Box 6.13.2 Recommended clinical surveillance of patients with CNC

1. Post-pubertal paediatric and adult patients:
   - Echocardiogram (annually or biannually for adolescent patients with a history of excised myxoma)
   - Testicular ultrasound (annually)
   - Thyroid ultrasound (baseline examination; it may be repeated, as needed)
   - Transabdominal ultrasound of the ovaries (baseline examination; it may be repeated, as needed)
   - Urinary free cortisol levels (annually)
   - Serum IGF-1 levels (annually)
2. Prepubertal paediatric patients:
   - Echocardiogram (annually; *biannually* for patients with a history of excised myxoma)
   - Testicular ultrasound for boys; close monitoring of growth rate and pubertal staging (annually)
3. Further evaluation of patients of all age groups, as needed:

   For **primary pigmented nodular adrenocortical disease**, in addition to urinary free cortisol levels:
   - Diurnal cortisol levels (11.30 p.m., 12.00MN and 7.30 a.m., 8.00 a.m. sampling)
   - Dexamethasone-stimulation test (modified Liddle's test, as per Stratakis *et al.* [10])
   - Adrenal computed tomography

   For **gigantism/acromegaly**, in addition to serum IGF-1 levels:
   - Pituitary magnetic resonance imaging
   - 3-hour oral glucose tolerance test (oGTT)
   - 90-minute thyrotropin-releasing hormone (TRH) testing

   For psammomatous melanotic schwannoma:
   - Magnetic resonance imaging (brain, spine, chest, abdomen, retroperitoneum, pelvis)

usually less than 0.5 cm in diameter, but these may differ in different ethnic groups. In African Americans, for example, lentigines may be slightly raised, dark papules, similar to nevi [17]. In contrast to the common freckles, on histological examination lentigines show basal cell layer hyperpigmentation associated with an increased number of melanocytes (hyperplasia), the majority of which appear hypertrophic. This distinguishes them from freckles (ephelides), which present with a regular number of melanocytes and are pigmented as a result of melanin disposition in the surrounding keratinocytes.

Lentiginosis is one of the manifestations of CNC that can occur early; lentigines usually acquire their typical intensity and distribution during the peripubertal period [10, 11, 18]. They typically involve the centrofacial area, including the vermilion border of the lips, and the conjunctiva, especially the lacrimal caruncle and the conjunctival semilunar fold; intraoral pigmented spots have also been reported [19]. In contrast to age-related skin lesions, CNC-associated lentigines tend to fade after the fourth decade of life, but may be detectable as late as the eighth decade [10, 18].

The next very common skin manifestation in CNC is a lesion known as blue nevus, which is infrequent in the general population. Blue nevi can be seen as small (usually <5 mm), blue to black-coloured marks with a circular or star-shaped appearance. Their distribution is variable; most often they occur on the face, trunk, and limbs, and less frequently on the hands or feet.

An interesting subtype of blue nevus, which is exceedingly rare as a sporadic lesion in the general population but is sometimes seen in patients with CNC, is the epithelioid blue nevus [19, 20]. Epithelioid blue nevus usually presents with intensive pigmentation and poorly circumscribed proliferative regions containing two cell types: heavily pigmented globular and fusiform cells; and lightly pigmented, polygonal spindle melanocytes with a single prominent nucleolus [19]. In contrast to blue nevi, epithelioid blue nevi

display no dermal fibrosis [19]. After comprehensive comparative analysis and based on the fact the epithelioid blue nevi have also been reported in patients with none of the other features of CNC, epithelioid blue nevi are not considered pathognomonic for CNC but simply associated with the disease [10, 19].

Blue nevi and lentigines in CNC are often accompanied by café-au-lait spots, which are otherwise rarely present as an isolated skin manifestation of CNC. Like lentigines, café-au-lait spots can be present at birth. In general, café-au-lait spots in CNC are less intensely pigmented than those seen in McCune–Albright syndrome and they are more similar to those seen in the neurofibromatosis syndromes.

The third most common skin manifestation of CNC—cutaneous myxoma—is reported in between 30% and 55% of the studied patients [5, 10, 11]. Cutaneous myxomas rarely exceed 1 cm in diameter and often affect the eyelids, ears, and nipples, but may also be seen on other areas of the face, ears, trunk, and perineum. They usually appear as asymptomatic, sessile, small, opalescent, or dark pink papules and large, finger-like, pedunculated lesions. They are typically diagnosed early in life, most often during the teenage years (mean age, 18 years). In the majority of patients (>70%) cutaneous myxomas show multiple appearance and a tendency to recur. The frequency of myxoma may be underestimated because clinical diagnosis may be uncertain at times; hence, histological examination is strongly recommended when in doubt. Histopathologically, myxomas are characterized by a location in the dermis or, occasionally, more superficially in the subcutaneous tissues, sharp circumscription (sometimes encapsulation), relative hypocellularity with abundant myxoid stroma, prominent capillaries, lobulation (larger lesions), and occasional presence of an epithelial component. It is estimated that approximately 80% of CNC patients with life-threatening cardiac myxoma present with cutaneous myxoma earlier in life; therefore, cutaneous myxoma can serve as good marker for the disease with high prognostic significance [5, 10, 11].

Other CNC-related skin abnormalities include melanocytic and atypical nevi, and the so-called Spitz nevus. Occasionally, depigmented lesions can be present at birth or, more often, develop in early childhood. These manifestations, although usually not considered specific, may be suggestive for the disease or may accompany other CNC signs of importance for the diagnosis.

Molecular Genetics

Most cases of CNC are caused by inactivating mutations in the gene encoding one of the subunits of the protein kinase A (PKA) tetrameric enzyme, namely regulatory subunit type 1 α (*PRKAR1A*), located at 17q22–24 [5]. Although a second locus (2p16) has been implicated, sequencing of the region in the linked families did not reveal alterations in known coding sequences [21].

PRKAR1A extends to a total genomic length of approximately 21 kb and consists of 11 exons, encoding a total of 381 amino acids, with a dimerization/ docking domain, and two cAMP binding domains, A and B. Since the identification of *PRKAR1A* mutations in CNC, more than 140 disease-causing pathogenic sequence changes have been reported (http://prkar1a.nichd.nih.gov/hmdb/intro.html); they are spread over the entire coding sequence of the gene, without a notable preference for a region or exon. Structurally, the majority of the mutations consists of base substitutions, small deletions, and insertions or combined rearrangements, involving up to 15 bp [5, 22]; although rare, large *PRKAR1A* deletions have been reported [23, 24].

Mutations in *PRKAR1A* are seen in more than 70% of the patients with classical CNC and, in most cases, they lead to complete inactivation of one of the *PRKAR1A* alleles as a result of premature stop codon generation and subsequent nonsense-mediated mRNA decay (NMD) [5, 11, 22]. In its inactive form, PKA is a tetramer composed of two regulatory and two catalytic subunits [25]. The decreased cellular concentration of regulatory subunits results in a balance shift between the formation and the disassembly of the PKA tetramer, towards the release of the catalytic subunits. The free catalytic subunits, which are active serine–threonine kinases, further phosphorylate a series of targets that regulate downstream effectors and transcription of specific genes, mediating cell growth and differentiation [26]. Thus, functionally, the mechanism by which *PRKAR1A* haploinsufficiency causes CNC is through excess cellular cAMP signalling in affected tissues [27]. CNC lesions frequently show loss-of-heterozygosity, suggesting a tumour suppressor function for PRKAR1A [4, 5].

Although significantly less frequent, mutations that escape NMD and lead to the expression of an abnormal, defective PRKAR1A protein have been reported [24, 28–30]. These expressed mutations may lead to a characteristic phenotype that reflects the location and the type of the genetic change. Examples include a germline in-frame deletion of exon 3 which results in severe expression of the majority of the CNC manifestations—a phenotype illustrating the importance of exon 3 in linking the dimerization/docking and the first cAMP binding domain [24]. In contrast, another in-frame variant—a splice-site deletion that eliminates exon 7—is seen associated mostly with lentiginosis and the adrenal component of CNC, PPNAD. Just as lentiginosis is the most common non-endocrine CNC manifestation, PPNAD is the most frequently observed endocrine tumour of the disease. Thus, the presence of only two features of CNC, the most common ones, with this splice-site variant is consistent with the anticipation of a milder phenotype associated with certain splice mutations, due to their incomplete penetrance at the mRNA level (i.e. not all DNA molecules harbouring the splice variant result in mRNA species lacking exon 7) [24, 28–31].

Apart from the above-mentioned, expressed mutant PRKAR1A protein isoforms, several other expressed isoforms that result from single amino acid substitutions have been reported [29, 30]. Detailed *in vitro* analysis of their effects on protein function have revealed important PRKAR1A domain features [30, 32]. The six naturally occurring missense substitutions examined by this study (p.Ser9Asn, p.Arg74Cys, p.Arg146Ser, p.Asp183Tyr, p.Ala213Asp, p.Gly289Trp) are spread over all the functional domains of the protein. Although, as mentioned before, the low number of individuals affected by each of these mutations prevented detailed phenotype–genotype analysis, these studies support the previous suggestion that the alteration of PRKAR1A function alone (and not only its complete loss) is sufficient to increase PKA activity, leading to CNC.

Until recently, no genotype–phenotype correlations had been found for the different stop codon mutations, which are expected to uniformly lead to lack of the *PRKAR1A* mutant allele's protein product in cells. This was because most of the mutations were identified in single patients only and only two (c.491–492delTG/

p.Val164fsX4, and c.709(-7-2) del6(TTTTTA)) had been seen in more than three kindreds [5, 28]. The first study to explore all *PRKAR1A* mutations found to date against all CNC phenotypes was recently completed; 353 individuals, 258 of whom (73%) were positive for a *PRKAR1A* mutation, were studied [11]. Several features that distinguish *PRKAR1A* mutation carriers from mutation-negative CNC patients were identified; the former presented more frequently and earlier in life with pigmented skin lesions, myxomas, thyroid, and gonadal tumours. In addition, essential correlations between certain genetic defects and the severity and type of CNC manifestations were found. Bertherat *et al.* [11] outlined subgroups of patients; the first group presented with isolated PPNAD, in some cases accompanied with lentiginosis. In this group the following tendencies were observed: (1) patients diagnosed before 8 years of age were rarely carriers of *PRKAR1A* mutations; and (2) most of the patients with isolated PPNAD and the presence of *PRKAR1A* mutation were carriers of either the c.709(-7-2) del6(TTTTTA) mutation (P <0.0001) or the c.1A>G/p.Met1Val substitution affecting the initiation codon of the protein. These observations were in line with previously published reports [5, 28] and both mutations are rather rare. Although the molecular mechanism of the p.Met1Val substitution is not completely clear, it is the only mutation that alters the protein initiation site, and may, in theory, result in alternative initiation [33]; c.709(-7-2) del6(TTTTTA) is a splice variant that is expected to result in an exon skip, frame shift, and premature stop codon generation. However, since it does not affect the two immediate nucleotides on either site of the splice junction, it is expected to lead to splicing in less than 100% of the molecules that harbour it, and thus, presumably, to lead to a milder phenotype. The fact that a milder phenotype involves only the adrenal and skin is suggestive of their high sensitivity to changes in PKA activity.

The second group of CNC patients that was suggested to have a particular genotype–phenotype correlation comprised individuals with myxomas (affecting all locations—skin, heart, and breast), PMS, thyroid tumours, and large-cell calcifying Sertoli cell tumours (LCCSCT). In these patients, *PRKAR1A* mutations were seen substantially more often. Related to this is the recognition that certain tumours present at a significantly younger age in *PRKAR1A* mutation carriers: cardiac myxomas (P = 0.02), thyroid tumours (P = 0.03), and LCCSCTs (P = 0.04) [11]. Another finding in these patients was that mutations that escaped NMD and led to an alternate, usually shorter, protein were associated with an overall higher total number of CNC manifestations (P = 0.04).

In terms of pigmented skin lesions in CNC, two important correlations have been observed: (1) lentigines (as well as PMS, acromegaly, and cardiac myxomas), were seen significantly more often in CNC patients with exonic *PRKAR1A* mutations, compared to those with intronic ones (P = 0.04); and (2) lentigines (as well as cardiac myxoma and thyroid tumours) were significantly associated with the hot spot c.491–492delTG mutation compared to all other *PRKAR1A* defects (P = 0.03). These data add greatly to the understanding of the molecular mechanisms of the involvement of *PRKAR1A* in endocrine and other tumourigenesis and, thus, for genetic counselling and prognosis in CNC families.

Interestingly, a 2.3-Mb deletion in chromosome band 17q24.2–q24.3, which involved *PRKAR1A* together with another 13 genes, resulted in a number of clinical features, including posterior laryngeal cleft, growth restriction, microcephaly, and moderate mental retardation. The only CNC manifestation was numerous freckles and lentigines at a young age [34]; the authors called the observed phenotype 'CNC plus'.

To date, the molecular causes underlying the formation of pigmented skin lesions in CNC are not fully understood. A possible mechanism involves the PKA-mediated activation of pathways downstream of the melanocortin receptors (MCRs), which form a subfamily of the G protein-coupled receptors (GPCRs) and regulate a wide variety of processes, including skin pigmentation [35–37]. The melanocortin 1 receptor (MC1R) is expressed preferentially in epidermal melanocytes and is known to be the key regulator of mammalian pigmentation [36, 38]. MC1R is stimulated by the proopiomelanocortin-derived melanocyte-stimulating hormone and adrenocorticotrophic hormone (ACTH) and, in turn, activates the rate-limiting enzyme in melanin synthesis, tyrosinase. As a GPCR, MC1R is positively coupled with adenylate cyclase, and its actions are mainly mediated by PKA, in coordination with other signalling molecules involving protein kinase C (PKC) and MAPKs [39–41].

Relationship to Other Syndromes

CNC shares clinical features and molecular pathways with several other familial lentiginosis syndromes, such as McCune–Albright syndrome (OMIM #174800), Peutz–Jeghers (OMIM #175200), LEOPARD (OMIM #151100), Noonan's (OMIM #163950), Cowden's disease (OMIM #158350), and Bannayan–Ruvalcaba–Riley syndrome (OMIM #153480). In all of these conditions skin lesions accompany underlying endocrine and/or other abnormalities, which, as in CNC, are considered an important diagnostic sign.

Probably the closest, at least in terms of a molecular pathway link, to CNC is McCune–Albright syndrome. Patients with this condition have characteristic lesions that affect predominantly three systems: the skin, the endocrine system, and the skeleton. The café-au-lait spots in McCune–Albright syndrome patients are similar to those observed in CNC, but tend to be more intensely pigmented. McCune–Albright syndrome is caused by postzygotic, activating, somatic mutations of *GNAS,* located on 20q13, which encodes the adenylate cyclase-stimulating G α protein (Gsa) of the heterotrimeric G protein [42]. G proteins couple hormone receptors to adenylyl cyclase and are therefore required for hormone-stimulated cAMP synthesis. Because of the somatic nature of the genetic defect, the presentation of the disease is mosaic and the level of clinical involvement of any tissue is highly variable. The mutations in *GNAS* are always missense substitutions at the critical sites for the GTPase inactivation (amino acid positions p.Arg201 and p.Gln227), and, in contrast to *PRKAR1A* defects, lead to constant protein activation and increased cAMP production.

We have reported another endocrine lesion that is associated with increased tissue levels of cAMP, isolated micronodular adrenocortical hyperplasia (iMAD). In these patients, inactivating mutations in the genes encoding phosphodiesterases types 11A (*PDE11A*) and 8B (*PDE8B*) have been reported [43–45]. iMAD patients were initially considered CNC patients, but it soon became clear that iMAD is not the same as PPNAD [46].

Peutz–Jeghers syndrome, another autosomal dominant familial lentiginosis syndrome, is characterized by melanocytic macules of the lips, buccal mucosa, and digits, multiple gastrointestinal hamartomatous polyps, and an increased risk of various neoplasms.

The lentigines observed in patients with Peutz–Jeghers syndrome shows similar density and distribution to the ones in CNC [17]. Peutz–Jeghers syndrome has been elucidated at the molecular level [47, 48]; the disease was first mapped to chromosome 19p13.3 and, soon after, the gene encoding the serine–threonine kinase 11 (*STK11* also known as *LKB1*) was found to be mutated in most patients [47–49]. The proposed mechanism of the disease is through elimination of the kinase activity of the STK11/LKB1 tumour suppressor protein.

LEOPARD is an acronym for the manifestations of the syndrome comprising: multiple lentigines, electrocardiographic conduction abnormalities, ocular hypertelorism, pulmonic stenosis, abnormal genitalia, retardation of growth, and sensorineural deafness [50]. LEOPARD is allelic to Noonan's syndrome; both diseases are linked to mutations in *PTPN11* (12q24), the gene encoding the non-receptor tyrosine phosphatase Shp-2 [51, 52]. The protein encoded by this gene is a member of the protein tyrosine phosphatase family, proteins that are known to regulate a variety of cellular processes including cell growth, differentiation, mitotic cycle, and oncogenic transformation.

Cowden's disease and Bannayan–Ruvalcaba–Riley syndrome share clinical characteristics, including mucocutaneous lesions, hamartomatous polyps of the gastrointestinal tract, and increased risk of developing neoplasms. They are described extensively elsewhere in this book (see Chapter 6.15). Both conditions are caused by mutations in the *PTEN* gene [53–55]. *PTEN* is located on 10q23.31 and encodes phosphatidylinositol-3, 4, 5-trisphosphate 3-phosphatase. The gene was recognized as a tumour suppressor gene and has been found to be mutated in a number of tumours [56]. It contains a tensin-like domain as well as a catalytic domain similar to that of the dual-specificity protein tyrosine phosphatases. Unlike most of the protein tyrosine phosphatases, PTEN preferentially dephosphorylates phosphoinositide substrates. It negatively regulates intracellular levels of phosphatidylinositol-3, 4, 5-trisphosphate in cells and its tumour suppressor effect is expressed by inhibition of the AKT/PKB signalling pathway.

The overlapping clinical manifestations of these syndromes, which are caused by distinct molecular defects, suggest crosstalk between the involved pathways. Indeed, PRKAR1A inactivation leads to phosphorylation of mTOR and ERK1/2 [57, 58], LKB1 is phosphorylated by PKA [59], and PTEN expression is positively regulated by transcription factor Egr-1 in a PKA-dependent manner [60].

ACKNOWLEDGEMENTS

Studies on CNC and related syndromes have been supported by the Eunice Kennedy Shriver National Institute of Child Health & Human Development, NIH, intramural project Z01-HD-000642–04 (to Dr C.A. Stratakis).

Molecular and Clinical Characteristics of the McCune–Albright Syndrome

Michael A. Levine and Steven A. Lietman

Introduction

Heterotrimeric guanine nucleotide binding proteins (G proteins) couple a diverse spectrum of extracellular receptor proteins to intracellular effector enzymes and ion channels. The observation that alterations in G protein-coupled signalling pathways can impact cellular function and proliferation, and cause human disease, has stimulated investigation into the molecular and pharmacological regulation of G protein expression and action. The most well-characterized models for altered G protein expression defects have been based on naturally occurring mutations in *GNAS*, a complex imprinted gene at 20q13 that encodes the α subunit of Gs, the G protein that stimulates adenylyl cyclase (AC). Somatic mutations in GNAS that activate Gαs (the *gsp* oncogene) are present in a subset of endocrine tumours, fibrous dysplasia, and in patients with the McCune–Albright syndrome, a sporadic disorder characterized by increased hormone production and/or cellular proliferation of many tissues [1]. The clinical phenotype is therefore highly variable, and depends upon the location and timing of the mutation during embryologic development as well as the parental origin of *GNAS* allele that carries the mutation.

By contrast, germline mutations of the *GNAS* gene that decrease expression or function of $G\alpha_s$ are present in subjects with Albright hereditary osteodystrophy (AHO), a heritable disorder associated with a constellation of developmental defects and, in many patients, reduced responsiveness to multiple hormones that signal through receptors that require $G\alpha_s$ to activate AC (i.e. pseudohypoparathyroidism type 1a) [2]. MAS and AHO represent contrasting gain of function and loss of function mutations in the *GNAS* gene, respectively. Clinical and biochemical analyses of subjects with these syndromes have extended our understanding of the developmental and functional consequences of dysfunctional G protein action, and have provided unexpected insights into the importance of cAMP as a regulator of the growth and/or function of many tissues. This chapter will focus on the clinical implications of activating mutations of *GNAS* as the basis for MAS.

G Protein Structure and Signalling

G proteins share a common heterotrimeric structure consisting of an α subunit and a tightly coupled βγ dimer. The α subunit interacts with detector and effector molecules, binds guanosine triphosphate (GTP), and possesses intrinsic GTPase activity. There are 16 genes in mammals that encode some 20 different α chains. The α subunits associate with a smaller group of β (at least 5) and γ (more than 12) subunits [3]. The Gα subunits are categorized in four classes, and include Gsα (G stimulatory); Giα (G inhibitory) and Goα (G other); Gq/11α; and G12/13α. They behave differently in the recognition of the effector, but share similar structures and mechanism of activation. The Gα subunits consist of two domains: a GTP-binding domain and a helical insertion domain. The GTP-binding domain is homologous to Ras-like small GTPases, and includes switch regions I and II, which change conformation during activation. The switch regions are loops of alpha-helices with conformations sensitive to guanine nucleotides. The helical insertion domain is inserted into the GTP-binding domain before switch region I and is unique to heterotrimeric G

proteins. This helical insertion domain functions to sequester the guanine nucleotide at the interface with the GTP-binding domain and must be displaced to enable nucleotide dissociation.

Combinatorial specificity in the associations between various G protein subunits provides the potential for enormous diversity, and may allow distinct heterotrimers to interact selectively with only a limited number of effector proteins and G protein-coupled receptor (GPCR) proteins. The GPCRs are encoded by more than 1% of the genome of vertebrates, and represent a large protein family of receptors that sense molecules outside the cell and activate inside signal transduction pathways and, ultimately, cellular responses. GPCRs, also termed 7TM receptors, heptahelical receptors, and serpentine receptors, contain alpha helical regions that pass through the cell membrane seven times. The human genome encodes roughly 950 GPCRs, which detect photons (light), hormones, growth factors, drugs, and other endogenous ligands. Approximately 150 of the GPCRs found in the human genome have unknown functions. GPCRs are activated by a wide variety of signals, including proteins, nucleotides, amino acid residues, Ca^{2+}, light photons, and odorants, and it is postulated that ligand-binding alters the conformation of transmembrane domains and intracellular loops, increasing the affinity of the receptor for specific heterotrimeric G proteins.

G protein coupled signalling is regulated by a mechanism in which the binding and hydrolysis of GTP acts as a molecular timing switch (Figure 6.14.1). In the basal (inactive) state, G proteins exist in the heterotrimeric form with GDP bound to the α chain. The interaction of a ligand-bound receptor with a G protein facilitates the release of tightly bound GDP and the subsequent binding of cytosolic GTP. The binding of GTP to the α chain induces conformational changes that facilitate the dissociation of the α-GTP chain from the βγ dimer and the receptor. The free α-GTP chain assumes an active conformation in which a new surface is formed that enables the α chain to interact with target enzymes and ion channels with 20- to 100-fold higher affinity than in the GDP bound state. The βγ dimers also participate in downstream signalling events through interaction with an ever-widening array of targets, including certain forms of AC and phospholipase C, potassium channels, and GPCR kinases.

G protein signalling is terminated by the hydrolysis of α-GTP to α-GDP by an intrinsic GTPase. The GTPase reaction is a high-energy transition state that requires association of the γ-phosphorus atom with the oxygen of a water molecule. To catalyse this reaction, the γ-phosphate of GTP must be stabilized so that a straight line, perpendicular to the plane of the γ-phosphate, connects the water, the γ-phosphorus, and the oxygen molecule leaving the β-phosphate. In $G\alpha_s$, amino acids arginine^{201} and glutamine^{227} function as 'fingers' to position the γ-phosphate of GTP. With hydrolysis of GTP to GDP, the α-GDP chain re-associates with the βγ dimer and the heterotrimeric G protein is capable of participating in another cycle of receptor-activated signalling (Figure 6.14.1).

The GTPase of the Gα chain provides a molecular timing switch that controls the duration, and thereby the intensity, of the signalling event. The intrinsic rates of GTP hydrolysis by G protein α chains differ widely, and interactions that influence the rate of the GTPase reaction can have profound consequences. Several factors, termed **GAPs** for 'GTPase activating proteins', can interact directly with specific α chains to accelerate the slow intrinsic rate of GTP hydrolysis. One important class of GAP's is represented by the evolutionarily conserved superfamily of RGS proteins, for 'regulators of G protein signalling', that can stimulate a 40-fold increase in the catalytic rate of GTP hydrolysis, and thus can markedly accelerate the termination of G protein signalling. On the other hand, inhibition of intrinsic GTPase by modification or replacement of key

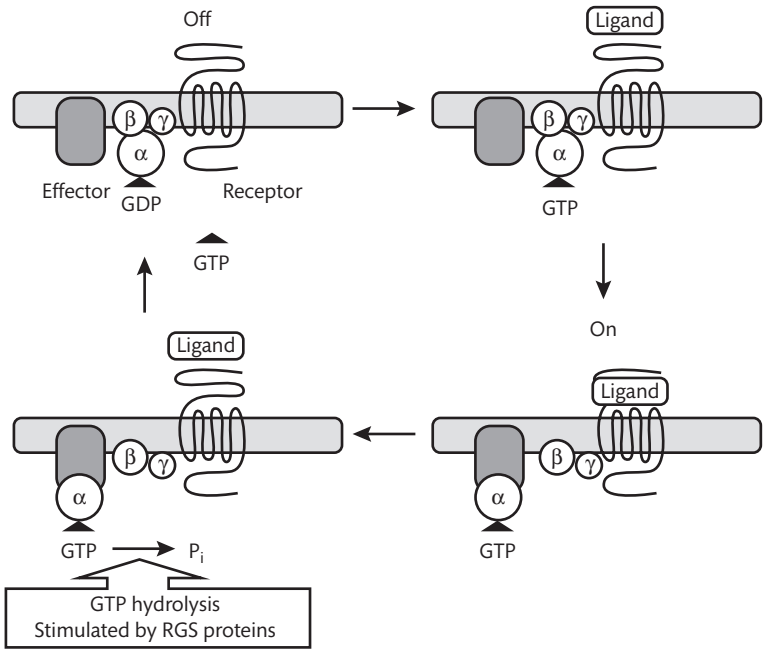

Figure 6.14.1 The cycle of hormone-dependent GTP binding and hydrolysis that regulates heterotrimeric G protein signal transduction. In the non-stimulated, basal (Off) state, GDP is tightly bound to the α chain of the heterotrimeric G protein. Binding of an agonist (Ligand) to its receptor (depicted with seven transmembrane spanning domains) induces a conformational change in the receptor, and enables it to activate the G protein. The G protein now releases GDP and binds GTP present in the cytosol. The binding of GTP to the α chain leads to dissociation of the α-GTP from the βγ dimer, and each of these molecules is now free to regulate downstream effector proteins. The hydrolysis of GTP to GDP by the intrinsic GTPase of the α chain promotes reassociation of α-GDP with βγ and the inactive state is restored. The heterotrimeric G protein is ready for another cycle of hormone-induced activation.

amino acid residues (e.g. arginine^{201} or glutamine^{227} in $G\alpha_s$) can delay termination of the signal transduction process, and cause persistent and excessive signalling. For example, exotoxins secreted by *Vibrio cholerae* and some strains of *E. coli* catalyse the addition of an ADP-ribose moiety to the side chain of arginine^{201} in $G\alpha_s$. This covalent modification markedly reduces GTP hydrolysis and maintains $G\alpha_s$ in its active GTP-bound form, thus resulting in persistent stimulation of AC [4]. The subsequent accumulation of cAMP in intestinal epithelial cells stimulates secretion of salt and water into the intestine and produces, in part, the watery diarrhoea associated with cholera. A drug screening assay has been developed to determine the efficacy of small molecule inhibitors for the constitutively active signalling with *gsp* mutations in MAS [5]. This assay could identify small molecule inhibitors for the treatment of MAS.

Activating Mutations of the *GNAS* Gene Induce Cellular Proliferation

Activity of AC is under dual regulatory control through receptors that interact with either G_s to stimulate AC or with G_i to inhibit AC. Increased intracellular cAMP stimulates proliferation of many cell types, and can increase synthesis and secretion of endogenous hormones and neurotransmitters. Both germline and somatic mutations in *GNAS* that lead to a gain of function in $G\alpha_s$ produce constitutive (i.e. hormone independent) activation of AC. Vallar *et al.* initially described a subset of human growth hormone secreting pituitary tumours in which basal AC activity *in vitro* was very high and failed to increase further with addition of growth hormone releasing hormone [6]. Subsequent studies showed that these somatotropic tumours contained unusual forms of $G\alpha_s$ that lacked GTPase activity due to somatic mutations in *GNAS* that replace either arginine^{201} or glutamine^{227} and thereby convert *GNAS* into the *gsp* oncogene. Arginine^{201} corresponds to the site of choleragen modification of $G\alpha_s$, whereas glutamine^{227} in $G\alpha_s$ corresponds to the cognate amino acid Gln^{61} in the low molecular weight GTP-binding protein $p21^{ras}$. Naturally occurring Gln^{61} mutations convert $p21^{ras}$ into an oncogene that plays a role in the development of a variety of human tumours [7]. Replacement of either arginine^{201} or glutamine^{227} in $G\alpha_s$ enable the protein to remain in the active, GTP-bound state, and the consequent increase in cAMP leads to cellular proliferation and excessive hormone secretion [8, 9]. Such activating mutations occur in approximately 40% of somatotropic tumours (Table 6.14.1). In addition to growth hormone secreting pituitary tumours, *gsp* mutations are also present in a small number

Table 6.14.1 Clinical manifestations of McCune–Albright syndrome. Clinical data compiled from over 250 cases of MAS reported in the literature (summarized in [36, 40, 44, 77, 84, 98, 112]). Evaluations include clinical and biochemical data; other rarely described manifestations include metabolic acidosis, nephrocalcinosis, intellectual disability, thymic and splenic hyperplasia, and colonic polyps

	% of all patients affected	% of males affected	% of females affected	Age at diagnosis, years (range)	Comments
Fibrous dysplasia	98	96	98	7.7 (0–52)	Polyostotic more common than mono-ostotic
Cafe'-au-lait lesions	85	92	82	7.7 (0–52)	Variable size and number of lesions, irregular border ('coast of Maine')
Precocious puberty	52	15	70	4.9 (0.3–9)	Common initial manifestation
Acromegaly/Gigantism	27	38	21	14.8 (0.2–42)	65% with adenoma on MRI/CT
Hyperprolactinaemia	15	17	13	16.0 (0.2–42)	55% of acromegalics with ↑ PRL
Hyperthyroidism	19	13	22	14.4 (0.5–37)	Euthyroid goitre is common; ultrasound generally shows nodules
Hypercortisolism	6	8	5	4.4 (0.2–17)	All primary adrenal
Myxomas	5	6	5	34 (17–50)	Extremity myxomas
Osteosarcoma	2	2	3	36 (34–37)	At sites of fibrous dysplasia, not related to prior radiation therapy
Rickets/Osteomalacia	3	2	3	27.3 (8–52)	Responsive to phosphorus plus calcitriol; most likely due to excess section of FGF23 from fibrous dysplasia
Cardiac abnormalities	11	15	9	(0.1–66)	Arrhythmias and CHF reported
Hepatic abnormalities	10	11	10	1.9 (0.3–4)	Neonatal icterus is most common
Testicular abnormalities	81				Hyperechoic lesions (49%), hypoechoic lesions (30%), microlithiasis (30%), heterogeneity (47%), and focal calcifications (11%). Precocious puberty in 21%
Gastrointestinal abnormalities	56%	52	48	35.1 years	Radiographic GI abnormalities: 46% with intraductal pancreatic papillary mucinous neoplasms; also, gastric heterotopia/metaplasia, gastric hyperplastic polyps, fundic gland polyps, and hamartomatous polyp
Hearing loss	22.4% of ears in patients with temporal bone fibrous dysplasia	55	45	Median age 19.6 years; range, 4.6–80.3 years	Conductive in 65.9%, sensorineural in 29.3%, and mixed in 4.9%. Hearing loss was mild and non-progressive in most participants

Abbreviations: PRL, prolactin; CHF, congestive heart failure.

Box 6.14.1 Clinical syndromes associated with activating mutations of *GNAS*

Missense mutations of *GNAS* at Arg^{201} and Gln^{227} which cause constitutive activation of AC and the cAMP signalling cascade have been identified in patients with McCune–Albright syndrome (MAS) and subsets of a variety of endocrine tumours.

- McCune–Albright syndrome (100%)
- Pituitary adenomas (4–50%)
  - Growth hormone-secreting adenomas (35–40%)
  - ACTH-secreting adenomas (4–9%)
  - Clinically non-functioning adenomas (rare)
- Thyroid neoplasms (3–70%)
  - Hyperfunctioning and non-functioning follicular adenomas
  - Papillary and follicular carcinomas
- Parathyroid neoplasms (<5%)
  - Parathyroid adenomas
- Adrenocortical disorders (<5%)
  - Aldosterone-producing adenomas
  - Adrenal hyperplasia
  - Phaeochromocytoma
- Leydig cell and ovarian neoplasms (66%)

of ACTH-secreting pituitary tumours [10, 11], a subset of thyroid neoplasms, and testicular and ovarian stromal Leydig tumours [12], but are rare in other endocrine tumours (Box 6.14.1). Moreover, *gsp* mutations have been described in ovarian cysts that cause isosexual gonadotropin-independent precocious puberty [13, 14], in intramuscular myxomas [15] and in isolated fibrous dysplasia of the bone [16].

Molecular Basis for the McCune–Albright Syndrome

In 1937, McCune and Bruch [17] and Albright and associates [18] independently described a sporadic syndrome characterized by the clinical triad of polyostotic fibrous dysplasia, *café-au-lait* skin lesions, and endocrine hyperfunction now known as McCune–Albright syndrome (MAS) (Figure 6.14.2). Despite excessive activity of endocrine tissues, serum levels of the relevant regulatory or tropic hormones were either normal or decreased, suggesting autonomous function. Based on the observation that the cutaneous hyperpigmentation in MAS typically follows the developmental lines of Blaschko, Happle proposed that the underlying genetic abnormality might be a dominantly acting somatic mutation that occurs early in development and which leads to a mosaic pattern of distribution of mutant cells [19]. Similarly, a lack of documented heritability of MAS has been interpreted as evidence that germline transmission of the mutation would be lethal [19].

The molecular basis for MAS is a somatic mutation in exon 8 of *GNAS* that replaces the residue arginine at position 201 by histidine or cysteine [20, 21]. Very infrequently, arginine is replaced by serine, glycine, or leucine [22]. Although missense mutations that replace the nearby glutamine at position 227 have been identified in solitary endocrine tumours, they have not been described in patients with MAS.

Consistent with a postzygotic somatic mutation, cells containing the *gsp* mutation are not present in all tissues of patients with MAS. Rather, cells containing a mutant *GNAS* gene are distributed in a mosaic pattern, with the greatest number of *gsp*-containing cells present in the most abnormal areas of affected tissues (Figure 6.14.3) [20, 21, 23]. In some cases, *gsp* alleles may be present in only some cell types within tissues that are derived from different embryological precursors. For example, a 3-year-old male MAS patient with macro-orchidism but no precocious puberty was reported to have a R201H *gsp* allele present only in Sertoli cells, resulting in isolated Sertoli cell hyperfunction, evidenced by increased Anti-Müllerian hormone (AMH) expression and cell hyperplasia leading to prepubertal macro-orchidism. There were no signs of Leydig cell activation, and no evidence of excess androgen action [24, 25]. The different early embryologic origin of precursors contributing to Sertoli and Leydig cell lineages may underlie the differential existence of the mutated *GNAS* gene.

Figure 6.14.2 Patient with McCune–Albright syndrome. This patient demonstrates the complete clinical triad of McCune–Albright syndrome, with café-au-lait, polyostotic fibrous dysplasia, and excessive endocrine function (hyperthyroidism). The fibrous dysplasia has affected his skull and long bones and led to progressive and debilitating deformity. The classic features (right panel) of fibrous dysplasia are illustrated in this radiograph of his right upper extremity, which reveals expansile, lytic lesions with a 'ground glass' pattern and a scalloped border secondary to endosteal erosion.

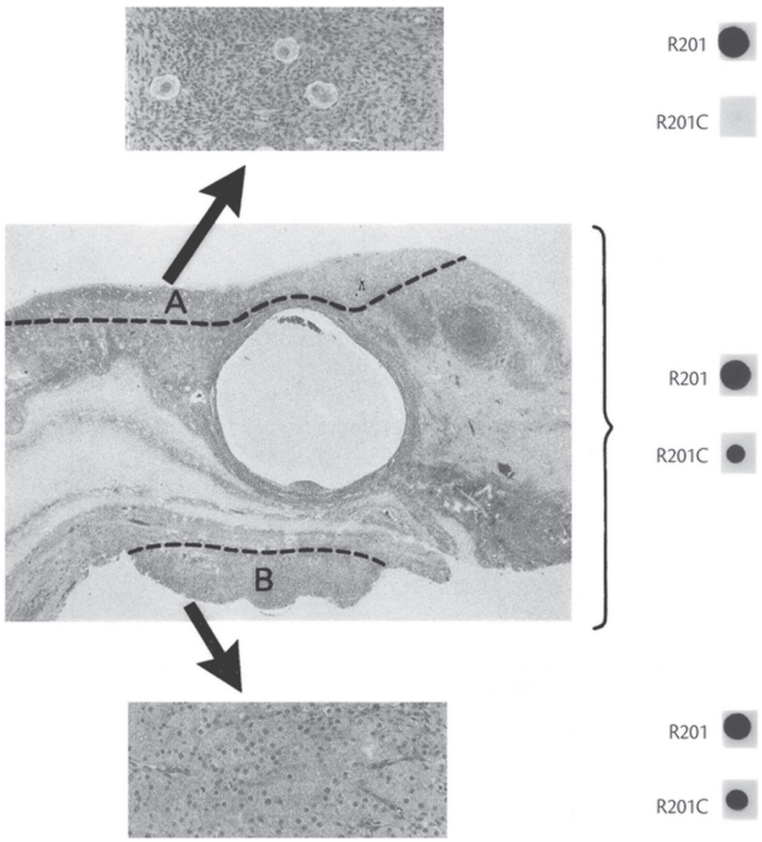

Figure 6.14.3 Correlation of the abundance of mutant alleles with the pathological abnormalities in ovarian tissue from a young girl with MAS and precocious puberty. A cross-section from a paraffin-embedded section of ovary from a patient (patient 1 in [21]) with MAS is shown in the centre (×50). The two outlined areas, shown at ×120, were dissected and analysed independently; area A shows ovarian cortex containing primordial follicles, and area B shows follicular cyst lining containing stimulated luteinized theca. On the right are blots showing the results of allele-specific oligonucleotide (ASO) hybridization of DNA with wild-type (R201) or mutant (R201C) radioactively labelled primers after PCR amplification; DNA was isolated from total ovary (centre) or specific regions as shown.

The variable involvement of different tissues in patients with MAS, as well as the clinical heterogeneity among affected patients, is assumed to be a result of several unique features. First, the number of tissues in which the *gsp* is present, and the proportion and distribution of affected cells in a tissue, will be determined by the timing of the mutational event. Thus, mutations that arise early in embryogenesis are likely to affect several cell lineages and produce a more severe phenotype than mutational events that occur later. For example, acquisition of a *gsp* mutation months or even years after birth could explain the development of a solitary endocrine tumour or a single fibrous dysplasia lesion in some patients.

Second, epigenetic and/or microenvironmental factors that regulate *GNAS* expression can influence the MAS phenotype. For example, stochastic effects, such as allelic imbalance, may favour expression of the mutant allele in some tissues [26], thus exaggerating the effect of a *gsp* mutation. Even more importantly, tissue-specific imprinting of *GNAS* can exert a discrete effect on expression of *gsp* alleles. *GNAS* transcripts that encode $G\alpha_s$ are preferentially expressed from the maternal allele in some cells (e.g. renal proximal tubule cells, thyroid follicular cells, and pituitary somatotrophs) [27, 28]. Theoretically, in those cells in which $G\alpha_s$ is expressed predominately if not exclusively from the maternal allele, only somatic of the maternal allele will have pathophysiological consequences. This is the case for sporadic GH-secreting pituitary adenomas as well as patients with MAS who have GH-secreting pituitary adenomas, where activating mutations of $G\alpha_s$ almost always occur on the maternal allele [1, 29]. By contrast, the parental origin of a *gsp* allele will be far less important in cells and tissues where both $G\alpha_s$ alleles are expressed.

Additional transcripts are generated by *GNAS* using alternative first exons that are spliced to exons 2–13, but the effect of these proteins on the MAS phenotype remains uncertain. Exon 1A, is located approximately 2.5 kb upstream of exon 1. Transcripts beginning with exon 1A are expressed only from the paternal allele, and are probably untranslated [30]. Further upstream are two additional alternative first exons; one encodes the amino terminus of the $XL\alpha_s$ protein, which is expressed only from paternal alleles. $XL\alpha_s$ shares carboxyl terminal sequences with $G\alpha_s$, and functions in G-protein coupled signal transduction. *gsp* mutations in $XL\alpha_s$ can affect signal transduction *in vitro* [31] and recent data suggests that constitutive $XL\alpha_s$ activity adds to the molecular pathogenesis of MAS [32]. The third alternative first exon is approximately 52 kb upstream of exon 1 and is expressed exclusively from the maternal allele. This exon contains the entire coding sequence for the neurosecretory protein NESP55 [33–35], a chromogranin-like protein that is present in secretory granules and shares no protein homology with $G\alpha_s$. Thus, activating mutations in exon 8 of *GNAS* would not be present in NESP55.

Third, the clinical and endocrinological features of MAS will be influenced by the effects of cAMP in a specific cell type. For example, a *gsp* oncogene will produce the most significant consequences in those tissues in which cAMP stimulates cellular proliferation and/or hormone secretion rather than differentiation. Cyclic adenosine monophosphate (AMP) is not mitogenic in all cell types, and in some cell types cAMP can actually inhibit growth. Moreover, even in cells in which cAMP is a strong growth stimulator, changes in the expression of other genes or induction of counter-regulatory responses (such as increased cAMP phosphodiesterase activity) could mitigate or even reverse the effects of the *gsp* oncogene.

Clinical Manifestations of McCune–Albright Syndrome

Comprehensive reviews of the clinical spectrum of MAS have extended our appreciation of this unusual disorder [36, 37] (Figure 6.14.2). The mean age at the time of clinical diagnosis of MAS is 5.7 years, with a range of 0.7 to 11 years. Almost all patients who ultimately manifest the complete clinical triad of pigmented skin lesions, excessive endocrine function, and fibrous dysplasia will have evidence of café-au-lait skin lesions at birth. There is a 50% likelihood of precocious puberty in females by age 4 years, and a 50% likelihood of bone lesions by age 8 years.

Fibrous Dysplasia

Fibrous dysplasia of the skeleton occurs in nearly all (98%) patients with MAS, and may manifest as either a solitary lesion (mono-ostotic, 13%) or multiple lesions (poly-ostotic, 87%) [35].

Fibrous dysplasia typically develops during the first decade of life (Table 6.14.1), and seems to progress over time in most patients, with an increase in both the extent and number of bone lesions. The femur and pelvis are most commonly involved, and the shepherd's crook deformity of the femur is a pathognomonic lesion. Spinal involvement, with progressive scoliosis, is apparently more common than originally thought [38, 39]. Bisphosphonates have not been effective in decreasing the progression of spine curvature [40].

Most MAS patients will experience at least one fracture (peak age 7–12 years) and many patients will have multiple fractures. Radiographs of affected bones reveal long expansile (long lesions in long bones), lytic lesions with a 'ground glass' (as in the ground glass stoppers for glass bottles) pattern and a scalloped cortical bone border secondary to endosteal erosion (Figure 6.14.2) [38, 39, 41]. The marrow cavity, which usually has a cellular fatty tissue, is replaced by fibro-osseous tissue. Bone histology discloses three primary, but distinct, histological patterns, defined as Chinese writing type, sclerotic/Pagetoid type, and sclerotic/hypercellular type, which are characteristically associated with the axial/appendicular skeleton, cranial bones, or gnathic bones, respectively [42]. Craniofacial involvement occurs in many patients, and should be evaluated with both CT and MRI in order to demonstrate the extent of disease, and potential compressive complications of fibrous dysplasia such as optic neuropathy [43]. While hearing loss appears to be common [44, 45], ocular complications are infrequent even with involvement of the optic nerve canals [45].

The basis for the unusual cellular changes in fibrous dysplasia is poorly understood. Recent evidence indicates that the fibrotic areas consist of an excess of pre-osteogenic cells, whereas the bone formed *de novo* within fibrotic areas is produced by mature but abnormal osteoblasts [42]. It is likely that at least some of the phenotypic changes in affected osteogenic cells result from cAMP-induced increases in expression of interleukin-6 and the *c-fos* proto-oncogene [22, 46, 47]. The mosaic distribution of lesions in fibrous dysplasia may also play an important pathogenic role, as close contact between transplanted normal bone cells and osteogenic cells containing the *gsp* mutation is necessary to reproduce the fibrous dysplasia lesion in mice [48]. Using mouse models that allow the conditional expression of a *gsp* mutation in the skeletal stem cell (SSC) lineage, Zhao *et al.* have shown that *GNAS* activation is sufficient for initiation of fibrous dysplasia, as cells containing the mutation proliferated along the osteogenic lineage but failed to differentiate to mature osteoblasts. Remarkably, silencing the *gsp* mutation resulted in regression of the fibrous dysplasia-like lesion, suggesting that targeting *gsp* might represent a strategy for cure of fibrous dysplasia [49].

Sarcomatous degeneration (e.g. osteosarcoma, fibrosarcoma, and chondrosarcoma, in descending order of frequency) occurs as a rare complication of fibrous dysplasia in MAS patients (mean age of 36 years) [50], and F-18 fluorodeoxyglucose positron emission tomography may be able to disclose early malignant transformation of fibrous dysplasia lesions [43, 51].

Treatment for fibrous dysplasia is principally based on surgery, with fracture repair and reconstruction of craniofacial deformity the most common procedures. Regrowth or recurrence of fibrous dysplasia after skull surgery is common (66%), and is more frequent after operations in subjects with MAS who have growth hormone excess (88%) than without growth hormone excess (58%) [52]. Therefore, patients with extensive fibrous dysplasia should be evaluated carefully for the presence of MAS in general, and growth hormone excess in particular. By contrast, outcomes are favourable for aneurysmal bone cysts and biopsies [52].

No medical treatment for fibrous dysplasia is entirely satisfactory. Most but not all studies have demonstrated that bisphosphonates can relieve bone pain, decrease bone resorption, and improve the radiological appearance (e.g. filling of lytic lesions and/or thickening of cortices) of bone lesions in about 50% of patients. Bone mineral density in affected sites is also significantly increased after treatment with pamidronate, a potent second-generation bisphosphonate that is administered intravenously. In a series of nine patients on long-term pamidronate treatment who became resistant to this medication, a switch to intravenous zoledronic acid did not produce any substantial improvement [53]. Recent case reports describe early and encouraging experiences with denosumab as a treatment for fibrous dysplasia in adults [54–56]. Studies in children are even more limited. Denosumab treatment of one 9-year-old boy with extremely painful and severe fibrous dysplasia led to a clinically significant reduction of osteolytic expansion and fibrous dysplasia-related bone pain, but was associated with worrisome disturbances of mineral metabolism both while on treatment and after discontinuation, limiting enthusiasm for use of this drug in children [56].

Anecdotally, 30 days after intranasal calcitonin administration a wheelchair bound patient had improved pain and at 90 days was able to walk without assistance [57]. Therefore, calcitonin may be

considered a short-term therapeutic option in cases of severe and refractory bone pain [57]. Finally, in patients with a high skeletal burden in fibrous dysplasia, consistent with MAS, addressing maladaptive illness perceptions may also improve quality of life [58].

Café-au-Lait Skin Lesions

Patients with MAS typically have one or more pigmented macules, termed *café-au-lait* lesions, that have irregular borders (coast of Maine) (Figure 6.14.4). By contrast, *café-au-lait* skin lesions that occur in patients with neurofibromatosis (Von Recklinghausen's syndrome) have a smooth border (coast of California) (Figure 6.14.5). The distribution of skin lesions in MAS is also characteristic (Figure 6.14.4), consisting of an S-shaped pattern on the chest, a V-shaped pattern on the back, and a linear distribution on the extremities, that conforms to the embryological lines of ectodermal migration (i.e. lines of Blashko) and reflects the dorsoventral outgrowth of two populations of cells [19]. Lesions rarely extend beyond the midline and in most patients the skin lesions tend to be on the same side of the body as the skeletal lesions. They occur most commonly on the buttocks and lumbosacral regions.

Endocrine Abnormalities

Autonomous endocrine function is common in MAS (Table 6.14.1) [59]. Precocious puberty is the most common endocrine disorder in MAS, and has been reported in over 60% of patients. Precocious puberty is a common initial manifestation of MAS in girls, and characteristically presents as thelarche and/or vaginal bleeding in a girl under 5 years of age. Vaginal bleeding may occur in the absence of significant breast development or pubarche. Some young girls will have seemingly regular menses and progressive pubertal development, including rapid advancement of bone age, whereas others will have irregular or intermittent bleeding that is associated with relatively normal rates of growth. The production of oestrogen appears related to the growth and involution of small ovarian cysts, and is typically not associated with follicular maturation or ovulation. Ovarian activity can undergo a spontaneous remission in some cases. Large, benign ovarian cysts may also occur [13, 14], and surgical excision may result in regression of secondary sexual characteristics until the onset of normal pubertal development. Patients typically have low or suppressed levels of serum LH and follicle-stimulating hormone (FSH), which fail to increase significantly after administration of gonadotropin-releasing hormone (GnRH), a characteristic of gonadotropin-independent precocious puberty (i.e. precocious 'pseudopuberty'). Testing may be normal during intervals of apparent ovarian inactivity, however. Given the episodic nature of oestrogen production, and the poor performance characteristic of many clinical assays for oestradiol, serum concentrations of this steroid are often not elevated. Of interest, after several years of excessive sex steroid exposure some girls experience a transition to central precocious puberty, particularly those whose bone age is 11 years or greater [60–62]. As adults, women with a past history of gonadotropin-independent precocious puberty may have irregular menses and reduced fertility due to continued autonomous production of oestrogen.

Treatment of precocious puberty in girls with MAS is challenging. Therapy with GnRH analogues and superagonists is not effective unless there has been a progression to central precocious puberty [62]. Treatment with first generation aromatase inhibitors was generally disappointing [61, 63], but recent long-term follow-up studies of girls treated with letrozole have been more promising [64], with sustained beneficial effects on skeletal maturation, growth velocity, and predicted adult height [65]. The efficacy of compounds with antioestrogenic activity, such as the selective oestrogen receptor modulators (SERMs) tamoxifen or raloxifene, also appears to be useful [65–67].

Contrary to prevailing thinking, the incidence of gonadal pathology in MAS is equal in males and females. The predominant histopathological finding is variable degrees of seminiferous tube development with Leydig cell hyperplasia, which carries a low risk of malignant transformation and can be managed conservatively [68]. Testicular enlargement is generally bilateral but can be unilateral [69]. Although testicular enlargement is usually associated with excessive production of testosterone and precocious puberty, occasionally the enlargement is limited to autonomous hyperfunction of Sertoli cells with no activation of Leydig cells [24]. Most boys with MAS will show testicular microlithiasis on ultrasound, which can

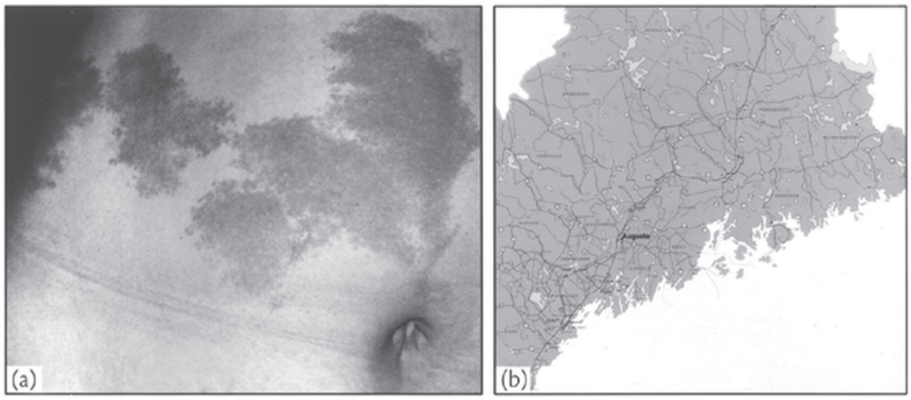

Figure 6.14.4 Café-au-lait lesions in McCune–Albright syndrome. The pigmented lesions follow the embryological lines of Blashko, and are typically ipsilateral to and near the skeletal lesions of fibrous dysplasia. The pigmented macules have irregular margins (left) that resemble the 'coast of Maine' (right).

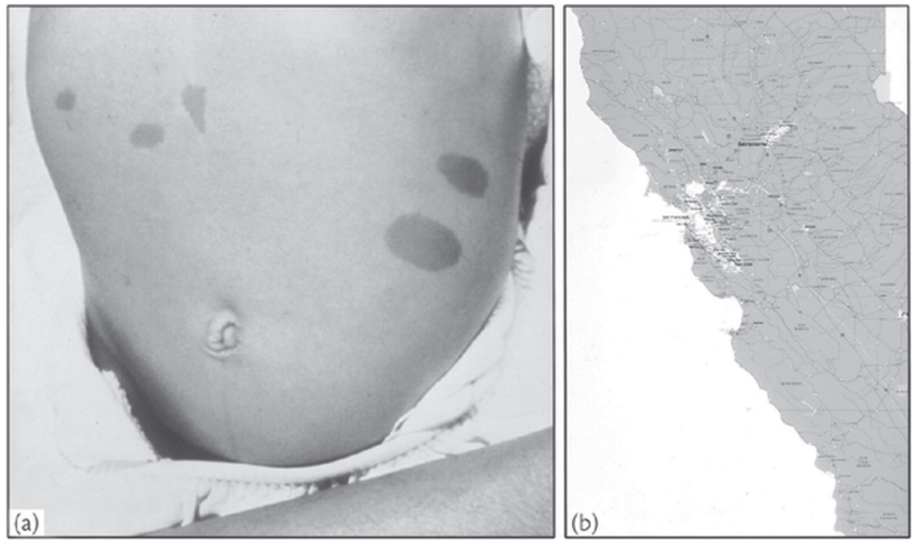

Figure 6.14.5 Café-au-lait lesions in neurofibromatosis. The pigmented macules have smooth margins (left) that resemble the 'coast of California' (right).

be a very useful screening test [68]. Treatment is similar to that for familial male precocious puberty due to activating mutations of the LH receptor (i.e. testitoxicosis) [70], and consists of the combination of an aromatase inhibitor plus an androgen receptor blocker [66, 68, 69, 71]. In those cases where gonadotropin-independent precocious puberty leads to early activation of central puberty, the addition of a GnRH analogue may be required to arrest further pubertal development and to allow boys to achieve a normal adult height [68, 72, 73].

Growth hormone (GH) excess is common in MAS [74], and may produce either gigantism or acromegaly [75, 76]. The biochemical behaviour of growth hormone-producing pituitary tumours in patients with MAS appears indistinguishable from that of sporadic tumours with and without *gsp* mutations. GH secretion is stimulated by TRH, GHRH, and sleep, and is incompletely suppressed by glucose administration. However, only 65% of MAS patients with GH excess have radiographic evidence of a pituitary tumour, a much lower incidence than in sporadic cases of acromegaly (99%) [77]. In addition, hyperprolactinemia occurs in over 50% of MAS patients with elevated GH levels, a frequency that is somewhat greater than occurs in patients with sporadic pituitary tumours (40%) [77]. The indications for surgical treatment (e.g. transphenoidal tumour excision) of GH-secreting pituitary tumours are similar for those in patients without MAS. Improved outcomes may be achieved with neuronavigational guidance and preoperative treatment with long-acting ostreotide analogues [78].

Medical therapy with bromocriptine may reduce tumour size and hormonal secretion in many, but not all patients [10, 79]. However, other medical treatments, such as long-acting octreotide and pegvisomant [80–82], appear more useful. Insulin growth factor 1 (IGF1) hyperactivity increases risk of morbidity in MAS presumably thru increased GH. Early medical therapy, for example, with long-acting octreotide (with or without pegvisomant) therapy is effective in normalizing IGF1 in most patients, and early treatment is associated with decreased risk of optic neuropathy and decreased growth of GH-secreting adenomas [83].

Hyperthyroidism and/or autonomous thyroid nodules have been identified in approximately 33% of MAS patients who underwent thyroid evaluation [77, 84–86]. Radioactive iodine ablation or surgery has been used to treat thyroid nodules. The degree of hyperthyroidism is variable, and serum concentrations of thyroid-stimulating hormone (TSH) are typically low and thyroid-stimulating immunoglobulins are undetectable. The thyroid gland will often appear normal by physical exam, but nodules are nearly always detectable by sonography.

Patients with MAS occasionally develop autonomous function of the adrenal gland and primary hypercortisolism at a young age (mean age of 4.4 years) [77]. Adrenal gland histopathology reveals either nodular hyperplasia or solitary adenoma [76].

Other Features

Recent analyses have documented the occurrence of additional non-endocrine features in patients with MAS that extend the clinical spectrum of the disorder. These include hypophosphataemia, hepatobiliary disease, and cardiac disease. Hypophosphataemia and/or decreased renal tubular reabsorption of phosphate occur in over 50% of subjects with MAS, and may lead to the development of rickets or osteomalacia [87]. A similar syndrome of hypophosphataemic rickets has been described in patients with fibrous dysplasia who lack other features of MAS, as well as in other patients who have various mesenchymal tumours, and appears due to secretion of circulating phosphaturic factors termed 'phosphatonins'. FGF23 is the best characterized of the phosphatonins, and is produced by the abnormal osteogenic precursors present in fibrous dysplasia lesions. The concentration of circulating FGF23 correlates with the extent of fibrous dysplasia throughout the skeleton [88, 89]. Based on the success of a fully humanized monoclonal antibody against FGF23, burosumab, for the treatment of adults and children with X-linked hypophosphataemic rickets [90, 91] and tumour-induced osteomalacia [92, 93], burosumab may emerge as a successful medical

therapy for the FGF23-dependent hypophosphataemic rickets and/or osteomalacia in patients with fibrous dysplasia [93, 94]. An alternative explanation for hypophosphataemia in patients with MAS is the presence of the *gsp* oncogene in the proximal renal tubule, where it induces increased cAMP production and an intrinsic defect in reabsorption of phosphate [95].

While neonatal jaundice in patients with MAS typical resolves, liver function enzymes typically remain mildly elevated. Liver histology varies from near normal to discrete portal fibrosis to giant cell hepatitis [96]. Liver disease is due to the presence of the *gsp* mutation in hepatic tissue [86, 96, 97], and the degree of histological abnormality correlates with the relative amount of abnormal Gαs protein and adenylyl cyclase activation [97]. Another unusual manifestation of MAS is cardiac disease [86]. Cardiac involvement in patients with MAS ranges from tachycardia and hypertension to cardiomegaly and sudden death [86]. Affected cardiac tissue contains cells with the *gsp* mutation [86], and it is likely that elevated levels of cAMP account directly for the abnormal cardiac function.

There are abnormalities in the gastrointestinal tract and pancreas in patients with MAS and patients with MAS should be evaluated for gastrointestinal pathology as well [98]. Intraductal papillary mucinous neoplasms (IPMNs), which are the most common cystic precursor lesions of invasive pancreatic cancer, *GNAS* mutations at codon 201 have been identified. Histological subtype of IPMNs correlates with *GNAS* mutational frequency [99].

Thus, the clinical MAS phenotype is highly variable, depending upon the location and timing of the mutation during embryologic development.

Diagnosis

The diagnosis of MAS remains a clinical exercise, and is straightforward when all three features are present in a candidate patient. However, many patients with MAS lack some features at the time of initial presentation, and it would therefore be desirable to have a molecular test for the disorder. The mosaic distribution of cells bearing the *GNAS* mutation, and the variable number of affected cells in a tissue, makes it technically difficult to detect mutant *GNAS* alleles even in affected tissues, as they may represent only a small proportion of the *GNAS* alleles present in a DNA sample. Detection of a *gsp* mutant in DNA samples can be greatly enhanced by protocols that enrich the relative abundance of mutant alleles as polymerase chain reaction (PCR) targets and thereby facilitate selective amplification. These techniques have relied upon either multiple rounds of PCR and restriction endonuclease digestion of wild-type amplicons [100] or inclusion of a peptide nucleic acid (PNA) in the PCR to block amplification of wild-type *GNAS* targets [101, 102]. The sensitivity of nested PCR and PNA clamping appears comparable, but the nested PCR method requires more time and expense than PNA clamping [37]. A recent improvement over standard PNA clamping uses a labelled PNA hybridization probe and fluorescence resonance energy transfer (FRET) to allow for the direct and rapid quantification of *gsp* alleles with a sensitivity that allows detection in tissues that contain as few as 5% mutant cells [103]. While analysis of DNA from lesional tissue affords greatest sensitivity, it is neither practical nor expedient to biopsy affected tissue(s) in all patients. Both nested PCR and PNA clamping have been used to detect *gsp* mutations in peripheral blood samples [37, 104]. Next generation sequencing can analyse millions of PCR amplicons. When PNA clamping and next generation sequencing are combined, the Arg201 mutation can be detected in virtually all affected tissues and in leukocytes of up to 75% of individuals [105], making this the most the most sensitive detection method.

The detection of a *gsp* mutation in circulating cells from a patient with FD or an isolated endocrinopathy (e.g. growth hormone-producing pituitary tumour, ovarian cysts) does not necessarily imply that the patient has MAS, however. Even with molecular demonstration of a *gsp* mutation, additional studies and clinical interpretation will be needed to distinguish between MAS and an isolated lesion.

On the other hand, identification of a *gsp* mutation can distinguish between fibrous dysplasia and similar lesion such as osteofibrous dysplasia [106], and may assist in distinguishing between atypical forms of MAS and Carney complex [107–109] or Mazabraud syndrome [110, 111].

Treatment

Each specific feature of MAS requires intensive management that follows the usual recommendations for an isolated lesion, with occasional special caveats based on the potential confounding interactions of other endocrine defects. The management of the various clinical characteristics of MAS is previously described in each preceding section.

Conclusion

The diagnosis of MAS remains a clinical one, and requires a careful integration of physical findings, biochemical evaluation, and radiological examination. The disorder can present as a form fruste, and identification of a specific *GNAS* mutation in DNA from affected tissues and in many cases peripheral blood cells can confirm a clinical diagnosis of MAS. Finally, the genetic basis for MAS, mosaicism of a somatic *gsp* mutation, provides new insights into the role of imprinting as a modulator of human disease.

Cowden Syndrome

Lamis Yehia, Shreya Malhotra, and Charis Eng

Introduction

Cowden syndrome (CS; OMIM 158350), named after the first-recognized patient Rachel Cowden, is an autosomal dominant inherited cancer predisposition syndrome characterized by multiple hamartomas involving organ systems derived from all three germ cell layers and a risk of breast, thyroid and other cancers [1–4]. Endocrinologists may make the diagnosis of CS when they are presented with these patients' endocrine lesions, chief of which are multinodular goitre, thyroid adenomas, and epithelial thyroid cancer. The first identified CS susceptibility gene, *PTEN*, is located on chromosome sub-band 10q23.3 [5, 6]. Because of the variable, protean, and often subtle external manifestations of CS, many cases remain undiagnosed. It is estimated that CS has an incidence of 1:200 000 individuals, although this is likely an underestimate [4].

Aetiology and Pathogenesis

Genetics

Inheritance patterns in families with CS implicate an autosomal dominant pattern. While expressivity is variable, CS is a highly penetrant disorder. Based on the earliest population-based clinical epidemiology study, some believe that the penetrance is 90% after the age of 20 years [5]. The precise penetrance was clarified after further study of the susceptibility gene within families and affected individuals. CS was mapped to 10q22–23, without genetic heterogeneity [5]. Further germline and somatic genetic analysis helped place the candidate predisposition gene between markers D10S215 and D10S541, a region of less than 1 cM [5].

PTEN

A candidate tumour suppressor gene *PTEN/MMAC1/TEP1* was located precisely in the CS critical interval [5, 7]. The gene comprises 1209 coding base pairs encoding a 403-amino acid protein. The protein has a tyrosine phosphatase domain and homology to tensin and auxilin [7, 8]. Hence, this new gene was dubbed *PTEN* for phosphatase and tensin homologue deleted on chromosome ten. *In vitro, PTEN* acts as a dual specificity phosphatase, meaning it is both a lipid phosphatase and a protein phosphatase as well as a tyrosine phosphatase and serine–threonine phosphatase [9, 10]. Subsequent *in vivo* work in mouse models suggested that PTEN plays a role in the PI3Kinase/AKT cell survival/apoptosis pathway [11–13]. Because of its homology to the focal adhesion molecules tensin and auxilin, it was hypothesized that PTEN may also play a role in cell migration and focal adhesion. When PTEN was overexpressed in NIH 3T3 cells, it appeared that cell migration was inhibited while antisense PTEN enhanced migration [14]. Evidence for PTEN interaction with focal adhesion kinase (FAK) was given when integrin-mediated cell spreading and focal adhesion formation were down-regulated by wild-type but not mutant PTEN; PTEN must interact with FAK to reduce its tyrosine phosphorylation [14]. This leads to the hypothesis that PTEN functions as a phosphatase by negatively regulating cell interactions with the extracellular matrix.

Although the genetic evidence that points to PTEN as a tumour suppressor—broad spectrum of mutations scattered throughout the gene, truncating mutations, and location of the gene in a region of loss of heterozygosity—is strong, functional demonstration was still required. When functional wild-type PTEN was transfected into a series of glioma cell lines, which carry endogenous *PTEN* mutations or are PTEN null, growth suppression was observed [15–17]. Multiple *in vitro* studies where wild-type and mutant PTEN were overexpressed in a broad variety of cancer cell lines, including those of the breast, thyroid, and prostate, demonstrate that PTEN-phosphatase- and PI3K-dependent G1 cell cycle arrest and/or apoptosis result in growth suppression [18]. This is *in vitro* functional evidence that PTEN acts as a tumour suppressor. Further studies demonstrated that PTEN has phosphatase-independent functions and critical roles within the nucleus [19]. As such, nuclear PTEN is involved in double-stranded break repair by upregulating RAD51 and genomic stability by interacting with centromere protein C

(CENP-C) [19]. In the nucleolus, PTEN regulates ribosomal DNA (rDNA) transcription and cellular proliferation [20].

PTEN is the Cowden Syndrome Gene

The experimental data, its putative function as suggested by structural motifs, and its location within 10q23.3 all argued strongly that *PTEN* was an ideal candidate for the Cowden syndrome susceptibility gene [6]. Therefore, to determine if germline *PTEN* mutations could be aetiological for CS, five families, with a high prior probability of having mutations, were chosen for initial analysis [5, 6]. Two families had nonsense mutations, Arg233X and Glu157X, while two unrelated families shared an identical missense mutation, Gly129Glu, which is a nonconservative amino acid alteration occurring in one of the conserved glycines of the phosphatase signature motif. No unaffected family member carried these mutations. In each family, the family-specific germline *PTEN* mutation segregated with disease but not in unaffected family members nor normal controls. Given these data, *PTEN* was believed to be the most likely susceptibility gene for CS. Early studies on families with CS and individuals with full-blown phenotypic features identified that germline *PTEN* mutations accounted for up to 85% of CS [21, 22]. Subsequent analysis including prospective community-accrued CS and CS-like (not meeting full diagnostic criteria) probands estimated that ~25% of patients who met more relaxed diagnostic criteria harboured pathogenic *PTEN* mutations [23].

PTEN is Also the Bannayan–Riley–Ruvalcaba Gene

Bannayan–Riley–Ruvalcaba syndrome (BRRS; OMIM 158350) is a rare autosomal dominant congenital disorder classically characterized by macrocephaly in combination with intestinal hamartomatous polyposis, vascular malformations, lipomas, haemangiomas, and genital freckling [24]. In addition to the cardinal clinical features, other reported phenotypes include high birth weight, developmental delay, mild to severe mental retardation, delayed psychomotor development, muscle hypotonia, lipid storage myopathy, joint hyperextensibility, pectus excavatum, and scoliosis [24, 25]. Endocrinologists might encounter BRRS as paediatric or young adult patients with benign thyroid manifestations such as Hashimoto thyroiditis, and/or with differentiated thyroid cancers [24, 26]. Clinically, differential diagnoses include other disorders with overlapping phenotypes of macrocephaly, gastrointestinal polyposis, and tumours, such as juvenile polyposis syndrome, Peutz–Jeghers syndrome, and neurofibromatosis type 1. BRRS is allelic to CS, as subsets of both disorders have been associated with germline mutations in *PTEN*, the latter excluded as a candidate locus for the other differential diagnoses except for juvenile polyposis of infancy [27, 28]. Multiple germline *PTEN* mutations have now been described in both familial and isolated cases of BRRS, such that ~60% of BRRS individuals harbour intragenic *PTEN* mutations [21, 29, 30]. Among those without intragenic mutations, another 10% harbour large deletions encompassing or including *PTEN* [22]. Since identical mutations (e.g. Arg233X) have been found in CS as well as BRRS, genetic and non-genetic modifiers must play a role in helping dictate the ultimate phenotype. BRRS patients with germline pathogenic *PTEN* mutations are thought to have the same lifetime cancer risks as *PTEN* mutation-positive CS patients. It is unclear whether these risks apply to BRRS patients who do not have *PTEN* alterations [4].

Concept of the *PTEN* Hamartoma Tumour Syndrome (PHTS)

In addition to CS and BRRS, germline *PTEN* mutations were found in variable subsets of several seemingly unrelated clinical syndromes. For example, up to 20% of individuals with Proteus syndrome have germline *PTEN* mutations [31]. Approximately 10–20% of individuals with autism spectrum disorder (ASD) and macrocephaly harbour germline *PTEN* mutations [32–36]. Single cases of VATER and megalencephaly and hemimegencephaly have been reported to carry germline *PTEN* mutations as well [37, 38]. The concept of PHTS to encompass any clinical disorder with germline *PTEN* mutation was proposed because it is clinically useful [4, 39]. A diagnosis of PHTS is established upon the identification of a pathogenic germline *PTEN* mutation on molecular genetic testing, regardless of phenotype. Finding a germline *PTEN* mutation should trigger cancer risk management and genetic counselling similar to those used for CS-*PTEN*. Additionally, healthcare providers benefit from understanding the clinical spectrum of PHTS in relation to other hereditary cancer syndromes (Table 6.15.1).

Table 6.15.1 Clinical characteristics of *PTEN* hamartoma tumour syndrome (PHTS)

General features
- Multiple hamartomas
- Cancer predisposition
- Autosomal dominant inheritance
- 10–44% caused by de novo *PTEN* mutation
- Extreme intrafamilial variability common
- Penetrance close to 100% by adulthood

Benign neoplasias
- Dermatologic
  - Palmoplantar keratoses
  - Trichilemmomas
  - Papillomatous papules
  - Lipomas
  - Fibromas
  - Freckling of the glans penis
- Vascular anomalies/haemangiomas
- Lhermitte-Duclos disease
- Genitourinary tumours/malformations
- Colorectal polyposis
- Mucosal lesions
- Thyroid goitre/nodules
- Hashimoto thyroiditis
- Proliferative breast changes

Malignancies
- Breast cancer
- Epithelial thyroid cancer
- Renal cancer
- Endometrial cancer
- Colorectal cancer
- Melanoma

Neurodevelopmental
- Macrocephaly
- Autism spectrum disorder
- Developmental delay
- Dysmorphic features (especially with large *PTEN* deletions)
- Dolichocephaly

PTEN Mutation Spectrum and Genotype–Phenotype Correlations

Pathogenic germline *PTEN* mutations have been reported in all 9 exons of the gene [23, 40, 41]. Exons 5, 7, and 8 are overrepresented in the *PTEN* germline mutation spectrum, likely reflecting encoded domain functions [23]. Exon 5 is a hotspot for germline mutations due to its biological significance as the catalytic core motif of PTEN [23, 30]. Additionally, although limited data are available for *PTEN* promoter variants, some pathogenic promoter mutations have been shown to affect *PTEN* transcription and translation, the latter due to altered RNA secondary structure [22]. Particular *PTEN* intronic variants can cause exon skipping, alternative splicing or the use of cryptic splice sites [42].

With the genotypic and phenotypic heterogeneity observed in PHTS, it became prudent to explore whether genotype–phenotype correlations exist. Earlier exploratory genotype–phenotype analyses identified two potential associations [21, 39]. The first is the association between germline *PTEN* mutations and the presence of malignant breast disease. The second is the association between missense mutation and/or position of mutation within the phosphatase core motif and the development of multiorgan disease. Expanded series of PHTS individuals revealed that germline *PTEN* frameshift mutations are overrepresented, but not absolute, in thyroid cancer [43], nonsense mutations in colorectal cancer [40], promoter mutations in breast cancer [40], and missense mutations in individuals with ASD [44]. In addition to cancer risk, research efforts have also identified differences in *PTEN* missense mutations impacting the three-dimensional dynamics and stability of PTEN protein structure to influence cancer versus ASD phenotypes [45]. Relatedly, multiple studies demonstrated that ASD-associated *PTEN* mutations tend to be less severe than non-ASD-associated mutations [46–48]. Conceivably, independent validation of consistent *PTEN* genotype–phenotype correlations is vital. If proven true, these preliminary associations will help in tailoring medical management with regard to surveillance. It is also suspected that with larger series, other associations might be found as well.

A proof-of-principle study established that other genetic modifiers modulate CS-related cancer risks and tumour histology [49]. Approximately 6–10% of CS/CS-like individuals harboured germline variants in succinate dehydrogenase subunit (mitochondrial complex II) genes, *SDHx*, on top of their pathogenic *PTEN* mutations [49]. The coexistence of a *PTEN* mutation with *SDHx* variants was associated with a 2.5–7-fold increase in breast cancer prevalence compared to individuals with either gene variant alone. Interestingly, while thyroid cancer prevalence was not elevated in individuals with both a *PTEN* mutation and an *SDHx* variant, the histology was papillary for all tumours in this group, in contrast to the follicular histology overrepresented in individuals with *PTEN* mutations alone [43].

PTEN Mutation-Negative CS and BRRS

Approximately 15% of classic CS and ~95% of CS-like individuals remain without detectable *PTEN* mutations [40]. Additionally, germline *PTEN* mutations exist in ~60% of BRRS patients [21, 22, 29, 39]. Therefore, non-*PTEN* aetiologies exist in *PTEN* wild-type patients. Studies have identified multiple susceptibility genes for *PTEN* wild-type CS and BRRS, including *SDHB-D, KLLN, AKT1, PIK3CA, SEC23B, USF3* and *TTN* [50]. More recently, known genes such as *BRCA1, BRCA2, RET* and others were associated with a rare subset of *PTEN* wild-type CS/CS-like and BRRS/BRRS-like patients [51]. The identification of other CS/CS-like and BRRS/BRRS-like susceptibility genes reflects the phenotypic heterogeneity in these patients. Validating these and other gene discoveries is important because while *PTEN* mutation-negative patients can be diagnosed clinically, they do not have the benefit of specific gene-informed genetic counselling, predictive testing of family members, precise risk assessment, and subsequent management.

Clinical Aspects

Diagnostic Criteria

Clinical diagnosis of CS is often challenging, particularly because of the protean manifestations that may occur in isolation and sporadically in the general population. Because of the lack of uniform diagnostic criteria for CS prior to 1995, a group of individuals, the International Cowden Consortium [52], interested in systematically studying this syndrome arrived at a set of consensus operational diagnostic criteria (Table 6.15.2). These guidelines form the basis for the US-based National Comprehensive Cancer Network (NCCN) guidelines. CS usually presents by the late 20s. It has variable expression and age-related penetrance. By the third decade, 99% of affected individuals would have developed the mucocutaneous stigmata although any of the features could be present already. The most commonly, but not uniformly, reported manifestations are macrocephaly (specifically, megalencephaly), mucocutaneous lesions, thyroid abnormalities, fibrocystic disease and carcinoma of the breast, gastrointestinal hamartomas, multiple, early-onset uterine leiomyoma, and developmental delay [3, 4, 53]. Pathognomonic mucocutaneous lesions are believed to exist in 100% of CS patients by age 30.

As a clinical decision support tool, a nomogram-based clinical predictor named Cleveland Clinic *PTEN* Risk Calculator, was developed to evaluate the pretest probability of harbouring a germline *PTEN* mutation [23]. Based on relevant age-adjusted phenotypic features, a weighted sum referred to as the *PTEN* Cleveland Clinic score (CC score) is generated. The questionnaire-based clinical decision tool is available online to assist clinicians at the point of patient care (http://www.lerner.ccf.org/gmi/ccscore/). In adults, a CC score of 10, indicating a pretest probability of 3% and a sensitivity of 90%, was a recommended threshold for referral of patients to genetic specialists for *PTEN* genetic testing [23]. A CC score of 15, corresponding to a 10% a priori risk of positive *PTEN* mutation status, is the most cost-effective cut-off to refer CS-like patients for *PTEN* germline testing [54]. For paediatric patients (<18 years), distinct criteria were developed to guide selection for germline *PTEN* mutation testing [23]. Macrocephaly is a major criterion based on 100% prevalence at diagnosis. Neurodevelopmental and dermatologic features were also present in 100% of PHTS paediatric patients (Table 6.15.3). However, since dermatologic features are often overlooked and difficult to recognize, less prevalent features such as vascular malformations, thyroid goitre, gastrointestinal polyps and early-onset cancers also warrant referral of the paediatric patient for

Table 6.15.2 International Cowden Consortium (ICC) operational diagnostic criteria

Pathognomonic	Major	Minor
• Adult Lhermitte-Duclos disease (LDD) • Mucocutaneous lesions • Trichilemmomas, facial • Acral keratoses • Papillomatous papules • Mucosal lesions	• Breast carcinoma • Thyroid carcinoma (non-medullary), especially follicular thyroid carcinoma • Macrocephaly (occipital frontal circumference ≥97th percentile) • Endometrial carcinoma	• Other thyroid lesions (e.g. adenoma, multinodular goitre) • Intellectual disability (i.e. IQ ≤75) • Gastrointestinal hamartomas • Fibrocystic breast disease • Lipomas • Fibromas • Genitourinary tumours (especially renal cell carcinoma) • Genitourinary malformations • Uterine fibroids
Operational diagnosis in an individual		
Any of following: • Mucocutaneous lesions alone, if ≥ six facial papules (three of which must be trichilemmomas) • Cutaneous facial papules and oral mucosal papillomatosis • Oral mucosal papillomatosis and acral keratoses • ≥ Six palmoplantar keratoses • ≥ Two major criteria (one of which must be macrocephaly or LDD) • One major and ≥ three minor criteria • ≥ Four minor criteria		
Operational diagnosis in a family where one individual is diagnostic for CS		
• Any one pathognomonic criterion • Any one major criterion ± minor criteria • Two minor criteria • History of Bannayan–Riley–Ruvalcaba syndrome (BRRS)		

Adapted with permission from Eng, C., Will the real Cowden syndrome please stand up: revised diagnostic criteria. *J Med Genet*, 2000. 37(11): p.828–30.

genetics evaluation for consideration of *PTEN* testing. Importantly, early diagnosis is vital to minimize morbidity and mortality.

Pathology

Like other inherited cancer syndromes, multifocality and bilateral involvement is the rule. Hamartomas are the hallmark of CS. These are classic hamartomas in general and are benign tumours comprising at least two (strictly three) elements of a particular organ but growing in a disorganized fashion. Of note, the hamartomatous polyps found in this syndrome are different in histomorphology from Peutz–Jeghers polyps, which have a distinct appearance. Hence, caution must be taken when the polyp histology is not read by a dedicated gastrointestinal pathologist as histological diagnoses are often incorrect when compared to genetic classification [55]. Importantly, the majority (>90%) of *PTEN* mutation-positive patients who had colonoscopy performed as part of clinical care, had colorectal polyps typically with a mix of histologic subtypes, including ganglioneuromas, hamartomatous, juvenile and adenomatous polyps [56]. Patients who developed colorectal cancer also tended to have pre-/coexisting colonic polyposis.

Table 6.15.3 Paediatric criteria for consideration of PHTS

Required criterion	Secondary criteria
Macrocephaly (≥2 standard deviations)	At least one of the following criteria should be present: • Autism spectrum disorder or developmental delay • Dermatologic features (lipomas, oral papillomas, trichilemmomas, penile freckling) • Vascular features (arteriovenous malformations or haemangiomas) • Gastrointestinal polyps • Paediatric-onset thyroid cancer or germ cell tumours

PTEN-Related Cancer Risks

The most serious complication of CS is the increased risk of cancer. Even before the discovery of *PTEN* as the first CS susceptibility gene, it was recognized that CS patients have elevated lifetime risks for breast and thyroid cancers [2, 57]. The identification of germline *PTEN* mutations in individuals with CS [6] subsequently led to the identification of other organ-specific cancer risk estimates [40]. Female breast cancer lifetime risk is the most pronounced, beginning at around age 30 and reaching an estimated lifetime risk of 85%. Although male breast cancer had been reported in CS cases [21, 58], an increased lifetime risk in *PTEN* mutation-positive males was not noted in this prospectively accrued series of >3000 patients [40]. Also noted are elevated lifetime risks of 35% for epithelial thyroid cancer, 28% for endometrial cancer, 34% for renal cell cancer, 9% for colorectal cancer and 6% for melanoma. Elevated cancer risks have been independently replicated by other groups [59, 60]. Individuals with germline *PTEN* mutations also have a 7-fold increased risk of developing a second malignant (primary) neoplasm as compared to the US general population [41]. Collectively, these observations resulted in tailoring clinical surveillance and medical management for PHTS patients (Table 6.15.4). As relevant to endocrinology clinic, earlier clinical surveillance may be advisable because Hashimoto thyroiditis and nodules are seen by the time

Table 6.15.4 Screening and management recommendations for PHTS

	Screening/surgical guidelines*	Age to start	Frequency
Breast	Breast awareness and self-exam: report changes to healthcare provider	18	Consistent
	Clinical breast exam	25**	Every 6–12 months
	Mammogram with consideration of tomosynthesis and breast MRI with contrast	30–35**	Every 12 months
	Discuss mastectomy	Personalized	As needed
Thyroid	Thyroid ultrasound	Time of PHTS diagnosis, including childhood	Every 12 months
	Discuss thyroidectomy	Personalized	As needed
Kidney	Consider renal ultrasound	40	Every 1–2 years
Endometrium	Encourage patient education and prompt response to symptoms (e.g. abnormal bleeding)	Not applicable	Not applicable
	Consider random endometrial biopsies and/or transvaginal ultrasound	30–35	Every 12 months
	Discuss hysterectomy with completion of childbearing	Personalized	As needed
Colon	Colonoscopy	35** unless symptomatic	Every 5 years or more frequently depending if patient is symptomatic or polyps are found
Dermatologic	Dermatologic exam	Personalized	Clinician's recommendation
Developmental	Consider psychomotor assessment in children	Time of PHTS diagnosis	Clinician's recommendation
	Brain MRI if symptomatic	Time of PHTS diagnosis	Clinician's recommendation

* Annual comprehensive physical exam starting at age 18 y or 5 y before the youngest age of diagnosis of a component cancer in the family (whichever comes first), with particular attention to thyroid exam. Encourage patient education regarding the signs and symptoms of cancer.
** Cancer screening should begin 5–10 years before the earliest known component cancer in the family or according to the ages listed in the above table, whichever comes first.

patients reach adolescence, and cancer diagnosis occurs on average 14 years earlier than expected, with the earliest thyroid cancer diagnosis reported at age 6 [23]. Furthermore, the thyroid cancer risks justify prophylactic total thyroidectomy in PHTS patients undergoing surgery for benign thyroid disease [4]. Relatedly, risk reduction surgery is considered for patients with ASD or cognitive deficits who do not permit ultrasound without sedation [61]. The dilemma in these groups of patients, however, is whether daily replacement thyroid hormone is feasible as they may have difficulties swallowing pills.

Role of Endocrinologists in Recognizing Clinical 'Red Flags'

There are several ways in which CS patients can come to the attention of endocrinologists or endocrine surgeons. Sometimes, an individual with known CS is referred for management of their endocrine problems, chief of which are multinodular goitre, thyroid adenomas, and epithelial thyroid carcinomas. More commonly, such patients are not previously diagnosed and seek endocrine-related care because of abnormal thyroid function or a thyroid mass. Over two-thirds of CS patients have thyroid problems, which may occur at any age. However, finding multifocal lesions, especially in young individuals, should raise suspicion. Endocrinologists and endocrine surgeons should be especially mindful of the differential diagnosis of CS should they see patients with these thyroid lesions. A careful history and physical examination, as well as a meticulous family history to look for other component symptoms and signs of CS, are warranted.

Rarely, CS individuals present with uncommon features such as hyperparathyroidism or parathyroid adenomas. When these occur together with 'a thyroid cancer', the initial diagnosis that endocrinologists might think of is multiple endocrine neoplasia (MEN) type 2a (also referred to as type 2) (see Chapter 6.11.2, 'Multiple Endocrine Neoplasia Type 2a and 2b') [3, 62]. However, it would be prudent to pursue the histology of the thyroid cancer as this might turn out to be a CS patient and not a MEN 2a (or MEN 2) case. Even more unusual, CS can present with ganglioneuromas of the gut and are referred to the endocrinologist for MEN 2B (also referred to as MEN 3). However, in general, MEN 2B (or MEN 3) and CS, are clinically and genetically distinct [3, 62]. A few MEN 2B (MEN 3) cases can present with apparently isolated intestinal ganglioneuromatosis without the other classic stigmata of MEN 2B, yet all were found to have the MEN 2B-defining germline *RET* mutation p.Met918Thr and all developed medullary thyroid carcinoma [63]. In contrast, follicular thyroid carcinoma and follicular variant of papillary thyroid carcinoma tend to be overrepresented in PHTS [43]. PHTS patients may also present with metabolic dysregulation in the form of significantly lower fasting plasma insulin levels, higher glucose infusion rate, and increased measures of obesity [64]. This insulin hypersensitivity phenotype reflects an apparently divergent effect of

PTEN mutations, with increased risks of obesity and cancer, but decreased risk of type 2 diabetes.

Genetic Counselling, Medical Management, and Therapeutic Approaches

The key to proper genetic counselling in CS is recognition of the syndrome. Families with CS should be counselled as for any autosomal dominant trait with high penetrance. What is unclear, however, is the variability of expression between and within families. We suspect that there are CS families who have nothing but trichilemmomas and, therefore, never come to medical attention. As an autosomal dominant disorder, children of an affected person have a 50% probability to inherit the gene mutation and relatives are at an increased risk as well. In up to 44% of cases, patients have a de novo *PTEN* mutation, which means the mutation is not shared by any of the parents [65]. If a family-specific mutation is known, then screening for that particular mutation in unaffected family members would yield results which are 100% accurate, barring administrative error. During the genetic testing process, genetic counselling is recommended by the American Society of Clinical Oncology and many other professional societies. Genetic counsellors can guide the patient to appropriate specialists and help them understand management. A relationship between the patient, primary care provider, and genetics team can be crucial for patient care. The key to successful management of PHTS/CS patients and their families is a multidisciplinary team (such an example can be viewed at my.clevelandclinic.org). There should always be a primary care provider, who orchestrates the care of such patients, some of whom will need the care of surgeons, endocrinologists, gynaecologists, dermatologists, gastroenterologists, oncologists and high-risk cancer specialists, neurologists, and geneticists.

As relevant to targeted therapeutics, because *PTEN* alterations result in enhanced PI3K/AKT/mTOR signalling, the latter represents a rational pathway to target in PHTS. A phase II open label clinical trial (NCT00971789) utilized the mTOR inhibitor sirolimus in adult (>18 years) PHTS patients, with ongoing follow-up data and analysis (https://theoncologist.onlinelibrary.wiley.com/doi/full/10.1634/theoncologist.2019-0514). Another mTOR inhibitor trial is currently accruing paediatric, adolescent, and young adult patients with germline pathogenic *PTEN* mutations and ASD [4]. It is warranted to explore the clinical utility of pharmacologically inhibiting other upstream components of the PTEN pathway such as PI3K and AKT. From a biological perspective, since PTEN regulates a vast array of cellular processes independent of PI3K/AKT/mTOR signalling, it is also critical to explore targeting such vulnerabilities. For example, since nuclear PTEN participates in maintaining genomic integrity, PARP inhibitors would make sense in individuals with mutations that disrupt nuclear PTEN function [66].

ACKNOWLEDGEMENTS

We are grateful to our patients and families who have participated in our research for over two decades. LY is an Ambrose Monell Foundation Cancer Genomic Medicine Fellow at the Cleveland Clinic Genomic Medicine Institute. CE is the Sondra J. and Stephen R. Hardis Chair of Cancer Genomic Medicine at the Cleveland Clinic and an American Cancer Society Clinical Research Professor.

Oxford Textbook of

Endocrinology and Diabetes

Oxford Textbook of

Endocrinology and Diabetes

THIRD EDITION

Volume 2: Sections 7–15

EDITED BY

John A.H. Wass

Professor of Endocrinology, Department of Endocrinology, Oxford Centre for Diabetes, Endocrinology, and Metabolism, Churchill Hospital, Oxford, UK

Wiebke Arlt

William Withering Chair of Medicine, Institute of Metabolism and Systems Research, University of Birmingham; Centre for Endocrinology, Diabetes and Metabolism, Birmingham Health Partners, Birmingham, UK

Robert K. Semple

Professor of Translational Molecular Medicine, University of Edinburgh Centre for Cardiovascular Science, Queen's Medical Research Institute, Edinburgh, UK

OXFORD
UNIVERSITY PRESS

United Kingdom

Oxford University Press is a department of the University of Oxford.
It furthers the University's objective of excellence in research, scholarship,
and education by publishing worldwide. Oxford is a registered trade mark of
Oxford University Press in the UK and in certain other countries

First Edition published in 2002

Second Edition published in 2011

Third Edition published in 2022

Impression: 1

Bell & Bain Ltd., Glasgow

Preface

It is now over a hundred and seventy years since Arnold Berthold demonstrated that endocrine glands convey their effects via the bloodstream and a hundred and ten years since the word 'hormone' was coined by Ernest Starling. Amazingly, it is just under a hundred years since one of the nascent specialty's most spectacular Nobel Prize-winning triumphs, the purification and use of insulin to transform Type I diabetes from a rapidly fatal wasting disease of childhood into a manageable chronic condition. Similarly, seventy years ago the Nobel Prize recognised the life-saving impact of glucocorticoids both for patients with adrenal insufficiency and as immunosuppressive therapy for chronic inflammatory disease. Since then endocrinology has continued to ride the crest of a wave of technological advances, most prominent recently in areas such as molecular genetics, imaging, immunotherapy and rational drug design.

The first edition of the *Oxford Textbook of Endocrinology & Diabetes* was published in 2002. The landscape of endocrine disease has evolved enormously since then, driven largely by burgeoning obesity and by population ageing. The spectrum of endocrinology has been further broadened by the increasing use of immunomodulatory therapies with endocrine complications, evolving patterns of recreational drug use impacting endocrine systems, and widespread exposure to endocrine disrupting chemicals. The therapeutic armamentarium of the endocrinologist has also expanded at pace, not only through development of novel small molecule and biological therapies, but also through step changes in e-technology and their application to chronic disease management and "precision" medicine.

We now comprehensively update the second edition of the *Textbook* published in 2012. The expanded first part of the book is devoted to overview chapters focusing on principles underpinning the science and practice of endocrinology. Elsewhere, other sections have also been enlarged to capture exciting developments in subspeciality practice, with separate sections now devoted to endocrine disease in pregnancy and transgender endocrinology.

The diabetes section has been extensively reorganised to reflect rapid advances in understanding the molecular pathogenesis of diabetes, step changes in the sophistication of technologies used for metabolic monitoring and insulin delivery, and innovations in immunotherapy, behaviour-focused and cell-based therapies. New chapters are devoted to current urgent responses to diabetes as a public health and economic challenge.

Fascination in the science underlying endocrinology continues to endure, and clinical endocrinologists have an ever more sophisticated ability to transform the length and quality of life of those with hormone-related diseases. This book aims both to illuminate the emerging scientific concepts that underlie endocrinology, and to provide an accessible and authoritative account of cutting edge endocrine practice.

We are very grateful indeed to our national and international colleagues who have kindly, expertly and cerebrally contributed to all sections. We are proud of this *magnum opus* and thank them sincerely for their significant efforts.

We also thank Claire Brankin, James Oates and Helen Liepman from Oxford University Press who have expertly and efficiently guided us through this whole process.

This book should be available to every endocrinologist, trainee and researcher and we hope that it provides as much enjoyment and intellectual satisfaction in the reading as it did in putting it together.

Contents

Volume 1

SECTION 4

Parathyroid, Calcium and Bone Metabolism Disorders

Section editor: John Bilezikian

SECTION 5

Adrenal Diseases

Section editor: Wiebke Arlt

Volume 2

SECTION 7
Disorders of Growth, and Development and Transition

Section editor: Peter Clayton

SECTION 8
Female Reproductive Endocrine Disorders

Section editor: Bulent Okan Yildiz

SECTION 9
Endocrine Disorders of Pregnancy

Section editors: Kristien Boelaert and Cathy Williamson

SECTION 10
Male Reproductive Endocrine Disorders

Section editors: Frederick Wu and Mathis Grossmann

SECTION 11
Management of the Transgender Patient

Section editor: Guy T'Sjoen

SECTION 12
Endocrine Responses to Systemic Diseases or Substance Misuse

Section editor: Ken Ho

SECTION 13
Endocrinology of Cancer

Section editor: David Ray

Symbols and Abbreviations

AAS	androgenic anabolic steroids
AC	adenylate cyclase (*also* arachnoid cysts)
ACE	American College of Endocrinology
ACE	angiotensin-converting enzyme
ACTH	adrenocorticotrophic hormone
AD	autosomal dominant
ADH	autosomal dominant hypocalcaemia
ADIS	agonist-driven insertional signalling
ADT	androgen deprivation therapy
AF	atrial fibrillation
AGHDA	assessment of GH deficiency in adults
AgRP	agouti-related peptide
AHA	Anterior hypothalamic area
AHO	Albright's hereditary osteodystrophy
AI	alcohol-induced (*also* aromatase inhibitors)
AIDS	acquired immunodeficiency syndrome
AIDS	advanced HIV disease
AIP	aryl hydrocarbon receptor-interacting protein
AIRE	autoimmune regulator
AKAP	A-kinase-anchoring proteins
ALS	acid-labile subunit
ALSPAC	Avon Longitudinal Study of Parents and Children
ANCA	antineutrophil cytoplasmic antibodies
ANF	atrial natriuretic factor
AP	anterior pituitary
APECED	autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy
APT	aggressive pituitary tumours
AR	androgen receptor
ARC	arcuate nucleus
ARE	androgen response elements
ART	assisted reproduction technologies
ASD	autism spectrum disorders
ATA	American Thyroid Association
ATD	antithyroid drug
ATMA	antithyroid microsomal antibody
ATOR	Australian thyroid-associated orbitopathy research
AVP	arginine-vasopressin (*also* antidiuretic hormone)
BMAD	bone mineral apparent density
BMD	bone mineral density
BMI	body mass index
BP	blood pressure
BST	bed nucleus of the stria terminalis
CAH	congenital adrenal hyperplasia
CAIS	complete androgen insensitivity syndrome
CAPTEM	capecitabine and temozolomide
CART	cocaine- and amphetamine-related transcript
CAS	clinical activity score
CAS	Court of Arbitration for Sport
CaSR	calcium-sensing receptor
CBG	corticosteroid-binding globulin
CBG	cortisol-binding globulin
CC	clivus chordoma (*also* clomiphene citrate)
CCCR	calcium-to-creatinine clearance ratio
CCH	central congenital hypothyroidism
CDI	central diabetes insipidus
CDK	cyclin-dependent kinase
CDP	constitutional delay of puberty
CE	calcium excretion
CEA	carcinoembryonic antigen
CG	chorionic gonadotrophin
CGTT	clinical genetics think tank
CH	cavernous haemangiomas (*also* congenital hypopituitarism)
CHH	congenital hypogonadotropic hypogonadism
CIRCI	critical illness-related corticosteroid insufficiency
CKD	chronic kidney disease
CLIP	corticotropin-like intermediate peptide
CLOCK	circadian locomotor output cycles kaput
CME	clathrin-mediated endocytosis
CNS	central nervous system
CNV	copy number variant
COPD	chronic obstructive pulmonary disease
CPAP	continuous positive airway pressure
CPHD	combined pituitary hormone deficiency
CPI	checkpoint inhibitors
CRE	CAMP-response elements
CREB	CAMP-Response Element Binding
CREB	cyclic AMP-response element binding
CRH	corticotropin-releasing hormone
CRP	C-reactive protein
CRPC	castration-resistant prostate cancer
CSF	cerebrospinal fluid
CSHI	continuous subcutaneous hydrocortisone infusion
CSM	cavernous sinus meningiomas
CT	computed tomography
DA	dopamine agonists
DAA	direct-acting antivirals
DALY	disability-adjusted life year
DBD	DNA-binding domain
DCV	dense-cored vesicles
DDT	dichloro-diphenyl-trichloroethane

DEXA	dual-energy X-ray absorptiometry
DHAES	dehydroepiandrosterone sulphate
DI	diabetes insipidus
DMD	Duchenne muscular dystrophy
DMH	dorsomedial hypothalamus
DON	dysthyroid optic neuropathy
DS	diaphragma sellae
DSA	digital subtraction angiography
DSD	disorder of sex development
dSPZ	dorsal subparaventricular zone
DXA	dual-energy X-ray absorptiometry
ED	endocrine disruptor (*also* erectile dysfunction)
EDC	endocrine disrupting compounds
EGF	epidermal growth factor
EGFR	epidermal growth factor receptor
ELISA	enzyme-linked immunosorbent assay
EMA	European Medicines Agency
EMAS	European Male Ageing Study
ENIGI	European Network for the Investigation of Gender Incongruence
EPP	ectopic posterior pituitary
EQA	external quality assurance
ER	endoplasmic reticulum
ERR	excess relative risk
ESE	European Society of Endocrinology
ESPGHAN	European Society of Paediatric Gastroenterology, Hepatology and Nutrition
ESPR	European Society of Paediatric Research
ESR	erythrocyte sedimentation rate
ESRD	end stage renal disease
ETA	European Thyroid Association
EUGOGO	European Group on Graves' Orbitopathy
FAP	familial amyloidotic polyneuropathy
FDA	US Food and Drug Administration
FDH	familial dysalbuminaemic hyperthyroxinaemia
FEO	food-entrainable oscillator
FHH	familial hypocalciuric hypercalcaemia
FHPP	familial hypokalaemic periodic paralysis
FIH	familial isolated hyperparathyroidism
FISH	fluorescent *in situ* hybridization
FN	follicular neoplasm
FNA	fine-needle aspiration
FNAB	fine-needle aspiration biopsy
FSH	follicle-stimulating hormone
GABA	gamma aminobutyric acid
GAD	glutamic acid decarboxylase
GAH	gender-affirming hormones
GBD	gracile bone dysplasia
GD	gender dysphoria (*also* Graves' disease)
GDNF	glial cell-derived neurotrophic factor
GDR	German Democratic Republic
GFR	glomerular filtration rate
GH	growth hormone
GHBP	growth hormone-binding protein
GHD	growth hormone deficiency
GHR	growth hormone receptor
GHRH	growth hormone-releasing hormone
GHS	growth hormone secretagogues
GK	Gamma Knife
GNAS	guanine nucleotide-binding protein G(S)
GnRH	gonadotropin-releasing hormone
GO	Graves' orbitopathy
GPCR	G-protein-coupled receptor
GREAT	Graves' Recurrent Events After Therapy
GRP	gastrin-releasing peptide
GTR	gross total resection
GTV	gross tumour volume
GWAS	genome-wide association studies
H&E	haematoxylin & eosin
HCG	human chorionic gonadotropin
HDL	high-density lipoprotein
HDR	hypoparathyroidism, deafness, and renal
HGPIN	high-grade prostatic intraepithelial neoplasia
HH	hypogonadotropic hypogonadism (*also* hypothalamic hamartoma)
HIF	hypoxia-inducing factor
HIV	human immunodeficiency virus
HLA	human leukocyte antigen
HOMA	homeostasis model assessment
HOS	hypo-osmotic swelling
HP	hypothalamo–pituitary
HPA	hypothalamic–pituitary–adrenal
HPF	high power field
HPT	hypothalamic-pituitary-testicular
HPT	hypothalamic–pituitary–thyroid
HPV	human papilloma virus
HRE	hormone response element
HRT	hormone replacement therapy
HSP	heat shock protein
HT	Hashimoto's thyroiditis
HyOb	hypothalamic obesity
IAD	isolated ACTH deficiency
IAPP	islet amyloid polypeptide
ICSI	intracytoplasmic sperm injection
ICU	intensive care unit
IDD	iodine deficiency disorders
IGF	insulin-like growth factor
IGF-1	insulin-like growth factor 1
IGF1R	insulin-like growth factor 1 receptor
IGHC	integrated growth hormone concentration
IGT	impaired glucose tolerance
IHH	idiopathic hypothalamic hypogonadism
IIH	idiopathic infantile hypercalcaemia
IJV	internal jugular vein
ILP	interstitial laser photocoagulation
IMRT	intensity-modulated radiotherapy
INSR	insulin receptor
IOC	International Olympic Committee
IOM	Institute of Medicine
IPEX	immunodysregulation polyendocrinopathy enteropathy X-linked
IPSC	induced pluripotent stem cells
IQ	intelligence quotient
IR	insulin resistance
IRAE	immune-related adverse effects
IRD	inner ring deiodination

ISE	ion-specific electrode
ISRS	International Stereotactic Radiosurgery Society
ITT	insulin tolerance test
IUI	intrauterine insemination
IVF	*in-vitro* fertilization
JNK	Jun N-terminal kinase
KS	Kallmann syndrome (*also* Klinefelter syndrome)
LAR	long-acting release
LATS	long-acting thyroid stimulator
LBD	ligand-binding domain
LC	liquid chromatography
LC	locus coeruleus
LCH	Langerhans cell histiocytosis
LDL	low-density lipoprotein
LDT	laterodorsal tegmental nucleus
LEPR	leptin receptor
LGBT	lesbian, gay, bisexual, and transgender
LH	luteinizing hormone
LHA	lateral hypothalamic area
LHRH	luteinizing hormone-releasing hormone
LIF	leukaemia inhibitory factor
LINAC	linear accelerator
LN	lymph node
LOH	local osteolytic hypercalcaemia
LOH	loss of heterozygosity
LS	Lugol's solution
LS	Lynch syndrome
LVMI	left ventricular mass index
MACE	major adverse cardiovascular events
MAI	mycobacterium avium intracellulare
MAP	mitogen-activated protein
MAPK	mitogen-activated protein kinase
MC2R	melanocortin-2 receptor
MCH	melanin-concentrating hormone
MCT	monocarboxylate transporter
MDD	major depressive disorder
MDT	multidisciplinary team
MEN	multiple endocrine neoplasia
MES	mineralocorticoid excess syndrome
MFB	medial forebrain bundle
MFS	metastasis-free survival
MHC	major histocompatibility complex
MHRA	Medicines and Healthcare products Regulatory Agency
MI	myocardial infarction
MIF	migration inhibition factor
MIP	minimally invasive parathyroidectomy
MMI	methyl-mercapto-imidazole
MMSE	Mini-Mental State Examination
MNG	multinodular goitre
MPB	male pattern baldness
MPN	medial preoptic nucleus
MPO	medial preoptic area
MR	magnetic resonance
MRI	magnetic resonance imaging
MSH	melanocyte-stimulating hormone
MTC	medullary thyroid cancer
MTC	medullary thyroid carcinoma
MTP	mitochondrial trifunctional protein
NAFLD	non-alcoholic fatty liver disease
NCD	non-communicable diseases
NCRP	National Council of Radiation Protection
NEFA	non-esterified fatty acids
NFPA	non-functioning pituitary adenomas
NGS	next generation sequencing
NHL	non-Hodgkin's lymphoma
NICE	National Institute for Clinical Excellence
NLS	nuclear localization sequence
NNRTI	non-nucleoside reverse transcriptase inhibitor
NOD	non-obese diabetic
NOGG	National Osteoporosis Guideline Group
NRTI	nucleoside reverse transcriptase inhibitors
NTCP	Na-taurocholate cotransporting polypeptide
NTD	N-terminal domain
NTD	N-terminal transcriptional regulation domain
NTE	neuropathy target esterase
NTG	non-toxic goitre
NTI	non-thyroidal illness
NYHA	New York Heart Association
OAR	organ at risk
OATP	organic anion transporting polypeptide
ODS	osmotic demyelination syndrome
OF	orbital fibroblasts
OGTT	oral glucose tolerance test
OHG	optico-hypothalamic gliomas
OI	osteogenesis imperfecta
OIS	oncogene-included senescence
ONH	optic nerve hypoplasia
OPG	optic pathway gliomas
OR	odds ratio
ORD	outer ring deiodination
OS	overall survival
OSA	obstructive sleep apnoea
OXT	oxytocin
PA	pituitary adenomas
PASS	pheochromocytoma of the adrenal gland scaled score
PC	pituitary carcinoma (*also* prohormone convertase)
PCB	polychlorinated biphenyls
PCOS	polycystic ovary syndrome
PCR	polymerase chain reaction
PCS	petroclival chondrosarcomas
PDX	patient-derived xenograft
PEARS	Parathyroid Epidemiology and Audit Research Study
PEG	polyethylene glycol
PET	positron emission tomography
PeVN	periventricular nucleus
PFS	progression-free survival
PH	pleckstrin homology
PI	protease inhibitor
PIA	proliferative inflammatory atrophy
PIC	pars intermedia cysts
PIN	prostatic intraepithelial neoplasia
PLAP	placental alkaline phosphatase
PPT	pedunculopontine tegmental nucleus
PREGO	presentation of Graves' orbitopathy

PROTAC	PROteolysis TArgeting Chimera
PRRT	peptide receptor radionuclide therapy
PRV	planning risk volume
PSA	prostate-specific antigen
PSIS	pituitary stalk interruption syndrome
PSMA	prostate-specific membrane antigen
PTC	papillary thyroid carcinoma
PTH	parathyroid hormone
PTHrP	parathyroid hormone-related protein
PTM	post-translational modification
PTPR	papillary tumours of the pineal region
PTSD	post-traumatic stress disorder
PTTG	pituitary tumour-transforming gene
PTV	planning target volume
PVH	periventricular hypothalamus
PVN	paraventricular nucleus
QC	quality control
QoL	quality of life
RAAS	renin angiotensin aldosterone system
RANKL	RANK ligand
RCC	Rathke's cleft cysts
RCOG	Royal College of Obstetrics and Gynaecology
RCT	randomized clinical trial
REM	rapid eye movement
REMS	risk evaluation and mitigation strategy
RL	RAS-like
RNI	reference nutrient intake
RR	relative risk
RRM	RNA recognition motifs
RS	radiosurgery
RTH	resistance to thyroid hormone
RTK	receptor tyrosine kinases
RXR	retinoid X receptor
SAH	subarachnoid haemorrhage
SCCM	Society of Critical Care Medicine
SCN	suprachiasmatic nucleus
SD	standard deviation
SDR	spontaneous dwarf rats
SDS	standard deviation score
SE	spin echo
SERM	selective oestrogen receptor modulator
SGK	serum glucocorticoid-regulated kinase
SH	subclinical hyperthyroidism
SHBG	sex-hormone-binding globulin
SIADH	syndrome of inappropriate antidiuretic hormone
SIBO	small intestinal bacterial overgrowth
SINE	selective inhibitors of nuclear export
SMR	standardized mortality ratio
SNP	single-nucleotide polymorphism
SOCS	suppressor of cytokine signalling
SOD	septo-optic dysplasia
SON	supraoptic nucleus
SPECT	single photon emission computed tomography
SRIF	somatotropin release inhibiting factor
SRL	somatostatin receptor ligands
SRS	sex reassignment surgery
SSA	senile systematic amyloidosis
SSRI	selective serotonin reuptake inhibitors
SST	short synacthen test
StAR	steroidogenic acute regulatory
SWS	slow-wave sleep
TAO	thyroid-associated orbitopathy
TBI	traumatic brain injury
TBS	trabecular bone score
TC	thyroid cancer
TCR	T-cell receptor
TDF	Tenofovir disoproxil fumarate
TED	thyroid eye disease
TGCC	testicular germ cell cancer
TGF	transforming growth factor
TH	thyroid hormone
THDP	thyroid hormone distributor protein
THR	thyroid hormone receptor
TKI	tyrosine kinase inhibitor
TMC	total motile count
TMD	transmembrane domains
TMN	tuberomammillary nucleus
TPP	thyrotoxic periodic paralysis
TR	thyroid hormone receptor
TR	thyroid receptor
TRH	thyrotropin-releasing hormone
TRT	testosterone replacement therapy
TSH	thyroid-stimulating hormone
TSHR	thyroid-stimulating hormone receptor
TSM	tuberculum sellae meningioma
TSS	transcriptional start site
TSS	transsphenoidal surgery
TVDT	tumour volume doubling time
UFC	urine-free cortisol
USI	universal salt iodization
VDDR	vitamin D-dependent rickets
VDR	vitamin D receptor
VEGF	vascular endothelial growth factor
VEGFR	vascular endothelial growth factor receptor
VEP	visual evoked potential
VFA	vertebral fracture assessment
VIP	vasoactive intestinal peptide
VLPO	ventrolateral preoptic area
VMH	ventromedial hypothalamus
VMN	ventromedial nucleus
vSPZ	ventral subparaventricular zone
VTA	ventral tegmental area
WADA	World Anti-Doping Agency
WBS	whole-body scan
WGS	whole genome sequencing
WHO	World Health Organization
WHR	waist/hip ratio
WT	Wilm's tumour
XLH	X-linked hypophosphataemia

SECTION 7

Disorders of Growth, and Development and Transition

7.1

Growth and Its Disorders

7.1.1 Recognizing Normal and Disordered Growth

Gary Butler

Introduction

The growth of a human being from a single cell to a fully mature individual is a remarkable process and something that is subject to a large number of influences across the whole age spectrum. Growth before birth is proportionately the most rapid and probably the least understood phase. The size of an infant at birth, therefore, is dependent on a number of factors which are primarily maternal such as the well-being of the feto-placental unit and its level of functioning. This unit is markedly affected in maternal undernutrition, which gives significant deleterious effects on fetal growth. Additionally maternal size is critical. A physically small mother will constrain growth even when the fetus has a large genetic potential size. Lastly, fetal factors are important themselves. Genetic or endocrine disturbances may constrain fetal growth.

In paediatric practice we are concerned about postnatal growth. It is useful to think of growth in three separate phases: infancy, childhood, and puberty [1]. The infancy phase is largely nutrition dependent and lasts for one to two years. After this, the childhood phase, which is predominantly growth hormone driven takes over and continues until the pubertal or adolescent phase. This final phase is under the influence of sex steroids and the speed of this phase determines the timing and rate of acceleration of the pubertal growth spurt and the cessation of growth. It is very helpful to consider the different influences on each phase when presented with the diagnostic challenge of a child with abnormal growth [2, 3]. However, the process of assessing growth variations begins with the need to make accurate and reproducible measurements.

Assessment of Growth

Equipment

As with any routine clinical assessment, using the correct equipment is important. This is certainly true for the assessment of growth where one of the biggest sources of error is broken, incorrectly calibrated, or out of date equipment. The other source of errors is poor measuring technique.

Although in specialist clinics very accurate equipment such as the Harpenden stadiometer is used, it requires regular calibration and maintenance. There are other types of stadiometer, including electronic ones which once installed accurately do not require recalibration and are suitable for routine use in clinics, wards, and surgeries. There is also relatively cheap portable equipment such as the Leicester height measure which, when used with the correct measurement technique can give an accurate height reading.

Weighing scales are often poorly maintained and calibrated and do not give an accurate readout across the whole range. Children's weight is best measured with correctly calibrated and zeroed class III electronic scales. Head circumference is best measured with a specially designed measure, such as a metal anthropometric tape or the plastic Lasso-o (Figure 7.1.1.1). If that is not available then a paper tape folded lengthways to reduce its width can be used.

Measuring Technique—Length and Height

It is now recommended that length should be measured in children up to the age of two years. The correct technique requires two people—one to hold the infant's head against the headboard with the eyes facing forwards and in the Frankfurt plane (the outer canthus of the eye in the same plane as the upper margin of the pinna). The other observer straightens the legs having removed the nappy beforehand and holds the legs extended and brings the board against both heels and the length is read to the nearest 0.1 cm (Figure 7.1.1.1). Height should be measured in children

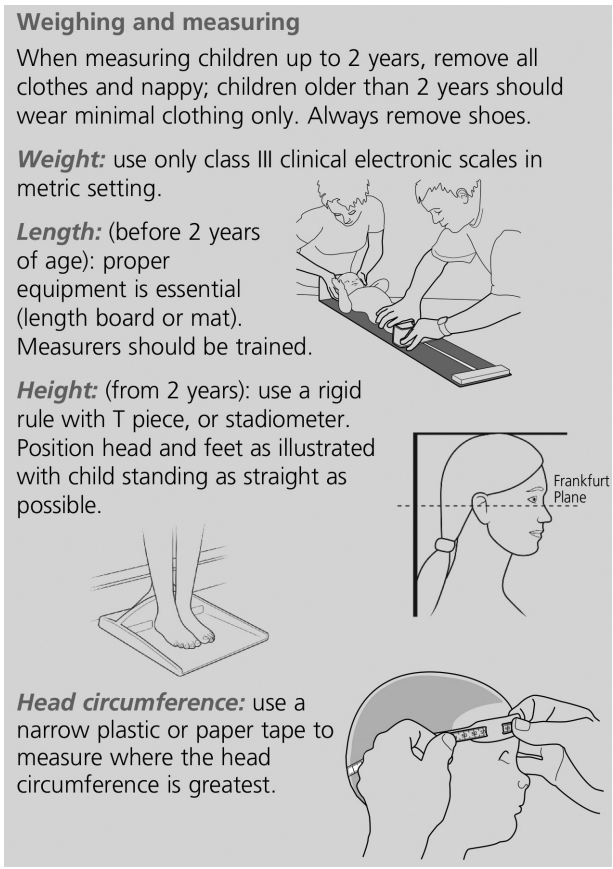

Figure 7.1.1.1 Recommended approach to measurement of supine length, weight, and occipito-frontal head circumference.

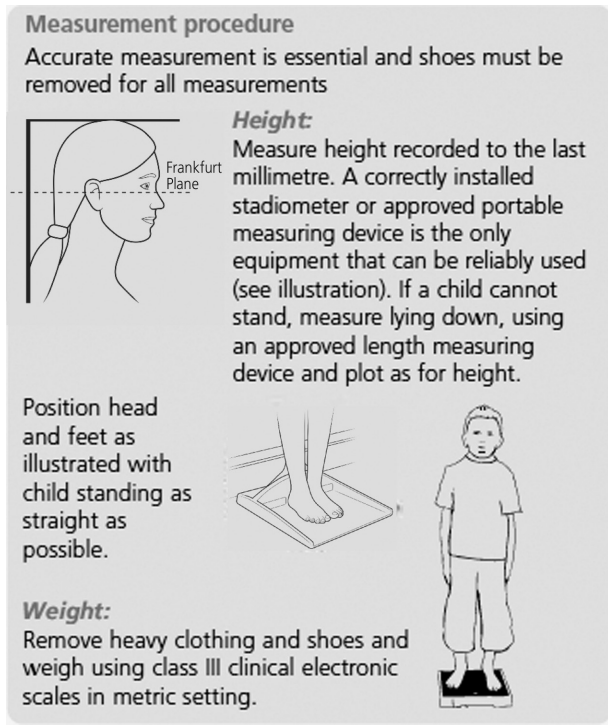

Figure 7.1.1.2 Recommended approach to measuring standing height indicating the Frankfurt plane, and weight.

over 2 years of age, using the appropriate equipment with the child standing as tall as possible, back touching the wall or backplate of the stadiometer, feet together, ankles together, and heels placed against the foot restraint. The head is placed in the Frankfurt plane and the measuring board is brought down on the top of the head (Figure 7.1.1.2). Shoes need to be removed and hair arrangements that prevent the measuring arm resting on the top of the head should be undone. The practice of stretching, putting upward pressure under the mastoid processes while the child takes a deep breath and then exhales is sometimes recommended to attempt to compensate for the up to 2 cm loss in height that occurs gradually throughout the day on account of spinal compression (diurnal variation). The difficulty here is that interobserver variations in stretching are difficult to control for, but the key to accuracy is that consistency of technique is applied, whether stretching is used or not. Instruction in measurement techniques and videos are available on the UK Royal College of Paediatrics and Child Health website [4].

Reliability and Reproducibility

With appropriately calibrated equipment the reproducibility of the measurement of length or height is usually within 0.5 cm. This variability is known as the measurement error. With a trained auxologist using a calibrated stadiometer this can be lower than 0.2 cm. Training is therefore vital and the recognition of measurement error is important as this is magnified when height velocity is calculated from two height values. For this reason, height velocity measurements at intervals of less than one year are likely to contain a greater proportion of measurement error. Furthermore, height velocity reference charts are only valid for calculation of the growth increment over a whole year. This also has the benefit that it cancels out any seasonal variation in growth which is well described, the timing of peaks and troughs in velocity varying between individuals.

Timing of Measurements

There is considerable debate as to what are the optimal ages for children to be measured. Weight, head circumference, and ideally length should be measured at birth. The infant should be weighed again within the first two weeks to assess postnatal weight loss. After that, it is recommended that infants are weighed at 2, 3, and 4 months coinciding with the UK vaccination schedule and subsequently at all other points of interaction with healthcare services. It is recommended that length is measured when required and certainly whenever there is concern about weight gain. However, it is good practice for an infant to have their length measured within the first year, then height in the toddler years and then also preschool to assess for any growth deviation. The UK National Child Measuring Programme includes height and weight estimation at school entry at age 4–5 years and on primary school exit at age 10–11 years. This was initiated as a childhood obesity surveillance scheme, and not primarily for screening for individual growth abnormalities [5].

Growth During Infancy

Growth during infancy is the most rapid phase of postnatal growth. In the first year of life, weight triples from 3 kg to approximately 10 kg on average and there is a 50% increase in stature from 50 cm to 75 cm. There is also a further 33% increase in head circumference especially within the initial 6 months of life which reflects the very rapid maturation and growth of the brain during this first year. Even in the presence of good nutrition and infant care there can be a normal drifting of measurements upwards or downwards across as many as two centile lines for length or weight, and one for head circumference over the first year, and this represents the infant determining their own genetic growth trajectory. Most of the parameters of birth size, as mentioned earlier, are determined by the intrauterine environment. Thus, the correlation between birth weight, birth length, head circumference, and the equivalent adult body proportions is actually very low.

Growth During Childhood

The variability in height velocity during the childhood phase is quite considerable, values of between 5 cm and 15 cm per year being quite normal. Although the overall trend is for the mean rate of growth to gradually decline, this is dependent upon a number of factors. First is the obvious fact that children with a taller height potential need to grow more quickly in the same time frame to reach their adult height. The converse is true for short children. Consequently, it can be problematic to determine the lowest acceptable limit of height velocity when presented with a short and slowly growing child. Calculating height velocity over intervals less than one year will be less accurate on account of a greater contribution of measurement error and subject to seasonal influences in growth rate. There are also the endogenous rhythms or cycles in growth to take into consideration [6, 7]. Normal children have phases of growth acceleration and deceleration every two to three years known as the prepubertal growth spurts (Figure 7.1.1.3), the most well-recognized and constant of these being the mid-childhood growth spurt, depicted on some national height velocity standards (e.g. US and Irish). Hence repeat height measurements to determine serial height velocity measurements are the best pointer to a growth disorder.

Given the inherent challenges of growth measurement accuracy and the knowledge about the variable pattern of childhood growth, what then is the best method for recognizing abnormal growth? In a review of practice from the Netherlands, Finland, and the UK, the most accurate parameters are deflection in height and distance from mid-parental target height [8]. Thus, there is a significantly greater chance of pathology in a child who is tall or short for their family, whose height increases or decreases by 0.5 SD over 1 year or more than 0.7 SD over 2 years. This, on the UK RCPCH growth charts, equates to a shift of over half a centile bandwidth over 1 year and across greater than one intercentile space (0.67 SD) over 2 years.

Puberty and Pubertal Growth

The staging described by Tanner is now the universally accepted method of describing this transitional phase of life [9]. Although

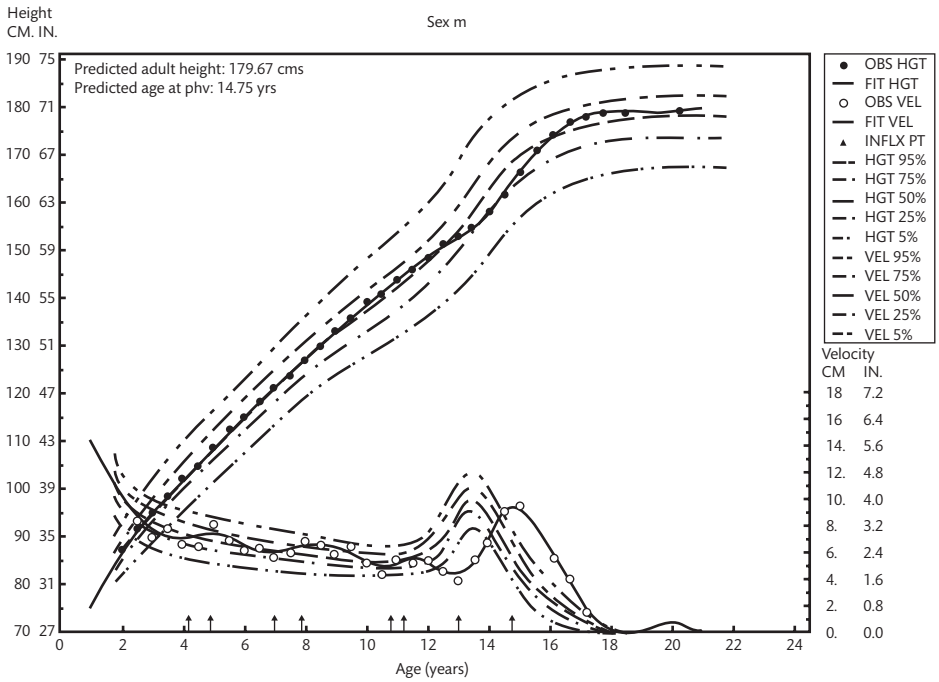

Figure 7.1.1.3 Height and height velocity curves for one boy on the background of standard height and height velocity curves. The curves are derived by mathematical modelling with raw height data. The height curve demonstrates the normal centile crossing that can occur when puberty is different from the mean. The height velocity curve demonstrates three prepubertal spurts in growth. PHV, peak height velocity; OBS HGT, observed height values; FIT HGT, fitted height curve; OBS VEL, observed height velocity values; FIT VEL, fitted height velocity curve; INFLX PTS, points of inflexion—peaks and troughs in velocity.

Table 7.1.1.1 Key milestones of the adolescent growth spurt in boys and girls indicating how rapidly puberty progresses around the peak stage of development, at what age in the process this occurs and what is the range of each parameter (given in SD). Height increase is given in cm/yr, puberty parameters in Tanner stages/yr and testis volume in ml/yr [10].

Sex	Marker	Age at peak velocity (yr)		Range of peak velocity (units/yr)	
		Mean	SD	Mean	SD
Boys	Height (cm)	14.1	1.03	9.7	0.83
	Genital stage	13.0	0.80	1.2	0.35
	Pubic hair stage	13.7	0.94	1.7	0.68
	Testis volume (ml)	13.3	1.13	6.3	2.7
Girls	Height (cm)	11.9	1.01	7.6	0.91
	Breast stage	12.0	1.09	1.5	0.39
	Pubic hair stage	12.6	0.97	1.8	0.68
	Menarche	13.1	1.21	–	–

pubertal development is continuous, an attempt to understand the process in defined stages can be very helpful. The details are well known and found in all reference texts. However, the description of five distinct stages can lead to misinterpretation unless what happens at each stage is fully understood. As stage 1 is that of the prepubertal child, and stage 5 that of the fully mature individual, there are in reality only three transitional phases of puberty: stage 2—early, stage 3—middle, and stage 4—late. The timing of the key events is what differs between the sexes. In early puberty, defined as testicular enlargement in boys and areolar growth in girls, external signs are negligible in boys but in girls, growth accelerates fast. By mid-puberty girls have reached peak height velocity and boys' growth is beginning to speed up. At stage 4 or late puberty most of the external changes in boys such as lowering of the voice, the development of pubic, axillary and facial hair, and rapid growth become apparent and testis volume increases to around 12–15 ml, whereas in girls the key event is menarche. Table 7.1.1.1 details the mean age and range of the key features of the pubertal growth spurt [10].

Tanner staging requires conducting a clinical examination and training of the clinician to ensure accuracy. In day-to-day clinical practice, this is not always feasible, possible, or desirable, yet the complete evaluation of growth in a girl over 8 years and a boy over 9 years necessitates knowing what is happening to pubertal development. Thus the use of the puberty 'phases' system may be more appropriate. The division of puberty into three phases, **prepuberty**, **in puberty**, and **completing puberty** allows ascertainment by history alone if examination is not possible (Table 7.1.1.2), and comparison with the vertical **puberty lines** on the 2–18 year or 2–20 year Childhood and Puberty Close Monitoring RCPCH growth charts can be made [11]. These lines depict the 99.6th and 0.4th centiles for the onset and completion of puberty and contain vertical reminders of the status of each puberty line (Figures 7.1.1.4 and 7.1.1.5).

The sequence of pubertal events does not normally vary between individuals. It is the timing of the onset of pubertal changes and the rate of progress which does. The childhood component of growth will continue until superseded by the pubertal phase, and variations in growth can usually be explained by what progress has or has not occurred in puberty. Although markedly variable from person to person, total pubertal growth in girls is usually 15–25 cm and in boys 20–30 cm, with smaller gains in later maturing adolescents. Hence the importance of pubertal assessment in the evaluation of growth during adolescence.

Weight and Other Related Measures

Weight and Body Composition

Weight in itself is a poor guide to complete well-being as it is compounded by many factors. Although it is the most commonly measured parameter in the first few postnatal weeks and months, the

Table 7.1.1.2 The phases of puberty as assessed by history

	Prepuberty (Tanner stage 1) If all of the following:	In puberty (Tanner stage 2–3) If any of the following:	Completing puberty (Tanner stage 4–5)
Girls	• No signs of nipple or breast development • No pubic hair	• Any breast enlargement so long as nipples also enlarged • Any pubic or axillary (armpit) hair growth	If all of the following: Started periods (menarche) with breast, pubic, and axillary hair development
Boys	• High voice • No growth of testes or penis • No pubic hair	• Slight voice deepening • Reddening of scrotum with growth of the testes • Early testicular or penile enlargement • Early pubic or axillary hair growth	If any of the following: • Voice fully changed (broken) • Adult size of penis with pubic and axillary hair growth • Moustache and early facial hair growth

total weight gain and the relative importance of the degree of gain needs to be compared with growth in length and measurement of the head as well.

It is difficult to comment accurately on gain in weight without knowing which component of weight has increased. Many attempts have been made to assess body composition, and most of these depend largely on the methodology available and are part of research studies. Cross-sectional CT scanning is the most accurate way of assessing fat and fat-free mass, but it is inconvenient and exposes the subject to considerable doses of radiation. Electronic measures of biometric impedance which give a proxy measurement of body composition are easily obtained in routine clinical practice such as with the Tanita® scale, but it is necessary to compare values obtained to reference standards supplied by the manufacturer of the equipment to interpret the data appropriately. Subcutaneous skinfold thicknesses can be measured, but there is inherent inaccuracy in the technique and many children find this unpleasant. Waist and hip circumferences may be measured but their value has yet to be fully determined as a predictor of cardiometabolic disease in paediatric practice. Mid-upper arm circumference is a very accurate and well described method of assessment of body composition in adults but is largely used for determination of the degree of undernutrition of children in developing countries [12].

Body Mass Index

This ratio of weight in kilogrammes over height in metres squared has become the benchmark of assessment for underweight and weight excess.

$$\text{BMI} = \frac{\text{weight (kg)}}{\left(\text{height (m)}\right)^2}$$

It is most easily calculated on a smartphone by entering weight in *kg* then dividing twice by height in *m*. BMI charts for childhood show a pattern of rapid gain in the first year of life, followed by decline over the preschool years until about 6 years of age, after which there is the normal pattern of adiposity rebound [11] (Figure 7.1.1.6 and 7.1.1.7). An Increase in BMI continues onwards and upwards in girls, whereas in adolescent boys under the influence of testosterone, there is a slowing down and then a decline from mid-puberty onwards. Overweight is defined as a BMI on the 91st centile or above, whereas obesity is classified as BMI on or above the 98th centile. Underweight is classified as low BMI below the 9th centile and very thin below the 2nd centile. The new UK-WHO charts contain a simple nomogram which enables the BMI to be looked up quickly from height and weight centiles without having to perform any calculations [13] (Figure 7.1.1.8).

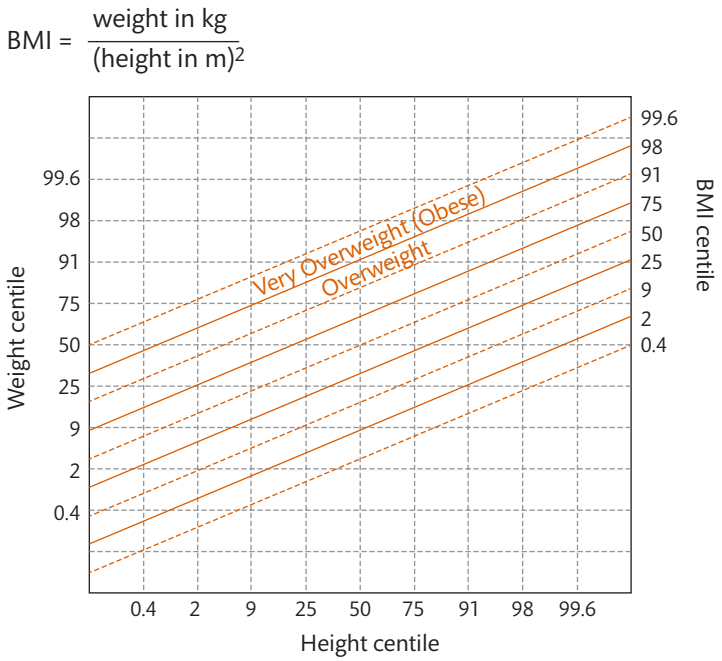

Figure 7.1.1.8 Weight–height to BMI conversion chart: the BMI look-up. Read off the weight and height centiles from the growth chart. Plot the weight centile (left axis) against the height centile (bottom axis). Read off the corresponding BMI centile from the slanting lines. Record centile with date in the data box. Accurate to ¼ centile space.

Body Surface Area

Body surface area (BSA) is preferred in the calculation of drug dose and regimens for infants. Calculating per unit of weight gives a relatively steeper increase in administered dose across all ages than by BSA. Infants have a large surface area in comparison with older children on account of the size of the head and neck, and so consequently when BSA is used to calculate fluid and drug regimens, infants will receive relatively larger amounts than using a weight-based guide. The converse is true in adolescence. BSA can be calculated by either looking up nomograms in paediatric reference manuals, apps, or read off from precalculated tables as a function of weight. Surface area can also be calculated as follows:

$$\text{BSA}\ \left(\text{m}^2\right) = \frac{\sqrt{\text{weight}\ (\text{kg}) \times \text{length}\ (\text{cm})}}{3600}$$

Types of Growth Charts and Their Use in Clinical Practice

Around the world various growth charts are in use, many of which are from locally derived populations and attempt to describe the normal variants in growth within that population. However, although there is a clear difference in physical shape and size of different ethnic groups among the human race, there has been an attempt to look at the mode of growth and pattern of gain in height, weight, and head circumference among different children of different racial backgrounds.

WHO Charts

The publication of the WHO growth charts has begun a new era in the way growth standards are constructed and presented. These have been based on prospectively collected data which are intended to represent how children should grow optimally rather than just a simple representation of how children in the population do grow—the basis behind existing growth references. The WHO growth study followed a cohort of selected babies from six countries around the world: Brazil, Oman, United States, Norway, India, and Ghana. These babies were born to non-smoking mothers, were breastfed exclusively for six months after which they were weaned and were reared in optimal social circumstances. They were followed up for five years. The complete longitudinal data for weight, head circumference, supine length until age 2 years and thereafter standing height have been used to generate these new standards. They are available on the WHO website [14] and have been combined for international usage at age 5 years with the existing United States National Centre for Health Statistics growth standards [15]. The Royal College of Paediatrics and Child Health and the Government Department of Health in the United Kingdom as well as the Government Health Departments of many countries worldwide decided to adopt the WHO standards as they best represent the growth of breastfed babies which should be regarded as the norm and represent the ideal trajectory of infant growth. These standards are now used in the UK charts from 2 weeks of age until four years of age for weight, length, and head circumference (Figures 7.1.1.9 and 7.1.1.10) [11]. There is a changeover from supine length to standing measurements at 2 years of age, a prospective decision taken in the WHO study, and therefore there is a small step downwards on the chart to account for the slight drop

from length to height measurement that occurs on account of the change in positioning. The birth data centiles were taken from the existing UK norms [16] as British babies are somewhat heavier than those in the WHO study. Thus, there is a gap for the first 2 weeks of life between the birth centiles on the charts and the start of the WHO centiles. This gap reminds us that the percentage weight loss in the first two weeks of life should be calculated which is usually no more than 10%. Community health staff are instructed to refer urgently any baby whose weight loss is greater than this amount as there is a significant chance of pathology if that is the case. After four years of age, children's growth can be plotted on the 2–18 years school age or 2–20 years Childhood and Puberty Close Monitoring RCPCH growth charts (Figures 7.1.1.4 and 7.1.1.5) [11].

The WHO growth study charts are designed to help identify growth problems and the mean and normal distribution is presented in either standard deviation score (SDS) or centile format. National practice determines which format is preferred, but the UK charts' centile lines are spaced exactly 0.67 standard deviations apart so conversion to SDS is straightforward, the normal range being plus and minus two standard deviations around the mean, this being represented by the 98th and 2nd centiles respectively. Specialist charts such as the 2–20-year Childhood and Puberty Close Monitoring Chart incorporate high and low reading lines of minus 4 to plus three standard deviations (Figures 7.1.1.4 and 7.1.1.5) [11].

Preterm Growth Charts

The UK-WHO charts have separate sections for the measurements of infants from 32 weeks' gestation until term. Weight and head circumference centiles for preterm infants from 32 weeks' gestation through to 42 weeks are included in separate boxes on these growth charts and in the parent/child health record kept by families. These centiles should be used over that period of time for any infant born before 37 completed weeks of pregnancy, which is the definition of preterm. Once the equivalent of 42 weeks postnatal age is reached, measurements are then plotted on the 0–4 years UK-WHO charts but with gestational age adjustment. The recommended approach to clarify whether or not correction has taken place is as follows: plot the measurement at the actual number of weeks of postnatal age and also at the gestationally corrected age. Link the two by a dotted line and an arrow as per the illustration (Figure 7.1.1.11). For infants who are of extremely low birth weight and who are also preterm (from 23 weeks gestational age), the Neonatal and Infant Close Monitoring charts are available [11]. These are derived from UK birthweight data and represent the size at birth of infants of that particular gestational age—head circumference, length, and weight. They do not describe how preterm infants grow postnatally as this pattern is very variable. It is quite usual for preterm infants, many of whom have severe respiratory disease, to show quite considerable weight loss, sometimes two centile spaces or more, and it may take several weeks or months to regain birth weight. Growth in length may also be affected by illness. Indeed, there are no standards currently available which reflect the growth of preterm infants on account of this variability. An additional feature of the preterm charts are centile lines showing minus 3, minus 4, and minus 5 standard deviations below the mean for all three measure to make allowance for the infant born small for gestational age after severe intrauterine growth retardation. These low birthweight charts continue up until two years of age, after which the 2–18-year school age, or 2–20 year Childhood and Puberty Close Monitoring RCPCH growth charts should be used (Figures 7.1.1.4 and 7.1.1.5) [11].

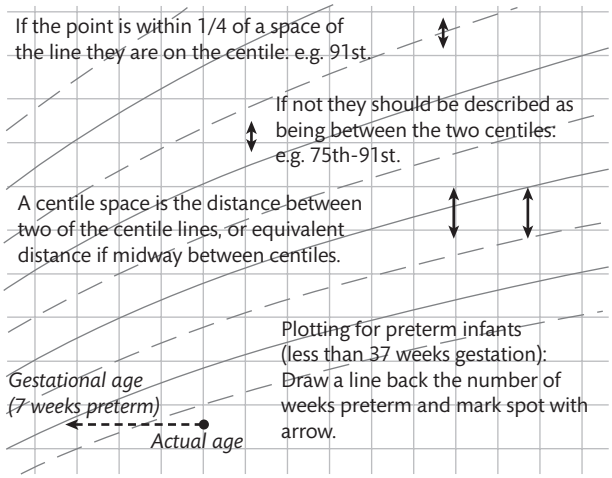

Figure 7.1.1.11 UK-WHO current recommendations for centile terminology and adjustment for prematurity.

Longitudinal Growth Charts

The majority of growth charts in routine use in countries worldwide, including the UK RCPCH [11] and US NCHS [15] charts are constructed from cross-sectional data. To produce such references many thousands of children of different ages are measured, usually only once and centile lines are constructed usually by mathematical means through the data set [16]. Such charts state the position of any child's growth parameters at a particular age with reference to the population distribution. They do not directly indicate normality or otherwise. Longitudinal charts, like the WHO charts, are derived from serial measurements of a smaller number of children from birth until maturity and the resulting values are used to construct the charts. The pattern of growth described is different, especially in early infancy and in the pubertal years and is closer to the course taken by an individual child. Longitudinal charts are preferred by some clinicians for follow-up of children with chronic conditions or growth disorders. The RCPCH charts are built around the pattern of the growth of around 190 children in the Edinburgh Growth Study, which remains the only pure longitudinal birth to maturity growth study ever conducted in the UK [10].

Individual Variability and Growth: Recognizing Abnormality

Growth charts and reference standards are constructed from the measurements of children who are growing within the normal range or close to it. There is enormous interindividual variation in growth and recognition of normal patterns of growth, so recognizing true deviations can be challenging. When a growth chart demonstrates an apparently abnormal pattern of growth it is important to be able to recognize easily that something is wrong. Before puberty, and after the postnatal period of *ex-utero* adjustment, most children

grow fairly steadily within one centile bandwidth. So much so that any deviation, up or down, may be considered as an indication of potential abnormality, especially if the child is tall or short for their target mid-parental height.

Growth Assessment During Puberty

The unpredictability of the onset of puberty and its subsequent pattern makes the development and presentation of a way of accurately assessing growth during puberty difficult. Current growth charts only represent the average amount of growth taking place for average children going through puberty at the average time, consequently, and paradoxically the charts do not represent the growth curve of any individual child or the wide variation in the timing and the intensity of growth spurt during puberty. The UK 2–18 year and 2–20-year charts have, for the first time, begun to address the issue of assessing pubertal growth [11].

Puberty Growth Charts

There have been several attempts to be able to design growth charts to allow for pubertal growth variations. There are four challenges that need to be met:

1. Age at the onset of puberty
2. The proportion of growth completed at the onset of puberty
3. The distance from target or genetic height
4. The pace of puberty

Additionally, the assessment of the degree of development during puberty either using Tanner stages or **puberty phases** has always been regarded as a separate assessment. The RCPCH UK charts for school age children and the Childhood and Puberty Close Monitoring specialist charts have attempted to combine these assessment by firstly depicting the normal ranges for beginning and completing puberty with vertical puberty lines creating zones on the growth chart to help interpret the appropriateness of growth (Figure 7.1.1.12). As in most cases, normally developing and growing adolescents will not cause concern. It is those that are at the extremes, the tall and advanced in maturing and the short and delayed in puberty who require some form of judgement as to whether their pattern of growth is acceptable. As a result of which additional lines at the extremes, 0.4th centile and 99.6th centile have been added which depict the upper ranges of normal growth, i.e. 99.6th centile for those adolescents who have completed puberty and a lower 0.4th centile for those adolescents who have not yet entered into puberty (Figure 7.1.1.13). Thus, for any young person whose height and weight plots within those ranges, consideration needs to be given as to what has happened to puberty and whether this is indeed normal; this may help to differentiate between pathology and normal variation. However, it is important to note that if a child's height falls within the shaded zone then their growth could still be abnormal if the child's height is below their target mid-parental centile range.

Syndrome-Specific Growth Charts

For children with recognized growth conditions there are a number of specialist growth charts available for children with Downs [17], Turner [18], Prader–Willi [19], Williams [20] syndromes, and achondroplasia [21]. These reference charts confer the advantage of being able to see whether a child is growing adequately, not only in comparison to the usual pattern of growth, but also with that particular diagnosis as children with these named conditions grow differently to the population. It also allows recognition of whether an intervention to ameliorate growth has had a significant effect compared with the spontaneous trajectory. They are also useful for reassurance of parents that their child is growing appropriately for their condition.

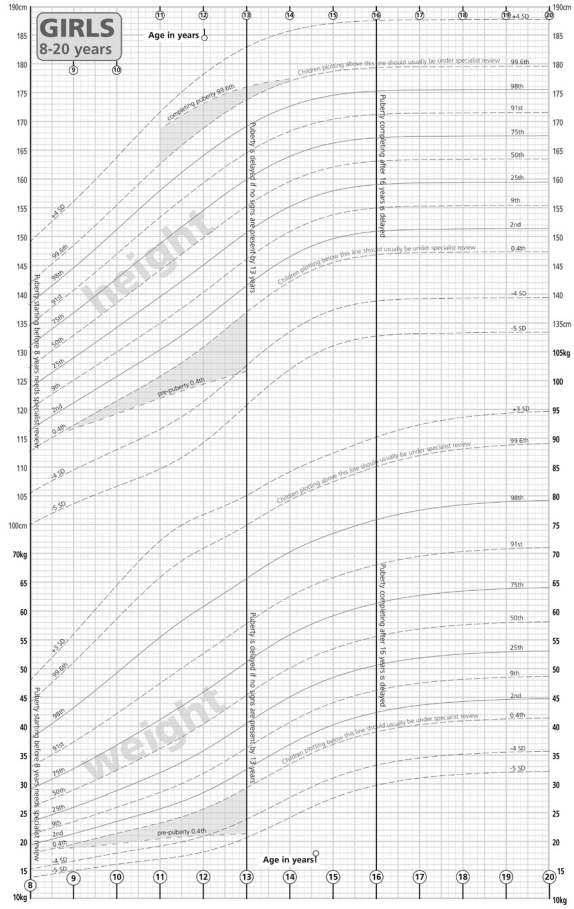

Figure 7.1.1.12 Puberty zones: vertical puberty lines depict the normal ranges for beginning and completing puberty. The shaded puberty zone marks area where 0.4th centile varies with **phase** of puberty. Heights in the shaded area below the 0.4th centile mark: (1) Prepuberty: If within two centiles of mid-parental height = **within** the normal range; and (2) in or completing puberty = **below** normal range.

Prediction of Height Gain

Prediction of height gain and adult height is always of interest to parents even when their child is growing normally, and even more so if there is a deviation from the normal pattern of growth. How, therefore can one estimate the potential growth of a child? Difficulty with accurate prediction arises on account of a number of variables involved. Firstly, there is only a relatively low correlation between a child's height and that of any one parent. Attempts to overcome this have been made by calculating a value and a

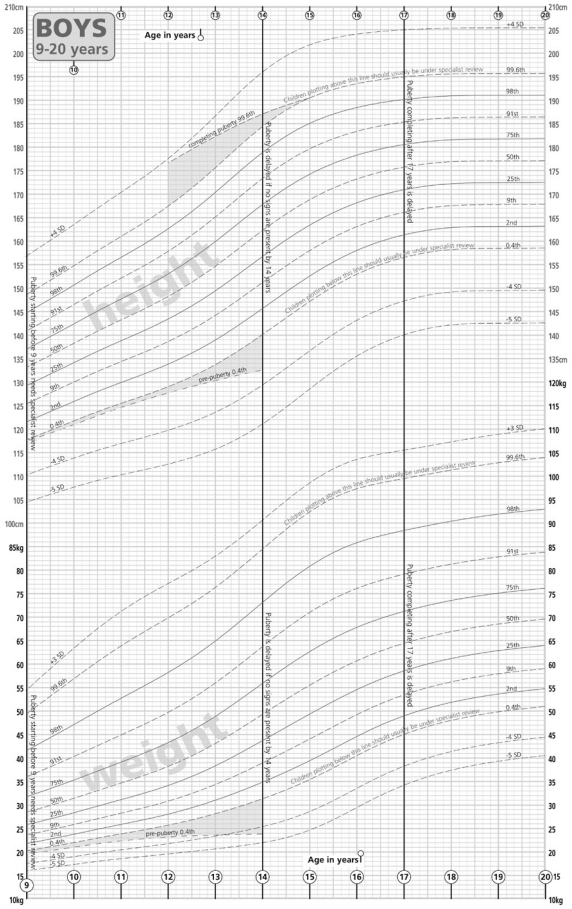

Figure 7.1.1.13 Lower 0.4th centile for prepuberty phase only. Children whose height lies within the shaded area may be normal if they are not short for their family. **Puberty lines** mark boundaries of normal pubertal development. Shaded zone marks area where 0.4th centile varies with **phase** of puberty.

range by combining both parents' heights (mid-parental height and target height range, see next). Even in the absence of pathology and illness, children show wide variation in their rate of growth and maturity. This is often referred to as the 'tempo of growth'. Children whose tempo is fast are advanced maturers and so will be tall for their age, usually with early normal puberty, but not necessarily tall as adults on account of earlier cessation of growth. The opposite is true for those with a slow tempo (the later maturers) and it is these children who often present to healthcare services with concerns over their short stature and slow growth. The variation in maturation may be estimated by taking a bone age (see next).

Mid-Parental Height (Target Height)

Since there is a reasonable association between the centile position of a child growing normally and the measured heights of *both* biological parents, there are several methods suggested for the calculation of mid-parental (or target) height. The RCPCH UK charts have a graphical mid-parental centile comparator where both parents' measured heights are plotted and when a line is drawn between these two points, the intersection identifies the mid-parental centile. Ninety-one per cent (91%) of children's adult heights will lie within two centile bandwidths of this point (i.e. plus or minus 1.33 standard deviations) and 98% will lie within plus or minus three bandwidths (plus or minus two standard deviations) (Figure 7.1.1.14).

A mathematical calculation can also be used. The difference between the 50th centile heights of male and female adults in the UK population is 14 cm, this sex difference when applied to the individual child is corrected for by adding 14 cm onto the mother's height for a boy and subtracting 14 cm from the father's height for a girl and then calculating the simple mean of both adjusted parents' heights. This value is the target height and 95% of children's adult heights will fall plus or minus 1.6 standard deviations of this value (10 cm in boys and 8.5 cm in girls). This simple approach also does not control for secular trend (i.e. the population increase in stature from one generation to the next). The method of Hermanussen and

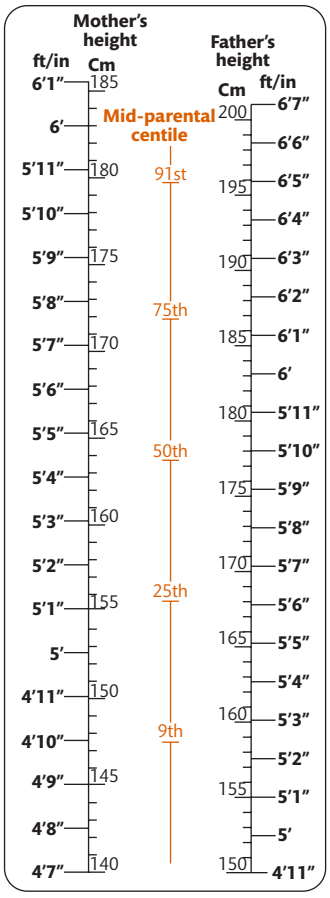

Figure 7.1.1.14 Mid-parental centile comparator where both parents' measured heights are plotted and when a line is drawn between these two points, the intersection identifies the mid-parental centile. 91% of children's adult heights will lie within two centile bandwidths of this point (i.e. plus or minus 1.33 standard deviations) and 98% will lie within plus or minus three bandwidths (plus or minus two standard deviations). Mark mother's height on the left-hand scale and the father's height on the right scale using arrows. Draw a line between arrowheads and read off mid-parental centile where this crosses the central line. Regression adjustment means that children of very short or tall parents have mid-parental centile nearer to average than expected.

Cole makes an attempt to control for this and may provide a slightly more accurate evaluation of parental height but requires the calculation of SDSs for parents' heights [22]. The authors state that by calculating parents' height SDS from growth standards (which are often constructed from measurements of children in a generation contemporary to the parents themselves), a simple correction factor can be applied to predict the target height in the child's current generation.

Calculating the target height and target centile range is useful in describing the expected range of adult stature. It can help to determine whether a child with extremes of stature is appropriately tall or short for their family, and if not, then set the clinician thinking about alternative reasons for this variation in growth.

Predictive Adult Height Calculator

An alternative approach to height prediction is the 'adult height look-up' which is incorporated into the UK-WHO charts [23]. Here the child's adult height centile can be predicted from the child's current height centile with a given accuracy of plus or minus 6 cm in 80% of cases (Figure 7.1.1.15). This method has been derived from a series of regression analyses predicting a child's actual adult height in comparison with their height at various ages beforehand as longitudinal data. There is usually a reasonably close correlation at most ages except at the time of puberty on account of the wide variation in the timing and magnitude of the adolescent growth spurt.

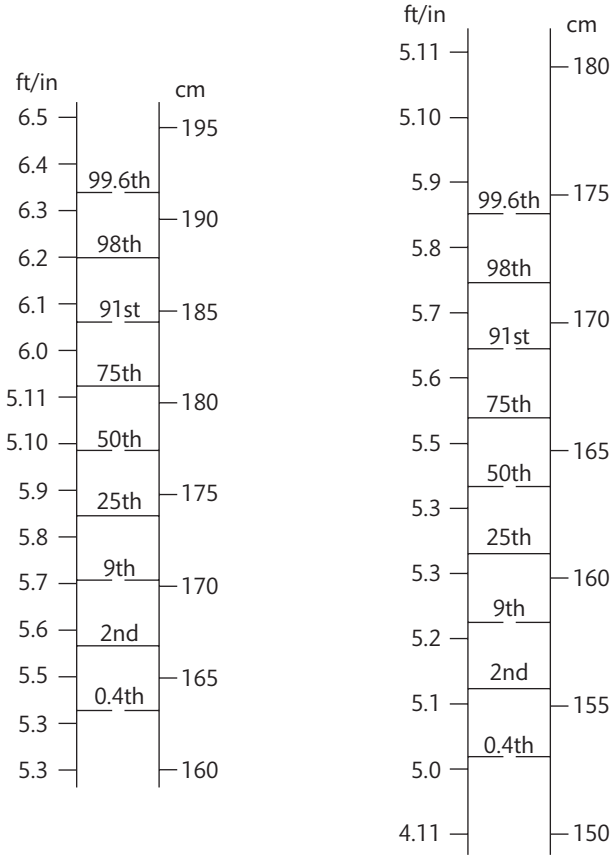

Figure 7.1.1.15 Adult height predictor. Plot the child's height centile on the lines (left-boy; right-girl). The values show the average male or female height (respectively) for this centile. 80% of children will have an adult height within +/– 6 cm of this value.

Bone Age

The bone age is the recognized standard method of assessing biological maturity. It is usually assessed on the left hand (by convention, even in left-handed children) and the X-ray should be taken in a standard radiographic position to view the wrist bones, carpals, the short bones of the hand. The accuracy in predicting maturity compared with biological status is less good than calculating the dental age from a dental radiograph, but the latter is not routinely done as the dose of radiation required is considerably higher. Bone age may be derived by a number of methods.

The most common method used in routine clinical practice is that of Greulich and Pyle, where the child's radiograph is compared with standards from an atlas compiled in 1959 derived from socially advantaged US children in the 1920s [24]. This has more recently been re-validated for Dutch children and therefore is appropriate to use in contemporary clinical practice [25]. The Tanner Whitehouse-3 (TW3) method is a different system which assesses the development of the radius, ulna, and the short bones (metacarpals and phalanges) separately and maturity scores are given to each of these bones [26]. The bone age is calculated by the summation of these maturity scores. Carpal bone maturity was scored in previous versions but as it did not contribute to improved height prediction it is no longer incorporated in height prediction. A computerized method, BoneXpert, has been derived which actually calculates the bone maturity in a three-phase process, analysing the size, shape, and density of the long and short bones [27]. This has the advantage of significantly reduced interobserver variability in rating and also reproducibility of bone age assessment especially for clinical research studies. It has also been shown to be reliable in routine clinical practice. None of the systems are compatible with each other and give different maturity ratings on the same X-ray images, so it is necessary to stick with one approach for internal consistency [28].

Uses of Bone Age

As with growth standards, bone age standards have been derived from radiographs in children growing at normal rates mostly within the normal range of stature. The index groups include few children whose growth is abnormal or who show different growth trajectories. In children growing normally, the bone age is mostly within plus or minus two years of their chronological age (equivalent to plus or minus two standard deviations from the mean). A bone age estimation within this range may not be useful for positive diagnostic purposes but may help confirm the absence of a major health issue. It is most helpful when a child has a significant pathology and the bone age is severely delayed or advanced. It may sometimes be useful for monitoring a response to treatment such as in precocious sexual maturation.

Bone Age and Prediction of Adult Height

The prediction of adult height is regarded by many as the main reason for assessing bone age. Predicted adult height may be

calculated by a number of methods. The simplest is the Bayley-Pinneau tables which, based on the Greulich and Pyle bone age measurement, are able to give an estimate of the percentage of height attained for a given child's bone age and consequently their height prognosis (i.e. their remaining growth) [29]. Although based on American children, this still has a degree of accuracy worldwide and appears to be consistently the most accurate way of predicting growth outcomes for short and tall children, although with notable under- and overprediction errors [28]. The TW3 method formulae describe residual growth for certain degrees of maturity and allows for the well-recognized acceleration in skeletal maturity that occurs during puberty. This has been described as the most accurate for the UK population. All of these methods need to be used with caution in pathological situations, even when a child has a known growth abnormality and an awareness of the variability in predictions in each pathological condition is required [28].

Conclusion

If a child's well-being is reflected in the normality of their growth, then knowing how to evaluate growth is crucial. It will require a knowledge of measuring techniques, selection of an appropriate growth chart and then determining whether a problem already exists due to abnormal size, or whether one is developing over time requiring repeated assessment. It is vital to recognize changes in growth trajectory and how they vary between infancy, childhood, and adolescence, as recognizing abnormal patterns of under- or overgrowth will aid in the more rapid diagnosis of disorders of growth and puberty.

7.1.2 Disorders of the GH-IGF Axis

Alexander A.L. Jorge, Fernanda A. Correa, and Renata C. Scalco

Introduction

Disorders of the growth hormone-insulin-like growth factor (GH-IGF) axis include a large heterogeneous group of conditions with distinct phenotypes (Figure 7.1.2.1, Box 7.1.2.1 and Table 7.1.2.1). Each of the defects identified in this axis is responsible for a rare and specific condition that endocrinologists need to be familiar with. Traditionally, clinical and hormonal evaluations are the cornerstones of diagnosis of these disorders but, in recent years, molecular genetic tests have become an important tool for the investigation of GH-IGF axis disorders. In this chapter, we will focus on genetic causes and highlight their main characteristics and the diagnostic approaches for each of them. If available, a number prefix that facilitates access to 'Online Mendelian Inheritance in Man' database (OMIM—https://www.omim.org/) will be provided, expediting the access to additional information for each disease.

The determination of an IGF-1 level and GH secretion status are usually the first step to assess the GH-IGF axis [1, 2] (Table 7.1.2.1). IGF-1 should be evaluated according to sex and chronological age [2, 3]. Because of the pulsatile nature of GH secretion, sufficiency or deficiency of GH is usually determined after a pharmacological stimulation test [2]. However, in many conditions described in this chapter, basal GH is already markedly elevated, excluding GH deficiency [4]. Based on clinical findings and IGF-1/GH levels, further evaluation of other components of this axis can be included: insulin-like growth factor-binding protein 3 (IGFBP-3), acid-labile subunit (ALS), insulin-like growth factor 2 (IGF-2), growth hormone-binding protein (GHBP). Additionally, the acute IGF-1 and IGFBP-3 response after exogenous GH therapy (the IGF Generation test) can give valuable information to better characterize the GH-IGF axis defect. Molecular genetic tests can then be used to define the precise defect in the GH-IGF axis [5].

GH deficiency is by far the most common defect in GH-IGF axis; its frequency is around 1–2% in non-selected groups of children with short stature [6]. In the last decade, several studies have suggested that *IGF1R* defects leading to variable degrees of IGF-1 insensitivity can be present in 2% of short children born small for gestational age (SGA) [7].

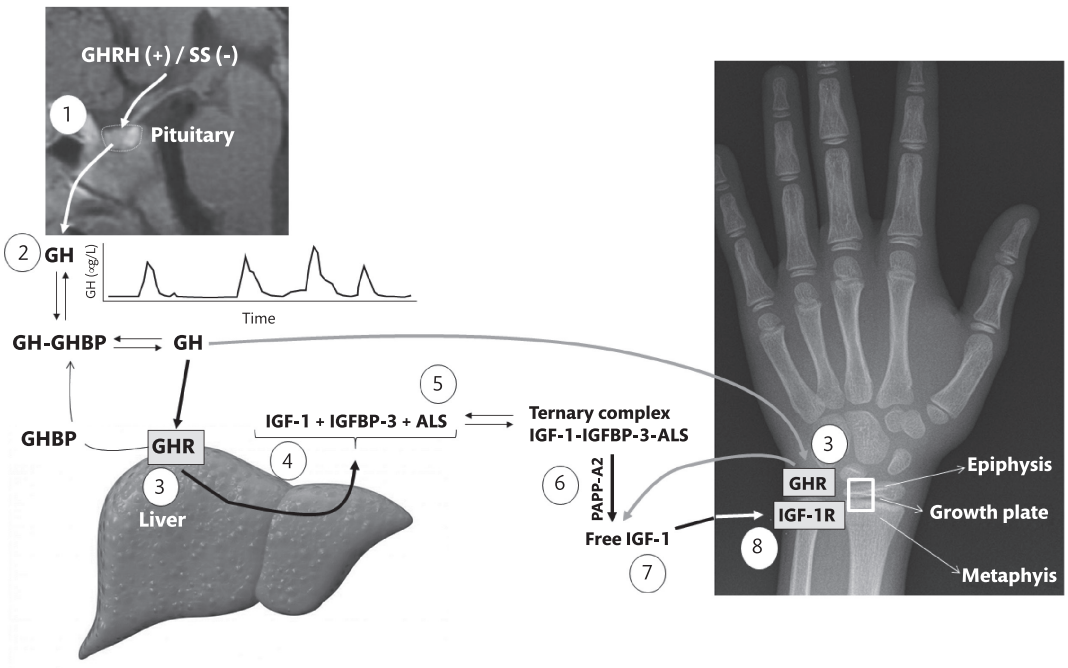

Figure 7.1.2.1 Schematic representation of the GH-IGF axis indicating the main disorders in this system: (1) growth hormone deficiency (GHD); (2) bioinactive GH; (3) GH insensitivity; (4) IGF-1 deficiency; (5) acid-labile subunit deficiency; (6) defects in the proteolytic cleavage of IGFBPs; (7) bioinactive IGF-1; and (8) IGF insensitivity.

Box 7.1.2.1 Disorders of the GH-IGF axis

GH deficiency
- Idiopathic
- Acquired (craniopharyngioma, pituitary tumours, autoimmune diseases, granulomatous diseases, central nervous system infections, post-radiotherapy, head trauma)
- Congenital: associated with structural defects
- Genetic
  - GH secretion (*GH1* and *GHRHR* genes)
  - Pituitary cells differentiation (*POU1F1* and *PROP1* genes)
  - Pituitary development (*HESX1*, *GLI2*, *OTX2*, *LHX3*, *LHX4*, and *SOX3* genes)

Bioinactive GH (Kowarski syndrome, OMIM 262650)

GH insensitivity (GHI)
- Complete GHI (OMIM 262500)
- Partial GHI (OMIM 604271)
- GHI associated to immune dysfunction (OMIM 245590)
- Atypical GHI
- Secondary or acquired GHI (anti-GH antibodies, malnutrition, liver disorders, poorly controlled diabetes mellitus, uraemia)

Ternary complex defects
- Acid-labile subunit deficiency (OMIM 615961)
- Defects on proteolytic cleavage of IGFBPs (*PAPPA2* gene)

Primary IGFs deficiency
- IGF1 defects (OMIM 608747)
- IGF2 defects (OMIM 616489)

Bioinactive IGF-1

IGF insensitivity (OMIM 270450)

GH, growth hormone; IGF-1, insulin-like growth factor type 1; IGFBP-3. insulin-like growth factors binding protein 3; ALS, acid-label subunit; IGFs, insulin-like growth factors.

GH-IGF Axis

Growth Hormone (GH) and Its Receptor (GHR)

GH is produced by somatotrophs in the anterior pituitary under the regulation of two main hypothalamic peptides: growth hormone-releasing hormone (GHRH) and somatostatin (SST) [8]. GHRH stimulates the synthesis and release of GH, whereas SST inhibits its release and regulates the pulsatile GH secretion. Besides GHRH, ghrelin, which is a peptide secreted mostly by gastric cells, can stimulate GH synthesis and release through its action on the GH secretagogue receptor (GHSR), located in the hypothalamus and pituitary. GH is secreted by the pituitary as monomeric and oligomeric isoforms, 22kDa being the main one, followed by 20kDa, both with biological activity. Approximately 50% of circulating GH is bound to GHBP, a high affinity binding protein that represents the GHR extracellular domain and is produced through GHR proteolysis.

GH acts by binding to growth hormone receptor (GHR; Figure 7.1.2.2), a transmembrane receptor that is a member of the class I cytokine receptor family. It has only one transmembrane domain and no intrinsic enzymatic activity, needing to be coupled to a tyrosine kinase called Janus kinase 2 (JAK2) to trigger the intracellular signal transduction. When GH binds to a pre-assembled receptor dimer, there is a conformational change in its intracytoplasmic region that allows JAK2 to become phosphorylated and then to phosphorylate tyrosine residues in GHR, which become binding sites for signalling molecules [8, 9]. In this manner, GHR and JAK2 activate signalling pathways that are common to other receptors, such as the mitogen-activated protein kinase (MAPK) and the

Table 7.1.2.1 Phenotype according to GH-IGF axis defects

	Gene	Inheritance	Growth disorder		Hormone measurement			Additional features
			Prenatal	Postnatal	GH	IGF-1	IGFBP-3	
GH deficiency	several	AR / AD	Nl	↓ to ↓↓↓	↓ to ↓↓↓	↓ to ↓↓↓	↓ to ↓↓↓	See Table 7.1.2.2
Bioinactive GH	*GH1*	AR / AD	Nl or ↓	↓↓↓	↑↑	↓↓	↓↓	Mild phenotype of Laron syndrome (*). IGF-1 increases after use of exogenous GH
GH insensitivity (GHI)	*GHR*	AR > AD	Nl or ↓	↓↓ to ↓↓↓	Nl to ↑↑	↓ to ↓↓↓	↓ to ↓↓↓	Phenotype of Laron syndrome in complete GHI. Low GHBP in 70% of cases. IGF-1 does not change after exogenous GH
GHI associated to immune dysfunction	*STAT5b*	AR > AD	Nl or ↓	↓↓↓	↑↑	↓↓	↓↓	Phenotype similar to Laron syndrome + immune dysfunction and elevated PRL in AR forms
Ternary complex defects	*IGFALS*	AR	Nl or ↓	↓	Nl to ↑	↓↓	↓↓↓	Laboratory abnormality disproportionate to mild short stature, pubertal delay
	PAPPA2	AR	Nl or ↓	↓ to ↓↓	↑↑	↑↑↑	↑↑↑	Mild microcephaly. Low free IGF-1 (*)
IGF1 defects	*IGF1*	AR/AD	↓↓↓	↓↓↓	↑↑	↓↓↓↓	Nl or ↑	Microcephaly, sensorineural deafness, developmental delay, intellectual disability, insulin resistance
IGF2 defects	*IGF2*	ADp	↓↓↓	↓↓ to ↓↓↓	Nl or ↑	Nl or ↑	Nl or ↑	Phenotype resembling Silver-Russell syndrome and low IGF-2 levels (*)
Bioinactive IGF-1	*IGF1*	AR	↓↓↓	↓↓↓	↑↑	↑↑↑↑	Nl	Microcephaly, sensorineural deafness, developmental delay, intellectual disability, insulin resistance (*)
IGF insensitivity	*IGF1R*	AD > AR	↓ to ↓↓↓	↓ to ↓↓↓	Nl to ↑↑	Nl to ↑↑	Nl to ↑↑	Variable clinical findings in the dominant forms. Microcephaly, developmental delay, and intellectual disability may be present

AR, autosomal recessive; AD, autosomal dominant; ADp, AD with paternal transmission; Nl, normal; ↑, increase; ↓, decrease; PRL, prolactin. *, phenotype based on a limited number of patients/families.

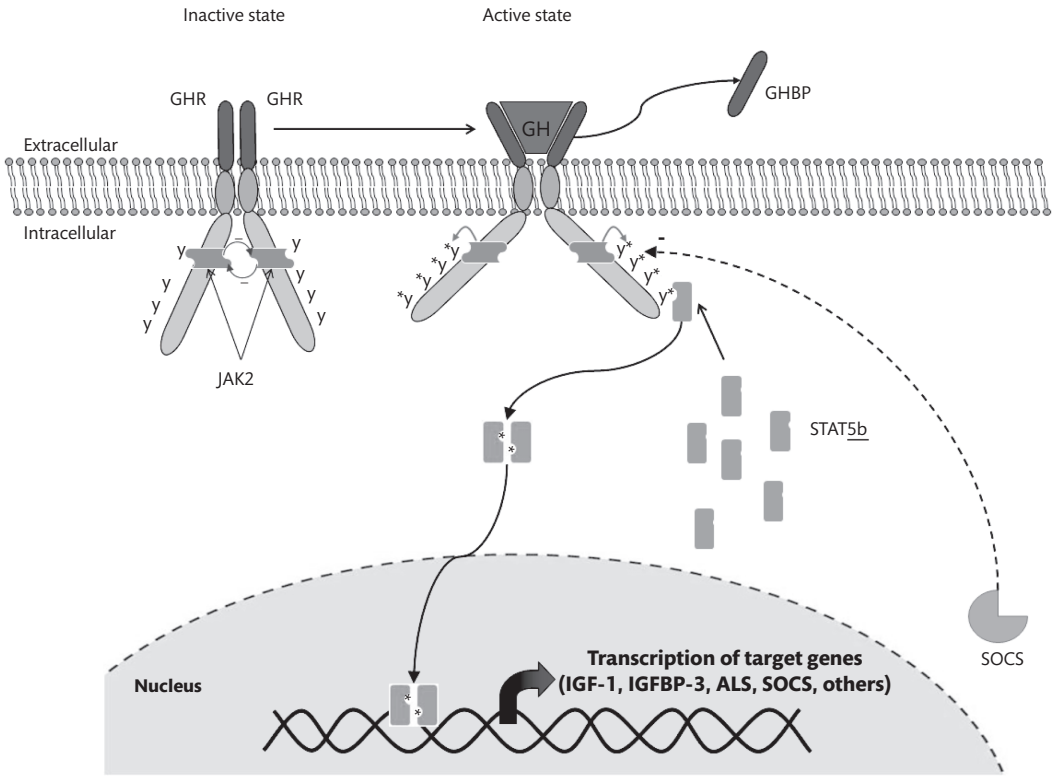

Figure 7.1.2.2 Schematic representation of GH-GHR signalling through JAK2-STAT5B pathway. In the inactive state, two GHR molecules are predimerized in the cell membrane. Each JAK2 protein bound to the intracytoplasmic portion of one receptor inhibits the catalytic activity of the other. Once GH binds to the two receptors, a change of the conformational structure takes place, moving apart the two JAK2 molecules that can then phosphorylate sites of tyrosine in themselves as well as in GHR. Tyrosine-phosphorylation creates docking sites for signalling proteins such as STAT5Bs that become phosphorylated, allowing their dimerization, transport to the nucleus and activation of transcription of target genes (IGF-1, IGFBP-3, ALS, and others). This signalling pathway also stimulates the synthesis of SOCS, which ultimately inhibits this signalling process.

inositol-1,4,5-trisphosphate 3-kinase (IP-3K) pathways, which are important to the metabolic and proliferative effects of GH. Besides these pathways, cytokine receptors have a unique signalling pathway that uses cytoplasmic proteins known as signal transducer and activator of transcription (STAT). Among the seven STAT proteins currently known, the most important for GHR signal transduction in humans is STAT5B. This protein, when phosphorylated, dimerizes, and translocates into the nucleus, where its binding to GH responsive elements in DNA stimulates the transcription of genes such as IGF-1, IGFBP3, and ALS [8, 9]. This signalling pathway also stimulates the synthesis of suppressors of cytokine signalling (SOCS), which ultimately inhibit this signalling process.

- **Insulin-like growth factor type 1 (IGF-1) and its receptor (IGF-1R)**

Most of the growth-promoting actions of GH are mediated by IGF-1 [10]. It has an essential role in pre- and postnatal growth, brain, and inner ear development. *In utero*, its secretion is independent of GH and regulated mainly by nutritional status while after birth its circulating fraction is mainly produced by the liver in response to GH. It also has a paracrine/autocrine action, being secreted by most tissues. The role of circulating versus locally produced IGF-1 in growth is still a matter of debate [11]. Circulating IGF-1 is bound to high affinity binding proteins, the insulin-like growth factor-binding proteins (IGFBP). Currently, six IGFBPs are well characterized. These proteins regulate IGF-1's availability to bind to its receptor IGF-1R and also have independent roles in the modulation of autocrine, paracrine, and endocrine IGF-1 actions. Some 70–80% of circulating IGF-1 is found in a ternary complex with IGFBP-3 and ALS, around 20% is bound to others IGFBPs and less than 5% is found in the free form. IGF-1 found in the ternary complex is unable to reach the extravascular compartment and consequently to act on target tissues. Through this mechanism, the ternary complex increases IGF-1 half-life from minutes to several hours and modulates its biological activity. Another IGF, IGF-2, is the most important factor in the regulation of intrauterine growth. Interestingly, the *IGF2* gene is located in an imprinting region where the paternally inherited allele is preferentially expressed [12].

Most of IGF-1 and IGF-2 actions are mediated by IGF-1R, a tyrosine kinase receptor structurally similar to the insulin receptor (Figure 7.1.2.3). When IGF-1 or IGF-2 binds to a homodimer of IGF-1R, there is a conformational change in the intracytoplasmic region that allows trans-autophosphorylation and creates docking sites for signalling molecules [13]. The main protein activated by IGF-1R is insulin receptor substrate 1 (IRS-1), a hydrophilic phosphoprotein that recruits and regulates the activity of other intracellular proteins. IRS-1 acts as an adaptor molecule and activates signalling cascades associated with tyrosine kinase receptors. One of the most important signalling pathways of IGF-1R is MAPK, which is responsible for the proliferative effects of IGF. Another

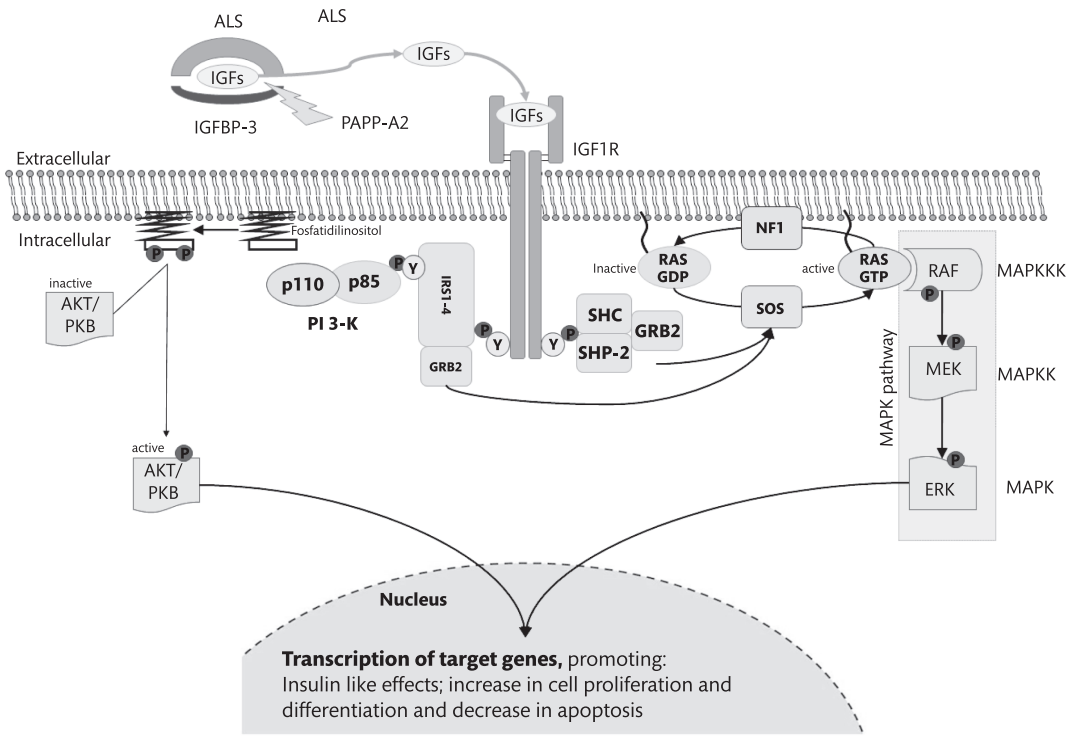

Figure 7.1.2.3 Schematic representation of IGF-IGF-1R signalling through RAS/MAPK and PI3K/PBK pathways. Once IGF-1 or IGF-2 binds to a homodimer of IGF-1R, there is a conformational change in the intracytoplasmic region that allows trans-autophosphorylation and creates docking sites for signalling molecules. Several proteins bind to these phosphorylated tyrosine sites and become activated. This initiates a cascade of events that activate RAS/MAPK and PI3K/PBK pathways that promote the genomic effects triggered by the IGFs.

signalling pathway is PI-3K, responsible for the metabolic effects of IGF, which are similar to insulin effects.

Growth Hormone Deficiency (GHD)

GHD can be either isolated (IGHD) or combined with other pituitary hormones deficiencies (CPHD). It can be congenital, usually due to a genetic defect, or acquired, due to tumours in the hypothalamic-pituitary region, neurosurgery, radiotherapy, autoimmune, and granulomatous diseases and even brain trauma. It is not unusual that patients with congenital/genetic causes present with associated complex phenotypes. The most common are: structural changes of the hypothalamic-pituitary region and/or the central nervous system (CNS); craniofacial malformations; septo-optic dysplasia (SOD); and developmental delay/intellectual disability [14]. Considering the genetic defects that cause hypopituitarism, we can classify them based on the main mechanism of pituitary dysfunction (Table 7.1.2.2).

- **Genetic defects in GH secretion leading to isolated growth hormone deficiency (IGHD)**

Classically, familial IGHD has been classified into four types depending on the inheritance pattern: autosomal recessive (types IA, OMIM 262400 and IB, OMIM 612781), autosomal dominant (type II, OMIM 173100), and X-linked (type III, OMIM 307200) [8]. Mutations in *GH1* can cause IGHD types IA, IB, and II, while IGHD type IB can also be caused by mutations in growth hormone-releasing hormone receptor (*GHRHR*). In relation to IGHD type III, a X-linked GHD associated with agammaglobulinemia has been described: although the *BTK* (Bruton tyrosine kinase) gene, a key regulator of B cell development, has been associated with this condition, its genetic aetiology remains unknown. Additionally, homozygous and heterozygous mutations in the GHSR, also known as ghrelin receptor, have been associated with partial IGHD (OMIM 615925). On neuroimaging, regardless of the genetic defect, patients have normal or hypoplastic anterior pituitary with a normally sited posterior pituitary 'bright' signal [15].

This traditional classification was made before the exact genetic defects were known. In this chapter, we have chosen to focus on the most well characterized genetic defects and mentioned the former classification for completeness.

GH1

Mutations in the *GH1* (growth hormone 1) gene are an excellent example of how different genetic defects and modes of inheritance lead to distinct phenotypes. Homozygous deletions of the *GH1* gene locus ranging from 6.7 to 45 kB lead to severe forms of IGHD. Patients usually present within the first 6 months of life with typical clinical features associated with complete GH deficiency: severe growth failure (height standard deviation score (SDS) <–3), low growth velocity, hypoglycaemia, prolonged jaundice, mid-facial hypoplasia, protruding forehead, saddle nose, high-pitched voice, and truncal obesity [8, 16]. Typically, they have undetectable IGF-1 and GH concentrations. These patients tend to develop high titres of anti-GH antibodies after hormone replacement therapy is initiated, which can neutralize GH actions and therefore lead to failure of response to recombinant human GH (r-hGH) therapy. Microdeletions

Table 7.1.2.2 Genes associated with growth hormone deficiency either isolated (IGHD) or combined (CPHD) and their clinical features

Gene	Inheritance	Hormonal deficiencies	Anterior pituitary	Posterior pituitary	Other features
GH1	Recessive	IGHD	NL or ↓	Topic	Severe IGHD, depending on the genetic defect anti-GH antibodies leads to ineffective treatment with r-hGH
	Dominant	IGHD, may evolve with other deficiencies	NL or ↓	Topic	Variable phenotypes regarding height and time of presentation. patients may develop additional pituitary hormone deficiencies
GHRHR	Recessive	IGHD	↓	Topic	Severe IGHD
PROP1	Recessive	GH+TSH+PRL+LH/FSH may evolve with ACTH deficiency	↑, NL or ↓	Topic	Hormonal deficiencies can emerge asynchronously
POU1F1	Recessive/dominant	GH+TSH+PRL	NL or ↓	Topic	
GLI2	Dominant	IGHD or CPHD	↓	Ectopic/NV	Polydactyly, HPE, craniofacial malformations
HESX1	Recessive/dominant	IGHD or CPHD	A, NL or↓	Topic or ectopic	SOD
LHX3	Recessive	CPHD	A, ↑, NL or ↑	Topic	Deafness, Limited neck rotation, elevated shoulders
LHX4	Dominant	CPHD	↓	Topic or ectopic	Chiari Malformation
SOX2	Dominant	HH + GHD	↓	Topic	Anophthalmia, forebrain defects, oesophagus atresia, deafness, learning difficulties
SOX3	X-linked	IGHD or CPHD	↓	Ectopic	Intellectual disability, infundibular hypoplasia, corpus callosum abnormalities
FGF8	Recessive	HH, IGHD, or CPHD	↑ or NL	Topic	SOD, HPE, KS, Moebius syndrome
FGFR1	Dominant	HH or CPHD	NL or ↓	Ectopic or topic	SOD, midline craniofacial malformations, corpus callosum abnormalities
PAX6	Dominant	IGHD or CPHD	↓	Topic	midline craniofacial malformations, ophthalmologic abnormalities
GLI3	Dominant	IGHD or CPHD	A or ↓	Topic	Pallister Hall syndrome
ARNT2	Recessive	CPHD	↓	Topic	Brain, eye, kidney, and urinary tract abnormalities, corpus callosum abnormalities
CDON	Dominant	CPHD	A	Topic or ectopic	HPE, maternal ethanol exposure worsens the phenotype
GPR161	Recessive	IGHD or CPHD	↓	Ectopic	
IGSF1	X-linked	CPHD	NL	Topic	Macro-orchidism, undetectable prolactin
PROKR2	Dominant or recessive	HH, IGHD, or CPHD	NL or ↓	Topic or Ectopic	SOD, Hirschsprung disease
TGIF1	Dominant	CPHD	↓	Ectopic	HPE, midline craniofacial malformations

IGHD, isolated growth hormone deficiency; CPHD, combined pituitary hormone deficiencies; HH, hypogonadotropic hypogonadism; A, aplastic; NL, normal; ↓, small; ↑, large; NV, non-visualized; r-hGH, recombinant human growth hormone; SOD, septo-optic dysplasia, HPE, holoprosencephaly, KS, Kallmann syndrome, DD/ID, developmental delay/intellectual disability.

and point mutations have also been reported to cause this phenotype, known as IGHD type IA [17]. In contrast, other homozygous mutations—splice-site, frameshift, or nonsense—cause a less severe phenotype also with marked short stature, delayed bone age, and low GH concentrations but with a good response to r-hGH without neutralizing antibody formation. This form is known as IGHD type IB.

In the autosomal dominant mode of inheritance, known as IGHD type II, patients present with low but usually detectable GH, a variable height deficit and time of presentation and they may or may not have anterior pituitary hypoplasia on magnetic resonance imaging (MRI) (38–50%) [18]. These patients may develop additional pituitary hormone deficiencies (ACTH, prolactin, TSH, and/or gonadotropin deficiencies) needing lifelong follow-up. Most mutations have been shown to affect the correct splicing of *GH1*, including single base mutations in the first six nucleotides of intron-3, mutations in the exonic splice enhancers ESE1 and ESE2 or disruption of sequences downstream of the consensus splicing sites that affect intronic splice enhancers. The result is the skipping of exon 3 and the production of a 17.5 kDa isoform that exerts a dominant-negative effect on the secretion of the 22 KDa molecule. In transgenic mice studies the overexpression of 17.5 kD isoform showed defective GH secretory vesicles with anterior pituitary hypoplasia, loss of somatotropes, and invasion by macrophages. The most severely affected animal developed other anterior pituitary cell line deficiencies [19]. There are also missense mutations with complex mechanisms of action which disturb GH secretion or reduce the binding affinity for the GH receptor.

GHRHR

The *GHRHR* gene encodes a G-protein coupled receptor. Its expression is upregulated by POU class 1 homeobox 1 (*POU1F1*, formerly called PIT1) and is required for the proliferation of somatotropes.

Patients with pathogenic variants in this gene present with early and severe growth failure, typical facial features, and have a good response to r-hGH therapy; other clinical findings such as neonatal hypoglycaemia and micropenis are absent [20]. On MRI, most patients have anterior pituitary hypoplasia with a normally placed posterior pituitary signal; however, there are some reports of a normal-sized anterior pituitary. These patients are also classified as having IGHD type IB (OMIM 612781). Homozygous or compound heterozygous mutations have been reported (missense, nonsense, splice-site, deletions, or regulatory mutations) and patients are usually of consanguineous pedigrees or certain ethnic backgrounds—Indian subcontinent and Brazil. There is a report of a heterozygous mutation in the signal peptide leading to a dominant form of inheritance with variable penetrance [15].

- **Genetic defects in pituitary cell differentiation leading to CPHD**

PROP1

PROP1 (Prophet of *POU1F1*) encodes a 226-amino acid paired-like homeodomain transcription factor which activates *POU1F1* expression and pituitary organogenesis. Currently, bi-allelic *PROP1* mutations are the most frequently recognized genetic cause of CPHD worldwide [21, 22]. In general, short stature is the first symptom reported, probably due to combined GH and TSH deficiency. Growth failure usually develops within the first year of life (height −1.5 ± 0.9 SDS at 1.5 years of age) and becomes more prominent later in childhood between the ages of 1.5 and 3 years (−3.6 ± 1.3 SDS at 3 years of age), when parents search for medical assistance [23]. At diagnosis, bone age is usually severely delayed (−4.0 SDS; 2.5 y) [24]. Gonadotropins deficiency may be manifested as a lack of pubertal development or a failure to complete puberty [25]. The hormonal deficiencies can emerge asynchronously over time, even among individuals carrying the same genotype. Some patients develop corticotrophin deficiency, so all patients with *PROP1* pathogenic variants deserve lifetime clinical surveillance [26]. Furthermore, as GH replacement can increase cortisol metabolism, it is necessary to be aware of the signs of an unveiled adrenal insufficiency [27]. On neuroimaging the pituitary stalk is normal and the posterior lobe is in the normal position. The anterior lobe in patients with *PROP1* mutations is usually hypoplastic, but may be normal or even enlarged, which may be misdiagnosed as a tumour. The pituitary can wax and wane in size before undergoing complete involution for reasons as yet undetermined [28].

PROP1 mutations lead to CPHD in an autosomal recessive inheritance pattern, therefore the prevalence of these mutations is higher in familial cases and in patients born to consanguineous parents. Different types of molecular defects have been described disrupting *PROP1* function, varying from complete gene deletion to frameshift, small deletions and insertions, and point mutations including missense, nonsense, splicing variants, and mutations affecting the initiation codon [22].

POU1F1

POU class 1 homeobox 1 (formerly called PIT1) is a member of the POU family of transcription factors that regulate mammalian development and is important for the development of GH, PRL, and TSH lineages. Usually GH and PRL deficiencies are detected at first presentation and severe short stature is the first complaint. TSH deficiency can be present from infancy and such patients may present with severe mental retardation, or it can emerge later in life [29]. On MRI, the anterior pituitary can be small or normal and the posterior pituitary is eutopic [30]. The first reports were about homozygous mutations but heterozygous mutations with dominant-negative effects have also been described, thus recessive and dominant inheritance modes are possible [31].

Genetic Defects in Pituitary Development Leading to IGHD or CPHD

Congenital hypopituitarism can be associated with abnormalities in the development of the anterior craniofacial midline, forebrain, and eye. This clinical picture and the growing knowledge of the genetic cascade of signalling molecules and transcription factors involved in hypothalamic-pituitary embryogenesis has led to the discovery of many genetic defects in early developmental genes. As a consequence, overlap with other conditions such as isolated hypogonadotropic hypogonadism and holoprosencephaly is seen in many patients [8]. A well-established clinical syndrome is the pituitary stalk interruption syndrome (PSIS) characterized by congenital hypopituitarism, absent or thin stalk, anterior pituitary hypoplasia, and ectopic posterior pituitary [32]. After a period of extensive study of individual developmental genes, the advent of large parallel sequencing methods like whole-exome sequencing (WES) has led to the discovery of novel genetic factors involved in hypopituitarism and its associated phenotypes. There is an ever-increasing list of candidate genes that is updated on a monthly basis. Here we describe in more detail three genes classically associated with hypopituitarism with defects in early developmental factors. Other genes are cited in Table 7.1.3.3 and Fang *et al.* [32].

GLI2

The GLI family zinc finger 2 is a mediator of Sonic hedgehog (Shh) signalling and plays a role during embryogenesis. Mutations in *GLI2* were at first associated with holoprosencephaly but the range of possible phenotypes has expanded and includes IGHD or CPHD with or without diabetes insipidus. Other complex phenotypes are developmental delay, seizures, polydactyly, midline craniofacial malformations, and cryptorchidism. On MRI there is a small anterior pituitary with a non-visualized or ectopic posterior pituitary. The mode of inheritance is autosomal dominant with incomplete penetrance. The variants classified as pathogenic are: complete gene deletions; nonsense or frameshift mutations that result in protein truncation; mutations in the universal splicing sites; and mutations within the zinc finger region [33].

HESX1

HESX homeobox 1 encodes a transcriptional repressor in the developing forebrain and pituitary gland. Homozygous mutations (missense, frameshift, splice donor site) in *HESX1* result in CPHD usually with associated phenotypes: SOD, forebrain midline malformations (absent septum pellucidum and agenesis of the corpus callosum), and ophthalmic abnormalities. Heterozygous mutations have incomplete penetrance and lead to a less severe phenotype with IGHD or CPHD and various degrees of SOD. The hypothalamic-pituitary

region shows hypoplasia or aplasia of the anterior pituitary with normal, non-visualized or ectopic posterior pituitary [31, 34].

OTX2

Orthodenticle homeobox 2 encodes a transcription factor that plays a role in brain, craniofacial, and sensory organ development. Heterozygous mutations in *OTX2* were initially associated with anophthalmia or microphthalmia, later it was observed that some patients had IGHD or CPHD. On neuroimaging the anterior pituitary can be normal or hypoplastic and the posterior pituitary can be normal or ectopic. Additionally, there are reports of absent or severely hypoplastic infundibulum [31, 34].

Bioinactive GH (Kowarski Syndrome, OMIM 262650)

The existence of defects in the GH molecule generating a biologically inactive but immunoreactive GH was first proposed by Kowarski *et al.* in 1978 [35]. These authors evaluated two children with proportional short stature, normal GH secretion and very low somatomedin (IGF-1) level. Contrary to what would be expected in a patient with GH insensitivity, these patients normalized their growth rate and IGF-1 levels with exogenous GH treatment. Although the molecular basis in these first patients was not elucidated, Takahashi *et al.* published two other patients at the end of the 1990s with similar phenotypes associated with heterozygous pathogenic variants in the *GH1* gene [36, 37].

After these initial reports, a small number of other patients with bioinactive GH have been reported [38, 39]. These patients had a common phenotype characterized by severe short stature (usually height SDS <–3), very low levels of IGF-1/IGFBP-3 and normal or elevated GH levels (basal or after a stimulation test). Some patients presented with mild clinical characteristics observed in severe GHD (prominent forehead and saddle nose). All patients showed some improvement in growth rate and IGF-1 concentrations with r-hGH treatment. In one patient, this improvement was suboptimal, possibly due to a marked dominant-negative effect of mutated GH [36]. The majority of the cases had an autosomal dominant inheritance pattern, but an autosomal recessive inheritance was observed in one family [38].

The mutated GH molecules were capable of binding to the receptor with lower, similar, or even with higher affinity than wild-type GH, but all of them were unable to properly activate the signal transduction by GH receptor. Mutations associated with an autosomal dominant inheritance had a dominant-negative effect on wild-type GH action by competing for binding to the receptor and thus preventing the wild-type GH from activating the receptor [36, 37]. This is analogous to the mechanism of action of pegvisomant, a GH receptor (GHR) antagonist used in the treatment of conditions of GH excess [40].

GH Insensitivity (GHI)

In the 1960s, Laron *et al.* [41] described three siblings from a consanguineous Jewish family with severe short stature and a physical appearance that resembled patients with complete GH deficiency. After the development of a methodology to measure circulating GH, it was observed that these patients had markedly elevated GH levels. In the subsequent years, other patients with a similar phenotype were identified by the same group. Multiple and sequential investigations allowed them to demonstrate that the circulating GH in these patients had normal biological activity, but ^{125}I-labelled GH was unable to bind to the liver membrane from affected patients, suggesting that the defect was located in GHR [41]. Only in 1989, after *GHR* was cloned and characterized, homozygous defects in this gene were demonstrated to cause severe GH insensitivity (GHI) [42, 43] and this presentation became known as Laron syndrome (OMIM 262500). In the last three decades, more than 250 patients with GHI have been described, expanding our knowledge on phenotype variability and associated molecular defects.

Complete GH Insensitivity (OMIM 262500)

Defects in *GHR* cause variable degrees of insensitivity to GH. The classical form of GHI, also known as Laron syndrome, is characterized by severe short stature observed during childhood (height SDS usually <–4) associated with dysmorphic features also presented in patients with complete congenital GH deficiency (craniofacial disproportion with a relatively small face, depressed nasal bridge, high-pitched voice, truncal obesity, and micropenis) [4, 41, 44]. The adult height of non-treated patients is around 40 centimetres or more below the population mean. These patients have very low levels of IGF-1, IGFBP-3, ALS, and GHBP, but elevated basal and stimulated GH levels. This condition is inherited in an autosomal recessive pattern, usually involving consanguineous parents or families from inbred communities.

Important insights on longevity of patients with complete GHI have been published in recent years. Despite obesity and a decrease in lean body mass due to a lifetime without GH action, these patients are protected from diabetes and cancer and have a longevity similar to controls [45]. In a similar manner, GHI animal models demonstrate an improvement of insulin sensitivity over time and extension of lifespan [46, 47].

Since the first description of homozygous defects in *GHR* causing complete GHI, more than 70 pathogenic variants in this gene have been identified [4], involving several types of mutations: gross deletions (6%); non-synonymous single nucleotide variants (41%) or premature stop codons (20%); small deletions causing a frameshift (14%); and nucleotide changes that directly affect the splicing process (19%). The majority of these mutations are located in exons that encode the extracellular domain of GHR (exons 4 to 7). The missense mutations usually disrupt the binding sites for GH and/or impair the transport of the receptor to the plasma membrane. Usually the diagnosis of these patients is not difficult and molecular studies add little additional information to the clinical assessment.

Partial GH Insensitivity (OMIM 604271)

After characterization of complete forms of GHI, several cases have been described with a milder phenotype. The clinical spectrum of partial GHI may vary from patients who are initially classified as having idiopathic short stature (ISS), to patients with typical laboratory findings of GHI who lack typical facial and dysmorphic features associated with Laron syndrome [4]. Two main molecular bases for partial GHI are described [4]: patients homozygous or compound heterozygous for hypomorphic mutations and patients heterozygous

for dominant-negative *GHR* mutations. In both situations, some residual GHR activity is retained causing variable partial phenotypes regarding the severity of growth impairment and hormonal profile. Additionally, GHBP is frequently detectable and even elevated in some cases. The absence of a typical phenotype raises a challenge for establishing the diagnosis of this condition based only on clinical and laboratory data. In this scenario, the use of genetic studies that analyse, besides *GHR*, several other genes described in this chapter can lead to a precise molecular diagnosis [48].

GHI Associated with Immune Dysfunction (OMIM 245590)

In 2003, Kofoed *et al.* described a girl with severe short stature (height SDS −7.5 with 16 years old), recurrent infections, and progressive respiratory failure. GH levels after a stimulation test with insulin were very high (53.8 μg/L), while IGF-1, IGFBP-3, and ALS were markedly low, even with r-hGH treatment, and GHBP was normal. The *GHR* gene was sequenced but it was normal. GHR signalling pathways were then analysed and a homozygous missense mutation was found in *STAT5B* gene, which prevented STAT5B activation by GH [49].

Since then, a total of ten patients have been reported harbouring seven different homozygous *STAT5B* mutations. These patients presented with severe postnatal growth failure (height SDS −3.0 to −9.9), normal to elevated GH levels and abnormally low IGF-1, IGFBP-3, and ALS, similar to Laron syndrome, but also with manifestations of immune dysregulation, including increased susceptibility for opportunistic infections and autoimmune-associated disorders like lymphocytic interstitial pneumonia and eczema [50]. The immune dysregulation is explained by the fact that other molecules use the STAT5B signalling pathway, including some interleukins. The defect in IL2 action is particularly important, since this interleukin participates in the activation of T lymphocytes and in the development of regulatory T lymphocytes [51]. Other unique features are the elevation of prolactin levels since its negative feedback also depends on STAT5B signalling and the normal levels of GHBP because the defect is intracellular and consequently does not affect the GHR extracellular domain [50]. Heterozygous carriers were approximately 4 cm shorter than non-carrier relatives. They also had lower IGF-1 and IGFBP-3 levels and a higher frequency of eczema than their wild-type relatives [52].

Besides these cases in which genetic inheritance was autosomal recessive, recently patients from three unrelated families with dominant-negative heterozygous *STAT5B* variants were reported to have postnatal growth failure, eczema, and elevated IgE but no severe immune diseases, expanding the variability of clinical and genetic presentations [53]). Moreover, there are some reports on patients with partial GHI and immune dysfunction who have *STAT3* gain of function variants associated with diminished *STAT5B* transcriptional activity [54].

Atypical GHI

The term atypical GHI refers to conditions that cause GHI, usually partial, due to mechanisms that do not directly involve genes on GHR-JAK2-STAT5B transduction pathway. This broad concept encompasses both acquired and congenital conditions. Several mechanisms of atypical GHI have been described: an increase of RAS/MAPK pathway activity, as observed in Noonan syndrome (OMIM 163950) [55]; an increase in NF-κB activity [56]; an increase in FGF21-FGFR1 signalling; and an increase of SOCS associated with chronic inflammatory state [56]. All these conditions are characterized by growth impairment associated with low IGF-1, normal GH secretion, and poor hormonal and growth responses to exogenous GH therapy. The study of these mechanisms will allow a better understanding of the interactions between the GH-IGF axis and several conditions that impair children's growth.

Ternary Complex Defects

Acid-Labile Subunit Deficiency (OMIM 615961)

In 2004, Domené *et al.* described an adolescent boy with mild short stature (height SDS—2.05), pubertal delay, and hyperinsulinemia with normal glucose levels, who had markedly reduced IGF-1 (5.3 SDS below the mean) and IGFBP-3 (9.7 SDS below the mean) and undetectable ALS [57]. A homozygous frameshift variant was found in the *IGFALS* gene, preventing the synthesis of this protein. Since then, more than 20 patients have been described, with mild to moderate short stature (height SDS −3.6 to −0.4, mean −2.3), undetectable or very low serum levels of ALS and very low serum levels of IGF-1 and IGFBP-3, with IGFBP-3 being more affected than IGF-1. Some of them also presented with variable reduction in birth size, pubertal delay, variable degrees of insulin insensitivity and/or low bone mineral density.

It was hypothesized that growth restriction is mild, despite the marked reduction in IGF-1 and IGFBP-3 levels (compatible with severe GHD or GHI) because of the preserved expression of locally produced IGF-1 [58]. The aetiology of hyperinsulinemia is still unknown; however, some authors have suggested that the reduced IGF-1 availability could impair glucose sensing and insulin sensitivity [59]. Genetic inheritance is autosomal recessive and patients are homozygous or compound heterozygous for ALS mutations. Heterozygous carriers have a mild reduction in height (height SDS lower by 0.9) in relation to their non-carrier relatives [60].

Defects in the Proteolytic Cleavage of IGFBPs (*PAPPA2* Gene)

Pregnancy-associated plasma protein A2 (PAPP-A2) is a protease highly specific for IGFBP-3 and -5, liberating IGF-1 from IGFBP-3 and ALS, and allowing free IGF-1 to exert its actions on target tissues. In 2016, two families were described with homozygous variants in *PAPPA2* gene. Their affected members presented with progressive growth failure (with normal or mildly affected birth length), microcephaly and thin long bones. They had a marked elevation of total IGF-1, IGFBP-3, IGFBP-5, and ALS concentrations, but low free IGF-1. GH is also elevated in the patients, probably due to decreased negative feedback secondary to low free IGF-1 concentrations. Genetic inheritance was autosomal recessive in both families.

Primary IGF Deficiency

IGF1 Defects (OMIM 608747)

IGF-1 deficiency was first described in humans in 1996, in a patient with severe intrauterine and postnatal growth failure, microcephaly,

sensorineural deafness, intellectual deficit and severe reduction in vertebral bone mass who had a homozygous partial deletion in the *IGF1* gene [61]. His basal GH and his peak after stimulation with clonidine were elevated, and IGFBP-3 and ALS were normal.

Since then, seven other index cases with *IGF1* variants were described, three of them with homozygous variants, inherited as an autosomal recessive trait. Besides the characteristics described in the first patient, they can also present with insulin resistance (secondary to GH excess), partial gonadal dysfunction, or obesity. One of the homozygous patients had a bioinactive IGF-1 (see next) and another had partial IGF-1 deficiency, presenting with pre- and postnatal growth retardation and microcephaly but with mild developmental delay and normal hearing [62]. Heterozygous parents of homozygous patients have a height SDS below the population mean, with some of them presenting with a height SDS lower than -2, compatible with a dose-dependent effect. Patients harbouring heterozygous mutations, inherited in an autosomal dominant manner, have a milder clinical presentation, with significant short stature but with variable presence of cognitive delay or hearing impairment [63–65].

IGF2 Defects (OMIM 616489)

In 2015, Begemann *et al*. described the first *IGF2* gene variant associated with growth restriction in humans [66]. Four members from one family presented with severe intrauterine (birth length SDS –4.2 to –4.9) and variable postnatal growth restriction. They also had clinical signs compatible with Silver-Russell syndrome (OMIM 180860), such as normal head circumference at birth, triangular face and micrognathia, and delayed psychomotor development. The IGF-2 level was low and IGF-1, IGFBP-3, and GH levels were normal to elevated. A heterozygous stop-gain variant, which introduces a premature termination codon, was found in the *IGF2* gene in seven family members, but only those who inherited the variant through paternal transmission were affected, a finding consistent with the maternal imprinting of the *IGF2* gene.

In 2018, Habib *et al* investigated a population of 192 patients with intrauterine growth retardation, suspected of Silver-Russell syndrome for whom a genetic or epigenetic diagnosis was not found. They found two *de novo* heterozygous variants in the *IGF2* gene, two heterozygous variants in *HMGA2* gene (one *de novo* and the other probably paternally inherited) and two heterozygous variants in *PLAG1* gene (one sporadic and one familiar case). *PLAG1* and *HMGA2* are oncogenes; PLAG1 activates *IGF2* through a promoter and HMGA2 is an upstream regulator of *PLAG1*. Both were associated with growth in mice models and in genome-wide association studies (GWAS) meta-analysis studies in humans [67].

Bioinactive IGF-1

In 2005, Walenkamp *et al*. described an adult patient who exhibited severe pre and postnatal growth failure (birth length –4.3 SDS and adult height –8.5 SDS), microcephaly, sensorineural deafness, mental retardation (IQ less than 40), and osteoporosis [68]. GH levels were very elevated in response to insulin-induced hypoglycaemia and IGF-1 was also markedly elevated (+7.3 SDS). They identified a missense variant in the *IGF1* gene and functional analysis showed a 90-fold reduced affinity of the mutated protein for the IGF-1 receptor. Heterozygous carriers had significantly lower birth weight, adult height (–1.0 height SDS, or 0.6 SDS below non-carrier relatives) and head circumference and higher fasting insulin than non-carriers.

IGF Insensitivity (OMIM 270450)

Various groups have searched for **IGF1 receptor (IGF1R)** variants in patients born SGA who did not show catch-up growth, because of the importance of this receptor for growth regulation and because of the abundance of mutations described in the insulin receptor, which is structurally closely related to IGF-1R. In 2003, Abuzzahab *et al*. [69] described the first two patients with intrauterine and postnatal growth failure associated with *IGF1R* gene defects. Since then, there have been many reports of other patients with *IGF1R* variants, the vast majority being heterozygous.

Patients with biallelic (homozygous or compound heterozygous) *IGF1R* defects have a clinical phenotype similar to the phenotype of patients with homozygous *IGF1* mutations. In contrast with this condition, which is rare and has a relatively homogeneous clinical presentation, heterozygous *IGF1R* variants are relatively frequent and manifest considerable clinical variability. In one study, two patients from a group of 100 SGA children without catch-up growth had heterozygous *IGF1R* variants [7]. The extent of growth restriction is variable as well as the degrees of psychomotor and mental development and the absence or presence of microcephaly. Bone age is delayed and IGF-1, IGFBP-3, and GH range from normal to high [13]. There are also reports of patients with abnormalities in chromosome 15 in which the *IGF1R* gene is deleted, with phenotypes varying according to the type and extent of the abnormality. As a rule, patients with biallelic *IGF1R* defects or heterozygous nonsense mutations have a more severe clinical presentation than patients heterozygous for missense mutations, reflecting a spectrum related to the residual activity of IGF-1 [13]. Due to the significant clinical variability, diagnosis based only on clinical and laboratory findings is not possible, reinforcing the importance of molecular genetic diagnosis for these patients.

Growth Promotion Treatment for Patients with GH-IGF Axis Disorders

In GHD, r-hGH is well established as an effective therapy for normalization of height during childhood [16]. Treatment should be initiated as soon as the diagnosis is made and is based on daily subcutaneous injections. The dose is usually adjusted based on body weight (25–50 μg/kg/day) every 3–6 months. In known CPHD, additional hormonal deficiencies should also be adequately replaced. In adult patients with persistent GHD, the treatment goals for r-hGH therapy are to improve body composition, bone mineral density and lipid metabolism [70].

Patients with GHI have, by definition, an inability to respond to r-hGH therapy. In complete GHI, r-hIGF-1 therapy is recommended. Nonetheless, the height gain achieved is inferior to the height gain seen in GHD children receiving r-hGH treatment [71, 72]. This lesser response could be explained in the following ways: a decrease in IGF-1 half-life due to the lack of other components of the ternary complex (i.e. IGFBP-3 and ALS); a reduction of IGF-1

generation in peripheral tissues, which compromises paracrine and autocrine IGF-1 effects; and the absence of GH dependent (IGF-1 independent) growth-promoting actions [71]. Treatment with r-hIGF-1 is administered as twice-daily subcutaneous injections after a carbohydrate-containing meal to reduce the risk of hypoglycaemia. For patients with partial GHI, a trial with r-hGH is advocated, which, if effective, is preferable to r-hIGF-1 for the reasons given earlier, and for safety and patient convenience [72]. In GHI associated with immune dysfunction, there has been only one report of treatment with r-hGH and r-hIGF-1, both without significant response [73]. This lack of response to r-hIGF-1 therapy could be partially explained by the impact of chronic illness.

Patients with *IGFALS* defects who have been treated with r-hGH [74] usually present a suboptimal growth response. There are no studies evaluating the response to r-hIGF-1 treatment, since these patients usually have mild short stature and can reach normal adult height spontaneously. In defects in the proteolytic cleavage of IGFBPs (*PAPPA2* gene), there is a report on two siblings who received r-hIGF-1, one with a modest growth response and improvement of insulin resistance and bone mass [75].

For patients with homozygous *IGF1* defects, treatment with r-hIGF-1 is the logical approach. Because of the rarity of these cases, this treatment was demonstrated in only one case with increased height velocity and markers of bone formation, and improved insulin sensitivity [76]. Patients with heterozygous defects in *IGF1* may show improvement in growth velocity and IGF-1 levels with r-hGH treatment, especially in high doses [64, 65]. Similar responses to r-hGH therapy have been reported in patients with heterozygous *IGF2* defects [66] and *IGF1R* haploinsufficiency [7, 77]. This last group of patients typically present with high IGF-1 levels during r-hGH treatment.

Future Perspectives

Traditionally, the diagnosis of disorders of the GH-IGF-1 axis was based on clinical and hormonal evaluations. In recent years, molecular genetic tests are progressively making these diagnoses easier and more accurate. Moreover, the use of next-generation sequencing techniques will probably allow the discovery of new genes associated with these disorders and the identification of genetic defects in GH-IGF-1 axis in atypical or mild cases. Additionally, the participation of genetic variants in this axis in the pathophysiology of common short stature should be further evaluated. The expansion of our knowledge in this field may lead to treatment based on the molecular defect.

7.1.3 Short Stature in Children Born Small for Gestational Age

Anita C.S. Hokken-Koelega

Introduction

Small-for-gestational-age (SGA) is defined as a birth weight and/or length <–2 standard deviation scores (SDS) [1, 2]. As the aetiology of SGA is multifactorial and includes maternal lifestyle and obstetric factors, placental dysfunction, and numerous (epi)genetic abnormalities, SGA-born children comprise a heterogeneous group. The majority of SGA-born infants show catch-up growth to a normal stature, but 10% remains short [3]. For more than 30 years, studies have been performed in short children after SGA birth, including children with Silver–Russell syndrome (SRS). Studies have generally excluded short SGA children with major dysmorphic features

or a (suspected) syndrome, primordial dwarfism, or DNA repair disorder. Thus present knowledge and management, particularly on growth hormone (GH) treatment, are based on the results in non-syndromic short SGA/SRS children.

This chapter presents our current knowledge of the (epi)genetic causes of short stature for those born SGA, the health consequences of SGA, and the diagnostic approach and management of short SGA-born children, including the efficacy and safety of GH treatment.

Definition of Small for Gestational (SGA)

SGA is not a diagnosis but refers to the size at birth, defined as a birth weight and/or length of at least two SDS below the median for gestational age [1, 2]. Accurate information on gestational age, birth weight, and birth length and appropriate reference data are required to determine if a child is born SGA.

The term intrauterine growth retardation (IUGR) is often used synonymously with the term SGA. IUGR is, however, a prenatal diagnosis referring to a deceleration of intrauterine growth, based on at least two fetal size measurements by ultrasound. Being born SGA does not necessarily mean that IUGR has occurred. Conversely, infants with documented IUGR are not inevitably born SGA. Neonates with SGA can be born either term or preterm.

SGA can be the result of maternal and paternal factors, placental insufficiency or fetal (epi)genetic factors [1]. The aetiology of SGA is unknown in 60% of cases, but precise diagnoses will expand due to the rapid advancement in genetic testing.

Early Growth

Most children born SGA show sufficient postnatal catch-up growth and have a normal height at the age of 2 years, but approximately 10% remain short (height <–2 SDS) [3]. Short stature after SGA accounts for approximately 20% of all cases of short stature [4]. Most of the catch-up growth occurs during the first year and is near completion by the age of 2 years, but it can take up to the age of 4 years in those born very prematurely [3].

Preterm infants might show extrauterine growth restriction (EUGR), due to a complicated neonatal course. When they have a length or weight <–2 SDS at the corrected age of 3 months and fail to catch-up subsequently, their risk of short adult stature is similar to term SGA infants [5].

Low birth size has been associated with an increased risk for cardiovascular disease, hypertension, and type 2 diabetes mellitus in adult life [6]. However, it has been shown that these risks are mainly associated with a rapid postnatal gain in weight for length [7].

Endocrine Consequences

GH-IGF Axis

Approximately 60% of short SGA children show reduced spontaneous GH secretion during a 24-hour sampling period and 25% a low GH peak during GH provocation tests, while serum IGF-I and IGFBP-3 levels are lower than in healthy controls, but not below –2 SDS [8]. This indicates that the majority of short SGA children do not have severe GH deficiency. Some short SGA children have normal or high serum IGF-I levels, suggestive of IGF-I resistance.

Pubertal Development

Puberty starts in SGA children slightly earlier than average but pubertal progression is normal [9], and adrenarche is age-appropriate [10].

Bone Mineral Density

Bone mineral density (BMD), corrected for height, is in the low normal range in short SGA children [11] but similar in SGA adults with or without short stature [12].

Gonadal Function

In prepubertal boys without cryptorchidism, serum inhibin B levels are not different between those born small for gestational age (SGA) or appropriate for gestational age (AGA) [13]. In adulthood, no differences in serum levels of inhibin B, testosterone, LH, and FSH were found between men born SGA or AGA [14]. Young SGA women have normal serum AMH levels, indicating that they do not have a smaller follicle pool size than AGA women [15].

Metabolic and Cardiovascular Consequences

Body Composition

In SGA children, total and abdominal fat mass at 4 years of age is closely related to the rate of weight gain in the first 2 years of life [16]. Short SGA adults have a similar fat mass percentage as AGA adults, while SGA adults who had spontaneous catch-up have a higher fat mass percentage than AGA adults. The lean body mass percentage is lower in all SGA adults compared to AGA adults, regardless of degree of catch-up growth [17], suggesting that in SGA-born subjects, lean body mass is reprogrammed during fetal life, with long-lasting effects on body composition.

Insulin Resistance and Type 2 Diabetes Mellitus

Low birth weight is associated with a higher risk of insulin resistance and type 2 DM in adulthood [6]. Short SGA children have a 38% reduction in insulin sensitivity adjusted for BMI compared to short AGA children, with higher insulin levels [18]. At the age of 4 years, SGA children with spontaneous catch-up growth are more insulin-resistant than AGA children [16]. Rapid fat accumulation in the first months of life is associated with a lower insulin sensitivity in early adulthood [7]. Insulin sensitivity is similar in short SGA and AGA adults, but lower in SGA adults with spontaneous catch-up growth to a normal height [19].

Cardiovascular Risk Factors

Birth weight has an inverse association with risk factors for hypertension and cardiovascular disease in adults [6]. Blood pressure is increased in short children born SGA, mainly in those born preterm [20]. Short SGA adults have a higher systolic and diastolic

blood pressure compared to AGA adults, irrespective of whether they had remained short or had caught up [21].

Metabolic and transcriptomic profiles in SGA children aged 4–9 years showed increased cardiometabolic risks [22]. However, serum lipid levels are within the normal range in short SGA children and adults [17, 23, 24].

Carotid intima media thickness (cIMT), a marker for generalized atherosclerosis, is higher in SGA children with spontaneous catch-up growth than in AGA children of a similar height, weight, and BMI [25]. Similarly, cIMT is higher in SGA adults with spontaneous catch-up growth compared to short adults born either SGA or AGA [26].

Neurodevelopment, Psychosocial Consequences, and Health-Related Quality of Life

SGA children have an IQ within the normal range but on average lower than AGA children [27]. Among SGA children in epidemiologic studies, those born smallest had the lowest IQ and more school failure and problem behaviour (attention deficit and social behaviour), particularly children with persistent short stature [28]. Short SGA children also have lower scores on tests of social functioning and health-related quality of life compared to reference populations [29].

(Epi) genetic Diagnoses in Short Children Born SGA

Non-syndromic children with short stature after SGA form a heterogeneous group, with a wide spectrum of clinical symptoms and responses to GH treatment. For many years, only very limited (epi) genetic causes were known, but the increasing use of next-generation sequencing, whole exome sequencing (WES), chromosomal microarrays, RNA sequencing, and methylation arrays has resulted in the discovery of novel (epi)genetic causes of short stature after SGA birth. Some monogenic disorders are now being found in children previously considered to have idiopathic short stature (ISS). Most currently known monogenic primordial growth disorders present with short stature after an SGA birth as one of their clinical features. For clinical purposes, first the monogenic disorders with a normal head circumference and short stature (either proportionate or disproportionate) are presented (Table 7.1.3.1), followed by monogenic primordial disorders with microcephaly (Table 7.1.3.2) and finally the currently known imprinting disorders and methylation disturbances (Table 7.1.3.3). This division is arbitrary, because some genetic aberrations were first reported for children with a very characteristic phenotype (including microcephaly), while over time milder phenotypes have been recognized. The genetic disorders in short SGA children can also be presented according to a pathophysiological classification (see recent review [30]).

Monogenic Disorders with Normal Head Circumference and Proportionate Short Stature

Children with GH deficiency due to a *GH-1 gene* mutation or GH insensitivity as result of an inactivating mutation of *GHR*, or *PIK3R1* or an activating *STAT3* mutation, have a lower mean birth weight and birth length, but most of them do not fulfil the criteria for SGA. However, in the case of a very low serum IGF-I and low GH peak during a provocative test or in the case of lack of growth response during GH treatment in a short SGA child, one may consider testing for these genes, because short SGA does not exclude an abnormality in the GH-IGF pathway.

Heterozygous *IGFALS* mutations are found in short SGA children [31], but also reported in children with ISS. Serum IGF-I and IGFBP-3 levels are low. GH treatment may increase growth in children with a heterozygous *IGFALS* mutation [32]. Absence of acid-labile subunit (ALS) due to homozygous *IGFALS* mutations (OMIM 615961) results in low IGF-I and very low IGFBP-3, birth weights varying from −3.7 to −0.1 SDS [31], while the effects of GH treatment are unknown.

3-M syndrome is characterized by pre- and postnatal growth failure and is caused by mutations in *CUL7* (OMIM 273750), *OBSL1* (MIM 610991) or *CCDC8* (MIM 614205) [33]. It is associated with reduced *IGF2* expression and increased *H19* expression, as also found in Silver–Russell syndrome. Growth response to GH treatment is disappointing.

Recently, a paternal IGF2 gene mutation was reported which leads to features resembling Silver–Russell syndrome. GH treatment is likely to be as effective as in other genetic variants of SRS [34].

Floating–Harbor syndrome occurs due to heterozygous mutations in the *SRCA gene (*(OMIM 136140). Only 26% of such children are born SGA and the phenotype is often mild [35]. Data on the effects of GH treatment are very limited.

Mulibrey nanism (MIM 253250) is caused by biallelic *TRIM37* mutations. Most children are born SGA and remain short but the progressive cardiomyopathy and other clinical problems are much more important. There are no data on GH treatment.

Monogenic Disorders with Normal Head Circumference and Disproportionate Short Stature

In most genetic disorders associated with disproportionate short stature, the genes are already abnormally expressed during fetal life which often results in a lower birth length SDS than birth weight SDS. The more severe forms of skeletal dysplasia can be easily diagnosed in young children, but clinical features can be so mild that many children are initially labelled as short SGA of unknown origin or ISS. Body disproportion and skeletal abnormalities can become more abnormal when the child becomes older. In each short SGA child, the clinician should therefore regularly assess body proportions, particularly in the case of a relatively lower birth length than birth weight. When an SGA child has disproportionate short stature (sitting/height >2 SDS and/or arm-span width > height), genetic testing can be an efficient diagnostic approach. A description of all skeletal dysplasias and their underlying genetic aberrations is beyond the scope of this chapter, but the most frequent ones in relation to SGA and short stature are given in Table 7.1.3.1.

Turner syndrome (TS), either due to 45XO or mosaicism, may explain disproportionate short stature after SGA. Birthweight is lower than normal, but only 30% are born SGA. It is nevertheless important to exclude TS in all short SGA girls when the height is a considerable distance below target height (>1.6 SDS, based on national growth references). The disturbed prenatal and postnatal growth is caused by short-stature-homeobox (*SHOX)* haploinsufficiency [36]. A full description of the medical care for girls with TS is beyond the

Table 7.1.3.1 Monogenic disorders in short children born SGA with normal head circumference

Syndrome [OMIM]	Genetic defect	Inheritance	Incidence	Mean BW/ BL SDS	Clinical features	Laboratory data	Treatment
Monogenic disorders with normal head circumference and proportionate short stature							
GH deficiency	*GH1, GHRHR, BTK*	AR, AD X-linked	1:5.000	−0.9 /−0.6	Wide variation in height deficit	↓GH peak during GH stimulation test, ↓IGF-I, ↓IGFBP-3, ↓ALS	GH registered
Laron syndrome [262500]	*GHR*	AR or rarely AD	>300 cases	−0.6 /−1.6	Wide variation in height, midfacial hypoplasia	↑GH, ↓IGF-I, ↓IGFBP-3, ↓ALS, variable GHBP	IGF-I treatment moderately effective
Multisystem infantile-onset autoimmune disease [615952]	Act *STAT3*	AD	19 cases	−1.7/−1.8	Early-onset multiorgan autoimmune disease	↓IGF-I, ↑TSH, abnormal immunoglobulins	No data
SHORT syndrome [269880]	*PIK3R1*	AD	32 cases	−3.3 85% SGA	Hyperextensibility, ocular depression, teething delay, lipoatrophy, insulin resistance	↓IGF-I non-responding to GH injections	No data
ALS deficiency [615961]	*IGFALS*	AR	>65 cases	−2.2	Mild to moderate short stature	↓IGF-I, ↓IGFBP-3, ↓ALS	No data
3-M syndrome [273750, 612921, 614205]	*CUL7, OBSL1, CCDC8*	AR	≈200 cases	−3.1	Facial features, normal mental development, long and slender tubular bones, reduced AP diameter of vertebral bodies, delayed bone age	NI GH, IGF-I, IGFBP-3	Effect of GH considered insufficient
Silver–Russell variant [616489]	*IGF2*	AD, paternal	8 cases	−3.9/−4.6	Dysmorphic features like SRS, fulfilling the Netchine–Harbison criteria for SRS, including relative macrocephaly	↑/normal GH, normal IGF-1, ↑/normal IGFBP-3, ↓IGF-2	GH treatment likely as effective as in other genetic variants of SRS
Floating–Harbor syndrome [136140]	*SCRAP*	AD	>52 cases	−2.5	Proportionate short stature, delayed bone age and speech, triangular face. deep-set eyes, long eyelashes, bulbous nose, wide columella, short philtrum, thin lips	NI GH, IGF-I, IGFBP-3	Insufficient data
Mulibrey nanism [253250]	*TRIM37*	AR	>110 cases	−2.8	Progressive cardiomyopathy, characteristic facial features, hypo- or hypergonadotropic hypogonadism, type 2 DM, predisposition to Wilms tumour	NI GH, IGF-I, IGFBP-3	Insufficient data
Monogenic disorders with normal head circumference and disproportionate short stature							
SHOX-associated short stature [300582]	*SHOX*	AD	2–17% of short stature	−0.4/−1.1	Short forearm and lower leg, bowing of forearm and tibia, dislocation of ulna at elbow, Madelung deformity, muscular hypertrophy, radiologic signs at wrist and forearm	NI GH, IGF-I, IGFBP-3	GH has similar efficacy as in Turner syndrome; registered in many countries
Achondroplasia [100800]	Act *FGFR3*	AD	1:15 000–40 000	−0.7/−1.0	Rhizomelic limb shortening, frontal bossing, midface hypoplasia, exaggerated lumbar lordosis, limitation of elbow extension, genu varum, trident hand	NI GH, IGF-I, IGFBP-3	Effects of GH considered insufficient
Hypochondroplasia [146000]	Act *FGFR3*		1:15 000–40 000	–	Rhizomelic limb shortening, limitation of elbow extension, brachydactyly, relative macrocephaly, generalized laxity, specific radiologic features	NI GH, IGF-I, IGFBP-3	Effect of GH considered insufficient
Short stature with mild disproportion [616255]	*NPR2*	AD	1–2% of short SGA and ISS	−0.8/−2.3	↑ sitting height/height ratio, phenotypic or radiographic indicators of *SHOX* HI (but no Madelung deformity)	NI GH, IGF-I, IGFBP-3	Insufficient data
Brachydactyly type A1 [1112500]	*IHH*	AD	1.6% of short SGA and ISS	−/ −1.4	↑ sitting height/height ratio, shortening of middle phalanx of 2nd and 5th fingers with cone-shaped epiphyses	NI GH, IGF-I, IGFBP-3	Preliminary data GH treatment positive
Short stature with early-onset osteoarthritis or osteochondritis [165800]	*ACAN*	AD	1–2% of short SGA and ISS	−0.7/−1.5	Proportionate or disproportionate short stature, with or without advanced bone age, brachydactyly, early-onset osteoarthritis	NI GH, IGF-I, IGFBP-3	Insufficient data
Noonan syndrome [163950]	*PTPN11*	AD	1:1000–2500	−1.0	Short stature, facial dysmorphism, wide spectrum of congenital heart defects, coagulation defect	NI GH, IGF-I, IGFBP-3	GH registered in US only; effect on adult height?

Abbreviations: act, activating; AD, autosomal dominant; AR, autosomal recessive; BL, birth length; BW, birth weight.

Table 7.1.3.2 Monogenic disorders in short children born SGA with microcephaly

Syndrome [OMIM]	Genetic defect	Inheritance	Incidence	Mean BW/BL SDS	Clinical features	Laboratory data	Treatment
Monogenic disorders with microcephaly							
IGF-I deficiency [608747]	*IGF1*	AR, AD	4 homozyg 7 heterozyg	hom −3.7 het −1.9	Microcephaly, deafness, reduced mental development	↑GH, variable IGF-I, ↑IGFBP-3,	IGF-I treatment moderately effective
Resistance to IGF-I [1270450]	*IGF1R*	AD	1–2% of short SGA	−2.1/−2.7	Microcephaly, reduced mental development	↑/normal GH, ↑/ normal IGF-I, ↑/ normal IGFBP-3	GH treatment moderately effective
PAPP-A2 deficiency	*PAPPA2* [homozyg]	AR	5 cases	−1.6/−1.3	Microcephaly, skeletal abnormalities	↑GH, ↑IGF-I, ↑IGFBP-3, ↑IGFBP-5, ↑ALS	IGF-I treatment possibly effective
Primordial dwarfism with microcephaly							
Cornelia de Lange syndrome (1–5) [122470]	*NIPBL*, *SMC1A*, *SMC3*, *RAD21*, *HDAC8*	AD	1/40 000	−3.4/−	Low anterior hairline, connected eyebrows, ante-verted nares, maxillary prognathism, long philtrum, thin lips, 'carp' mouth	Not available	No data on GH, likely ineffective
Meier-Gorlin syndrome (1–5) [224690]	*ORC1*, *ORC4*, *ORC6*, *CDT1*, *CDC6*	AR	>67 cases	−3.8/−	Bilateral microtia, aplasia, or hypoplasia of the patellae, normal intelligence	Not available	No data on GH, likely ineffective
MOPD I [210710]	*RNU4ATAC*	AR	<1/ 1 000 000	Extremely low	Neurologic abnormalities, including intellectual disability, brain malformations, ocular or auditory sensory deficits	Not available	No data on GH, likely ineffective
MOPD II [210720]	*PCNT*	AR	Extremely rare	−3.9	No or mild mental impairment, truncal obesity, DM, moyamoya disease, small loose teeth, radiologic abnormalities	Not available	No data on GH, likely ineffective
Seckel syndrome (1–8) [210600]	*ATR*, *RBBP8*, *CENPJ*, *CEP152*, *CEP63*, *NIN*, *DNA2*, *ATRIP*	AR	<1/ 1 000 000	Extremely low	Microcephaly, intellectual disability, characteristic 'bird-headed' face (receding forehead and micrognathia)	Not available	No data on GH, likely ineffective
Smit-Lemli-Opitz [270400]	*DHCR7*	AR	1/50 000 (mainly in Caucasians)	Extremely low	Microcephaly, moderate to severe intellectual disability, dysmorphic features, and organ malformations (heart, palate, syndactyly 2nd and 3rd toes, underdeveloped genitalia boys)	Not available	No data on GH, likely ineffective
DNA repair defects with microcephaly							
Bloom syndrome [210900]	*RECQL3*	AR	1/48 000 (Ashk Jews, but also others)	−4.7/−4.8	Microcephaly, sun-sensitivity, telangiectatic, hypo- and hyperpigmented skin lesions, predisposition to cancer, maturity-onset DM	Not available	GH contraindicated
Fanconi anaemia [many]	*FANCA* and 14 other genes	AR or X-linked	1/160 000	−1.8/−2.1	Microcephaly, genomic instability, hypo- and hyperpigmentation, skin lesions abnormalities in major organ systems, bone marrow failure, predisposition to cancer	Not available	GH contraindicated
Nijmegen breakage Syndrome [#251260]	*NBN*	AR	Extremely rare	−1.8/−2.2	Microcephaly, mild to moderate intellectual disability, immunodeficiency, predisposition to cancer	Not available	GH contraindicated
LIG 4 syndrome [606593]	*LIG4*	AR	Extremely rare	−3.0/−3.8	Microcephaly, sun-sensitive, combined immunodeficiency	Not available	GH contraindicated
XRCC4 syndrome	*XRCC4*	AR	Extremely rare	−1.6/−2.5	Microcephaly, progressively short, hypergonadotropic hypogonadism, multinodular goitre, diabetes mellitus	Not available	GH contraindicated

Table 7.1.3.3 Imprinting disorders and methylation disturbances in short children born SGA

Syndrome [OMIM]	Epigenetic defect	Incidence	Mean BW/BL SDS	Clinical features besides SGA	Treatment
Silver–Russell syndrome (SRS) [180860]	11p15 LOM (30–60%), upd(7)mat (5–10%), upd(20)mat, upd(16)mat act *CDKN1C*, *HMAG2*, *PLAG1*, and CNVs # Paternal *IGF2* mutation (see Table 7.1.3.1)	1:30 000–100 000	11p15: –3.2/–4.5 UPD7: –2.3/–2.5 Clinical: –2.7/–1.8	Relative macrocephaly, protruding forehead, body asymmetry, feeding problems, and/or low BMI	GH effective (in label of GH treatment for short SGA)
Temple syndrome [616222]	14q32 abnormalities: upd(14) mat, paternal microdeletions, hypomethylation of DLK1/GTL2 IG-DMR	>50 cases	–1.9/–1.6	Postnatal growth failure, hypotonia, delayed development of motor skills, feeding problems in infancy, early puberty, broad forehead, short nose with wide nasal tip, small hands, and feet	Insufficient data
IMAGe syndrome [614732]	Maternally inherited activating mutations in *CDKN1C*	>15 cases	–2.0 to –4.0	Relative macrocephaly at birth, no or mild intellectual disability, frontal bossing, low-set ears, flat nasal bridge, short nose, congenital adrenal hypoplasia, metaphyseal, and/or epiphyseal dysplasia, male genital anomalies, early-onset type 1 DM	Insufficient data
Prader–Willi syndrome [176270]	Paternal 15q11.2q13 deletion (60%), upd(15)mat (40%), or imprinting centre mutation (1–3%). Loss of *SNRPN* and *NDN* expression	1:16 000	–1.2/–1.1	Diminished fetal activity, obesity, muscular hypotonia, intellectual disability, short stature, hypogonadotropic hypogonadism, small hands, and feet	GH registered for PWS
Pseudohypoparathyroidism type 1a/c * [103580]	Heterozygous *GNAS1* mutation inherited from the mother	1:150 000	–0.6/–1.1 35% born SGA	Resistance to PTH and other hormones (TSH, LH, FSH, and GHRH), Albright hereditary osteodystrophy (short stature, obesity, round face, subcutaneous ossifications, brachydactyly, mild intellectual disability)	Insufficient data
Pseudopseudohypoparathyroidism [612463])	Heterozygous *GNAS1* mutation inherited from the father	1:150 000	–2.7/–3.0 95% born SGA	Albright hereditary osteodystrophy without multiple hormone resistance and no hypocalcaemia	Insufficient data

* Pseudohypoparathyroidism type 1b [OMIM 603233] is associated with normal or increased birth weight and overgrowth in childhood.

Abbreviations: act, activating; BL, birth length; BW, birth weight; PTH, parathyroid hormone.

scope of this chapter, but GH treatment at higher doses than recommended for growth hormone deficiency (GHD) children improves growth and adult height. The younger age at GH start, the better the growth response and adult height will be [36].

Mutations or deletions in the *SHOX* gene can be present in short SGA children. These are located at the tip of the X and Y chromosome, and transmitted in a pseudoautosomal fashion [36]. Bi-allelic inactivating *SHOX* mutations cause the severe Langer mesomelic dysplasia (OMIM 249700), while heterozygous mutations or deletions of *SHOX* or its enhancers (or even duplications) cause a milder skeletal dysplasia, Leri-Weill dyschondrosteosis with a Madelung deformity of the wrist (OMIM 127300) [37]. This mutation can present as SGA or ISS, with minor or no dysmorphic features, and no or mild body disproportion (OMIM 300582), particularly *SHOX* enhancer deletions. Birth length and weight show wide variations (–4.3 to 1.5 and –3.3 to 3.2 SDS, resp.) [38]. GH treatment results in a similar growth response and adult height gain as seen in girls with TS syndrome [39].

Heterozygous activating mutations in *FGFR3* lead to a wide range of disorders, including achondroplasia (OMIM 100800), hypochondroplasia (MIM 146000) and even proportionate short stature. Neonates with achondroplasia have a birth length around –1 SDS, but SGA is uncommon. The effect of GH treatment on adult height results in a modest increase of +0.5 SDS [40]. GH is only registered for this condition in Japan.

Children with hypochondroplasia (OMIM 146000) have rhizomelic limb shortening, limitation of elbow extension, brachydactyly, and relative macrocephaly. It is a relatively frequent genetic mutation in children with SGA and ISS. GH treatment results in better growth in the first years, but there are limited data on adult height [41].

Heterozygous carriers of *NPR2* mutations (OMIM 616255) show a similar phenotype to *SHOX* haploinsufficiency, with short forearms and short lower legs (mesomelia), but without Madelung deformity. *NPR2* mutations explain ~2% of cases with short stature due to SGA or ISS [42]. No data on GH treatment are available.

Heterozygous mutations of *Indian hedgehog (IHH)* are associated with brachydactyly type A1 (OMIM 1112500), but may also have mild disproportion [43]. Most children are born SGA for length, and 50% have shortening of the middle phalanx of the second and fifth fingers with cone-shaped epiphyses. No data on GH treatment are available.

A heterozygous mutation of *ACAN* (encoding aggrecan) leads to abnormal cartilage matrix formation, with mild skeletal dysplasia, spondyloepiphyseal dysplasia (OMIM 608361), or short stature without radiographic skeletal dysplasia (OMIM 165800) [44]. Approximately 30–40% of cases are born SGA and 14% of short SGA children with a bone age advancement of 6 or more months, had a heterozygous ACAN mutation [45]. However, bone age can be normal. Birth length SDS is always lower than birth weight SDS and patients often have early-onset osteoarthritis and/or osteochondritis dissecans. At present, there are only limited data on the effects of GH treatment, either alone or combined with a gonadotropin-releasing hormone (GnRH) analogue and/or an aromatase inhibitor [44].

Noonan syndrome may also explain disproportionate short stature after an SGA birth. Activation of the Ras/Mitogen activated protein kinase (MAPK) signalling pathway results in a number of overlapping syndromes, so-called rasopathies, including Noonan (OMIM 163950), Leopard (OMIM 151100), Costello (OMIM 218040), Cardiofaciocutaneous (OMIM 115150) and Neurofibromatosis-Noonan syndromes (OMIM 601321). All have a varying degree of postnatal growth failure and sometimes there are no obvious clinical features [46]. Twenty-four per cent (24%) are born SGA. GH treatment improves height SDS during childhood and can improve adult height [47]. GH is registered for Noonan syndrome in the USA, but not in Europe and Japan.

Monogenic Disorders with Microcephaly and Short Stature

Children with a *IGF1* mutation (OMIM-608747) are born with a very low birth weight and length and microcephaly, although some have a milder phenotype. Recombinant IGF-I treatment is moderately effective [47, 48]. Children with complete loss-of-function mutations also have sensorineural deafness (OMIM-608747) [49].

Children with a heterozygous *IGF1R* mutation (MIM 270450) have a wide range of birth weight (–3.5 to –1.5 SDS), birth length (–5.0 to 0.3 SDS) and head circumference (–3.0 to 0 SDS [48]. The prevalence of heterozygous *IGF1R* mutations or deletions is estimated at 1–2% in short SGA children [50]. Other features include normal baseline serum IGF-I levels and very high IGF-I levels during GH treatment, early feeding problems, variable delay in psychomotor development, and mild dysmorphic features. GH treatment results in a moderate growth response [50]. Homozygous mutations have a more severe phenotype [51].

Terminal 15q deletion with allelic loss of *IGF1R* leads to pre- and postnatal growth retardation and cardiac symptoms, intellectual disability, diaphragmatic hernia, hearing problems, aortic root dilatation, neonatal lymphedema, and aplasia cutis [52]. Limited data on GH treatment are available [53].

Homozygous pregnancy-associated-plasma-protein-A2 (*PAPPA2)* mutations were recently found in short children with ISS or born SGA [53]. They had progressive growth failure, moderate microcephaly, thin long bones, mildly decreased bone density, and *elevated* levels of serum IGF-I, IGFBP-3, IGFBP-5, ALS, and IGF-2. Lack of PAPP-A2 protein decreases the liberation of IGF-I from the ternary complex and likely results in lower IGF bioavailability. Two years of biosynthetic IGF-I treatment resulted in a height gain of +0.4 to 1.0 SDS [54].

Primordial dwarfism is a group of rare genetic disorders characterized by severe IUGR and SGA, extreme short stature, and distinct microcephaly, which occur as a result of disorganized molecular and genomic changes during embryonic development. Most children can be easily recognized, like those with Cornelia de Lange syndrome (OMIM 122470), Meier-Gorlin syndrome (OMIM 224690), microcephalic osteodysplastic primordial dwarfism (MOPD) types I (OMIM 210710) and II (OMIM 210720), and Seckel syndrome (OMIM 210600)] [55]. There are no data on GH treatment, which is likely to be ineffective.

Smith-Lemli-Opitz syndrome (OMIM 270400) is an autosomal recessive disorder characterized by SGA, short stature, microcephaly, dysmorphic features, mild to severe mental retardation, and multiple malformations. Patients have decreased serum cholesterol levels due a deficient cholesterol synthesis as result of mutations of the 3beta-hydroxysterol-delta7 reductase gene (*DHCR7*). There are no data on GH, which is likely to be ineffective.

Disorders of DNA repair or genomic instability are frequently associated with SGA, short stature, and microcephaly. Bloom syndrome (OMIM 210900) is a DNA repair disorder caused by a mutation in the gene encoding DNA helicase RecQ protein-like-3 (*RECQL3*) and features include skin hypersensitivity to sunlight, particularly recognizable on the face. Fanconi syndrome (OMIM 227650) has genomic instability and clinical features include an irregular pattern of skin pigmentations which increases over time, abnormalities in major organ systems, early-onset bone marrow failure, and a high predisposition to cancer. Other syndromes in this category are Nijmegen breakage syndrome (OMIM#251260), *LIG4* (MIM 606593) and *XRCC4* mutations (OMIM 616541), Cockayne syndrome (OMIM 216400) and Rothmund-Thomson syndrome (OMIM 268400). GH treatment is *contraindicated* in these conditions, given the unknown long-term effects on cell division and their predisposition to cancer,

Imprinting Disorders (ID) and Methylation Disturbances

IDs are characterized by molecular disturbances affecting genomically imprinted chromosomal regions and genes. Genomic imprinting describes the expression of specific genes in a parent-of-origin specific manner (i.e. they are expressed only from the maternal or from the paternal gene copy) [56]. Silver–Russell syndrome (SRS) is well-known, but there are several other imprinting disorders associated with short SGA [57]. It was recently reported that methylation disturbances can also occur in non-imprinted genes [58].

Silver–Russell Syndrome (SRS)

Children with SRS (OMIM 180860) are mostly born SGA, have short stature and relative macrocephaly, a triangular shaped face with frontal bossing, clinodactyly, and asymmetry of face and/or extremities [34]. Severe feeding difficulties are often present, especially during infancy. Mean adult height is around –4 SDS. SRS is primarily a clinical diagnosis, which can be established with the Netchine–Harbison clinical scoring system [34].

In around 60% of children with SRS, an underlying cause can be identified. Fifty percent are caused by a loss of methylation (LOM) of the telomeric domain in the 11p15.5 region, resulting in downregulation of paternal *IGF2* expression [34]. The 11p15.5 region has two imprinting control regions, which affect imprinted genes involved in the regulation of pre- and postnatal growth. Two rare genetic causes of SRS were found in the same 11p15 region: (1) an increased expression of *CDKN1C* (by a gain-of-function mutation or maternal duplication) [59], which can be associated with the IMAGe syndrome (OMIM 614732); the latter is characterized by pre- and postnatal growth failure, metaphyseal dysplasia, congenital adrenal hypoplasia, genital anomalies and early-onset DM; and (2) an *IGF2* loss-of-function mutation (OMIM 616489) resulting in a paternally transmitted SRS (Table 7.1.3.1) [60]. Disruptions in the HMGA2-PLAG1-IGF2 pathway can also cause an SRS phenotype [61], while copy number variants (CNVs) involving the 11p15.5 region can result in a specific SRS phenotype depending on CNV size, location, and parental origin [62].

Between 5% and 10% of children with SRS have a maternal uniparental disomy of chromosome 7 (upd(7)mat), with potential causative genes including *GRB10* (7p12.1) and *MEST* (7q32) [34]. In 35%, the genetic cause is yet unknown (i.e. clinical SRS). Patients with 11p15 LOM have a more 'classic' SRS phenotype with a higher prevalence of asymmetry than those with upd(7)mat, but the latter ones carry a higher risk of behavioural problems [34]. More widespread use of methylation studies will probably uncover more epigenetic disorders in short SGA children, as shown by a study in patients with suspected SRS or unexplained short stature/IUGR, in whom 37% showed abnormal methylation in eleven imprinted loci [63].

A typical feature of children with SRS is their very poor appetite, severely reduced food intake, and very slim appearance. Most children have a rapid bone age advancement around the age of 8–9 years, a relatively young age at onset of puberty albeit within the normal range [56]. Males with SRS have an increased risk of genital abnormalities such as cryptorchidism and hypospadias, which could be associated with reproductive problems later in life. In females, Mayer–Rokitansky–Küster–Hauser syndrome, characterized by hypoplasia or aplasia of the uterus and upper part of the vagina, has been reported [64].

Long-term GH treatment has proven to be safe and effective in improving adult height in SRS, with similar results as non-SRS subjects born SGA [65]. As the rapid bone maturation during puberty may compromise adult height, it is recommended to add (2 years of) GnRH agonist treatment in GH-treated SRS patients with a poor adult height prognosis at the onset of puberty [34]. The metabolic health profile of GH-treated young adults with SRS was similar to that of GH-treated non-SRS subjects born SGA [66].

Other Imprinting Disorders

Besides upd(7)mat (SRS), there are several other IDs associated with SGA and short stature. Maternal UPD of chromosome 20, upd(20)mat, causes SGA, short stature, and prominent feeding difficulties with failure to thrive, but the patients differ from SRS because there is no asymmetry, prominence of the forehead and relative macrocephaly [66]. Upd(16)mat has also been associated with SGA [34]. Temple syndrome (OMIM 616222) due to by maternal UPD 14 (upd14mat), paternal deletion, distal 14q duplication, or LOM at the intergenic differentially methylated region, is characterized by hypotonia, early puberty, short stature and sometimes SGA [67, 68]. Prader–Willi syndrome (OMIM 176270) is a genetic disorder resulting from the absence of locus q11-q13 (PWS region) on the paternally derived chromosome 15, mostly due to a paternal deletion or maternal uniparental disomy (upd(15)mat) and leads to a characteristic phenotype including muscular hypotonia, short stature, hypogonadism, obesity, psychomotor delay, behavioural problems, and cognitive impairment. Long-term GH treatment improves body composition, growth, physical strength, psychomotor development, and cognitive functioning [69]. Fifty per cent (50%) of children with PWS have a birth weight below the 10th percentile and almost all remain short. Recently, quantitative DNA methylation analyses found abnormal methylation of several non-imprinted genes in SGA [70].

Management of Short Children Born SGA

Follow-Up of Young Children

An SGA-born child should have measurements of length, weight, and head circumference every 3 months during the first year of life and every 6 months thereafter [2]. Children with microcephaly

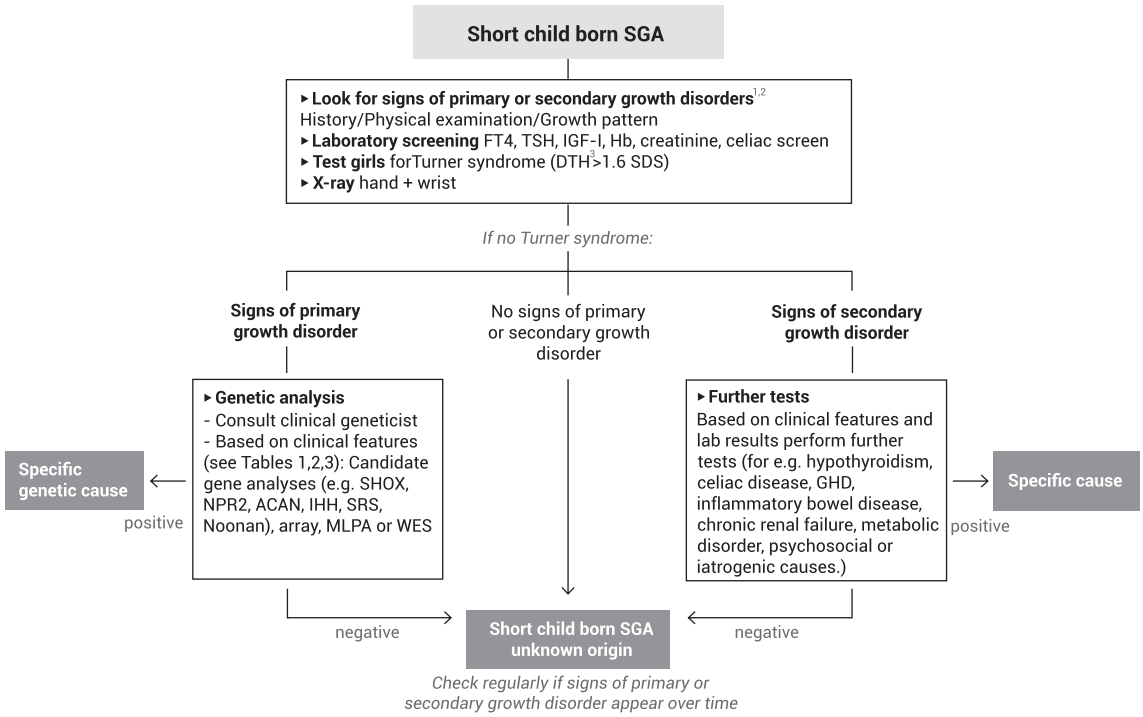
might have a syndrome (Table 7.1.3.2) and those who do not show significant catch-up in length in the first year and are short by the age of 2 years, may have an underlying disorder that limits growth. These children should be identified and referred to a paediatric endocrinologist with experience in short stature after SGA birth.

Diagnostic Approach in Short SGA Children

Figure 7.1.3.1 presents a stepwise diagnostic approach for short children born SGA. As a first step, the clinician needs to identify diagnostic signs from the medical history, physical examination, and growth pattern, followed by a screening laboratory panel and an X-ray of the left hand and wrist to assess skeletal age and search for anatomic abnormalities associated with genetic disorders like *SHOX, NPR2, ACAN, IHH*. In addition, in all girls whose height is well below target height (>1.6 SDS), TS should be excluded, by array analysis (SNP array or CGH array) or a karyotype. The diagnostic power of an array to detect TS is similar to that of a karyotype [71], but with a SNP array CNVs and uniparental isodisomy can be detected. When there are signs of a secondary growth disorder, conditions like hypothyroidism, celiac disease, GH-IGF-axis disturbance, or chronic disease should be evaluated. Only when serum IGF-I level is low for age and gender, is a GH stimulation test indicated. When there are signs of a primary growth disorder and TS is excluded, further genetic testing could be performed. When there are dysmorphic features and/or microcephaly, one may consider evaluation by a clinical geneticist. Repeatedly high serum IGF-I levels (> 1 SDS) requires genetic testing of the *IGF1R* gene. If there is a strong suspicion of a specific genetic syndrome, DNA sequencing combined with an MLPA (Multiplex Ligation-dependent Probe Amplification) test of one specific gene can be performed ('candidate gene approach'), but one may also decide to perform a growth-specific gene panel or a specific exome-based gene panel targeted to growth-related genes [72]. When the child has a positive Netchine–Harbison score [34], genetic testing for Silver–Russell syndrome is indicated. In the case of dysmorphic signs or (some) suspicion of a primordial disorder, an array analysis is probably more efficient to find a genetic cause. As last step, RNA sequencing or a methylation array could be considered [58]. In special cases (e.g. if a novel monogenic disorder is suspected), WES in a 'trio' (patient and both parents, or including siblings) can be performed. The latter is mostly done after consultation with a clinical geneticist. Presently, the yield of genetic diagnoses after such analyses is disappointingly low in non-syndromic short SGA children. However, as genetic techniques are extended, a cause will be identified in an increasing number of short SGA children and it might turn out that many cases of SGA are caused by a combination of multiple (epi)genetic variants [58].

Growth Hormone Treatment of Short Children Born SGA

Biosynthetic GH is officially approved for short SGA children by the Food and Drug Administration in USA since 2001, the European Agency for the Evaluation of Medicinal Products since 2003 and in Japan since 2008. The criteria at which GH treatment can be started are somewhat different between Europe, USA, and Japan [2]. Short



1. Signs for primary growth disorder: Medical history: alcohol abuse mother, developmental delay, behavior problems, dominant pattern of short stature, early-onset osteoarthritis and parental body disproportion; Physical examination: body disproportion, dysmorphic features, short upper or forearm, microcephaly, cryptorchidism, muscular hypertrophy; Growth: DTH[3] >1.6 SDS, parental short stature; X-hand/wrist: anatomic abnormalities.
2. Signs for secondary growth disorder: Medical history: decreasing or increasing BMI SDS, anorexia, fatigue, polyuria, polydipsia, medication (corticosteroids, methylphenidate), symptoms of increased intracranial pressure, vomiting, disturbed vision; Physical examination: low or high BMI SDS, Cushingoid appearance, hypertension; Growth: decreasing height SDS, decreasing BMI SDS (IBD) or increasing BMI SDS (Cushing, hypothyroidism, GHD); X-hand/wrist: delayed bone age
3. DTH = Distance to target height

Figure 7.1.3.1 A stepwise diagnostic approach of a short child born SGA.

children with a dysmorphic syndrome, except those with Silver–Russell syndrome, tend to show poor growth to GH [2].

The registered starting dose of GH is 0.033 mg/kg/day (~1 mg/m²/day) in Europe and Japan, while in the USA the recommended dose ranges from 0.033 to 0.067 ug/kg/day (~1–2 mg/m²/day) [2].

Effect on Growth and Adult Height

GH treatment effectively induces catch-up growth and improves adult height in most short children born SGA [73, 74]. A systematic review reported that the mean height gain was on average 1.25 SDS [75].

The growth response to GH is, however, highly variable, which is probably associated with multiple gene variants. Prediction models could explain 52% of the variability of the growth response in the first year and 40% of adult height [76, 77], but it is impossible to reliably predict the individual growth response both before and during treatment [77]. The growth response to GH treatment does not differ between those born preterm or term [78].

No difference in adult height SDS was found between children treated with a GH dose of 0.033 mg/kg/day and 0.067 mg/kg/day [73], while the higher GH dose led to an average serum IGF-I of +2 SDS. For that reason, it is recommended to treat short SGA children with a GH dose of 0.033 mg/kg/day, and to sonly increase the GH dose when the growth response is unsatisfactory and other causes of a poor growth response are ruled out [2]. High serum IGF-I levels >2 SDS during GH treatment with 0.033 mg/kg/day might be due to a heterozygous *IGF1R* defect. Consideration should be given to undertaking genetic testing for this diagnosis. These children require a higher GH dose to obtain an acceptable growth response, and an elevated serum IGF-I on GH treatment may be accepted due to their partial IGF-I insensitivity. Persistently high serum IGF-I levels are also found in short SGA children with syndromes like Bloom and Fanconi, which may not have been identified due to lack of clear dysmorphic features. Again, genetic testing would be helpful to achieve a specific diagnosis. If such a syndrome is identified, then GH should be discontinued. Children with SRS (15p11) can also show high IGF-I levels, likely due to a relative IGF-I resistance, but until this has become clear, it is recommended to lower the GH dose. GH dosing based on IGF-I titration results in a poorer growth response than treatment based on a fixed GH dose, and is therefore not recommended [79]. Adult height is greater when treatment is started at least 2 years before the onset of puberty [74]. However, some short SGA children come to medical attention when they have just started puberty. When their predicted adult height is <–2.5 SDS at onset of puberty, their adult height can improve by combined treatment of GH and 2 years of a GnRHa [80].

Effect on Pubertal Development

On average, GH-treated SGA children start puberty at a similar age as the normal population, although some start relatively early. GH treatment has no influence on the onset and progression of puberty compared to AGA controls, regardless of GH dose (0.033 vs. 0.067 mg/kg/day) [9].

Effect on Metabolism, Insulin Sensitivity, and Cardiovascular Health

GH has lipolytic, anabolic, and insulin-antagonistic effects and leads in short SGA children to an increase in lean body mass and decrease in fat mass [81]. Short SGA children have reduced insulin sensitivity before the start of GH treatment, a further reduction in insulin sensitivity with a compensatory increase in insulin secretion during GH [18], but a complete normalization after cessation of GH. Assessment of the impact of long-term GH treatment in large study groups has shown that none of the GH-treated SGA-born subjects developed β-cell dysfunction or type 2 DM [17].

Blood pressure and cholesterol levels decline during GH treatment, and become significantly lower than in untreated SGA children [21]. The few studies reporting on the carotid intima media thickness (cIMT) in GH-treated SGA children showed no effect of GH treatment [26, 82].

Treatment with combined GH/GnRHa in SGA children results in similar body composition, insulin sensitivity, β-cell function, blood pressure, and lipid levels at adult height as those treated with GH only [83].

Effect on Bone Mineral Density

During long-term GH treatment, the total-body BMD improves from –1.00 SDS to –0.44 SDS, and lumbar-spine BMD corrected for height, from –0.48 SDS to –0.14 SDS [84].

Effect on Cognitive Functioning and Health-Related Quality of Life

Short SGA children have on average lower cognitive functioning. One study showed that long-term GH treatment improved performance IQ and attention while the estimated total IQ scores significantly increased by 5–10 points, to the same range as the normal population [27].

Long-term GH treatment improves health-related quality of life (HRQoL) in short SGA children [29].

Safety

Since the early nineties, multiple large cohort studies in short children born SGA have been conducted, showing that GH treatment is well tolerated, and that serious adverse effects are uncommon [75].

Diagnosing syndromes can be challenging, particularly when children have mild symptoms, but identifying the genetic aetiology is important for health prognosis, genetic counselling, and treatment. GH treatment is contraindicated in several conditions, such as chromosomal breakage syndromes and DNA repair disorders [85].

Monitoring During GH Treatment

Height, weight, and Tanner pubertal stage should be monitored regularly. It is recommended to determine the serum IGF-I level 3 to 6 months after the start of treatment, to evaluate whether the GH dose requires adjustment and/or further evaluation. Thereafter, it is advised to determine the serum IGF-I level annually. When IGF-I levels remain high even with a relatively low GH dose, one should consider performing *IGF1R* mutational analysis, and to examine for the presence of a possible underlying dysmorphic syndrome like Bloom syndrome [85]. As serum-free T_4 levels decrease to levels just below the norm in 14% of GH-treated SGA children but thyroid-stimulating hormone (TSH) levels remained normal [86], it is recommended to annually assess serum-free T_4 and TSH.

As bone maturation in short children born SGA is highly variable and unreliable for growth prediction, radiological investigations are not very informative [2]. Since SGA birth is associated with a

higher risk of the metabolic syndrome [6], one could argue that metabolic syndrome parameters should be checked annually. On the other hand, many studies have shown that GH has very limited effects on cardiometabolic parameters during treatment and several years thereafter. For that reason, it is recommended to only monitor blood pressure, BMI, abdominal waist circumference, fasting glucose, and lipid levels. Periodical measurement of fasting insulin is not recommended for clinical care because of the absence of criteria to differentiate normal from abnormal. However, additional monitoring and testing should be performed when indicated (e.g. in the case of a positive family history for DM or cardiometabolic diseases) [2].

Conclusions

GH treatment in short SGA children increases longitudinal growth and adult height, and has positive effects on cardiometabolic health and cognitive functioning. The addition of GnRHa for 2 years in early pubertal children with a low predicted adult height can improve adult height. The safety profile of GH treatment alone or combined with GnRHa is good.
